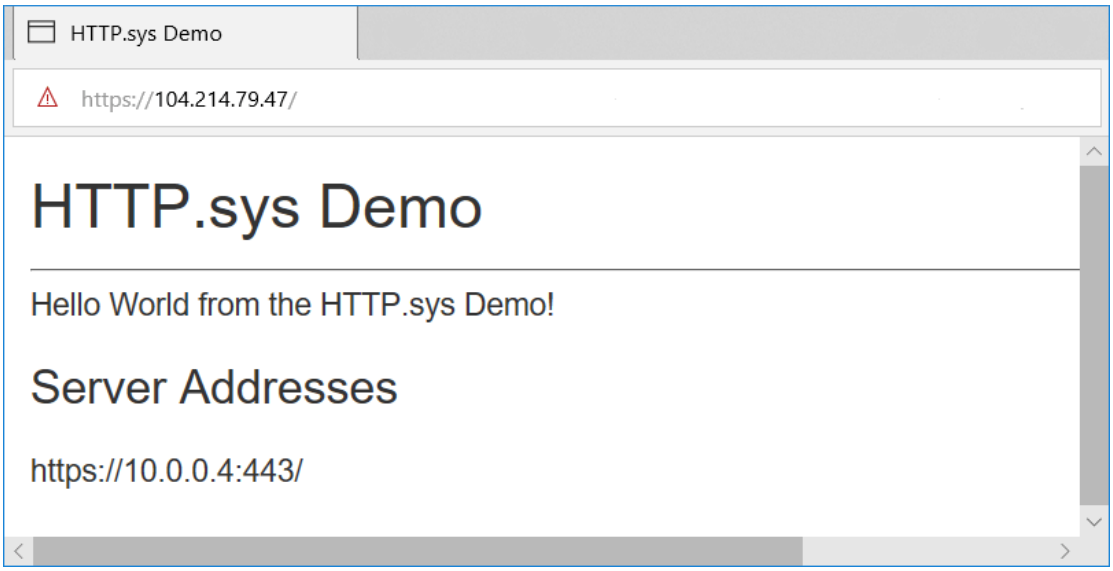
   Administrator privileges aren't required to run the app when binding to localhost using HTTP (not HTTPS) with a port number greater than 1024. For other configurations (for example, using a local IP address or binding to port 443), run the app with administrator privileges.

   The app responds at the server's public IP address. In this example, the server is reached from the Internet at its public IP address of `104.214.79.47`.

   A development certificate is used in this example. The page loads securely after bypassing the browser's untrusted certificate warning.



Proxy server and load balancer scenarios

For apps hosted by HTTP.sys that interact with requests from the Internet or a corporate network, additional configuration might be required when hosting behind proxy servers and load balancers. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Additional resources

- Enable Windows Authentication with HTTP.sys
- HTTP Server API
- aspnet/HttpSysServer GitHub repository (source code)

- The host
- Troubleshoot and debug ASP.NET Core projects

HTTP.sys is a web server for ASP.NET Core that only runs on Windows. HTTP.sys is an alternative to Kestrel server and offers some features that Kestrel doesn't provide.

> **IMPORTANT**
> HTTP.sys isn't compatible with the ASP.NET Core Module and can't be used with IIS or IIS Express.

HTTP.sys supports the following features:

- Windows Authentication
- Port sharing
- HTTPS with SNI
- HTTP/2 over TLS (Windows 10 or later)
- Direct file transmission
- Response caching
- WebSockets (Windows 8 or later)

Supported Windows versions:

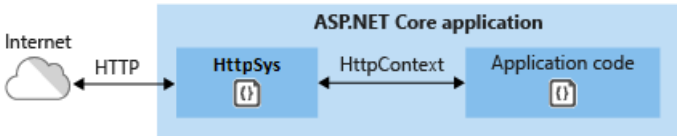
- Windows 7 or later
- Windows Server 2008 R2 or later

View or download sample code (how to download)

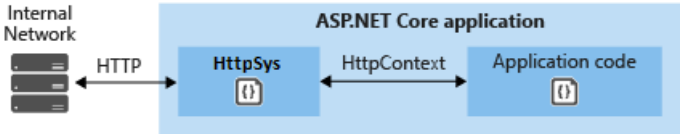
When to use HTTP.sys

HTTP.sys is useful for deployments where:

- There's a need to expose the server directly to the Internet without using IIS.



- An internal deployment requires a feature not available in Kestrel, such as Windows Authentication.



HTTP.sys is mature technology that protects against many types of attacks and provides the robustness, security, and scalability of a full-featured web server. IIS itself runs as an HTTP listener on top of HTTP.sys.

HTTP/2 support

HTTP/2 is enabled for ASP.NET Core apps if the following base requirements are met:

- Windows Server 2016/Windows 10 or later
- Application-Layer Protocol Negotiation (ALPN) connection
- TLS 1.2 or later connection

If an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/1.1`.

HTTP/2 is enabled by default. If an HTTP/2 connection isn't established, the connection falls back to HTTP/1.1. In a future release of Windows, HTTP/2 configuration flags will be available, including the ability to disable HTTP/2 with HTTP.sys.

Kernel mode authentication with Kerberos

HTTP.sys delegates to kernel mode authentication with the Kerberos authentication protocol. User mode authentication isn't supported with Kerberos and HTTP.sys. The machine account must be used to decrypt the Kerberos token/ticket that's obtained from Active Directory and forwarded by the client to the server to authenticate the user. Register the Service Principal Name (SPN) for the host, not the user of the app.

How to use HTTP.sys

Configure the ASP.NET Core app to use HTTP.sys

A package reference in the project file isn't required when using the Microsoft.AspNetCore.App metapackage (nuget.org). When not using the `Microsoft.AspNetCore.App` metapackage, add a package reference to Microsoft.AspNetCore.Server.HttpSys.

Call the UseHttpSys extension method when building the host, specifying any required HttpSysOptions. The following example sets options to their default values:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseHttpSys(options =>
        {
            options.AllowSynchronousIO = true;
            options.Authentication.Schemes = AuthenticationSchemes.None;
            options.Authentication.AllowAnonymous = true;
            options.MaxConnections = null;
            options.MaxRequestBodySize = 30000000;
            options.UrlPrefixes.Add("http://localhost:5000");
        });
```

Additional HTTP.sys configuration is handled through registry settings.

HTTP.sys options

PROPERTY	DESCRIPTION	DEFAULT
AllowSynchronousIO	Control whether synchronous input/output is allowed for the `HttpContext.Request.Body` and `HttpContext.Response.Body`.	`true`
Authentication.AllowAnonymous	Allow anonymous requests.	`true`
Authentication.Schemes	Specify the allowed authentication schemes. May be modified at any time prior to disposing the listener. Values are provided by the AuthenticationSchemes enum: `Basic`, `Kerberos`, `Negotiate`, `None`, and `NTLM`.	`None`

PROPERTY	DESCRIPTION	DEFAULT
EnableResponseCaching	Attempt kernel-mode caching for responses with eligible headers. The response may not include `Set-Cookie`, `Vary`, or `Pragma` headers. It must include a `Cache-Control` header that's `public` and either a `shared-max-age` or `max-age` value, or an `Expires` header.	`true`
MaxAccepts	The maximum number of concurrent accepts.	5 × Environment.ProcessorCount
MaxConnections	The maximum number of concurrent connections to accept. Use `-1` for infinite. Use `null` to use the registry's machine-wide setting.	`null` (machine-wide setting)
MaxRequestBodySize	See the MaxRequestBodySize section.	30000000 bytes (~28.6 MB)
RequestQueueLimit	The maximum number of requests that can be queued.	1000
ThrowWriteExceptions	Indicate if response body writes that fail due to client disconnects should throw exceptions or complete normally.	`false` (complete normally)

PROPERTY	DESCRIPTION	DEFAULT
Timeouts	Expose the HTTP.sys TimeoutManager configuration, which may also be configured in the registry. Follow the API links to learn more about each setting, including default values: • TimeoutManager.DrainEntityBody: Time allowed for the HTTP Server API to drain the entity body on a Keep-Alive connection. • TimeoutManager.EntityBody: Time allowed for the request entity body to arrive. • TimeoutManager.HeaderWait: Time allowed for the HTTP Server API to parse the request header. • TimeoutManager.IdleConnection: Time allowed for an idle connection. • TimeoutManager.MinSendBytesPerSecond: The minimum send rate for the response. • TimeoutManager.RequestQueue: Time allowed for the request to remain in the request queue before the app picks it up.	
UrlPrefixes	Specify the UrlPrefixCollection to register with HTTP.sys. The most useful is UrlPrefixCollection.Add, which is used to add a prefix to the collection. These may be modified at any time prior to disposing the listener.	

MaxRequestBodySize

The maximum allowed size of any request body in bytes. When set to `null`, the maximum request body size is unlimited. This limit has no effect on upgraded connections, which are always unlimited.

The recommended method to override the limit in an ASP.NET Core MVC app for a single `IActionResult` is to use the RequestSizeLimitAttribute attribute on an action method:

```
[RequestSizeLimit(100000000)]
public IActionResult MyActionMethod()
```

An exception is thrown if the app attempts to configure the limit on a request after the app has started reading the request. An `IsReadOnly` property can be used to indicate if the `MaxRequestBodySize` property is in a read-only state, meaning it's too late to configure the limit.

If the app should override MaxRequestBodySize per-request, use the IHttpMaxRequestBodySizeFeature:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env,
    ILogger<Startup> logger, IServer server)
{
    app.Use(async (context, next) =>
    {
        context.Features.Get<IHttpMaxRequestBodySizeFeature>()
            .MaxRequestBodySize = 10 * 1024;

        var serverAddressesFeature =
            app.ServerFeatures.Get<IServerAddressesFeature>();
        var addresses = string.Join(", ", serverAddressesFeature?.Addresses);

        logger.LogInformation("Addresses: {Addresses}", addresses);

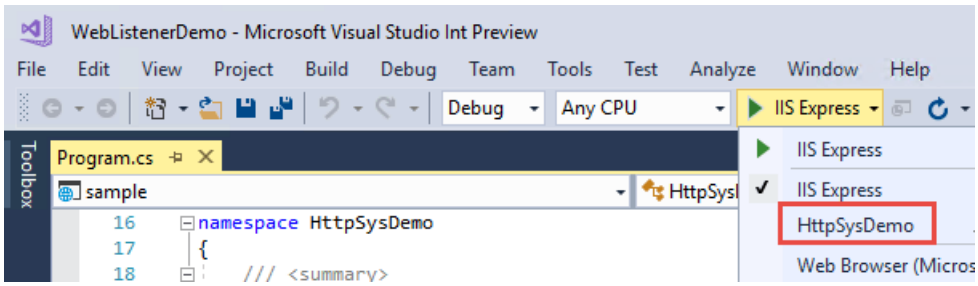
        await next.Invoke();
    });

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    // Enable HTTPS Redirection Middleware when hosting the app securely.
    //app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseCookiePolicy();
    app.UseMvc();
}
```

If using Visual Studio, make sure the app isn't configured to run IIS or IIS Express.

In Visual Studio, the default launch profile is for IIS Express. To run the project as a console app, manually change the selected profile, as shown in the following screen shot:



Configure Windows Server

1. Determine the ports to open for the app and use Windows Firewall or the New-NetFirewallRule PowerShell cmdlet to open firewall ports to allow traffic to reach HTTP.sys. In the following commands and app configuration, port 443 is used.

2. When deploying to an Azure VM, open the ports in the Network Security Group. In the following commands and app configuration, port 443 is used.

3. Obtain and install X.509 certificates, if required.

   On Windows, create self-signed certificates using the New-SelfSignedCertificate PowerShell cmdlet. For an unsupported example, see UpdateIISExpressSSLForChrome.ps1.

   Install either self-signed or CA-signed certificates in the server's **Local Machine** > **Personal** store.

4. If the app is a framework-dependent deployment, install .NET Core, .NET Framework, or both (if the app is a .NET Core app targeting the .NET Framework).

   - **.NET Core**: If the app requires .NET Core, obtain and run the **.NET Core Runtime** installer from .NET Core Downloads. Don't install the full SDK on the server.
   - **.NET Framework**: If the app requires .NET Framework, see the .NET Framework installation guide. Install the required .NET Framework. The installer for the latest .NET Framework is available from the .NET Core Downloads page.

   If the app is a self-contained deployment, the app includes the runtime in its deployment. No framework installation is required on the server.

5. Configure URLs and ports in the app.

   By default, ASP.NET Core binds to `http://localhost:5000`. To configure URL prefixes and ports, options include:

   - UseUrls
   - `urls` command-line argument
   - `ASPNETCORE_URLS` environment variable
   - UrlPrefixes

   The following code example shows how to use UrlPrefixes with the server's local IP address `10.0.0.4` on port 443:

   ```
   public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
       WebHost.CreateDefaultBuilder(args)
           .UseStartup<Startup>()
           .UseHttpSys(options =>
           {
               options.UrlPrefixes.Add("https://10.0.0.4:443");
           });
   ```

   An advantage of `UrlPrefixes` is that an error message is generated immediately for improperly formatted prefixes.

   The settings in `UrlPrefixes` override `UseUrls` / `urls` / `ASPNETCORE_URLS` settings. Therefore, an advantage of `UseUrls`, `urls`, and the `ASPNETCORE_URLS` environment variable is that it's easier to switch between Kestrel and HTTP.sys.

   HTTP.sys uses the HTTP Server API UrlPrefix string formats.

   > **WARNING**
   > Top-level wildcard bindings (`http://*:80/` and `http://+:80`) should **not** be used. Top-level wildcard bindings create app security vulnerabilities. This applies to both strong and weak wildcards. Use explicit host names or IP addresses rather than wildcards. Subdomain wildcard binding (for example, `*.mysub.com`) isn't a security risk if you control the entire parent domain (as opposed to `*.com`, which is vulnerable). For more information, see RFC 7230: Section 5.4: Host.

6. Preregister URL prefixes on the server.

   The built-in tool for configuring HTTP.sys is *netsh.exe*. *netsh.exe* is used to reserve URL prefixes and assign X.509 certificates. The tool requires administrator privileges.

   Use the *netsh.exe* tool to register URLs for the app:

```
netsh http add urlacl url=<URL> user=<USER>
```

- `<URL>`: The fully qualified Uniform Resource Locator (URL). Don't use a wildcard binding. Use a valid hostname or local IP address. *The URL must include a trailing slash.*
- `<USER>`: Specifies the user or user-group name.

In the following example, the local IP address of the server is `10.0.0.4`:

```
netsh http add urlacl url=https://10.0.0.4:443/ user=Users
```

When a URL is registered, the tool responds with `URL reservation successfully added`.

To delete a registered URL, use the `delete urlacl` command:

```
netsh http delete urlacl url=<URL>
```

7. Register X.509 certificates on the server.

   Use the *netsh.exe* tool to register certificates for the app:

   ```
   netsh http add sslcert ipport=<IP>:<PORT> certhash=<THUMBPRINT> appid="{<GUID>}"
   ```

   - `<IP>`: Specifies the local IP address for the binding. Don't use a wildcard binding. Use a valid IP address.
   - `<PORT>`: Specifies the port for the binding.
   - `<THUMBPRINT>`: The X.509 certificate thumbprint.
   - `<GUID>`: A developer-generated GUID to represent the app for informational purposes.

   For reference purposes, store the GUID in the app as a package tag:

   - In Visual Studio:
     - Open the app's project properties by right-clicking on the app in **Solution Explorer** and selecting **Properties**.
     - Select the **Package** tab.
     - Enter the GUID that you created in the **Tags** field.
   - When not using Visual Studio:
     - Open the app's project file.
     - Add a `<PackageTags>` property to a new or existing `<PropertyGroup>` with the GUID that you created:

       ```
       <PropertyGroup>
         <PackageTags>9412ee86-c21b-4eb8-bd89-f650fbf44931</PackageTags>
       </PropertyGroup>
       ```

   In the following example:

   - The local IP address of the server is `10.0.0.4`.
   - An online random GUID generator provides the `appid` value.

```
netsh http add sslcert
    ipport=10.0.0.4:443
    certhash=b66ee04419d4ee37464ab8785ff02449980eae10
    appid="{9412ee86-c21b-4eb8-bd89-f650fbf44931}"
```

When a certificate is registered, the tool responds with `SSL Certificate successfully added`.

To delete a certificate registration, use the `delete sslcert` command:

```
netsh http delete sslcert ipport=<IP>:<PORT>
```

Reference documentation for *netsh.exe*:

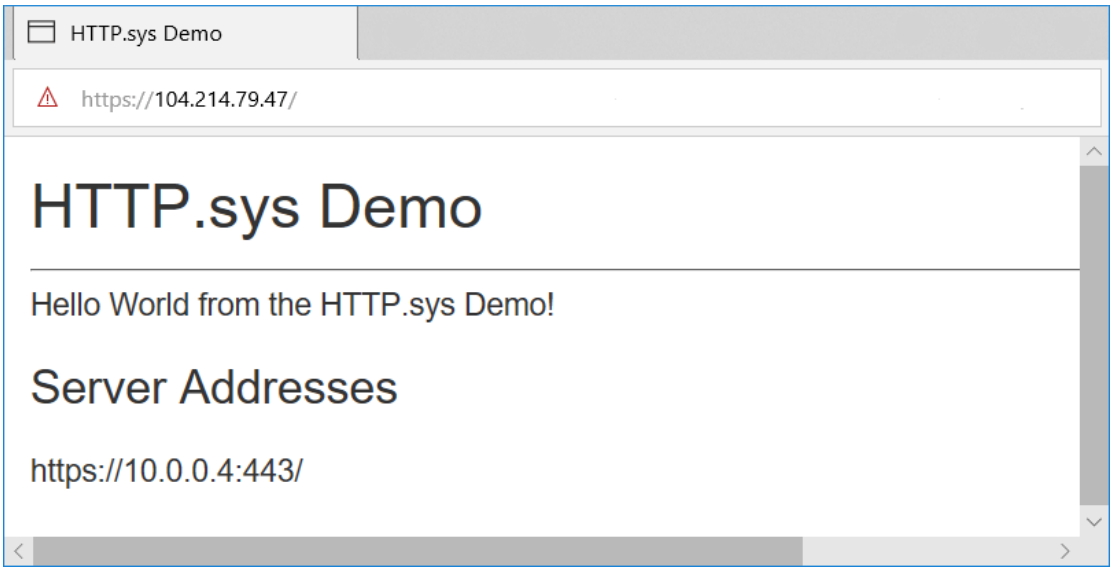
- Netsh Commands for Hypertext Transfer Protocol (HTTP)
- UrlPrefix Strings

8. Run the app.

   Administrator privileges aren't required to run the app when binding to localhost using HTTP (not HTTPS) with a port number greater than 1024. For other configurations (for example, using a local IP address or binding to port 443), run the app with administrator privileges.

   The app responds at the server's public IP address. In this example, the server is reached from the Internet at its public IP address of `104.214.79.47`.

   A development certificate is used in this example. The page loads securely after bypassing the browser's untrusted certificate warning.



Proxy server and load balancer scenarios

For apps hosted by HTTP.sys that interact with requests from the Internet or a corporate network, additional configuration might be required when hosting behind proxy servers and load balancers. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Additional resources

- Enable Windows Authentication with HTTP.sys
- HTTP Server API
- aspnet/HttpSysServer GitHub repository (source code)

- The host
- Troubleshoot and debug ASP.NET Core projects

Host ASP.NET Core in a Windows Service

9/22/2020 • 32 minutes to read • Edit Online

An ASP.NET Core app can be hosted on Windows as a Windows Service without using IIS. When hosted as a Windows Service, the app automatically starts after server reboots.

View or download sample code (how to download)

Prerequisites

- ASP.NET Core SDK 2.1 or later
- PowerShell 6.2 or later

Worker Service template

The ASP.NET Core Worker Service template provides a starting point for writing long running service apps. To use the template as a basis for a Windows Service app:

1. Create a Worker Service app from the .NET Core template.
2. Follow the guidance in the App configuration section to update the Worker Service app so that it can run as a Windows Service.

- Visual Studio
- Visual Studio for Mac
- .NET Core CLI

1. Create a new project.
2. Select **Worker Service**. Select **Next**.
3. Provide a project name in the **Project name** field or accept the default project name. Select **Create**.
4. In the **Create a new Worker service** dialog, select **Create**.

App configuration

The app requires a package reference for Microsoft.Extensions.Hosting.WindowsServices.

`IHostBuilder.UseWindowsService` is called when building the host. If the app is running as a Windows Service, the method:

- Sets the host lifetime to `WindowsServiceLifetime`.
- Sets the content root to AppContext.BaseDirectory. For more information, see the Current directory and content root section.
- Enables logging to the event log:
  - The application name is used as the default source name.
  - The default log level is *Warning* or higher for an app based on an ASP.NET Core template that calls `CreateDefaultBuilder` to build the host.
  - Override the default log level with the `Logging:EventLog:LogLevel:Default` key in *appsettings.json*/*appsettings.{Environment}.json* or other configuration provider.
  - Only administrators can create new event sources. When an event source can't be created using the application name, a warning is logged to the *Application* source and event logs are disabled.

In `CreateHostBuilder` of *Program.cs*:

```
Host.CreateDefaultBuilder(args)
    .UseWindowsService()
    ...
```

The following sample apps accompany this topic:

- Background Worker Service Sample: A non-web app sample based on the Worker Service template that uses hosted services for background tasks.
- Web App Service Sample: A Razor Pages web app sample that runs as a Windows Service with hosted services for background tasks.

For MVC guidance, see the articles under Overview of ASP.NET Core MVC and Migrate from ASP.NET Core 2.2 to 3.0.

Deployment type

For information and advice on deployment scenarios, see .NET Core application deployment.

SDK

For a web app-based service that uses the Razor Pages or MVC frameworks, specify the Web SDK in the project file:

```
<Project Sdk="Microsoft.NET.Sdk.Web">
```

If the service only executes background tasks (for example, hosted services), specify the Worker SDK in the project file:

```
<Project Sdk="Microsoft.NET.Sdk.Worker">
```

Framework-dependent deployment (FDD)

Framework-dependent deployment (FDD) relies on the presence of a shared system-wide version of .NET Core on the target system. When the FDD scenario is adopted following the guidance in this article, the SDK produces an executable (*.exe*), called a *framework-dependent executable*.

If using the Web SDK, a *web.config* file, which is normally produced when publishing an ASP.NET Core app, is unnecessary for a Windows Services app. To disable the creation of the *web.config* file, add the `<IsTransformWebConfigDisabled>` property set to `true`.

```
<PropertyGroup>
  <TargetFramework>netcoreapp3.0</TargetFramework>
  <IsTransformWebConfigDisabled>true</IsTransformWebConfigDisabled>
</PropertyGroup>
```

Self-contained deployment (SCD)

Self-contained deployment (SCD) doesn't rely on the presence of a shared framework on the host system. The runtime and the app's dependencies are deployed with the app.

A Windows Runtime Identifier (RID) is included in the `<PropertyGroup>` that contains the target framework:

```
<RuntimeIdentifier>win7-x64</RuntimeIdentifier>
```

To publish for multiple RIDs:

- Provide the RIDs in a semicolon-delimited list.
- Use the property name <RuntimeIdentifiers> (plural).

For more information, see .NET Core RID Catalog.

Service user account

To create a user account for a service, use the New-LocalUser cmdlet from an administrative PowerShell 6 command shell.

On Windows 10 October 2018 Update (version 1809/build 10.0.17763) or later:

```
New-LocalUser -Name {SERVICE NAME}
```

On Windows OS earlier than the Windows 10 October 2018 Update (version 1809/build 10.0.17763):

```
powershell -Command "New-LocalUser -Name {SERVICE NAME}"
```

Provide a strong password when prompted.

Unless the `-AccountExpires` parameter is supplied to the New-LocalUser cmdlet with an expiration DateTime, the account doesn't expire.

For more information, see Microsoft.PowerShell.LocalAccounts and Service User Accounts.

An alternative approach to managing users when using Active Directory is to use Managed Service Accounts. For more information, see Group Managed Service Accounts Overview.

Log on as a service rights

To establish *Log on as a service* rights for a service user account:

1. Open the Local Security Policy editor by running *secpol.msc*.
2. Expand the **Local Policies** node and select **User Rights Assignment**.
3. Open the **Log on as a service** policy.
4. Select **Add User or Group**.
5. Provide the object name (user account) using either of the following approaches:
   a. Type the user account (`{DOMAIN OR COMPUTER NAME\USER}`) in the object name field and select **OK** to add the user to the policy.
   b. Select **Advanced**. Select **Find Now**. Select the user account from the list. Select **OK**. Select **OK** again to add the user to the policy.
6. Select **OK** or **Apply** to accept the changes.

Create and manage the Windows Service

Create a service

Use PowerShell commands to register a service. From an administrative PowerShell 6 command shell, execute the following commands:

```
$acl = Get-Acl "{EXE PATH}"
$aclRuleArgs = {DOMAIN OR COMPUTER NAME\USER}, "Read,Write,ReadAndExecute", "ContainerInherit,ObjectInherit",
"None", "Allow"
$accessRule = New-Object System.Security.AccessControl.FileSystemAccessRule($aclRuleArgs)
$acl.SetAccessRule($accessRule)
$acl | Set-Acl "{EXE PATH}"

New-Service -Name {SERVICE NAME} -BinaryPathName {EXE FILE PATH} -Credential {DOMAIN OR COMPUTER NAME\USER} -
Description "{DESCRIPTION}" -DisplayName "{DISPLAY NAME}" -StartupType Automatic
```

- `{EXE PATH}`: Path to the app's folder on the host (for example, `d:\myservice`). Don't include the app's executable in the path. A trailing slash isn't required.
- `{DOMAIN OR COMPUTER NAME\USER}`: Service user account (for example, `Contoso\ServiceUser`).
- `{SERVICE NAME}`: Service name (for example, `MyService`).
- `{EXE FILE PATH}`: The app's executable path (for example, `d:\myservice\myservice.exe`). Include the executable's file name with extension.
- `{DESCRIPTION}`: Service description (for example, `My sample service`).
- `{DISPLAY NAME}`: Service display name (for example, `My Service`).

Start a service

Start a service with the following PowerShell 6 command:

```
Start-Service -Name {SERVICE NAME}
```

The command takes a few seconds to start the service.

Determine a service's status

To check the status of a service, use the following PowerShell 6 command:

```
Get-Service -Name {SERVICE NAME}
```

The status is reported as one of the following values:

- `Starting`
- `Running`
- `Stopping`
- `Stopped`

Stop a service

Stop a service with the following Powershell 6 command:

```
Stop-Service -Name {SERVICE NAME}
```

Remove a service

After a short delay to stop a service, remove a service with the following Powershell 6 command:

```
Remove-Service -Name {SERVICE NAME}
```

Proxy server and load balancer scenarios

Services that interact with requests from the Internet or a corporate network and are behind a proxy or load

balancer might require additional configuration. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Configure endpoints

By default, ASP.NET Core binds to `http://localhost:5000`. Configure the URL and port by setting the `ASPNETCORE_URLS` environment variable.

For additional URL and port configuration approaches, see the relevant server article:

- Kestrel web server implementation in ASP.NET Core
- HTTP.sys web server implementation in ASP.NET Core

The preceding guidance covers support for HTTPS endpoints. For example, configure the app for HTTPS when authentication is used with a Windows Service.

> **NOTE**
> Use of the ASP.NET Core HTTPS development certificate to secure a service endpoint isn't supported.

Current directory and content root

The current working directory returned by calling GetCurrentDirectory for a Windows Service is the *C:\WINDOWS\system32* folder. The *system32* folder isn't a suitable location to store a service's files (for example, settings files). Use one of the following approaches to maintain and access a service's assets and settings files.

Use ContentRootPath or ContentRootFileProvider

Use IHostEnvironment.ContentRootPath or ContentRootFileProvider to locate an app's resources.

When the app runs as a service, UseWindowsService sets the ContentRootPath to AppContext.BaseDirectory.

The app's default settings files, *appsettings.json* and *appsettings.{Environment}.json*, are loaded from the app's content root by calling CreateDefaultBuilder during host construction.

For other settings files loaded by developer code in ConfigureAppConfiguration, there's no need to call SetBasePath. In the following example, the *custom_settings.json* file exists in the app's content root and is loaded without explicitly setting a base path:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .UseWindowsService()
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddJsonFile("custom_settings.json");
            })
            .ConfigureServices((hostContext, services) =>
            {
                services.AddHostedService<Worker>();
            });
}
```

Don't attempt to use GetCurrentDirectory to obtain a resource path because a Windows Service app returns the *C:\WINDOWS\system32* folder as its current directory.

Store a service's files in a suitable location on disk

Specify an absolute path with SetBasePath when using an IConfigurationBuilder to the folder containing the files.

Troubleshoot

To troubleshoot a Windows Service app, see Troubleshoot and debug ASP.NET Core projects.

Common errors

- An old or pre-release version of PowerShell is in use.
- The registered service doesn't use the app's **published** output from the dotnet publish command. Output of the dotnet build command isn't supported for app deployment. Published assets are found in either of the following folders depending on the deployment type:
  - *bin/Release/{TARGET FRAMEWORK}/publish* (FDD)
  - *bin/Release/{TARGET FRAMEWORK}/{RUNTIME IDENTIFIER}/publish* (SCD)
- The service isn't in the RUNNING state.
- The paths to resources that the app uses (for example, certificates) are incorrect. The base path of a Windows Service is *c:\Windows\System32*.
- The user doesn't have *Log on as a service* rights.
- The user's password is expired or incorrectly passed when executing the `New-Service` PowerShell command.
- The app requires ASP.NET Core authentication but isn't configured for secure connections (HTTPS).
- The request URL port is incorrect or not configured correctly in the app.

System and Application Event Logs

Access the System and Application Event Logs:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.
2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **System** to open the System Event Log. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app.

Run the app at a command prompt

Many startup errors don't produce useful information in the event logs. You can find the cause of some errors by running the app at a command prompt on the hosting system. To log additional detail from the app, lower the log level or run the app in the Development environment.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.
2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

Slow or hanging app

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`.
2. Run the EnableDumps PowerShell script with the application executable name:

   ```
   .\EnableDumps {APPLICATION EXE} c:\dumps
   ```

3. Run the app under the conditions that cause the crash to occur.
4. After the crash has occurred, run the DisableDumps PowerShell script:

   ```
   .\DisableDumps {APPLICATION EXE}
   ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> **WARNING**
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App hangs, fails during startup, or runs normally

When an app *hangs* (stops responding but doesn't crash), fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Additional resources

- Kestrel endpoint configuration (includes HTTPS configuration and SNI support)
- .NET Generic Host
- Troubleshoot and debug ASP.NET Core projects

An ASP.NET Core app can be hosted on Windows as a Windows Service without using IIS. When hosted as a Windows Service, the app automatically starts after server reboots.

View or download sample code (how to download)

Prerequisites

- ASP.NET Core SDK 2.1 or later
- PowerShell 6.2 or later

App configuration

The app requires package references for Microsoft.AspNetCore.Hosting.WindowsServices and Microsoft.Extensions.Logging.EventLog.

To test and debug when running outside of a service, add code to determine if the app is running as a service or a

console app. Inspect if the debugger is attached or a `--console` switch is present. If either condition is true (the app isn't run as a service), call Run. If the conditions are false (the app is run as a service):

- Call SetCurrentDirectory and use a path to the app's published location. Don't call GetCurrentDirectory to obtain the path because a Windows Service app returns the *C:\WINDOWS\system32* folder when GetCurrentDirectory is called. For more information, see the Current directory and content root section. This step is performed before the app is configured in `CreateWebHostBuilder`.
- Call RunAsService to run the app as a service.

Because the Command-line Configuration Provider requires name-value pairs for command-line arguments, the `--console` switch is removed from the arguments before CreateDefaultBuilder receives the arguments.

To write to the Windows Event Log, add the EventLog provider to ConfigureLogging. Set the logging level with the `Logging:LogLevel:Default` key in the *appsettings.Production.json* file.

In the following example from the sample app, `RunAsCustomService` is called instead of RunAsService in order to handle lifetime events within the app. For more information, see the Handle starting and stopping events section.

```
public class Program
{
    public static void Main(string[] args)
    {
        var isService = !(Debugger.IsAttached || args.Contains("--console"));

        if (isService)
        {
            var pathToExe = Process.GetCurrentProcess().MainModule.FileName;
            var pathToContentRoot = Path.GetDirectoryName(pathToExe);
            Directory.SetCurrentDirectory(pathToContentRoot);
        }

        var builder = CreateWebHostBuilder(
            args.Where(arg => arg != "--console").ToArray());

        var host = builder.Build();

        if (isService)
        {
            // To run the app without the CustomWebHostService change the
            // next line to host.RunAsService();
            host.RunAsCustomService();
        }
        else
        {
            host.Run();
        }
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .ConfigureLogging((hostingContext, logging) =>
            {
                logging.AddEventLog();
            })
            .ConfigureAppConfiguration((context, config) =>
            {
                // Configure the app here.
            })
            .UseStartup<Startup>();
}
```

Deployment type

For information and advice on deployment scenarios, see .NET Core application deployment.

SDK

For a web app-based service that uses the Razor Pages or MVC frameworks, specify the Web SDK in the project file:

```
<Project Sdk="Microsoft.NET.Sdk.Web">
```

If the service only executes background tasks (for example, hosted services), specify the Worker SDK in the project file:

```
<Project Sdk="Microsoft.NET.Sdk.Worker">
```

Framework-dependent deployment (FDD)

Framework-dependent deployment (FDD) relies on the presence of a shared system-wide version of .NET Core on the target system. When the FDD scenario is adopted following the guidance in this article, the SDK produces an executable (*.exe*), called a *framework-dependent executable*.

The Windows Runtime Identifier (RID) (<RuntimeIdentifier>) contains the target framework. In the following example, the RID is set to `win7-x64`. The `<SelfContained>` property is set to `false`. These properties instruct the SDK to generate an executable (*.exe*) file for Windows and an app that depends on the shared .NET Core framework.

A *web.config* file, which is normally produced when publishing an ASP.NET Core app, is unnecessary for a Windows Services app. To disable the creation of the *web.config* file, add the `<IsTransformWebConfigDisabled>` property set to `true`.

```
<PropertyGroup>
  <TargetFramework>netcoreapp2.2</TargetFramework>
  <RuntimeIdentifier>win7-x64</RuntimeIdentifier>
  <SelfContained>false</SelfContained>
  <IsTransformWebConfigDisabled>true</IsTransformWebConfigDisabled>
</PropertyGroup>
```

Self-contained deployment (SCD)

Self-contained deployment (SCD) doesn't rely on the presence of a shared framework on the host system. The runtime and the app's dependencies are deployed with the app.

A Windows Runtime Identifier (RID) is included in the `<PropertyGroup>` that contains the target framework:

```
<RuntimeIdentifier>win7-x64</RuntimeIdentifier>
```

To publish for multiple RIDs:

- Provide the RIDs in a semicolon-delimited list.
- Use the property name <RuntimeIdentifiers> (plural).

For more information, see .NET Core RID Catalog.

A `<SelfContained>` property is set to `true`:

```
<SelfContained>true</SelfContained>
```

Service user account

To create a user account for a service, use the New-LocalUser cmdlet from an administrative PowerShell 6 command shell.

On Windows 10 October 2018 Update (version 1809/build 10.0.17763) or later:

```
New-LocalUser -Name {SERVICE NAME}
```

On Windows OS earlier than the Windows 10 October 2018 Update (version 1809/build 10.0.17763):

```
powershell -Command "New-LocalUser -Name {SERVICE NAME}"
```

Provide a strong password when prompted.

Unless the `-AccountExpires` parameter is supplied to the New-LocalUser cmdlet with an expiration DateTime, the account doesn't expire.

For more information, see Microsoft.PowerShell.LocalAccounts and Service User Accounts.

An alternative approach to managing users when using Active Directory is to use Managed Service Accounts. For more information, see Group Managed Service Accounts Overview.

Log on as a service rights

To establish *Log on as a service* rights for a service user account:

1. Open the Local Security Policy editor by running *secpol.msc*.
2. Expand the **Local Policies** node and select **User Rights Assignment**.
3. Open the **Log on as a service** policy.
4. Select **Add User or Group**.
5. Provide the object name (user account) using either of the following approaches:
   a. Type the user account (`{DOMAIN OR COMPUTER NAME\USER}`) in the object name field and select **OK** to add the user to the policy.
   b. Select **Advanced**. Select **Find Now**. Select the user account from the list. Select **OK**. Select **OK** again to add the user to the policy.
6. Select **OK** or **Apply** to accept the changes.

Create and manage the Windows Service

Create a service

Use PowerShell commands to register a service. From an administrative PowerShell 6 command shell, execute the following commands:

```
$acl = Get-Acl "{EXE PATH}"
$aclRuleArgs = {DOMAIN OR COMPUTER NAME\USER}, "Read,Write,ReadAndExecute", "ContainerInherit,ObjectInherit",
"None", "Allow"
$accessRule = New-Object System.Security.AccessControl.FileSystemAccessRule($aclRuleArgs)
$acl.SetAccessRule($accessRule)
$acl | Set-Acl "{EXE PATH}"

New-Service -Name {SERVICE NAME} -BinaryPathName {EXE FILE PATH} -Credential {DOMAIN OR COMPUTER NAME\USER} -
Description "{DESCRIPTION}" -DisplayName "{DISPLAY NAME}" -StartupType Automatic
```

- `{EXE PATH}`: Path to the app's folder on the host (for example, `d:\myservice`). Don't include the app's executable in the path. A trailing slash isn't required.
- `{DOMAIN OR COMPUTER NAME\USER}`: Service user account (for example, `Contoso\ServiceUser`).
- `{SERVICE NAME}`: Service name (for example, `MyService`).
- `{EXE FILE PATH}`: The app's executable path (for example, `d:\myservice\myservice.exe`). Include the executable's file name with extension.
- `{DESCRIPTION}`: Service description (for example, `My sample service`).
- `{DISPLAY NAME}`: Service display name (for example, `My Service`).

Start a service

Start a service with the following PowerShell 6 command:

```
Start-Service -Name {SERVICE NAME}
```

The command takes a few seconds to start the service.

Determine a service's status

To check the status of a service, use the following PowerShell 6 command:

```
Get-Service -Name {SERVICE NAME}
```

The status is reported as one of the following values:

- `Starting`
- `Running`
- `Stopping`
- `Stopped`

Stop a service

Stop a service with the following Powershell 6 command:

```
Stop-Service -Name {SERVICE NAME}
```

Remove a service

After a short delay to stop a service, remove a service with the following Powershell 6 command:

```
Remove-Service -Name {SERVICE NAME}
```

Handle starting and stopping events

To handle OnStarting, OnStarted, and OnStopping events:

1. Create a class that derives from WebHostService with the `OnStarting`, `OnStarted`, and `OnStopping` methods:

```
[DesignerCategory("Code")]
internal class CustomWebHostService : WebHostService
{
    private ILogger _logger;

    public CustomWebHostService(IWebHost host) : base(host)
    {
        _logger = host.Services
            .GetRequiredService<ILogger<CustomWebHostService>>();
    }

    protected override void OnStarting(string[] args)
    {
        _logger.LogInformation("OnStarting method called.");
        base.OnStarting(args);
    }

    protected override void OnStarted()
    {
        _logger.LogInformation("OnStarted method called.");
        base.OnStarted();
    }

    protected override void OnStopping()
    {
        _logger.LogInformation("OnStopping method called.");
        base.OnStopping();
    }
}
```

2. Create an extension method for IWebHost that passes the `CustomWebHostService` to Run:

```
public static class WebHostServiceExtensions
{
    public static void RunAsCustomService(this IWebHost host)
    {
        var webHostService = new CustomWebHostService(host);
        ServiceBase.Run(webHostService);
    }
}
```

3. In `Program.Main`, call the `RunAsCustomService` extension method instead of RunAsService:

```
host.RunAsCustomService();
```

   To see the location of RunAsService in `Program.Main`, refer to the code sample shown in the Deployment type section.

Proxy server and load balancer scenarios

Services that interact with requests from the Internet or a corporate network and are behind a proxy or load balancer might require additional configuration. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Configure endpoints

By default, ASP.NET Core binds to `http://localhost:5000`. Configure the URL and port by setting the `ASPNETCORE_URLS` environment variable.

For additional URL and port configuration approaches, see the relevant server article:

- Kestrel web server implementation in ASP.NET Core
- HTTP.sys web server implementation in ASP.NET Core

The preceding guidance covers support for HTTPS endpoints. For example, configure the app for HTTPS when authentication is used with a Windows Service.

> **NOTE**
> Use of the ASP.NET Core HTTPS development certificate to secure a service endpoint isn't supported.

Current directory and content root

The current working directory returned by calling GetCurrentDirectory for a Windows Service is the *C:\WINDOWS\system32* folder. The *system32* folder isn't a suitable location to store a service's files (for example, settings files). Use one of the following approaches to maintain and access a service's assets and settings files.

Set the content root path to the app's folder

The ContentRootPath is the same path provided to the `binPath` argument when a service is created. Instead of calling `GetCurrentDirectory` to create paths to settings files, call SetCurrentDirectory with the path to the app's content root.

In `Program.Main`, determine the path to the folder of the service's executable and use the path to establish the app's content root:

```
var pathToExe = Process.GetCurrentProcess().MainModule.FileName;
var pathToContentRoot = Path.GetDirectoryName(pathToExe);
Directory.SetCurrentDirectory(pathToContentRoot);

CreateWebHostBuilder(args)
    .Build()
    .RunAsService();
```

Store a service's files in a suitable location on disk

Specify an absolute path with SetBasePath when using an IConfigurationBuilder to the folder containing the files.

Troubleshoot

To troubleshoot a Windows Service app, see Troubleshoot and debug ASP.NET Core projects.

Common errors

- An old or pre-release version of PowerShell is in use.
- The registered service doesn't use the app's **published** output from the dotnet publish command. Output of the dotnet build command isn't supported for app deployment. Published assets are found in either of the following folders depending on the deployment type:
  - *bin/Release/{TARGET FRAMEWORK}/publish* (FDD)
  - *bin/Release/{TARGET FRAMEWORK}/{RUNTIME IDENTIFIER}/publish* (SCD)
- The service isn't in the RUNNING state.
- The paths to resources that the app uses (for example, certificates) are incorrect. The base path of a Windows Service is *c:\Windows\System32*.
- The user doesn't have *Log on as a service* rights.
- The user's password is expired or incorrectly passed when executing the `New-Service` PowerShell command.

- The app requires ASP.NET Core authentication but isn't configured for secure connections (HTTPS).
- The request URL port is incorrect or not configured correctly in the app.

System and Application Event Logs

Access the System and Application Event Logs:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.
2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **System** to open the System Event Log. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app.

Run the app at a command prompt

Many startup errors don't produce useful information in the event logs. You can find the cause of some errors by running the app at a command prompt on the hosting system. To log additional detail from the app, lower the log level or run the app in the Development environment.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.
2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

Slow or hanging app

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`.
2. Run the EnableDumps PowerShell script with the application executable name:

   ```
   .\EnableDumps {APPLICATION EXE} c:\dumps
   ```
3. Run the app under the conditions that cause the crash to occur.
4. After the crash has occurred, run the DisableDumps PowerShell script:

   ```
   .\DisableDumps {APPLICATION EXE}
   ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> **WARNING**
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App hangs, fails during startup, or runs normally

When an app *hangs* (stops responding but doesn't crash), fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Additional resources

- Kestrel endpoint configuration (includes HTTPS configuration and SNI support)
- ASP.NET Core Web Host
- Troubleshoot and debug ASP.NET Core projects

An ASP.NET Core app can be hosted on Windows as a Windows Service without using IIS. When hosted as a Windows Service, the app automatically starts after server reboots.

View or download sample code (how to download)

Prerequisites

- ASP.NET Core SDK 2.1 or later
- PowerShell 6.2 or later

App configuration

The app requires package references for Microsoft.AspNetCore.Hosting.WindowsServices and Microsoft.Extensions.Logging.EventLog.

To test and debug when running outside of a service, add code to determine if the app is running as a service or a console app. Inspect if the debugger is attached or a `--console` switch is present. If either condition is true (the app isn't run as a service), call Run. If the conditions are false (the app is run as a service):

- Call SetCurrentDirectory and use a path to the app's published location. Don't call GetCurrentDirectory to obtain the path because a Windows Service app returns the *C:\WINDOWS\system32* folder when GetCurrentDirectory is called. For more information, see the Current directory and content root section. This step is performed before the app is configured in `CreateWebHostBuilder`.
- Call RunAsService to run the app as a service.

Because the Command-line Configuration Provider requires name-value pairs for command-line arguments, the `--console` switch is removed from the arguments before CreateDefaultBuilder receives the arguments.

To write to the Windows Event Log, add the EventLog provider to ConfigureLogging. Set the logging level with the `Logging:LogLevel:Default` key in the *appsettings.Production.json* file.

In the following example from the sample app, `RunAsCustomService` is called instead of RunAsService in order to handle lifetime events within the app. For more information, see the Handle starting and stopping events section.

```
public class Program
{
    public static void Main(string[] args)
    {
        var isService = !(Debugger.IsAttached || args.Contains("--console"));

        if (isService)
        {
            var pathToExe = Process.GetCurrentProcess().MainModule.FileName;
            var pathToContentRoot = Path.GetDirectoryName(pathToExe);
            Directory.SetCurrentDirectory(pathToContentRoot);
        }

        var builder = CreateWebHostBuilder(
            args.Where(arg => arg != "--console").ToArray());

        var host = builder.Build();

        if (isService)
        {
            // To run the app without the CustomWebHostService change the
            // next line to host.RunAsService();
            host.RunAsCustomService();
        }
        else
        {
            host.Run();
        }
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .ConfigureLogging((hostingContext, logging) =>
            {
                logging.AddEventLog();
            })
            .ConfigureAppConfiguration((context, config) =>
            {
                // Configure the app here.
            })
            .UseStartup<Startup>();
}
```

Deployment type

For information and advice on deployment scenarios, see .NET Core application deployment.

SDK

For a web app-based service that uses the Razor Pages or MVC frameworks, specify the Web SDK in the project file:

```
<Project Sdk="Microsoft.NET.Sdk.Web">
```

If the service only executes background tasks (for example, hosted services), specify the Worker SDK in the project file:

```
<Project Sdk="Microsoft.NET.Sdk.Worker">
```

Framework-dependent deployment (FDD)

Framework-dependent deployment (FDD) relies on the presence of a shared system-wide version of .NET Core on

the target system. When the FDD scenario is adopted following the guidance in this article, the SDK produces an executable (*.exe*), called a *framework-dependent executable*.

The Windows Runtime Identifier (RID) (<RuntimeIdentifier>) contains the target framework. In the following example, the RID is set to `win7-x64`. The `<SelfContained>` property is set to `false`. These properties instruct the SDK to generate an executable (*.exe*) file for Windows and an app that depends on the shared .NET Core framework.

The `<UseAppHost>` property is set to `true`. This property provides the service with an activation path (an executable, *.exe*) for an FDD.

A *web.config* file, which is normally produced when publishing an ASP.NET Core app, is unnecessary for a Windows Services app. To disable the creation of the *web.config* file, add the `<IsTransformWebConfigDisabled>` property set to `true`.

```
<PropertyGroup>
  <TargetFramework>netcoreapp2.2</TargetFramework>
  <RuntimeIdentifier>win7-x64</RuntimeIdentifier>
  <UseAppHost>true</UseAppHost>
  <SelfContained>false</SelfContained>
  <IsTransformWebConfigDisabled>true</IsTransformWebConfigDisabled>
</PropertyGroup>
```

Self-contained deployment (SCD)

Self-contained deployment (SCD) doesn't rely on the presence of a shared framework on the host system. The runtime and the app's dependencies are deployed with the app.

A Windows Runtime Identifier (RID) is included in the `<PropertyGroup>` that contains the target framework:

```
<RuntimeIdentifier>win7-x64</RuntimeIdentifier>
```

To publish for multiple RIDs:

- Provide the RIDs in a semicolon-delimited list.
- Use the property name <RuntimeIdentifiers> (plural).

For more information, see .NET Core RID Catalog.

A `<SelfContained>` property is set to `true`:

```
<SelfContained>true</SelfContained>
```

Service user account

To create a user account for a service, use the New-LocalUser cmdlet from an administrative PowerShell 6 command shell.

On Windows 10 October 2018 Update (version 1809/build 10.0.17763) or later:

```
New-LocalUser -Name {SERVICE NAME}
```

On Windows OS earlier than the Windows 10 October 2018 Update (version 1809/build 10.0.17763):

```
powershell -Command "New-LocalUser -Name {SERVICE NAME}"
```

Provide a strong password when prompted.

Unless the `-AccountExpires` parameter is supplied to the New-LocalUser cmdlet with an expiration DateTime, the account doesn't expire.

For more information, see Microsoft.PowerShell.LocalAccounts and Service User Accounts.

An alternative approach to managing users when using Active Directory is to use Managed Service Accounts. For more information, see Group Managed Service Accounts Overview.

Log on as a service rights

To establish *Log on as a service* rights for a service user account:

1. Open the Local Security Policy editor by running *secpol.msc*.
2. Expand the **Local Policies** node and select **User Rights Assignment**.
3. Open the **Log on as a service** policy.
4. Select **Add User or Group**.
5. Provide the object name (user account) using either of the following approaches:
   a. Type the user account (`{DOMAIN OR COMPUTER NAME\USER}`) in the object name field and select **OK** to add the user to the policy.
   b. Select **Advanced**. Select **Find Now**. Select the user account from the list. Select **OK**. Select **OK** again to add the user to the policy.
6. Select **OK** or **Apply** to accept the changes.

Create and manage the Windows Service

Create a service

Use PowerShell commands to register a service. From an administrative PowerShell 6 command shell, execute the following commands:

```
$acl = Get-Acl "{EXE PATH}"
$aclRuleArgs = {DOMAIN OR COMPUTER NAME\USER}, "Read,Write,ReadAndExecute", "ContainerInherit,ObjectInherit",
"None", "Allow"
$accessRule = New-Object System.Security.AccessControl.FileSystemAccessRule($aclRuleArgs)
$acl.SetAccessRule($accessRule)
$acl | Set-Acl "{EXE PATH}"

New-Service -Name {SERVICE NAME} -BinaryPathName {EXE FILE PATH} -Credential {DOMAIN OR COMPUTER NAME\USER} -
Description "{DESCRIPTION}" -DisplayName "{DISPLAY NAME}" -StartupType Automatic
```

- `{EXE PATH}` : Path to the app's folder on the host (for example, `d:\myservice`). Don't include the app's executable in the path. A trailing slash isn't required.
- `{DOMAIN OR COMPUTER NAME\USER}` : Service user account (for example, `Contoso\ServiceUser`).
- `{SERVICE NAME}` : Service name (for example, `MyService`).
- `{EXE FILE PATH}` : The app's executable path (for example, `d:\myservice\myservice.exe`). Include the executable's file name with extension.
- `{DESCRIPTION}` : Service description (for example, `My sample service`).
- `{DISPLAY NAME}` : Service display name (for example, `My Service`).

Start a service

Start a service with the following PowerShell 6 command:

```
Start-Service -Name {SERVICE NAME}
```

The command takes a few seconds to start the service.

Determine a service's status

To check the status of a service, use the following PowerShell 6 command:

```
Get-Service -Name {SERVICE NAME}
```

The status is reported as one of the following values:

- `Starting`
- `Running`
- `Stopping`
- `Stopped`

Stop a service

Stop a service with the following Powershell 6 command:

```
Stop-Service -Name {SERVICE NAME}
```

Remove a service

After a short delay to stop a service, remove a service with the following Powershell 6 command:

```
Remove-Service -Name {SERVICE NAME}
```

Handle starting and stopping events

To handle OnStarting, OnStarted, and OnStopping events:

1. Create a class that derives from WebHostService with the `OnStarting`, `OnStarted`, and `OnStopping` methods:

```
[DesignerCategory("Code")]
internal class CustomWebHostService : WebHostService
{
    private ILogger _logger;

    public CustomWebHostService(IWebHost host) : base(host)
    {
        _logger = host.Services
            .GetRequiredService<ILogger<CustomWebHostService>>();
    }

    protected override void OnStarting(string[] args)
    {
        _logger.LogInformation("OnStarting method called.");
        base.OnStarting(args);
    }

    protected override void OnStarted()
    {
        _logger.LogInformation("OnStarted method called.");
        base.OnStarted();
    }

    protected override void OnStopping()
    {
        _logger.LogInformation("OnStopping method called.");
        base.OnStopping();
    }
}
```

2. Create an extension method for IWebHost that passes the `CustomWebHostService` to Run:

```
public static class WebHostServiceExtensions
{
    public static void RunAsCustomService(this IWebHost host)
    {
        var webHostService = new CustomWebHostService(host);
        ServiceBase.Run(webHostService);
    }
}
```

3. In `Program.Main`, call the `RunAsCustomService` extension method instead of RunAsService:

```
host.RunAsCustomService();
```

   To see the location of RunAsService in `Program.Main`, refer to the code sample shown in the Deployment type section.

Proxy server and load balancer scenarios

Services that interact with requests from the Internet or a corporate network and are behind a proxy or load balancer might require additional configuration. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Configure endpoints

By default, ASP.NET Core binds to `http://localhost:5000`. Configure the URL and port by setting the `ASPNETCORE_URLS` environment variable.

For additional URL and port configuration approaches, see the relevant server article:

- Kestrel web server implementation in ASP.NET Core
- HTTP.sys web server implementation in ASP.NET Core

The preceding guidance covers support for HTTPS endpoints. For example, configure the app for HTTPS when authentication is used with a Windows Service.

> **NOTE**
> Use of the ASP.NET Core HTTPS development certificate to secure a service endpoint isn't supported.

Current directory and content root

The current working directory returned by calling GetCurrentDirectory for a Windows Service is the *C:\WINDOWS\system32* folder. The *system32* folder isn't a suitable location to store a service's files (for example, settings files). Use one of the following approaches to maintain and access a service's assets and settings files.

Set the content root path to the app's folder

The ContentRootPath is the same path provided to the `binPath` argument when a service is created. Instead of calling `GetCurrentDirectory` to create paths to settings files, call SetCurrentDirectory with the path to the app's content root.

In `Program.Main`, determine the path to the folder of the service's executable and use the path to establish the app's content root:

```
var pathToExe = Process.GetCurrentProcess().MainModule.FileName;
var pathToContentRoot = Path.GetDirectoryName(pathToExe);
Directory.SetCurrentDirectory(pathToContentRoot);

CreateWebHostBuilder(args)
    .Build()
    .RunAsService();
```

Store a service's files in a suitable location on disk

Specify an absolute path with SetBasePath when using an IConfigurationBuilder to the folder containing the files.

Troubleshoot

To troubleshoot a Windows Service app, see Troubleshoot and debug ASP.NET Core projects.

Common errors

- An old or pre-release version of PowerShell is in use.
- The registered service doesn't use the app's **published** output from the dotnet publish command. Output of the dotnet build command isn't supported for app deployment. Published assets are found in either of the following folders depending on the deployment type:
  - *bin/Release/{TARGET FRAMEWORK}/publish* (FDD)
  - *bin/Release/{TARGET FRAMEWORK}/{RUNTIME IDENTIFIER}/publish* (SCD)
- The service isn't in the RUNNING state.
- The paths to resources that the app uses (for example, certificates) are incorrect. The base path of a Windows Service is *c:\Windows\System32*.
- The user doesn't have *Log on as a service* rights.
- The user's password is expired or incorrectly passed when executing the `New-Service` PowerShell command.

- The app requires ASP.NET Core authentication but isn't configured for secure connections (HTTPS).
- The request URL port is incorrect or not configured correctly in the app.

System and Application Event Logs

Access the System and Application Event Logs:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.
2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **System** to open the System Event Log. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app.

Run the app at a command prompt

Many startup errors don't produce useful information in the event logs. You can find the cause of some errors by running the app at a command prompt on the hosting system. To log additional detail from the app, lower the log level or run the app in the Development environment.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.
2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

Slow or hanging app

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`.
2. Run the EnableDumps PowerShell script with the application executable name:

   ```
   .\EnableDumps {APPLICATION EXE} c:\dumps
   ```
3. Run the app under the conditions that cause the crash to occur.
4. After the crash has occurred, run the DisableDumps PowerShell script:

   ```
   .\DisableDumps {APPLICATION EXE}
   ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> **WARNING**
>
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App hangs, fails during startup, or runs normally

When an app *hangs* (stops responding but doesn't crash), fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Host ASP.NET Core on Linux with Nginx

9/22/2020 • 14 minutes to read • Edit Online

By Sourabh Shirhatti

This guide explains setting up a production-ready ASP.NET Core environment on an Ubuntu 16.04 server. These instructions likely work with newer versions of Ubuntu, but the instructions haven't been tested with newer versions.

For information on other Linux distributions supported by ASP.NET Core, see Prerequisites for .NET Core on Linux.

> **NOTE**
> For Ubuntu 14.04, *supervisord* is recommended as a solution for monitoring the Kestrel process. *systemd* isn't available on Ubuntu 14.04. For Ubuntu 14.04 instructions, see the previous version of this topic.

This guide:

- Places an existing ASP.NET Core app behind a reverse proxy server.
- Sets up the reverse proxy server to forward requests to the Kestrel web server.
- Ensures the web app runs on startup as a daemon.
- Configures a process management tool to help restart the web app.

Prerequisites

1. Access to an Ubuntu 16.04 server with a standard user account with sudo privilege.
2. Install the .NET Core runtime on the server.
   a. Visit the Download .NET Core page.
   b. Select the latest non-preview .NET Core version.
   c. Download the latest non-preview runtime in the table under **Run apps - Runtime**.
   d. Select the Linux **Package manager instructions** link and follow the Ubuntu instructions for your version of Ubuntu.
3. An existing ASP.NET Core app.

At any point in the future after upgrading the shared framework, restart the ASP.NET Core apps hosted by the server.

Publish and copy over the app

Configure the app for a framework-dependent deployment.

If the app is run locally and isn't configured to make secure connections (HTTPS), adopt either of the following approaches:

- Configure the app to handle secure local connections. For more information, see the HTTPS configuration section.
- Remove `https://localhost:5001` (if present) from the `applicationUrl` property in the *Properties/launchSettings.json* file.

Run dotnet publish from the development environment to package an app into a directory (for example, *bin/Release/<target_framework_moniker>/publish*) that can run on the server:

```
dotnet publish --configuration Release
```

The app can also be published as a self-contained deployment if you prefer not to maintain the .NET Core runtime on the server.

Copy the ASP.NET Core app to the server using a tool that integrates into the organization's workflow (for example, SCP, SFTP). It's common to locate web apps under the *var* directory (for example, *var/www/helloapp*).

> **NOTE**
> Under a production deployment scenario, a continuous integration workflow does the work of publishing the app and copying the assets to the server.

Test the app:

1. From the command line, run the app: `dotnet <app_assembly>.dll`.
2. In a browser, navigate to `http://<serveraddress>:<port>` to verify the app works on Linux locally.

Configure a reverse proxy server

A reverse proxy is a common setup for serving dynamic web apps. A reverse proxy terminates the HTTP request and forwards it to the ASP.NET Core app.

Use a reverse proxy server

Kestrel is great for serving dynamic content from ASP.NET Core. However, the web serving capabilities aren't as feature rich as servers such as IIS, Apache, or Nginx. A reverse proxy server can offload work such as serving static content, caching requests, compressing requests, and HTTPS termination from the HTTP server. A reverse proxy server may reside on a dedicated machine or may be deployed alongside an HTTP server.

For the purposes of this guide, a single instance of Nginx is used. It runs on the same server, alongside the HTTP server. Based on requirements, a different setup may be chosen.

Because requests are forwarded by reverse proxy, use the Forwarded Headers Middleware from the Microsoft.AspNetCore.HttpOverrides package. The middleware updates the `Request.Scheme`, using the `X-Forwarded-Proto` header, so that redirect URIs and other security policies work correctly.

Forwarded Headers Middleware should run before other middleware. This ordering ensures that the middleware relying on forwarded headers information can consume the header values for processing. To run Forwarded Headers Middleware after diagnostics and error handling middleware, see Forwarded Headers Middleware order.

Invoke the UseForwardedHeaders method at the top of `Startup.Configure` before calling other middleware. Configure the middleware to forward the `X-Forwarded-For` and `X-Forwarded-Proto` headers:

```
// using Microsoft.AspNetCore.HttpOverrides;

app.UseForwardedHeaders(new ForwardedHeadersOptions
{
    ForwardedHeaders = ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto
});

app.UseAuthentication();
```

If no ForwardedHeadersOptions are specified to the middleware, the default headers to forward are `None`.

Proxies running on loopback addresses (127.0.0.0/8, [::1]), including the standard localhost address (127.0.0.1), are trusted by default. If other trusted proxies or networks within the organization handle requests between the Internet and the web server, add them to the list of KnownProxies or KnownNetworks with ForwardedHeadersOptions. The following example adds a trusted proxy server at IP address 10.0.0.100 to the Forwarded Headers Middleware `KnownProxies` in `Startup.ConfigureServices`:

```
// using System.Net;

services.Configure<ForwardedHeadersOptions>(options =>
{
    options.KnownProxies.Add(IPAddress.Parse("10.0.0.100"));
});
```

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Install Nginx

Use `apt-get` to install Nginx. The installer creates a *systemd* init script that runs Nginx as daemon on system startup. Follow the installation instructions for Ubuntu at Nginx: Official Debian/Ubuntu packages.

> **NOTE**
> If optional Nginx modules are required, building Nginx from source might be required.

Since Nginx was installed for the first time, explicitly start it by running:

```
sudo service nginx start
```

Verify a browser displays the default landing page for Nginx. The landing page is reachable at `http://<server_IP_address>/index.nginx-debian.html`.

Configure Nginx

To configure Nginx as a reverse proxy to forward requests to your ASP.NET Core app, modify */etc/nginx/sites-available/default*. Open it in a text editor, and replace the contents with the following:

```
server {
    listen        80;
    server_name   example.com *.example.com;
    location / {
        proxy_pass         http://localhost:5000;
        proxy_http_version 1.1;
        proxy_set_header   Upgrade $http_upgrade;
        proxy_set_header   Connection keep-alive;
        proxy_set_header   Host $host;
        proxy_cache_bypass $http_upgrade;
        proxy_set_header   X-Forwarded-For $proxy_add_x_forwarded_for;
        proxy_set_header   X-Forwarded-Proto $scheme;
    }
}
```

If the app is a Blazor Server app that relies on SignalR WebSockets, see Host and deploy ASP.NET Core Blazor Server for information on how to set the `Connection` header.

When no `server_name` matches, Nginx uses the default server. If no default server is defined, the first server in the configuration file is the default server. As a best practice, add a specific default server which returns a status

code of 444 in your configuration file. A default server configuration example is:

```
server {
    listen   80 default_server;
    # listen [::]:80 default_server deferred;
    return   444;
}
```

With the preceding configuration file and default server, Nginx accepts public traffic on port 80 with host header `example.com` or `*.example.com`. Requests not matching these hosts won't get forwarded to Kestrel. Nginx forwards the matching requests to Kestrel at `http://localhost:5000`. See How nginx processes a request for more information. To change Kestrel's IP/port, see Kestrel: Endpoint configuration.

> **WARNING**
> Failure to specify a proper server_name directive exposes your app to security vulnerabilities. Subdomain wildcard binding (for example, `*.example.com`) doesn't pose this security risk if you control the entire parent domain (as opposed to `*.com`, which is vulnerable). See rfc7230 section-5.4 for more information.

Once the Nginx configuration is established, run `sudo nginx -t` to verify the syntax of the configuration files. If the configuration file test is successful, force Nginx to pick up the changes by running `sudo nginx -s reload`.

To directly run the app on the server:

1. Navigate to the app's directory.
2. Run the app: `dotnet <app_assembly.dll>`, where `app_assembly.dll` is the assembly file name of the app.

If the app runs on the server but fails to respond over the Internet, check the server's firewall and confirm that port 80 is open. If using an Azure Ubuntu VM, add a Network Security Group (NSG) rule that enables inbound port 80 traffic. There's no need to enable an outbound port 80 rule, as the outbound traffic is automatically granted when the inbound rule is enabled.

When done testing the app, shut the app down with `Ctrl+C` at the command prompt.

Monitor the app

The server is setup to forward requests made to `http://<serveraddress>:80` on to the ASP.NET Core app running on Kestrel at `http://127.0.0.1:5000`. However, Nginx isn't set up to manage the Kestrel process. *systemd* can be used to create a service file to start and monitor the underlying web app. *systemd* is an init system that provides many powerful features for starting, stopping, and managing processes.

Create the service file

Create the service definition file:

```
sudo nano /etc/systemd/system/kestrel-helloapp.service
```

The following is an example service file for the app:

```
[Unit]
Description=Example .NET Web API App running on Ubuntu

[Service]
WorkingDirectory=/var/www/helloapp
ExecStart=/usr/bin/dotnet /var/www/helloapp/helloapp.dll
Restart=always
# Restart service after 10 seconds if the dotnet service crashes:
RestartSec=10
KillSignal=SIGINT
SyslogIdentifier=dotnet-example
User=www-data
Environment=ASPNETCORE_ENVIRONMENT=Production
Environment=DOTNET_PRINT_TELEMETRY_MESSAGE=false

[Install]
WantedBy=multi-user.target
```

In the preceding example, the user that manages the service is specified by the `User` option. The user (`www-data`) must exist and have proper ownership of the app's files.

Use `TimeoutStopSec` to configure the duration of time to wait for the app to shut down after it receives the initial interrupt signal. If the app doesn't shut down in this period, SIGKILL is issued to terminate the app. Provide the value as unitless seconds (for example, `150`), a time span value (for example, `2min 30s`), or `infinity` to disable the timeout. `TimeoutStopSec` defaults to the value of `DefaultTimeoutStopSec` in the manager configuration file (*systemd-system.conf*, *system.conf.d*, *systemd-user.conf*, *user.conf.d*). The default timeout for most distributions is 90 seconds.

```
# The default value is 90 seconds for most distributions.
TimeoutStopSec=90
```

Linux has a case-sensitive file system. Setting ASPNETCORE_ENVIRONMENT to "Production" results in searching for the configuration file *appsettings.Production.json*, not *appsettings.production.json*.

Some values (for example, SQL connection strings) must be escaped for the configuration providers to read the environment variables. Use the following command to generate a properly escaped value for use in the configuration file:

```
systemd-escape "<value-to-escape>"
```

Colon (`:`) separators aren't supported in environment variable names. Use a double underscore (`__`) in place of a colon. The Environment Variables configuration provider converts double-underscores into colons when environment variables are read into configuration. In the following example, the connection string key `ConnectionStrings:DefaultConnection` is set into the service definition file as `ConnectionStrings__DefaultConnection` :

Colon (`:`) separators aren't supported in environment variable names. Use a double underscore (`__`) in place of a colon. The Environment Variables configuration provider converts double-underscores into colons when environment variables are read into configuration. In the following example, the connection string key `ConnectionStrings:DefaultConnection` is set into the service definition file as `ConnectionStrings__DefaultConnection` :

```
Environment=ConnectionStrings__DefaultConnection={Connection String}
```

Save the file and enable the service.

```
sudo systemctl enable kestrel-helloapp.service
```

Start the service and verify that it's running.

```
sudo systemctl start kestrel-helloapp.service
sudo systemctl status kestrel-helloapp.service

● kestrel-helloapp.service - Example .NET Web API App running on Ubuntu
   Loaded: loaded (/etc/systemd/system/kestrel-helloapp.service; enabled)
   Active: active (running) since Thu 2016-10-18 04:09:35 NZDT; 35s ago
Main PID: 9021 (dotnet)
   CGroup: /system.slice/kestrel-helloapp.service
           └─9021 /usr/local/bin/dotnet /var/www/helloapp/helloapp.dll
```

With the reverse proxy configured and Kestrel managed through systemd, the web app is fully configured and can be accessed from a browser on the local machine at `http://localhost`. It's also accessible from a remote machine, barring any firewall that might be blocking. Inspecting the response headers, the `Server` header shows the ASP.NET Core app being served by Kestrel.

```
HTTP/1.1 200 OK
Date: Tue, 11 Oct 2016 16:22:23 GMT
Server: Kestrel
Keep-Alive: timeout=5, max=98
Connection: Keep-Alive
Transfer-Encoding: chunked
```

View logs

Since the web app using Kestrel is managed using `systemd`, all events and processes are logged to a centralized journal. However, this journal includes all entries for all services and processes managed by `systemd`. To view the `kestrel-helloapp.service`-specific items, use the following command:

```
sudo journalctl -fu kestrel-helloapp.service
```

For further filtering, time options such as `--since today`, `--until 1 hour ago` or a combination of these can reduce the amount of entries returned.

```
sudo journalctl -fu kestrel-helloapp.service --since "2016-10-18" --until "2016-10-18 04:00"
```

Data protection

The ASP.NET Core Data Protection stack is used by several ASP.NET Core middlewares, including authentication middleware (for example, cookie middleware) and cross-site request forgery (CSRF) protections. Even if Data Protection APIs aren't called by user code, data protection should be configured to create a persistent cryptographic key store. If data protection isn't configured, the keys are held in memory and discarded when the app restarts.

If the key ring is stored in memory when the app restarts:

- All cookie-based authentication tokens are invalidated.
- Users are required to sign in again on their next request.
- Any data protected with the key ring can no longer be decrypted. This may include CSRF tokens and ASP.NET Core MVC TempData cookies.

To configure data protection to persist and encrypt the key ring, see:

- Key storage providers in ASP.NET Core
- Key encryption at rest in Windows and Azure using ASP.NET Core

Long request header fields

Proxy server default settings typically limit request header fields to 4 K or 8 K depending on the platform. An app may require fields longer than the default (for example, apps that use Azure Active Directory). If longer fields are required, the proxy server's default settings require adjustment. The values to apply depend on the scenario. For more information, see your server's documentation.

- proxy_buffer_size
- proxy_buffers
- proxy_busy_buffers_size
- large_client_header_buffers

> **WARNING**
> Don't increase the default values of proxy buffers unless necessary. Increasing these values increases the risk of buffer overrun (overflow) and Denial of Service (DoS) attacks by malicious users.

Secure the app

Enable AppArmor

Linux Security Modules (LSM) is a framework that's part of the Linux kernel since Linux 2.6. LSM supports different implementations of security modules. AppArmor is a LSM that implements a Mandatory Access Control system which allows confining the program to a limited set of resources. Ensure AppArmor is enabled and properly configured.

Configure the firewall

Close off all external ports that are not in use. Uncomplicated firewall (ufw) provides a front end for `iptables` by providing a CLI for configuring the firewall.

> **WARNING**
> A firewall will prevent access to the whole system if not configured correctly. Failure to specify the correct SSH port will effectively lock you out of the system if you are using SSH to connect to it. The default port is 22. For more information, see the introduction to ufw and the manual.

Install `ufw` and configure it to allow traffic on any ports needed.

```
sudo apt-get install ufw

sudo ufw allow 22/tcp
sudo ufw allow 80/tcp
sudo ufw allow 443/tcp

sudo ufw enable
```

Secure Nginx

Change the Nginx response name

Edit *src/http/ngx_http_header_filter_module.c*.

```
static char ngx_http_server_string[] = "Server: Web Server" CRLF;
static char ngx_http_server_full_string[] = "Server: Web Server" CRLF;
```

Configure options

Configure the server with additional required modules. Consider using a web app firewall, such as ModSecurity, to harden the app.

HTTPS configuration

Configure the app for secure (HTTPS) local connections

The dotnet run command uses the app's *Properties/launchSettings.json* file, which configures the app to listen on the URLs provided by the `applicationUrl` property (for example, `https://localhost:5001;http://localhost:5000`).

Configure the app to use a certificate in development for the `dotnet run` command or development environment (F5 or Ctrl+F5 in Visual Studio Code) using one of the following approaches:

- Replace the default certificate from configuration (*Recommended*)
- KestrelServerOptions.ConfigureHttpsDefaults

Configure the reverse proxy for secure (HTTPS) client connections

- Configure the server to listen to HTTPS traffic on port `443` by specifying a valid certificate issued by a trusted Certificate Authority (CA).
- Harden the security by employing some of the practices depicted in the following */etc/nginx/nginx.conf* file. Examples include choosing a stronger cipher and redirecting all traffic over HTTP to HTTPS.
- Adding an `HTTP Strict-Transport-Security` (HSTS) header ensures all subsequent requests made by the client are over HTTPS.
- If HTTPS will be disabled in the future, use one of the following approaches:
  - Don't add the HSTS header.
  - Choose a short `max-age` value.

Add the */etc/nginx/proxy.conf* configuration file:

```
proxy_redirect          off;
proxy_set_header        Host $host;
proxy_set_header        X-Real-IP $remote_addr;
proxy_set_header        X-Forwarded-For $proxy_add_x_forwarded_for;
proxy_set_header        X-Forwarded-Proto $scheme;
client_max_body_size    10m;
client_body_buffer_size 128k;
proxy_connect_timeout   90;
proxy_send_timeout      90;
proxy_read_timeout      90;
proxy_buffers           32 4k;
```

Edit the */etc/nginx/nginx.conf* configuration file. The example contains both `http` and `server` sections in one configuration file.

```
http {
    include        /etc/nginx/proxy.conf;
    limit_req_zone $binary_remote_addr zone=one:10m rate=5r/s;
    server_tokens  off;

    sendfile on;
    keepalive_timeout   29; # Adjust to the lowest possible value that makes sense for your use case.
    client_body_timeout 10; client_header_timeout 10; send_timeout 10;

    upstream helloapp{
        server localhost:5000;
    }

    server {
        listen     *:80;
        add_header Strict-Transport-Security max-age=15768000;
        return     301 https://$host$request_uri;
    }

    server {
        listen                    *:443 ssl;
        server_name               example.com;
        ssl_certificate           /etc/ssl/certs/testCert.crt;
        ssl_certificate_key       /etc/ssl/certs/testCert.key;
        ssl_protocols             TLSv1.1 TLSv1.2;
        ssl_prefer_server_ciphers on;
        ssl_ciphers               "EECDH+AESGCM:EDH+AESGCM:AES256+EECDH:AES256+EDH";
        ssl_ecdh_curve            secp384r1;
        ssl_session_cache         shared:SSL:10m;
        ssl_session_tickets       off;
        ssl_stapling              on; #ensure your cert is capable
        ssl_stapling_verify       on; #ensure your cert is capable

        add_header Strict-Transport-Security "max-age=63072000; includeSubdomains; preload";
        add_header X-Frame-Options DENY;
        add_header X-Content-Type-Options nosniff;

        #Redirects all traffic
        location / {
            proxy_pass http://helloapp;
            limit_req  zone=one burst=10 nodelay;
        }
    }
}
```

> **NOTE**
>
> Blazor WebAssembly apps require a larger `burst` parameter value to accommodate the larger number of requests made by an app. For more information, see Host and deploy ASP.NET Core Blazor WebAssembly.

Secure Nginx from clickjacking

Clickjacking, also known as a *UI redress attack*, is a malicious attack where a website visitor is tricked into clicking a link or button on a different page than they're currently visiting. Use `X-FRAME-OPTIONS` to secure the site.

To mitigate clickjacking attacks:

1. Edit the *nginx.conf* file:

```
sudo nano /etc/nginx/nginx.conf
```

Add the line `add_header X-Frame-Options "SAMEORIGIN";`.

2. Save the file.
3. Restart Nginx.

MIME-type sniffing

This header prevents most browsers from MIME-sniffing a response away from the declared content type, as the header instructs the browser not to override the response content type. With the `nosniff` option, if the server says the content is "text/html", the browser renders it as "text/html".

Edit the *nginx.conf* file:

```
sudo nano /etc/nginx/nginx.conf
```

Add the line `add_header X-Content-Type-Options "nosniff";` and save the file, then restart Nginx.

Additional Nginx suggestions

After upgrading the shared framework on the server, restart the ASP.NET Core apps hosted by the server.

Host ASP.NET Core on Linux with Apache

9/22/2020 • 13 minutes to read • Edit Online

By Shayne Boyer

Using this guide, learn how to set up Apache as a reverse proxy server on CentOS 7 to redirect HTTP traffic to an ASP.NET Core web app running on Kestrel server. The mod_proxy extension and related modules create the server's reverse proxy.

Prerequisites

- Server running CentOS 7 with a standard user account with sudo privilege.
- Install the .NET Core runtime on the server.
  1. Visit the Download .NET Core page.
  2. Select the latest non-preview .NET Core version.
  3. Download the latest non-preview runtime in the table under **Run apps - Runtime**.
  4. Select the Linux **Package manager instructions** link and follow the CentOS instructions.
- An existing ASP.NET Core app.

At any point in the future after upgrading the shared framework, restart the ASP.NET Core apps hosted by the server.

Publish and copy over the app

Configure the app for a framework-dependent deployment.

If the app is run locally and isn't configured to make secure connections (HTTPS), adopt either of the following approaches:

- Configure the app to handle secure local connections. For more information, see the HTTPS configuration section.
- Remove `https://localhost:5001` (if present) from the `applicationUrl` property in the *Properties/launchSettings.json* file.

Run dotnet publish from the development environment to package an app into a directory (for example, *bin/Release/<target_framework_moniker>/publish*) that can run on the server:

```
dotnet publish --configuration Release
```

The app can also be published as a self-contained deployment if you prefer not to maintain the .NET Core runtime on the server.

Copy the ASP.NET Core app to the server using a tool that integrates into the organization's workflow (for example, SCP, SFTP). It's common to locate web apps under the *var* directory (for example, *var/www/helloapp*).

> **NOTE**
> Under a production deployment scenario, a continuous integration workflow does the work of publishing the app and copying the assets to the server.

Configure a proxy server

A reverse proxy is a common setup for serving dynamic web apps. The reverse proxy terminates the HTTP request and forwards it to the ASP.NET app.

A proxy server is one which forwards client requests to another server instead of fulfilling requests itself. A reverse proxy forwards to a fixed destination, typically on behalf of arbitrary clients. In this guide, Apache is configured as the reverse proxy running on the same server that Kestrel is serving the ASP.NET Core app.

Because requests are forwarded by reverse proxy, use the Forwarded Headers Middleware from the Microsoft.AspNetCore.HttpOverrides package. The middleware updates the `Request.Scheme`, using the `X-Forwarded-Proto` header, so that redirect URIs and other security policies work correctly.

Any component that depends on the scheme, such as authentication, link generation, redirects, and geolocation, must be placed after invoking the Forwarded Headers Middleware.

Forwarded Headers Middleware should run before other middleware. This ordering ensures that the middleware relying on forwarded headers information can consume the header values for processing. To run Forwarded Headers Middleware after diagnostics and error handling middleware, see Forwarded Headers Middleware order.

Invoke the UseForwardedHeaders method at the top of `Startup.Configure` before calling other middleware. Configure the middleware to forward the `X-Forwarded-For` and `X-Forwarded-Proto` headers:

```
// using Microsoft.AspNetCore.HttpOverrides;

app.UseForwardedHeaders(new ForwardedHeadersOptions
{
    ForwardedHeaders = ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto
});

app.UseAuthentication();
```

If no ForwardedHeadersOptions are specified to the middleware, the default headers to forward are `None`.

Proxies running on loopback addresses (127.0.0.0/8, [::1]), including the standard localhost address (127.0.0.1), are trusted by default. If other trusted proxies or networks within the organization handle requests between the Internet and the web server, add them to the list of KnownProxies or KnownNetworks with ForwardedHeadersOptions. The following example adds a trusted proxy server at IP address 10.0.0.100 to the Forwarded Headers Middleware `KnownProxies` in `Startup.ConfigureServices`:

```
// using System.Net;

services.Configure<ForwardedHeadersOptions>(options =>
{
    options.KnownProxies.Add(IPAddress.Parse("10.0.0.100"));
});
```

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Install Apache

Update CentOS packages to their latest stable versions:

```
sudo yum update -y
```

Install the Apache web server on CentOS with a single `yum` command:

```
sudo yum -y install httpd mod_ssl
```

Sample output after running the command:

```
Downloading packages:
httpd-2.4.6-40.el7.centos.4.x86_64.rpm               | 2.7 MB  00:00:01
Running transaction check
Running transaction test
Transaction test succeeded
Running transaction
Installing : httpd-2.4.6-40.el7.centos.4.x86_64      1/1
Verifying  : httpd-2.4.6-40.el7.centos.4.x86_64      1/1

Installed:
httpd.x86_64 0:2.4.6-40.el7.centos.4

Complete!
```

> **NOTE**
> In this example, the output reflects httpd.86_64 since the CentOS 7 version is 64 bit. To verify where Apache is installed, run `whereis httpd` from a command prompt.

Configure Apache

Configuration files for Apache are located within the `/etc/httpd/conf.d/` directory. Any file with the *.conf* extension is processed in alphabetical order in addition to the module configuration files in `/etc/httpd/conf.modules.d/`, which contains any configuration files necessary to load modules.

Create a configuration file, named *helloapp.conf*, for the app:

```
<VirtualHost *:*>
    RequestHeader set "X-Forwarded-Proto" expr=%{REQUEST_SCHEME}
</VirtualHost>

<VirtualHost *:80>
    ProxyPreserveHost On
    ProxyPass / http://127.0.0.1:5000/
    ProxyPassReverse / http://127.0.0.1:5000/
    ServerName www.example.com
    ServerAlias *.example.com
    ErrorLog ${APACHE_LOG_DIR}helloapp-error.log
    CustomLog ${APACHE_LOG_DIR}helloapp-access.log common
</VirtualHost>
```

The `VirtualHost` block can appear multiple times, in one or more files on a server. In the preceding configuration file, Apache accepts public traffic on port 80. The domain `www.example.com` is being served, and the `*.example.com` alias resolves to the same website. See Name-based virtual host support for more information. Requests are proxied at the root to port 5000 of the server at 127.0.0.1. For bi-directional communication, `ProxyPass` and `ProxyPassReverse` are required. To change Kestrel's IP/port, see Kestrel: Endpoint configuration.

> **WARNING**
> Failure to specify a proper ServerName directive in the **VirtualHost** block exposes your app to security vulnerabilities. Subdomain wildcard binding (for example, `*.example.com`) doesn't pose this security risk if you control the entire parent domain (as opposed to `*.com`, which is vulnerable). See rfc7230 section-5.4 for more information.

Logging can be configured per `VirtualHost` using `ErrorLog` and `CustomLog` directives. `ErrorLog` is the location where the server logs errors, and `CustomLog` sets the filename and format of log file. In this case, this is where request information is logged. There's one line for each request.

Save the file and test the configuration. If everything passes, the response should be `Syntax [OK]`.

```
sudo service httpd configtest
```

Restart Apache:

```
sudo systemctl restart httpd
sudo systemctl enable httpd
```

Monitor the app

Apache is now setup to forward requests made to `http://localhost:80` to the ASP.NET Core app running on Kestrel at `http://127.0.0.1:5000`. However, Apache isn't set up to manage the Kestrel process. Use *systemd* and create a service file to start and monitor the underlying web app. *systemd* is an init system that provides many powerful features for starting, stopping, and managing processes.

Create the service file

Create the service definition file:

```
sudo nano /etc/systemd/system/kestrel-helloapp.service
```

An example service file for the app:

```
[Unit]
Description=Example .NET Web API App running on CentOS 7

[Service]
WorkingDirectory=/var/www/helloapp
ExecStart=/usr/local/bin/dotnet /var/www/helloapp/helloapp.dll
Restart=always
# Restart service after 10 seconds if the dotnet service crashes:
RestartSec=10
KillSignal=SIGINT
SyslogIdentifier=dotnet-example
User=apache
Environment=ASPNETCORE_ENVIRONMENT=Production

[Install]
WantedBy=multi-user.target
```

In the preceding example, the user that manages the service is specified by the `User` option. The user (`apache`) must exist and have proper ownership of the app's files.

Use `TimeoutStopSec` to configure the duration of time to wait for the app to shut down after it receives the initial interrupt signal. If the app doesn't shut down in this period, SIGKILL is issued to terminate the app. Provide the value as unitless seconds (for example, `150`), a time span value (for example, `2min 30s`), or `infinity` to disable the timeout. `TimeoutStopSec` defaults to the value of `DefaultTimeoutStopSec` in the manager configuration file (*systemd-system.conf*, *system.conf.d*, *systemd-user.conf*, *user.conf.d*). The default timeout for most distributions is 90 seconds.

```
# The default value is 90 seconds for most distributions.
TimeoutStopSec=90
```

Some values (for example, SQL connection strings) must be escaped for the configuration providers to read the environment variables. Use the following command to generate a properly escaped value for use in the configuration file:

```
systemd-escape "<value-to-escape>"
```

Colon (`:`) separators aren't supported in environment variable names. Use a double underscore (`__`) in place of a colon. The Environment Variables configuration provider converts double-underscores into colons when environment variables are read into configuration. In the following example, the connection string key `ConnectionStrings:DefaultConnection` is set into the service definition file as `ConnectionStrings__DefaultConnection`:

Colon (`:`) separators aren't supported in environment variable names. Use a double underscore (`__`) in place of a colon. The Environment Variables configuration provider converts double-underscores into colons when environment variables are read into configuration. In the following example, the connection string key `ConnectionStrings:DefaultConnection` is set into the service definition file as `ConnectionStrings__DefaultConnection`:

```
Environment=ConnectionStrings__DefaultConnection={Connection String}
```

Save the file and enable the service:

```
sudo systemctl enable kestrel-helloapp.service
```

Start the service and verify that it's running:

```
sudo systemctl start kestrel-helloapp.service
sudo systemctl status kestrel-helloapp.service

● kestrel-helloapp.service - Example .NET Web API App running on CentOS 7
   Loaded: loaded (/etc/systemd/system/kestrel-helloapp.service; enabled)
   Active: active (running) since Thu 2016-10-18 04:09:35 NZDT; 35s ago
Main PID: 9021 (dotnet)
   CGroup: /system.slice/kestrel-helloapp.service
           └─9021 /usr/local/bin/dotnet /var/www/helloapp/helloapp.dll
```

With the reverse proxy configured and Kestrel managed through *systemd*, the web app is fully configured and can be accessed from a browser on the local machine at `http://localhost`. Inspecting the response headers, the **`Server`** header indicates that the ASP.NET Core app is served by Kestrel:

```
HTTP/1.1 200 OK
Date: Tue, 11 Oct 2016 16:22:23 GMT
Server: Kestrel
Keep-Alive: timeout=5, max=98
Connection: Keep-Alive
Transfer-Encoding: chunked
```

View logs

Since the web app using Kestrel is managed using *systemd*, events and processes are logged to a centralized

journal. However, this journal includes entries for all of the services and processes managed by *systemd*. To view the `kestrel-helloapp.service`-specific items, use the following command:

```
sudo journalctl -fu kestrel-helloapp.service
```

For time filtering, specify time options with the command. For example, use `--since today` to filter for the current day or `--until 1 hour ago` to see the previous hour's entries. For more information, see the man page for journalctl.

```
sudo journalctl -fu kestrel-helloapp.service --since "2016-10-18" --until "2016-10-18 04:00"
```

Data protection

The ASP.NET Core Data Protection stack is used by several ASP.NET Core middlewares, including authentication middleware (for example, cookie middleware) and cross-site request forgery (CSRF) protections. Even if Data Protection APIs aren't called by user code, data protection should be configured to create a persistent cryptographic key store. If data protection isn't configured, the keys are held in memory and discarded when the app restarts.

If the key ring is stored in memory when the app restarts:

- All cookie-based authentication tokens are invalidated.
- Users are required to sign in again on their next request.
- Any data protected with the key ring can no longer be decrypted. This may include CSRF tokens and ASP.NET Core MVC TempData cookies.

To configure data protection to persist and encrypt the key ring, see:

- Key storage providers in ASP.NET Core
- Key encryption at rest in Windows and Azure using ASP.NET Core

Secure the app

Configure firewall

Firewalld is a dynamic daemon to manage the firewall with support for network zones. Ports and packet filtering can still be managed by iptables. *Firewalld* should be installed by default. `yum` can be used to install the package or verify it's installed.

```
sudo yum install firewalld -y
```

Use `firewalld` to open only the ports needed for the app. In this case, port 80 and 443 are used. The following commands permanently set ports 80 and 443 to open:

```
sudo firewall-cmd --add-port=80/tcp --permanent
sudo firewall-cmd --add-port=443/tcp --permanent
```

Reload the firewall settings. Check the available services and ports in the default zone. Options are available by inspecting `firewall-cmd -h`.

```
sudo firewall-cmd --reload
sudo firewall-cmd --list-all
```

```
public (default, active)
interfaces: eth0
sources:
services: dhcpv6-client
ports: 443/tcp 80/tcp
masquerade: no
forward-ports:
icmp-blocks:
rich rules:
```

HTTPS configuration

Configure the app for secure (HTTPS) local connections

The dotnet run command uses the app's *Properties/launchSettings.json* file, which configures the app to listen on the URLs provided by the `applicationUrl` property (for example, `https://localhost:5001;http://localhost:5000`).

Configure the app to use a certificate in development for the `dotnet run` command or development environment (F5 or Ctrl+F5 in Visual Studio Code) using one of the following approaches:

- Replace the default certificate from configuration (*Recommended*)
- KestrelServerOptions.ConfigureHttpsDefaults

Configure the reverse proxy for secure (HTTPS) client connections

To configure Apache for HTTPS, the *mod_ssl* module is used. When the *httpd* module was installed, the *mod_ssl* module was also installed. If it wasn't installed, use `yum` to add it to the configuration.

```
sudo yum install mod_ssl
```

To enforce HTTPS, install the `mod_rewrite` module to enable URL rewriting:

```
sudo yum install mod_rewrite
```

Modify the *helloapp.conf* file to enable URL rewriting and secure communication on port 443:

```
<VirtualHost *:*>
    RequestHeader set "X-Forwarded-Proto" expr=%{REQUEST_SCHEME}
</VirtualHost>

<VirtualHost *:80>
    RewriteEngine On
    RewriteCond %{HTTPS} !=on
    RewriteRule ^/?(.*) https://%{SERVER_NAME}/$1 [R,L]
</VirtualHost>

<VirtualHost *:443>
    ProxyPreserveHost On
    ProxyPass / http://127.0.0.1:5000/
    ProxyPassReverse / http://127.0.0.1:5000/
    ErrorLog /var/log/httpd/helloapp-error.log
    CustomLog /var/log/httpd/helloapp-access.log common
    SSLEngine on
    SSLProtocol all -SSLv2
    SSLCipherSuite ALL:!ADH:!EXPORT:!SSLv2:!RC4+RSA:+HIGH:+MEDIUM:!LOW:!RC4
    SSLCertificateFile /etc/pki/tls/certs/localhost.crt
    SSLCertificateKeyFile /etc/pki/tls/private/localhost.key
</VirtualHost>
```

> **NOTE**
>
> This example is using a locally-generated certificate. **SSLCertificateFile** should be the primary certificate file for the domain name. **SSLCertificateKeyFile** should be the key file generated when CSR is created. **SSLCertificateChainFile** should be the intermediate certificate file (if any) that was supplied by the certificate authority.

Save the file and test the configuration:

```
sudo service httpd configtest
```

Restart Apache:

```
sudo systemctl restart httpd
```

Additional Apache suggestions

Restart apps with shared framework updates

After upgrading the shared framework on the server, restart the ASP.NET Core apps hosted by the server.

Additional headers

In order to secure against malicious attacks, there are a few headers that should either be modified or added. Ensure that the `mod_headers` module is installed:

```
sudo yum install mod_headers
```

Secure Apache from clickjacking attacks

Clickjacking, also known as a *UI redress attack*, is a malicious attack where a website visitor is tricked into clicking a link or button on a different page than they're currently visiting. Use `X-FRAME-OPTIONS` to secure the site.

To mitigate clickjacking attacks:

1. Edit the *httpd.conf* file:

   ```
   sudo nano /etc/httpd/conf/httpd.conf
   ```

   Add the line `Header append X-FRAME-OPTIONS "SAMEORIGIN"`.

2. Save the file.

3. Restart Apache.

MIME-type sniffing

The `X-Content-Type-Options` header prevents Internet Explorer from *MIME-sniffing* (determining a file's `Content-Type` from the file's content). If the server sets the `Content-Type` header to `text/html` with the `nosniff` option set, Internet Explorer renders the content as `text/html` regardless of the file's content.

Edit the *httpd.conf* file:

```
sudo nano /etc/httpd/conf/httpd.conf
```

Add the line `Header set X-Content-Type-Options "nosniff"`. Save the file. Restart Apache.

Load Balancing

This example shows how to setup and configure Apache on CentOS 7 and Kestrel on the same instance machine. In order to not have a single point of failure; using *mod_proxy_balancer* and modifying the **VirtualHost** would allow for managing multiple instances of the web apps behind the Apache proxy server.

```
sudo yum install mod_proxy_balancer
```

In the configuration file shown below, an additional instance of the `helloapp` is set up to run on port 5001. The *Proxy* section is set with a balancer configuration with two members to load balance *byrequests*.

```
<VirtualHost *:*>
    RequestHeader set "X-Forwarded-Proto" expr=%{REQUEST_SCHEME}
</VirtualHost>

<VirtualHost *:80>
    RewriteEngine On
    RewriteCond %{HTTPS} !=on
    RewriteRule ^/?(.*) https://%{SERVER_NAME}/$1 [R,L]
</VirtualHost>

<VirtualHost *:443>
    ProxyPass / balancer://mycluster/

    ProxyPassReverse / http://127.0.0.1:5000/
    ProxyPassReverse / http://127.0.0.1:5001/

    <Proxy balancer://mycluster>
        BalancerMember http://127.0.0.1:5000
        BalancerMember http://127.0.0.1:5001
        ProxySet lbmethod=byrequests
    </Proxy>

    <Location />
        SetHandler balancer
    </Location>
    ErrorLog /var/log/httpd/helloapp-error.log
    CustomLog /var/log/httpd/helloapp-access.log common
    SSLEngine on
    SSLProtocol all -SSLv2
    SSLCipherSuite ALL:!ADH:!EXPORT:!SSLv2:!RC4+RSA:+HIGH:+MEDIUM:!LOW:!RC4
    SSLCertificateFile /etc/pki/tls/certs/localhost.crt
    SSLCertificateKeyFile /etc/pki/tls/private/localhost.key
</VirtualHost>
```

Rate Limits

Using *mod_ratelimit*, which is included in the *httpd* module, the bandwidth of clients can be limited:

```
sudo nano /etc/httpd/conf.d/ratelimit.conf
```

The example file limits bandwidth as 600 KB/sec under the root location:

```
<IfModule mod_ratelimit.c>
    <Location />
        SetOutputFilter RATE_LIMIT
        SetEnv rate-limit 600
    </Location>
</IfModule>
```

Long request header fields

Proxy server default settings typically limit request header fields to 8,190 bytes. An app may require fields longer than the default (for example, apps that use Azure Active Directory). If longer fields are required, the proxy server's LimitRequestFieldSize directive requires adjustment. The value to apply depends on the scenario. For more information, see your server's documentation.

> **WARNING**
>
> Don't increase the default value of `LimitRequestFieldSize` unless necessary. Increasing the value increases the risk of buffer overrun (overflow) and Denial of Service (DoS) attacks by malicious users.

Host ASP.NET Core in Docker containers

9/22/2020 • 2 minutes to read • Edit Online

The following articles are available for learning about hosting ASP.NET Core apps in Docker:

Introduction to Containers and Docker

See how containerization is an approach to software development in which an application or service, its dependencies, and its configuration are packaged together as a container image. The image can be tested and then deployed to a host.

What is Docker

Discover how Docker is an open-source project for automating the deployment of apps as portable, self-sufficient containers that can run on the cloud or on-premises.

Docker Terminology

Learn terms and definitions for Docker technology.

Docker containers, images, and registries

Find out how Docker container images are stored in an image registry for consistent deployment across environments.

Docker images for ASP.NET Core Learn how to build and dockerize an ASP.NET Core app. Explore Docker images maintained by Microsoft and examine use cases.

Visual Studio Container Tools

Discover how Visual Studio supports building, debugging, and running ASP.NET Core apps targeting either .NET Framework or .NET Core on Docker for Windows. Both Windows and Linux containers are supported.

Publish to Azure Container Registry

Find out how to use the Visual Studio Container Tools extension to deploy an ASP.NET Core app to a Docker host on Azure using PowerShell.

Configure ASP.NET Core to work with proxy servers and load balancers

Additional configuration might be required for apps hosted behind proxy servers and load balancers. Passing requests through a proxy often obscures information about the original request, such as the scheme and client IP. It might be necessary to forwarded some information about the request manually to the app.

GC using Docker and small containers Discusses GC selection with small containers.

Docker images for ASP.NET Core

9/22/2020 • 5 minutes to read • Edit Online

This tutorial shows how to run an ASP.NET Core app in Docker containers.

In this tutorial, you:

- Learn about Microsoft .NET Core Docker images
- Download an ASP.NET Core sample app
- Run the sample app locally
- Run the sample app in Linux containers
- Run the sample app in Windows containers
- Build and deploy manually

ASP.NET Core Docker images

For this tutorial, you download an ASP.NET Core sample app and run it in Docker containers. The sample works with both Linux and Windows containers.

The sample Dockerfile uses the Docker multi-stage build feature to build and run in different containers. The build and run containers are created from images that are provided in Docker Hub by Microsoft:

- `dotnet/core/sdk`

  The sample uses this image for building the app. The image contains the .NET Core SDK, which includes the Command Line Tools (CLI). The image is optimized for local development, debugging, and unit testing. The tools installed for development and compilation make this a relatively large image.

- `dotnet/core/aspnet`

  The sample uses this image for running the app. The image contains the ASP.NET Core runtime and libraries and is optimized for running apps in production. Designed for speed of deployment and app startup, the image is relatively small, so network performance from Docker Registry to Docker host is optimized. Only the binaries and content needed to run an app are copied to the container. The contents are ready to run, enabling the fastest time from `Docker run` to app startup. Dynamic code compilation isn't needed in the Docker model.

Prerequisites

- .NET Core 2.2 SDK
- .NET Core SDK 3.0
- Docker client 18.03 or later
  - Linux distributions
    - CentOS
    - Debian
    - Fedora
    - Ubuntu
  - macOS
  - Windows

- Git

Download the sample app

- Download the sample by cloning the .NET Core Docker repository:

```
git clone https://github.com/dotnet/dotnet-docker
```

Run the app locally

- Navigate to the project folder at *dotnet-docker/samples/aspnetapp/aspnetapp*.
- Run the following command to build and run the app locally:

```
dotnet run
```

- Go to `http://localhost:5000` in a browser to test the app.
- Press Ctrl+C at the command prompt to stop the app.

Run in a Linux container

- In the Docker client, switch to Linux containers.
- Navigate to the Dockerfile folder at *dotnet-docker/samples/aspnetapp*.
- Run the following commands to build and run the sample in Docker:

```
docker build -t aspnetapp .
docker run -it --rm -p 5000:80 --name aspnetcore_sample aspnetapp
```

  The `build` command arguments:

  - Name the image aspnetapp.
  - Look for the Dockerfile in the current folder (the period at the end).

  The run command arguments:

  - Allocate a pseudo-TTY and keep it open even if not attached. (Same effect as `--interactive --tty`.)
  - Automatically remove the container when it exits.
  - Map port 5000 on the local machine to port 80 in the container.
  - Name the container aspnetcore_sample.
  - Specify the aspnetapp image.
- Go to `http://localhost:5000` in a browser to test the app.

Run in a Windows container

- In the Docker client, switch to Windows containers.

Navigate to the docker file folder at `dotnet-docker/samples/aspnetapp`.

- Run the following commands to build and run the sample in Docker:

```
docker build -t aspnetapp .
docker run -it --rm --name aspnetcore_sample aspnetapp
```

- For Windows containers, you need the IP address of the container (browsing to `http://localhost:5000` won't work):
  - Open up another command prompt.
  - Run `docker ps` to see the running containers. Verify that the "aspnetcore_sample" container is there.
  - Run `docker exec aspnetcore_sample ipconfig` to display the IP address of the container. The output from the command looks like this example:

    ```
    Ethernet adapter Ethernet:

       Connection-specific DNS Suffix  . : contoso.com
       Link-local IPv6 Address . . . . . : fe80::1967:6598:124:cfa3%4
       IPv4 Address. . . . . . . . . . . : 172.29.245.43
       Subnet Mask . . . . . . . . . . . : 255.255.240.0
       Default Gateway . . . . . . . . . : 172.29.240.1
    ```

- Copy the container IPv4 address (for example, 172.29.245.43) and paste into the browser address bar to test the app.

Build and deploy manually

In some scenarios, you might want to deploy an app to a container by copying to it the application files that are needed at run time. This section shows how to deploy manually.

- Navigate to the project folder at *dotnet-docker/samples/aspnetapp/aspnetapp*.
- Run the dotnet publish command:

  ```
  dotnet publish -c Release -o published
  ```

  The command arguments:

  - Build the application in release mode (the default is debug mode).
  - Create the files in the *published* folder.
- Run the application.
  - Windows:

    ```
    dotnet published\aspnetapp.dll
    ```

  - Linux:

    ```
    dotnet published/aspnetapp.dll
    ```

- Browse to `http://localhost:5000` to see the home page.

To use the manually published application within a Docker container, create a new Dockerfile and use the `docker build .` command to build the container.

```
FROM mcr.microsoft.com/dotnet/core/aspnet:2.2 AS runtime
WORKDIR /app
COPY published/aspnetapp.dll ./
ENTRYPOINT ["dotnet", "aspnetapp.dll"]
```

The Dockerfile

Here's the *Dockerfile* used by the `docker build` command you ran earlier. It uses `dotnet publish` the same way you did in this section to build and deploy.

```
FROM mcr.microsoft.com/dotnet/core/sdk:2.2 AS build
WORKDIR /app

# copy csproj and restore as distinct layers
COPY *.sln .
COPY aspnetapp/*.csproj ./aspnetapp/
RUN dotnet restore

# copy everything else and build app
COPY aspnetapp/. ./aspnetapp/
WORKDIR /app/aspnetapp
RUN dotnet publish -c Release -o out

FROM mcr.microsoft.com/dotnet/core/aspnet:2.2 AS runtime
WORKDIR /app
COPY --from=build /app/aspnetapp/out ./
ENTRYPOINT ["dotnet", "aspnetapp.dll"]
```

```
FROM mcr.microsoft.com/dotnet/core/aspnet:3.0 AS runtime
WORKDIR /app
COPY published/aspnetapp.dll ./
ENTRYPOINT ["dotnet", "aspnetapp.dll"]
```

The Dockerfile

Here's the *Dockerfile* used by the `docker build` command you ran earlier. It uses `dotnet publish` the same way you did in this section to build and deploy.

```
FROM mcr.microsoft.com/dotnet/core/sdk:3.0 AS build
WORKDIR /app

# copy csproj and restore as distinct layers
COPY *.sln .
COPY aspnetapp/*.csproj ./aspnetapp/
RUN dotnet restore

# copy everything else and build app
COPY aspnetapp/. ./aspnetapp/
WORKDIR /app/aspnetapp
RUN dotnet publish -c Release -o out

FROM mcr.microsoft.com/dotnet/core/aspnet:3.0 AS runtime
WORKDIR /app
COPY --from=build /app/aspnetapp/out ./
ENTRYPOINT ["dotnet", "aspnetapp.dll"]
```

As noted in the preceding Dockerfile, the `*.csproj` files are copied and restored as distinct *layers*. When the `docker build` command builds an image, it uses a built-in cache. If the `*.csproj` files haven't changed since the `docker build` command last ran, the `dotnet restore` command doesn't need to run again. Instead, the built-in cache for the corresponding `dotnet restore` layer is reused. For more information, see Best practices for writing

Dockerfiles.

Developing ASP.NET Core Applications with Docker over HTTPS

Visual Studio Container Tools with ASP.NET Core

9/22/2020 • 9 minutes to read • Edit Online

Visual Studio 2017 and later versions support building, debugging, and running containerized ASP.NET Core apps targeting .NET Core. Both Windows and Linux containers are supported.

View or download sample code (how to download)

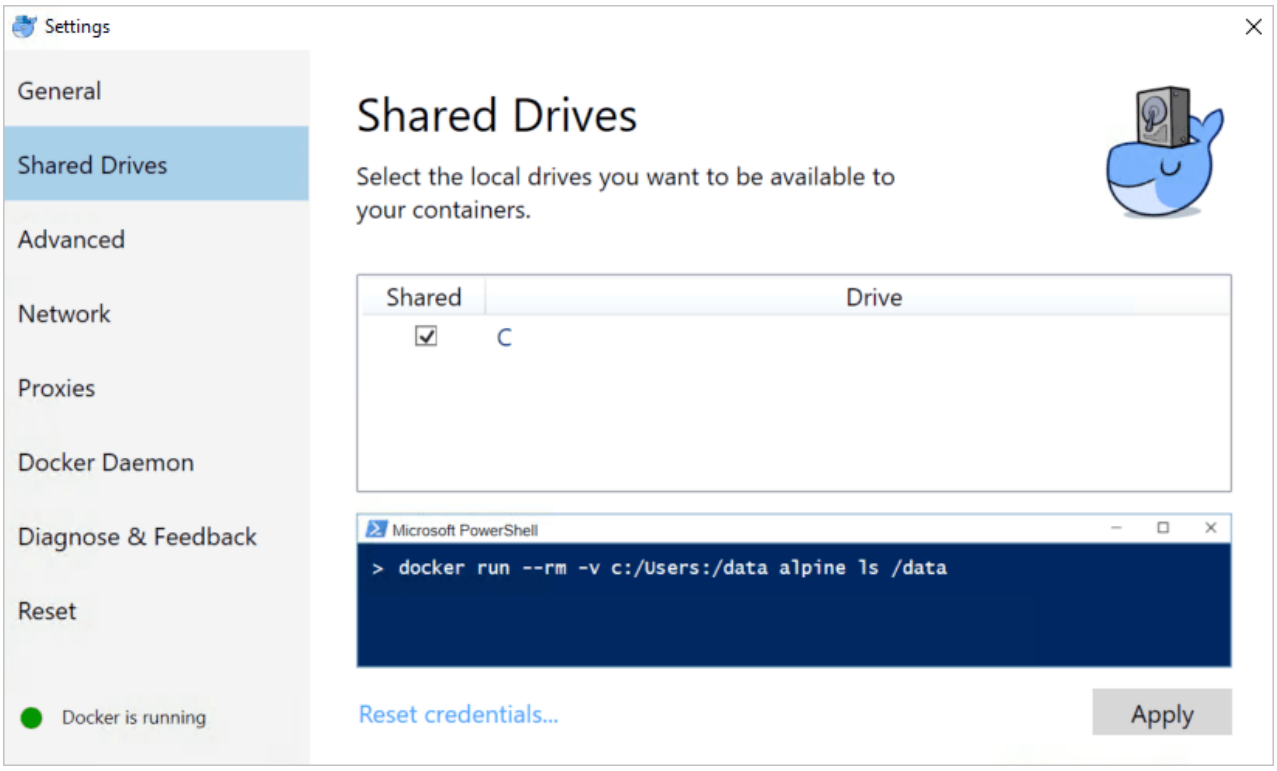
Prerequisites

- Docker for Windows
- Visual Studio 2019 with the **.NET Core cross-platform development** workload

Installation and setup

For Docker installation, first review the information at Docker for Windows: What to know before you install. Next, install Docker For Windows.

Shared Drives in Docker for Windows must be configured to support volume mapping and debugging. Right-click the System Tray's Docker icon, select **Settings**, and select **Shared Drives**. Select the drive where Docker stores files. Click **Apply**.



TIP

Visual Studio 2017 versions 15.6 and later prompt when **Shared Drives** aren't configured.

Add a project to a Docker container

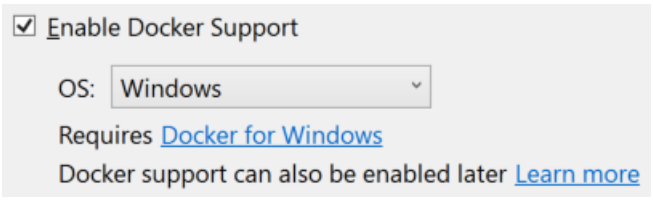
To containerize an ASP.NET Core project, the project must target .NET Core. Both Linux and Windows containers are

supported.

When adding Docker support to a project, choose either a Windows or a Linux container. The Docker host must be running the same container type. To change the container type in the running Docker instance, right-click the System Tray's Docker icon and choose **Switch to Windows containers...** or **Switch to Linux containers...**.

New app

When creating a new app with the **ASP.NET Core Web Application** project templates, select the **Enable Docker Support** check box:



If the target framework is .NET Core, the **OS** drop-down allows for the selection of a container type.

Existing app

For ASP.NET Core projects targeting .NET Core, there are two options for adding Docker support via the tooling. Open the project in Visual Studio, and choose one of the following options:

- Select **Docker Support** from the **Project** menu.
- Right-click the project in **Solution Explorer** and select **Add** > **Docker Support**.

The Visual Studio Container Tools don't support adding Docker to an existing ASP.NET Core project targeting .NET Framework.

Dockerfile overview

A *Dockerfile*, the recipe for creating a final Docker image, is added to the project root. Refer to Dockerfile reference for an understanding of the commands within it. This particular *Dockerfile* uses a multi-stage build with four distinct, named build stages:

```
FROM mcr.microsoft.com/dotnet/core/aspnet:2.1 AS base
WORKDIR /app
EXPOSE 59518
EXPOSE 44364

FROM mcr.microsoft.com/dotnet/core/sdk:2.1 AS build
WORKDIR /src
COPY HelloDockerTools/HelloDockerTools.csproj HelloDockerTools/
RUN dotnet restore HelloDockerTools/HelloDockerTools.csproj
COPY . .
WORKDIR /src/HelloDockerTools
RUN dotnet build HelloDockerTools.csproj -c Release -o /app

FROM build AS publish
RUN dotnet publish HelloDockerTools.csproj -c Release -o /app

FROM base AS final
WORKDIR /app
COPY --from=publish /app .
ENTRYPOINT ["dotnet", "HelloDockerTools.dll"]
```

The preceding *Dockerfile* is based on the microsoft/dotnet image. This base image includes the ASP.NET Core runtime and NuGet packages. The packages are just-in-time (JIT) compiled to improve startup performance.

When the new project dialog's **Configure for HTTPS** check box is checked, the *Dockerfile* exposes two ports. One

port is used for HTTP traffic; the other port is used for HTTPS. If the check box isn't checked, a single port (80) is exposed for HTTP traffic.

```
FROM microsoft/aspnetcore:2.0 AS base
WORKDIR /app
EXPOSE 80

FROM microsoft/aspnetcore-build:2.0 AS build
WORKDIR /src
COPY HelloDockerTools/HelloDockerTools.csproj HelloDockerTools/
RUN dotnet restore HelloDockerTools/HelloDockerTools.csproj
COPY . .
WORKDIR /src/HelloDockerTools
RUN dotnet build HelloDockerTools.csproj -c Release -o /app

FROM build AS publish
RUN dotnet publish HelloDockerTools.csproj -c Release -o /app

FROM base AS final
WORKDIR /app
COPY --from=publish /app .
ENTRYPOINT ["dotnet", "HelloDockerTools.dll"]
```

The preceding *Dockerfile* is based on the microsoft/aspnetcore image. This base image includes the ASP.NET Core NuGet packages, which are just-in-time (JIT) compiled to improve startup performance.

Add container orchestrator support to an app

Visual Studio 2017 versions 15.7 or earlier support Docker Compose as the sole container orchestration solution. The Docker Compose artifacts are added via **Add** > **Docker Support**.

Visual Studio 2017 versions 15.8 or later add an orchestration solution only when instructed. Right-click the project in **Solution Explorer** and select **Add** > **Container Orchestrator Support**. The following choices are available:

- Docker Compose
- Service Fabric
- Kubernetes/Helm

Docker Compose

The Visual Studio Container Tools add a *docker-compose* project to the solution with the following files:

- *docker-compose.dcproj*: The file representing the project. Includes a `<DockerTargetOS>` element specifying the OS to be used.
- *.dockerignore*: Lists the file and directory patterns to exclude when generating a build context.
- *docker-compose.yml*: The base Docker Compose file used to define the collection of images built and run with `docker-compose build` and `docker-compose run`, respectively.
- *docker-compose.override.yml*: An optional file, read by Docker Compose, with configuration overrides for services. Visual Studio executes `docker-compose -f "docker-compose.yml" -f "docker-compose.override.yml"` to merge these files.

The *docker-compose.yml* file references the name of the image that's created when the project runs:

```
version: '3.4'

services:
  hellodockertools:
    image: ${DOCKER_REGISTRY}hellodockertools
    build:
      context: .
      dockerfile: HelloDockerTools/Dockerfile
```

In the preceding example, `image: hellodockertools` generates the image `hellodockertools:dev` when the app runs in **Debug** mode. The `hellodockertools:latest` image is generated when the app runs in **Release** mode.

Prefix the image name with the Docker Hub username (for example, `dockerhubusername/hellodockertools`) if the image is pushed to the registry. Alternatively, change the image name to include the private registry URL (for example, `privateregistry.domain.com/hellodockertools`) depending on the configuration.

If you want different behavior based on the build configuration (for example, Debug or Release), add configuration-specific *docker-compose* files. The files should be named according to the build configuration (for example, *docker-compose.vs.debug.yml* and *docker-compose.vs.release.yml*) and placed in the same location as the *docker-compose-override.yml* file.

Using the configuration-specific override files, you can specify different configuration settings (such as environment variables or entry points) for Debug and Release build configurations.

For Docker Compose to display an option to run in Visual Studio, the docker project must be the startup project.

Service Fabric

In addition to the base Prerequisites, the Service Fabric orchestration solution demands the following prerequisites:

- Microsoft Azure Service Fabric SDK version 2.6 or later
- Visual Studio's **Azure Development** workload

Service Fabric doesn't support running Linux containers in the local development cluster on Windows. If the project is already using a Linux container, Visual Studio prompts to switch to Windows containers.

The Visual Studio Container Tools do the following tasks:

- Adds a *<project_name>Application* **Service Fabric Application** project to the solution.
- Adds a *Dockerfile* and a *.dockerignore* file to the ASP.NET Core project. If a *Dockerfile* already exists in the ASP.NET Core project, it's renamed to *Dockerfile.original*. A new *Dockerfile*, similar to the following, is created:

  ```
  # See https://aka.ms/containerimagehelp for information on how to use Windows Server 1709 containers
  with Service Fabric.
  # FROM microsoft/aspnetcore:2.0-nanoserver-1709
  FROM microsoft/aspnetcore:2.0-nanoserver-sac2016
  ARG source
  WORKDIR /app
  COPY ${source:-obj/Docker/publish} .
  ENTRYPOINT ["dotnet", "HelloDockerTools.dll"]
  ```

- Adds an `<IsServiceFabricServiceProject>` element to the ASP.NET Core project's *.csproj* file:

  ```
  <IsServiceFabricServiceProject>True</IsServiceFabricServiceProject>
  ```

- Adds a *PackageRoot* folder to the ASP.NET Core project. The folder includes the service manifest and settings

for the new service.

For more information, see Deploy a .NET app in a Windows container to Azure Service Fabric.

Debug

Select **Docker** from the debug drop-down in the toolbar, and start debugging the app. The **Docker** view of the **Output** window shows the following actions taking place:

- The *2.1-aspnetcore-runtime* tag of the *microsoft/dotnet* runtime image is acquired (if not already in the cache). The image installs the ASP.NET Core and .NET Core runtimes and associated libraries. It's optimized for running ASP.NET Core apps in production.
- The `ASPNETCORE_ENVIRONMENT` environment variable is set to `Development` within the container.
- Two dynamically assigned ports are exposed: one for HTTP and one for HTTPS. The port assigned to localhost can be queried with the `docker ps` command.
- The app is copied to the container.
- The default browser is launched with the debugger attached to the container using the dynamically assigned port.

The resulting Docker image of the app is tagged as *dev*. The image is based on the *2.1-aspnetcore-runtime* tag of the *microsoft/dotnet* base image. Run the `docker images` command in the **Package Manager Console** (PMC) window. The images on the machine are displayed:

```
REPOSITORY        TAG                   IMAGE ID      CREATED         SIZE
hellodockertools  dev                   d72ce0f1dfe7  30 seconds ago  255MB
microsoft/dotnet  2.1-aspnetcore-runtime  fcc3887985bb  6 days ago      255MB
```

- The *microsoft/aspnetcore* runtime image is acquired (if not already in the cache).
- The `ASPNETCORE_ENVIRONMENT` environment variable is set to `Development` within the container.
- Port 80 is exposed and mapped to a dynamically assigned port for localhost. The port is determined by the Docker host and can be queried with the `docker ps` command.
- The app is copied to the container.
- The default browser is launched with the debugger attached to the container using the dynamically assigned port.

The resulting Docker image of the app is tagged as *dev*. The image is based on the *microsoft/aspnetcore* base image. Run the `docker images` command in the **Package Manager Console** (PMC) window. The images on the machine are displayed:

```
REPOSITORY            TAG  IMAGE ID      CREATED        SIZE
hellodockertools      dev  5fafe5d1ad5b  4 minutes ago  347MB
microsoft/aspnetcore  2.0  c69d39472da9  13 days ago    347MB
```

> **NOTE**
>
> The *dev* image lacks the app contents, as **Debug** configurations use volume mounting to provide the iterative experience. To push an image, use the **Release** configuration.

Run the `docker ps` command in PMC. Notice the app is running using the container:

```
CONTAINER ID        IMAGE                  COMMAND                  CREATED             STATUS
PORTS                   NAMES
baf9a678c88d        hellodockertools:dev   "C:\\remote_debugge..."   21 seconds ago      Up 19 seconds
0.0.0.0:37630->80/tcp   dockercompose4642749010770307127_hellodockertools_1
```

Edit and continue

Changes to static files and Razor views are automatically updated without the need for a compilation step. Make the change, save, and refresh the browser to view the update.

Code file modifications require compilation and a restart of Kestrel within the container. After making the change, use `CTRL+F5` to perform the process and start the app within the container. The Docker container isn't rebuilt or stopped. Run the `docker ps` command in PMC. Notice the original container is still running as of 10 minutes ago:

```
CONTAINER ID        IMAGE                  COMMAND                  CREATED             STATUS
PORTS                   NAMES
baf9a678c88d        hellodockertools:dev   "C:\\remote_debugge..."   10 minutes ago      Up 10 minutes
0.0.0.0:37630->80/tcp   dockercompose4642749010770307127_hellodockertools_1
```

Publish Docker images

Once the develop and debug cycle of the app is completed, the Visual Studio Container Tools assist in creating the production image of the app. Change the configuration drop-down to **Release** and build the app. The tooling acquires the compile/publish image from Docker Hub (if not already in the cache). An image is produced with the *latest* tag, which can be pushed to the private registry or Docker Hub.

Run the `docker images` command in PMC to see the list of images. Output similar to the following is displayed:

```
REPOSITORY        TAG                    IMAGE ID      CREATED             SIZE
hellodockertools  latest                 e3984a64230c  About a minute ago  258MB
hellodockertools  dev                    d72ce0f1dfe7  4 minutes ago       255MB
microsoft/dotnet  2.1-sdk                9e243db15f91  6 days ago          1.7GB
microsoft/dotnet  2.1-aspnetcore-runtime  fcc3887985bb  6 days ago          255MB
```

```
REPOSITORY                  TAG     IMAGE ID      CREATED         SIZE
hellodockertools            latest  cd28f0d4abbd  12 seconds ago  349MB
hellodockertools            dev     5fafe5d1ad5b  23 minutes ago  347MB
microsoft/aspnetcore-build  2.0     7fed40fbb647  13 days ago     2.02GB
microsoft/aspnetcore        2.0     c69d39472da9  13 days ago     347MB
```

The `microsoft/aspnetcore-build` and `microsoft/aspnetcore` images listed in the preceding output are replaced with `microsoft/dotnet` images as of .NET Core 2.1. For more information, see the Docker repositories migration announcement.

> **NOTE**
>
> The `docker images` command returns intermediary images with repository names and tags identified as *<none>* (not listed above). These unnamed images are produced by the multi-stage build *Dockerfile*. They improve the efficiency of building the final image—only the necessary layers are rebuilt when changes occur. When the intermediary images are no longer needed, delete them using the docker rmi command.

There may be an expectation for the production or release image to be smaller in size by comparison to the *dev* image. Because of the volume mapping, the debugger and app were running from the local machine and not

within the container. The *latest* image has packaged the necessary app code to run the app on a host machine. Therefore, the delta is the size of the app code.

Configure ASP.NET Core to work with proxy servers and load balancers

9/22/2020 • 26 minutes to read • Edit Online

By Chris Ross

In the recommended configuration for ASP.NET Core, the app is hosted using IIS/ASP.NET Core Module, Nginx, or Apache. Proxy servers, load balancers, and other network appliances often obscure information about the request before it reaches the app:

- When HTTPS requests are proxied over HTTP, the original scheme (HTTPS) is lost and must be forwarded in a header.
- Because an app receives a request from the proxy and not its true source on the Internet or corporate network, the originating client IP address must also be forwarded in a header.

This information may be important in request processing, for example in redirects, authentication, link generation, policy evaluation, and client geolocation.

Forwarded headers

By convention, proxies forward information in HTTP headers.

HEADER	DESCRIPTION
X-Forwarded-For	Holds information about the client that initiated the request and subsequent proxies in a chain of proxies. This parameter may contain IP addresses (and, optionally, port numbers). In a chain of proxy servers, the first parameter indicates the client where the request was first made. Subsequent proxy identifiers follow. The last proxy in the chain isn't in the list of parameters. The last proxy's IP address, and optionally a port number, are available as the remote IP address at the transport layer.
X-Forwarded-Proto	The value of the originating scheme (HTTP/HTTPS). The value may also be a list of schemes if the request has traversed multiple proxies.
X-Forwarded-Host	The original value of the Host header field. Usually, proxies don't modify the Host header. See Microsoft Security Advisory CVE-2018-0787 for information on an elevation-of-privileges vulnerability that affects systems where the proxy doesn't validate or restrict Host headers to known good values.

The Forwarded Headers Middleware, from the Microsoft.AspNetCore.HttpOverrides package, reads these headers and fills in the associated fields on HttpContext.

The middleware updates:

- HttpContext.Connection.RemoteIpAddress: Set using the `X-Forwarded-For` header value. Additional settings influence how the middleware sets `RemoteIpAddress`. For details, see the Forwarded Headers Middleware options.

- HttpContext.Request.Scheme: Set using the `X-Forwarded-Proto` header value.
- HttpContext.Request.Host: Set using the `X-Forwarded-Host` header value.

Forwarded Headers Middleware default settings can be configured. The default settings are:

- There is only *one proxy* between the app and the source of the requests.
- Only loopback addresses are configured for known proxies and known networks.
- The forwarded headers are named `X-Forwarded-For` and `X-Forwarded-Proto`.

Not all network appliances add the `X-Forwarded-For` and `X-Forwarded-Proto` headers without additional configuration. Consult your appliance manufacturer's guidance if proxied requests don't contain these headers when they reach the app. If the appliance uses different header names than `X-Forwarded-For` and `X-Forwarded-Proto`, set the ForwardedForHeaderName and ForwardedProtoHeaderName options to match the header names used by the appliance. For more information, see Forwarded Headers Middleware options and Configuration for a proxy that uses different header names.

IIS/IIS Express and ASP.NET Core Module

Forwarded Headers Middleware is enabled by default by IIS Integration Middleware when the app is hosted out-of-process behind IIS and the ASP.NET Core Module. Forwarded Headers Middleware is activated to run first in the middleware pipeline with a restricted configuration specific to the ASP.NET Core Module due to trust concerns with forwarded headers (for example, IP spoofing). The middleware is configured to forward the `X-Forwarded-For` and `X-Forwarded-Proto` headers and is restricted to a single localhost proxy. If additional configuration is required, see the Forwarded Headers Middleware options.

Other proxy server and load balancer scenarios

Outside of using IIS Integration when hosting out-of-process, Forwarded Headers Middleware isn't enabled by default. Forwarded Headers Middleware must be enabled for an app to process forwarded headers with UseForwardedHeaders. After enabling the middleware if no ForwardedHeadersOptions are specified to the middleware, the default ForwardedHeadersOptions.ForwardedHeaders are ForwardedHeaders.None.

Configure the middleware with ForwardedHeadersOptions to forward the `X-Forwarded-For` and `X-Forwarded-Proto` headers in `Startup.ConfigureServices`.

Forwarded Headers Middleware order

Forwarded Headers Middleware should run before other middleware. This ordering ensures that the middleware relying on forwarded headers information can consume the header values for processing. Forwarded Headers Middleware can run after diagnostics and error handling, but it must be run before calling `UseHsts`:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddControllersWithViews();
        services.Configure<ForwardedHeadersOptions>(options =>
        {
            options.ForwardedHeaders =
                ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto;
        });
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
            app.UseForwardedHeaders();
        }
        else
        {
            app.UseExceptionHandler("/Home/Error");
            app.UseForwardedHeaders();
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapControllerRoute(
                name: "default",
                pattern: "{controller=Home}/{action=Index}/{id?}");
        });
    }
}
```

Alternatively, call `UseForwardedHeaders` before diagnostics:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    app.UseForwardedHeaders();

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllerRoute(
            name: "default",
            pattern: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

NOTE

If no ForwardedHeadersOptions are specified in `Startup.ConfigureServices` or directly to the extension method with UseForwardedHeaders, the default headers to forward are ForwardedHeaders.None. The ForwardedHeaders property must be configured with the headers to forward.

Nginx configuration

To forward the `X-Forwarded-For` and `X-Forwarded-Proto` headers, see Host ASP.NET Core on Linux with Nginx. For more information, see NGINX: Using the Forwarded header.

Apache configuration

`X-Forwarded-For` is added automatically (see Apache Module mod_proxy: Reverse Proxy Request Headers). For information on how to forward the `X-Forwarded-Proto` header, see Host ASP.NET Core on Linux with Apache.

Forwarded Headers Middleware options

ForwardedHeadersOptions control the behavior of the Forwarded Headers Middleware. The following example changes the default values:

- Limit the number of entries in the forwarded headers to `2`.
- Add a known proxy address of `127.0.10.1`.
- Change the forwarded header name from the default `X-Forwarded-For` to `X-Forwarded-For-My-Custom-Header-Name`.

```
services.Configure<ForwardedHeadersOptions>(options =>
{
    options.ForwardLimit = 2;
    options.KnownProxies.Add(IPAddress.Parse("127.0.10.1"));
    options.ForwardedForHeaderName = "X-Forwarded-For-My-Custom-Header-Name";
});
```

OPTION	DESCRIPTION
AllowedHosts	Restricts hosts by the `X-Forwarded-Host` header to the values provided. • Values are compared using ordinal-ignore-case. • Port numbers must be excluded. • If the list is empty, all hosts are allowed. • A top-level wildcard `*` allows all non-empty hosts. • Subdomain wildcards are permitted but don't match the root domain. For example, `*.contoso.com` matches the subdomain `foo.contoso.com` but not the root domain `contoso.com`. • Unicode host names are allowed but are converted to Punycode for matching. • IPv6 addresses must include bounding brackets and be in conventional form (for example, `[ABCD:EF01:2345:6789:ABCD:EF01:2345:6789]`). IPv6 addresses aren't special-cased to check for logical equality between different formats, and no canonicalization is performed. • Failure to restrict the allowed hosts may allow an attacker to spoof links generated by the service. The default value is an empty `IList<string>`.
ForwardedForHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XForwardedForHeaderName. This option is used when the proxy/forwarder doesn't use the `X-Forwarded-For` header but uses some other header to forward the information. The default is `X-Forwarded-For`.
ForwardedHeaders	Identifies which forwarders should be processed. See the ForwardedHeaders Enum for the list of fields that apply. Typical values assigned to this property are `ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto`. The default value is ForwardedHeaders.None.

OPTION	DESCRIPTION
ForwardedHostHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XForwardedHostHeaderName. This option is used when the proxy/forwarder doesn't use the `X-Forwarded-Host` header but uses some other header to forward the information. The default is `X-Forwarded-Host`.
ForwardedProtoHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XForwardedProtoHeaderName. This option is used when the proxy/forwarder doesn't use the `X-Forwarded-Proto` header but uses some other header to forward the information. The default is `X-Forwarded-Proto`.
ForwardLimit	Limits the number of entries in the headers that are processed. Set to `null` to disable the limit, but this should only be done if `KnownProxies` or `KnownNetworks` are configured. Setting a non-`null` value is a precaution (but not a guarantee) to guard against misconfigured proxies and malicious requests arriving from side-channels on the network. Forwarded Headers Middleware processes headers in reverse order from right to left. If the default value (`1`) is used, only the rightmost value from the headers is processed unless the value of `ForwardLimit` is increased. The default is `1`.
KnownNetworks	Address ranges of known networks to accept forwarded headers from. Provide IP ranges using Classless Interdomain Routing (CIDR) notation. If the server is using dual-mode sockets, IPv4 addresses are supplied in an IPv6 format (for example, `10.0.0.1` in IPv4 represented in IPv6 as `::ffff:10.0.0.1`). See IPAddress.MapToIPv6. Determine if this format is required by looking at the HttpContext.Connection.RemoteIpAddress. For more information, see the Configuration for an IPv4 address represented as an IPv6 address section. The default is an `IList`<IPNetwork> containing a single entry for `IPAddress.Loopback`.

OPTION	DESCRIPTION
KnownProxies	Addresses of known proxies to accept forwarded headers from. Use `KnownProxies` to specify exact IP address matches. If the server is using dual-mode sockets, IPv4 addresses are supplied in an IPv6 format (for example, `10.0.0.1` in IPv4 represented in IPv6 as `::ffff:10.0.0.1`). See IPAddress.MapToIPv6. Determine if this format is required by looking at the HttpContext.Connection.RemoteIpAddress. For more information, see the Configuration for an IPv4 address represented as an IPv6 address section. The default is an `IList`<IPAddress> containing a single entry for `IPAddress.IPv6Loopback`.
OriginalForHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XOriginalForHeaderName. The default is `X-Original-For`.
OriginalHostHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XOriginalHostHeaderName. The default is `X-Original-Host`.
OriginalProtoHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XOriginalProtoHeaderName. The default is `X-Original-Proto`.
RequireHeaderSymmetry	Require the number of header values to be in sync between the ForwardedHeadersOptions.ForwardedHeaders being processed. The default in ASP.NET Core 1.x is `true`. The default in ASP.NET Core 2.0 or later is `false`.

Scenarios and use cases

When it isn't possible to add forwarded headers and all requests are secure

In some cases, it might not be possible to add forwarded headers to the requests proxied to the app. If the proxy is enforcing that all public external requests are HTTPS, the scheme can be manually set in `Startup.Configure` before using any type of middleware:

```
app.Use((context, next) =>
{
    context.Request.Scheme = "https";
    return next();
});
```

This code can be disabled with an environment variable or other configuration setting in a development or staging environment.

Deal with path base and proxies that change the request path

Some proxies pass the path intact but with an app base path that should be removed so that routing works properly. UsePathBaseExtensions.UsePathBase middleware splits the path into HttpRequest.Path and the app base path into HttpRequest.PathBase.

If `/foo` is the app base path for a proxy path passed as `/foo/api/1`, the middleware sets `Request.PathBase` to `/foo` and `Request.Path` to `/api/1` with the following command:

```
app.UsePathBase("/foo");
```

The original path and path base are reapplied when the middleware is called again in reverse. For more information on middleware order processing, see ASP.NET Core Middleware.

If the proxy trims the path (for example, forwarding `/foo/api/1` to `/api/1`), fix redirects and links by setting the request's PathBase property:

```
app.Use((context, next) =>
{
    context.Request.PathBase = new PathString("/foo");
    return next();
});
```

If the proxy is adding path data, discard part of the path to fix redirects and links by using StartsWithSegments and assigning to the Path property:

```
app.Use((context, next) =>
{
    if (context.Request.Path.StartsWithSegments("/foo", out var remainder))
    {
        context.Request.Path = remainder;
    }

    return next();
});
```

Configuration for a proxy that uses different header names

If the proxy doesn't use headers named `X-Forwarded-For` and `X-Forwarded-Proto` to forward the proxy address/port and originating scheme information, set the ForwardedForHeaderName and ForwardedProtoHeaderName options to match the header names used by the proxy:

```
services.Configure<ForwardedHeadersOptions>(options =>
{
    options.ForwardedForHeaderName = "Header_Name_Used_By_Proxy_For_X-Forwarded-For_Header";
    options.ForwardedProtoHeaderName = "Header_Name_Used_By_Proxy_For_X-Forwarded-Proto_Header";
});
```

Configuration for an IPv4 address represented as an IPv6 address

If the server is using dual-mode sockets, IPv4 addresses are supplied in an IPv6 format (for example, `10.0.0.1` in IPv4 represented in IPv6 as `::ffff:10.0.0.1` or `::ffff:a00:1`). See IPAddress.MapToIPv6. Determine if this format is required by looking at the HttpContext.Connection.RemoteIpAddress.

In the following example, a network address that supplies forwarded headers is added to the

`KnownNetworks` list in IPv6 format.

IPv4 address: `10.11.12.1/8`

Converted IPv6 address: `::ffff:10.11.12.1`
Converted prefix length: 104

You can also supply the address in hexadecimal format (`10.11.12.1` represented in IPv6 as `::ffff:0a0b:0c01`). When converting an IPv4 address to IPv6, add 96 to the CIDR Prefix Length (`8` in the example) to account for the additional `::ffff:` IPv6 prefix (8 + 96 = 104).

```
// To access IPNetwork and IPAddress, add the following namespaces:
// using System.Net;
// using Microsoft.AspNetCore.HttpOverrides;
services.Configure<ForwardedHeadersOptions>(options =>
{
    options.ForwardedHeaders =
        ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto;
    options.KnownNetworks.Add(new IPNetwork(
        IPAddress.Parse("::ffff:10.11.12.1"), 104));
});
```

Forward the scheme for Linux and non-IIS reverse proxies

Apps that call UseHttpsRedirection and UseHsts put a site into an infinite loop if deployed to an Azure Linux App Service, Azure Linux virtual machine (VM), or behind any other reverse proxy besides IIS. TLS is terminated by the reverse proxy, and Kestrel isn't made aware of the correct request scheme. OAuth and OIDC also fail in this configuration because they generate incorrect redirects. UseIISIntegration adds and configures Forwarded Headers Middleware when running behind IIS, but there's no matching automatic configuration for Linux (Apache or Nginx integration).

To forward the scheme from the proxy in non-IIS scenarios, add and configure Forwarded Headers Middleware. In `Startup.ConfigureServices`, use the following code:

```
// using Microsoft.AspNetCore.HttpOverrides;

if (string.Equals(
    Environment.GetEnvironmentVariable("ASPNETCORE_FORWARDEDHEADERS_ENABLED"),
    "true", StringComparison.OrdinalIgnoreCase))
{
    services.Configure<ForwardedHeadersOptions>(options =>
    {
        options.ForwardedHeaders = ForwardedHeaders.XForwardedFor |
            ForwardedHeaders.XForwardedProto;
        // Only loopback proxies are allowed by default.
        // Clear that restriction because forwarders are enabled by explicit
        // configuration.
        options.KnownNetworks.Clear();
        options.KnownProxies.Clear();
    });
}
```

Certificate forwarding

Azure

To configure Azure App Service for certificate forwarding, see Configure TLS mutual authentication for Azure App Service. The following guidance pertains to configuring the ASP.NET Core app.

In `Startup.Configure`, add the following code before the call to `app.UseAuthentication();`:

```
app.UseCertificateForwarding();
```

Configure Certificate Forwarding Middleware to specify the header name that Azure uses. In `Startup.ConfigureServices`, add the following code to configure the header from which the middleware builds a certificate:

```
services.AddCertificateForwarding(options =>
    options.CertificateHeader = "X-ARR-ClientCert");
```

Other web proxies

If a proxy is used that isn't IIS or Azure App Service's Application Request Routing (ARR), configure the proxy to forward the certificate that it received in an HTTP header. In `Startup.Configure`, add the following code before the call to `app.UseAuthentication();`:

```
app.UseCertificateForwarding();
```

Configure the Certificate Forwarding Middleware to specify the header name. In `Startup.ConfigureServices`, add the following code to configure the header from which the middleware builds a certificate:

```
services.AddCertificateForwarding(options =>
    options.CertificateHeader = "YOUR_CERTIFICATE_HEADER_NAME");
```

If the proxy isn't base64-encoding the certificate (as is the case with Nginx), set the `HeaderConverter` option. Consider the following example in `Startup.ConfigureServices`:

```
services.AddCertificateForwarding(options =>
{
    options.CertificateHeader = "YOUR_CUSTOM_HEADER_NAME";
    options.HeaderConverter = (headerValue) =>
    {
        var clientCertificate =
           /* some conversion logic to create an X509Certificate2 */
        return clientCertificate;
    }
});
```

Troubleshoot

When headers aren't forwarded as expected, enable logging. If the logs don't provide sufficient information to troubleshoot the problem, enumerate the request headers received by the server. Use inline middleware to write request headers to an app response or log the headers.

To write the headers to the app's response, place the following terminal inline middleware immediately after the call to UseForwardedHeaders in `Startup.Configure`:

```
app.Run(async (context) =>
{
    context.Response.ContentType = "text/plain";

    // Request method, scheme, and path
    await context.Response.WriteAsync(
        $"Request Method: {context.Request.Method}{Environment.NewLine}");
    await context.Response.WriteAsync(
        $"Request Scheme: {context.Request.Scheme}{Environment.NewLine}");
    await context.Response.WriteAsync(
        $"Request Path: {context.Request.Path}{Environment.NewLine}");

    // Headers
    await context.Response.WriteAsync($"Request Headers:{Environment.NewLine}");

    foreach (var header in context.Request.Headers)
    {
        await context.Response.WriteAsync($"{header.Key}: " +
            $"{header.Value}{Environment.NewLine}");
    }

    await context.Response.WriteAsync(Environment.NewLine);

    // Connection: RemoteIp
    await context.Response.WriteAsync(
        $"Request RemoteIp: {context.Connection.RemoteIpAddress}");
});
```

You can write to logs instead of the response body. Writing to logs allows the site to function normally while debugging.

To write logs rather than to the response body:

- Inject `ILogger<Startup>` into the `Startup` class as described in Create logs in Startup.
- Place the following inline middleware immediately after the call to UseForwardedHeaders in `Startup.Configure`.

```
app.Use(async (context, next) =>
{
    // Request method, scheme, and path
    _logger.LogDebug("Request Method: {Method}", context.Request.Method);
    _logger.LogDebug("Request Scheme: {Scheme}", context.Request.Scheme);
    _logger.LogDebug("Request Path: {Path}", context.Request.Path);

    // Headers
    foreach (var header in context.Request.Headers)
    {
        _logger.LogDebug("Header: {Key}: {Value}", header.Key, header.Value);
    }

    // Connection: RemoteIp
    _logger.LogDebug("Request RemoteIp: {RemoteIpAddress}",
        context.Connection.RemoteIpAddress);

    await next();
});
```

When processed, `X-Forwarded-{For|Proto|Host}` values are moved to `X-Original-{For|Proto|Host}`. If there are multiple values in a given header, Forwarded Headers Middleware processes headers in reverse order from right to left. The default `ForwardLimit` is `1` (one), so only the rightmost value from the headers is processed unless the value of `ForwardLimit` is increased.

The request's original remote IP must match an entry in the `KnownProxies` or `KnownNetworks` lists before forwarded headers are processed. This limits header spoofing by not accepting forwarders from untrusted proxies. When an unknown proxy is detected, logging indicates the address of the proxy:

```
September 20th 2018, 15:49:44.168 Unknown proxy: 10.0.0.100:54321
```

In the preceding example, 10.0.0.100 is a proxy server. If the server is a trusted proxy, add the server's IP address to `KnownProxies` (or add a trusted network to `KnownNetworks`) in `Startup.ConfigureServices`. For more information, see the Forwarded Headers Middleware options section.

```
services.Configure<ForwardedHeadersOptions>(options =>
{
    options.KnownProxies.Add(IPAddress.Parse("10.0.0.100"));
});
```

> **IMPORTANT**
> Only allow trusted proxies and networks to forward headers. Otherwise, IP spoofing attacks are possible.

Additional resources

- Host ASP.NET Core in a web farm
- Microsoft Security Advisory CVE-2018-0787: ASP.NET Core Elevation Of Privilege Vulnerability

In the recommended configuration for ASP.NET Core, the app is hosted using IIS/ASP.NET Core Module, Nginx, or Apache. Proxy servers, load balancers, and other network appliances often obscure information about the request before it reaches the app:

- When HTTPS requests are proxied over HTTP, the original scheme (HTTPS) is lost and must be forwarded in a header.
- Because an app receives a request from the proxy and not its true source on the Internet or corporate network, the originating client IP address must also be forwarded in a header.

This information may be important in request processing, for example in redirects, authentication, link generation, policy evaluation, and client geolocation.

Forwarded headers

By convention, proxies forward information in HTTP headers.

HEADER	DESCRIPTION
X-Forwarded-For	Holds information about the client that initiated the request and subsequent proxies in a chain of proxies. This parameter may contain IP addresses (and, optionally, port numbers). In a chain of proxy servers, the first parameter indicates the client where the request was first made. Subsequent proxy identifiers follow. The last proxy in the chain isn't in the list of parameters. The last proxy's IP address, and optionally a port number, are available as the remote IP address at the transport layer.

HEADER	DESCRIPTION
X-Forwarded-Proto	The value of the originating scheme (HTTP/HTTPS). The value may also be a list of schemes if the request has traversed multiple proxies.
X-Forwarded-Host	The original value of the Host header field. Usually, proxies don't modify the Host header. See Microsoft Security Advisory CVE-2018-0787 for information on an elevation-of-privileges vulnerability that affects systems where the proxy doesn't validate or restrict Host headers to known good values.

The Forwarded Headers Middleware, from the Microsoft.AspNetCore.HttpOverrides package, reads these headers and fills in the associated fields on HttpContext.

The middleware updates:

- HttpContext.Connection.RemoteIpAddress: Set using the `X-Forwarded-For` header value. Additional settings influence how the middleware sets `RemoteIpAddress`. For details, see the Forwarded Headers Middleware options.
- HttpContext.Request.Scheme: Set using the `X-Forwarded-Proto` header value.
- HttpContext.Request.Host: Set using the `X-Forwarded-Host` header value.

Forwarded Headers Middleware default settings can be configured. The default settings are:

- There is only *one proxy* between the app and the source of the requests.
- Only loopback addresses are configured for known proxies and known networks.
- The forwarded headers are named `X-Forwarded-For` and `X-Forwarded-Proto`.

Not all network appliances add the `X-Forwarded-For` and `X-Forwarded-Proto` headers without additional configuration. Consult your appliance manufacturer's guidance if proxied requests don't contain these headers when they reach the app. If the appliance uses different header names than `X-Forwarded-For` and `X-Forwarded-Proto`, set the ForwardedForHeaderName and ForwardedProtoHeaderName options to match the header names used by the appliance. For more information, see Forwarded Headers Middleware options and Configuration for a proxy that uses different header names.

IIS/IIS Express and ASP.NET Core Module

Forwarded Headers Middleware is enabled by default by IIS Integration Middleware when the app is hosted out-of-process behind IIS and the ASP.NET Core Module. Forwarded Headers Middleware is activated to run first in the middleware pipeline with a restricted configuration specific to the ASP.NET Core Module due to trust concerns with forwarded headers (for example, IP spoofing). The middleware is configured to forward the `X-Forwarded-For` and `X-Forwarded-Proto` headers and is restricted to a single localhost proxy. If additional configuration is required, see the Forwarded Headers Middleware options.

Other proxy server and load balancer scenarios

Outside of using IIS Integration when hosting out-of-process, Forwarded Headers Middleware isn't enabled by default. Forwarded Headers Middleware must be enabled for an app to process forwarded headers with UseForwardedHeaders. After enabling the middleware if no ForwardedHeadersOptions are specified to the middleware, the default ForwardedHeadersOptions.ForwardedHeaders are ForwardedHeaders.None.

Configure the middleware with ForwardedHeadersOptions to forward the `X-Forwarded-For` and

`X-Forwarded-Proto` headers in `Startup.ConfigureServices`. Invoke the UseForwardedHeaders method in `Startup.Configure` before calling other middleware:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc();

    services.Configure<ForwardedHeadersOptions>(options =>
    {
        options.ForwardedHeaders =
            ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto;
    });
}

public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    app.UseForwardedHeaders();

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
    }

    app.UseStaticFiles();
    // In ASP.NET Core 1.x, replace the following line with: app.UseIdentity();
    app.UseAuthentication();
    app.UseMvc();
}
```

NOTE

If no ForwardedHeadersOptions are specified in `Startup.ConfigureServices` or directly to the extension method with UseForwardedHeaders, the default headers to forward are ForwardedHeaders.None. The ForwardedHeaders property must be configured with the headers to forward.

Nginx configuration

To forward the `X-Forwarded-For` and `X-Forwarded-Proto` headers, see Host ASP.NET Core on Linux with Nginx. For more information, see NGINX: Using the Forwarded header.

Apache configuration

`X-Forwarded-For` is added automatically (see Apache Module mod_proxy: Reverse Proxy Request Headers). For information on how to forward the `X-Forwarded-Proto` header, see Host ASP.NET Core on Linux with Apache.

Forwarded Headers Middleware options

ForwardedHeadersOptions control the behavior of the Forwarded Headers Middleware. The following example changes the default values:

- Limit the number of entries in the forwarded headers to `2`.
- Add a known proxy address of `127.0.10.1`.
- Change the forwarded header name from the default `X-Forwarded-For` to

`X-Forwarded-For-My-Custom-Header-Name`.

```
services.Configure<ForwardedHeadersOptions>(options =>
{
    options.ForwardLimit = 2;
    options.KnownProxies.Add(IPAddress.Parse("127.0.10.1"));
    options.ForwardedForHeaderName = "X-Forwarded-For-My-Custom-Header-Name";
});
```

OPTION	DESCRIPTION
AllowedHosts	Restricts hosts by the `X-Forwarded-Host` header to the values provided. • Values are compared using ordinal-ignore-case. • Port numbers must be excluded. • If the list is empty, all hosts are allowed. • A top-level wildcard `*` allows all non-empty hosts. • Subdomain wildcards are permitted but don't match the root domain. For example, `*.contoso.com` matches the subdomain `foo.contoso.com` but not the root domain `contoso.com`. • Unicode host names are allowed but are converted to Punycode for matching. • IPv6 addresses must include bounding brackets and be in conventional form (for example, `[ABCD:EF01:2345:6789:ABCD:EF01:2345:6789]`). IPv6 addresses aren't special-cased to check for logical equality between different formats, and no canonicalization is performed. • Failure to restrict the allowed hosts may allow an attacker to spoof links generated by the service. The default value is an empty `IList<string>`.
ForwardedForHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XForwardedForHeaderName. This option is used when the proxy/forwarder doesn't use the `X-Forwarded-For` header but uses some other header to forward the information. The default is `X-Forwarded-For`.
ForwardedHeaders	Identifies which forwarders should be processed. See the ForwardedHeaders Enum for the list of fields that apply. Typical values assigned to this property are `ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto`. The default value is ForwardedHeaders.None.

OPTION	DESCRIPTION
ForwardedHostHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XForwardedHostHeaderName. This option is used when the proxy/forwarder doesn't use the `X-Forwarded-Host` header but uses some other header to forward the information. The default is `X-Forwarded-Host`.
ForwardedProtoHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XForwardedProtoHeaderName. This option is used when the proxy/forwarder doesn't use the `X-Forwarded-Proto` header but uses some other header to forward the information. The default is `X-Forwarded-Proto`.
ForwardLimit	Limits the number of entries in the headers that are processed. Set to `null` to disable the limit, but this should only be done if `KnownProxies` or `KnownNetworks` are configured. Setting a non-`null` value is a precaution (but not a guarantee) to guard against misconfigured proxies and malicious requests arriving from side-channels on the network. Forwarded Headers Middleware processes headers in reverse order from right to left. If the default value (`1`) is used, only the rightmost value from the headers is processed unless the value of `ForwardLimit` is increased. The default is `1`.
KnownNetworks	Address ranges of known networks to accept forwarded headers from. Provide IP ranges using Classless Interdomain Routing (CIDR) notation. If the server is using dual-mode sockets, IPv4 addresses are supplied in an IPv6 format (for example, `10.0.0.1` in IPv4 represented in IPv6 as `::ffff:10.0.0.1`). See IPAddress.MapToIPv6. Determine if this format is required by looking at the HttpContext.Connection.RemoteIpAddress. For more information, see the Configuration for an IPv4 address represented as an IPv6 address section. The default is an `IList`<IPNetwork> containing a single entry for `IPAddress.Loopback`.

OPTION	DESCRIPTION
KnownProxies	Addresses of known proxies to accept forwarded headers from. Use `KnownProxies` to specify exact IP address matches. If the server is using dual-mode sockets, IPv4 addresses are supplied in an IPv6 format (for example, `10.0.0.1` in IPv4 represented in IPv6 as `::ffff:10.0.0.1`). See IPAddress.MapToIPv6. Determine if this format is required by looking at the HttpContext.Connection.RemoteIpAddress. For more information, see the Configuration for an IPv4 address represented as an IPv6 address section. The default is an `IList`<IPAddress> containing a single entry for `IPAddress.IPv6Loopback`.
OriginalForHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XOriginalForHeaderName. The default is `X-Original-For`.
OriginalHostHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XOriginalHostHeaderName. The default is `X-Original-Host`.
OriginalProtoHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XOriginalProtoHeaderName. The default is `X-Original-Proto`.
RequireHeaderSymmetry	Require the number of header values to be in sync between the ForwardedHeadersOptions.ForwardedHeaders being processed. The default in ASP.NET Core 1.x is `true`. The default in ASP.NET Core 2.0 or later is `false`.

Scenarios and use cases

When it isn't possible to add forwarded headers and all requests are secure

In some cases, it might not be possible to add forwarded headers to the requests proxied to the app. If the proxy is enforcing that all public external requests are HTTPS, the scheme can be manually set in `Startup.Configure` before using any type of middleware:

```
app.Use((context, next) =>
{
    context.Request.Scheme = "https";
    return next();
});
```

This code can be disabled with an environment variable or other configuration setting in a development or staging environment.

Deal with path base and proxies that change the request path

Some proxies pass the path intact but with an app base path that should be removed so that routing works properly. UsePathBaseExtensions.UsePathBase middleware splits the path into HttpRequest.Path and the app base path into HttpRequest.PathBase.

If `/foo` is the app base path for a proxy path passed as `/foo/api/1`, the middleware sets `Request.PathBase` to `/foo` and `Request.Path` to `/api/1` with the following command:

```
app.UsePathBase("/foo");
```

The original path and path base are reapplied when the middleware is called again in reverse. For more information on middleware order processing, see ASP.NET Core Middleware.

If the proxy trims the path (for example, forwarding `/foo/api/1` to `/api/1`), fix redirects and links by setting the request's PathBase property:

```
app.Use((context, next) =>
{
    context.Request.PathBase = new PathString("/foo");
    return next();
});
```

If the proxy is adding path data, discard part of the path to fix redirects and links by using StartsWithSegments and assigning to the Path property:

```
app.Use((context, next) =>
{
    if (context.Request.Path.StartsWithSegments("/foo", out var remainder))
    {
        context.Request.Path = remainder;
    }

    return next();
});
```

Configuration for a proxy that uses different header names

If the proxy doesn't use headers named `X-Forwarded-For` and `X-Forwarded-Proto` to forward the proxy address/port and originating scheme information, set the ForwardedForHeaderName and ForwardedProtoHeaderName options to match the header names used by the proxy:

```
services.Configure<ForwardedHeadersOptions>(options =>
{
    options.ForwardedForHeaderName = "Header_Name_Used_By_Proxy_For_X-Forwarded-For_Header";
    options.ForwardedProtoHeaderName = "Header_Name_Used_By_Proxy_For_X-Forwarded-Proto_Header";
});
```

Configuration for an IPv4 address represented as an IPv6 address

If the server is using dual-mode sockets, IPv4 addresses are supplied in an IPv6 format (for example, `10.0.0.1` in IPv4 represented in IPv6 as `::ffff:10.0.0.1` or `::ffff:a00:1`). See IPAddress.MapToIPv6. Determine if this format is required by looking at the HttpContext.Connection.RemoteIpAddress.

In the following example, a network address that supplies forwarded headers is added to the

`KnownNetworks` list in IPv6 format.

IPv4 address: `10.11.12.1/8`

Converted IPv6 address: `::ffff:10.11.12.1`
Converted prefix length: 104

You can also supply the address in hexadecimal format (`10.11.12.1` represented in IPv6 as `::ffff:0a0b:0c01`). When converting an IPv4 address to IPv6, add 96 to the CIDR Prefix Length (`8` in the example) to account for the additional `::ffff:` IPv6 prefix (8 + 96 = 104).

```
// To access IPNetwork and IPAddress, add the following namespaces:
// using System.Net;
// using Microsoft.AspNetCore.HttpOverrides;
services.Configure<ForwardedHeadersOptions>(options =>
{
    options.ForwardedHeaders =
        ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto;
    options.KnownNetworks.Add(new IPNetwork(
        IPAddress.Parse("::ffff:10.11.12.1"), 104));
});
```

Forward the scheme for Linux and non-IIS reverse proxies

Apps that call UseHttpsRedirection and UseHsts put a site into an infinite loop if deployed to an Azure Linux App Service, Azure Linux virtual machine (VM), or behind any other reverse proxy besides IIS. TLS is terminated by the reverse proxy, and Kestrel isn't made aware of the correct request scheme. OAuth and OIDC also fail in this configuration because they generate incorrect redirects. UseIISIntegration adds and configures Forwarded Headers Middleware when running behind IIS, but there's no matching automatic configuration for Linux (Apache or Nginx integration).

To forward the scheme from the proxy in non-IIS scenarios, add and configure Forwarded Headers Middleware. In `Startup.ConfigureServices`, use the following code:

```
// using Microsoft.AspNetCore.HttpOverrides;

if (string.Equals(
    Environment.GetEnvironmentVariable("ASPNETCORE_FORWARDEDHEADERS_ENABLED"),
    "true", StringComparison.OrdinalIgnoreCase))
{
    services.Configure<ForwardedHeadersOptions>(options =>
    {
        options.ForwardedHeaders = ForwardedHeaders.XForwardedFor |
            ForwardedHeaders.XForwardedProto;
        // Only loopback proxies are allowed by default.
        // Clear that restriction because forwarders are enabled by explicit
        // configuration.
        options.KnownNetworks.Clear();
        options.KnownProxies.Clear();
    });
}
```

Troubleshoot

When headers aren't forwarded as expected, enable logging. If the logs don't provide sufficient information to troubleshoot the problem, enumerate the request headers received by the server. Use inline middleware to write request headers to an app response or log the headers.

To write the headers to the app's response, place the following terminal inline middleware immediately after the call to UseForwardedHeaders in `Startup.Configure`:

```
app.Run(async (context) =>
{
    context.Response.ContentType = "text/plain";

    // Request method, scheme, and path
    await context.Response.WriteAsync(
        $"Request Method: {context.Request.Method}{Environment.NewLine}");
    await context.Response.WriteAsync(
        $"Request Scheme: {context.Request.Scheme}{Environment.NewLine}");
    await context.Response.WriteAsync(
        $"Request Path: {context.Request.Path}{Environment.NewLine}");

    // Headers
    await context.Response.WriteAsync($"Request Headers:{Environment.NewLine}");

    foreach (var header in context.Request.Headers)
    {
        await context.Response.WriteAsync($"{header.Key}: " +
            $"{header.Value}{Environment.NewLine}");
    }

    await context.Response.WriteAsync(Environment.NewLine);

    // Connection: RemoteIp
    await context.Response.WriteAsync(
        $"Request RemoteIp: {context.Connection.RemoteIpAddress}");
});
```

You can write to logs instead of the response body. Writing to logs allows the site to function normally while debugging.

To write logs rather than to the response body:

- Inject `ILogger<Startup>` into the `Startup` class as described in Create logs in Startup.
- Place the following inline middleware immediately after the call to UseForwardedHeaders in `Startup.Configure`.

```
app.Use(async (context, next) =>
{
    // Request method, scheme, and path
    _logger.LogDebug("Request Method: {Method}", context.Request.Method);
    _logger.LogDebug("Request Scheme: {Scheme}", context.Request.Scheme);
    _logger.LogDebug("Request Path: {Path}", context.Request.Path);

    // Headers
    foreach (var header in context.Request.Headers)
    {
        _logger.LogDebug("Header: {Key}: {Value}", header.Key, header.Value);
    }

    // Connection: RemoteIp
    _logger.LogDebug("Request RemoteIp: {RemoteIpAddress}",
        context.Connection.RemoteIpAddress);

    await next();
});
```

When processed, `X-Forwarded-{For|Proto|Host}` values are moved to `X-Original-{For|Proto|Host}`. If there are multiple values in a given header, Forwarded Headers Middleware processes headers in reverse

order from right to left. The default `ForwardLimit` is `1` (one), so only the rightmost value from the headers is processed unless the value of `ForwardLimit` is increased.

The request's original remote IP must match an entry in the `KnownProxies` or `KnownNetworks` lists before forwarded headers are processed. This limits header spoofing by not accepting forwarders from untrusted proxies. When an unknown proxy is detected, logging indicates the address of the proxy:

```
September 20th 2018, 15:49:44.168 Unknown proxy: 10.0.0.100:54321
```

In the preceding example, 10.0.0.100 is a proxy server. If the server is a trusted proxy, add the server's IP address to `KnownProxies` (or add a trusted network to `KnownNetworks`) in `Startup.ConfigureServices`. For more information, see the Forwarded Headers Middleware options section.

```
services.Configure<ForwardedHeadersOptions>(options =>
{
    options.KnownProxies.Add(IPAddress.Parse("10.0.0.100"));
});
```

> **IMPORTANT**
>
> Only allow trusted proxies and networks to forward headers. Otherwise, IP spoofing attacks are possible.

Host ASP.NET Core in a web farm

9/22/2020 • 5 minutes to read • Edit Online

By Chris Ross

A *web farm* is a group of two or more web servers (or *nodes*) that host multiple instances of an app. When requests from users arrive to a web farm, a *load balancer* distributes the requests to the web farm's nodes. Web farms improve:

- **Reliability/availability**: When one or more nodes fail, the load balancer can route requests to other functioning nodes to continue processing requests.
- **Capacity/performance**: Multiple nodes can process more requests than a single server. The load balancer balances the workload by distributing requests to the nodes.
- **Scalability**: When more or less capacity is required, the number of active nodes can be increased or decreased to match the workload. Web farm platform technologies, such as Azure App Service, can automatically add or remove nodes at the request of the system administrator or automatically without human intervention.
- **Maintainability**: Nodes of a web farm can rely on a set of shared services, which results in easier system management. For example, the nodes of a web farm can rely upon a single database server and a common network location for static resources, such as images and downloadable files.

This topic describes configuration and dependencies for ASP.NET core apps hosted in a web farm that rely upon shared resources.

General configuration

Host and deploy ASP.NET Core
Learn how to set up hosting environments and deploy ASP.NET Core apps. Configure a process manager on each node of the web farm to automate app starts and restarts. Each node requires the ASP.NET Core runtime. For more information, see the topics in the Host and deploy area of the documentation.

Configure ASP.NET Core to work with proxy servers and load balancers
Learn about configuration for apps hosted behind proxy servers and load balancers, which often obscure important request information.

Deploy ASP.NET Core apps to Azure App Service
Azure App Service is a Microsoft cloud computing platform service for hosting web apps, including ASP.NET Core. App Service is a fully managed platform that provides automatic scaling, load balancing, patching, and continuous deployment.

App data

When an app is scaled to multiple instances, there might be app state that requires sharing across nodes. If the state is transient, consider sharing an IDistributedCache. If the shared state requires persistence, consider storing the shared state in a database.

Required configuration

Data Protection and Caching require configuration for apps deployed to a web farm.

Data Protection

The ASP.NET Core Data Protection system is used by apps to protect data. Data Protection relies upon a set of cryptographic keys stored in a *key ring*. When the Data Protection system is initialized, it applies default settings that store the key ring locally. Under the default configuration, a unique key ring is stored on each node of the web farm. Consequently, each web farm node can't decrypt data that's encrypted by an app on any other node. The default configuration isn't generally appropriate for hosting apps in a web farm. An alternative to implementing a shared key ring is to always route user requests to the same node. For more information on Data Protection system configuration for web farm deployments, see Configure ASP.NET Core Data Protection.

Caching

In a web farm environment, the caching mechanism must share cached items across the web farm's nodes. Caching must either rely upon a common Redis cache, a shared SQL Server database, or a custom caching implementation that shares cached items across the web farm. For more information, see Distributed caching in ASP.NET Core.

Dependent components

The following scenarios don't require additional configuration, but they depend on technologies that require configuration for web farms.

SCENARIO	DEPENDS ON ...
Authentication	Data Protection (see Configure ASP.NET Core Data Protection). For more information, see Use cookie authentication without ASP.NET Core Identity and Share authentication cookies among ASP.NET apps.
Identity	Authentication and database configuration. For more information, see Introduction to Identity on ASP.NET Core.
Session	Data Protection (encrypted cookies) (see Configure ASP.NET Core Data Protection) and Caching (see Distributed caching in ASP.NET Core). For more information, see Session and state management: Session state.
TempData	Data Protection (encrypted cookies) (see Configure ASP.NET Core Data Protection) or Session (see Session and state management: Session state). For more information, see Session and state management: TempData.
Anti-forgery	Data Protection (see Configure ASP.NET Core Data Protection). For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

Troubleshoot

Data Protection and caching

When Data Protection or caching isn't configured for a web farm environment, intermittent errors occur when

requests are processed. This occurs because nodes don't share the same resources and user requests aren't always routed back to the same node.

Consider a user who signs into the app using cookie authentication. The user signs into the app on one web farm node. If their next request arrives at the same node where they signed in, the app is able to decrypt the authentication cookie and allows access to the app's resource. If their next request arrives at a different node, the app can't decrypt the authentication cookie from the node where the user signed in, and authorization for the requested resource fails.

When any of the following symptoms occur **intermittently**, the problem is usually traced to improper Data Protection or caching configuration for a web farm environment:

- Authentication breaks: The authentication cookie is misconfigured or can't be decrypted. OAuth (Facebook, Microsoft, Twitter) or OpenIdConnect logins fail with the error "Correlation failed."
- Authorization breaks: Identity is lost.
- Session state loses data.
- Cached items disappear.
- TempData fails.
- POSTs fail: The anti-forgery check fails.

For more information on Data Protection configuration for web farm deployments, see Configure ASP.NET Core Data Protection. For more information on caching configuration for web farm deployments, see Distributed caching in ASP.NET Core.

Obtain data from apps

If the web farm apps are capable of responding to requests, obtain request, connection, and additional data from the apps using terminal inline middleware. For more information and sample code, see Troubleshoot and debug ASP.NET Core projects.

Visual Studio publish profiles (.pubxml) for ASP.NET Core app deployment

9/22/2020 • 13 minutes to read • Edit Online

By Sayed Ibrahim Hashimi and Rick Anderson

This document focuses on using Visual Studio 2019 or later to create and use publish profiles. The publish profiles created with Visual Studio can be used with MSBuild and Visual Studio. For instructions on publishing to Azure, see Publish an ASP.NET Core app to Azure with Visual Studio.

The `dotnet new mvc` command produces a project file containing the following root-level <Project> element:

```
<Project Sdk="Microsoft.NET.Sdk.Web">
    <!-- omitted for brevity -->
</Project>
```

The preceding `<Project>` element's `Sdk` attribute imports the MSBuild properties and targets from *$(MSBuildSDKsPath)\Microsoft.NET.Sdk.Web\Sdk\Sdk.props* and *$(MSBuildSDKsPath)\Microsoft.NET.Sdk.Web\Sdk\Sdk.targets*, respectively. The default location for `$(MSBuildSDKsPath)` (with Visual Studio 2019 Enterprise) is the *%programfiles(x86)%\Microsoft Visual Studio\2019\Enterprise\MSBuild\Sdks* folder.

`Microsoft.NET.Sdk.Web` (Web SDK) depends on other SDKs, including `Microsoft.NET.Sdk` (.NET Core SDK) and `Microsoft.NET.Sdk.Razor` (Razor SDK). The MSBuild properties and targets associated with each dependent SDK are imported. Publish targets import the appropriate set of targets based on the publish method used.

When MSBuild or Visual Studio loads a project, the following high-level actions occur:

- Build project
- Compute files to publish
- Publish files to destination

Compute project items

When the project is loaded, the MSBuild project items (files) are computed. The item type determines how the file is processed. By default, *.cs* files are included in the `Compile` item list. Files in the `Compile` item list are compiled.

The `Content` item list contains files that are published in addition to the build outputs. By default, files matching the patterns `wwwroot\**`, `**\*.config`, and `**\*.json` are included in the `Content` item list. For example, the `wwwroot\**` globbing pattern matches all files in the *wwwroot* folder and its subfolders.

The Web SDK imports the Razor SDK. As a result, files matching the patterns `**\*.cshtml` and `**\*.razor` are also included in the `Content` item list.

The Web SDK imports the Razor SDK. As a result, files matching the `**\*.cshtml` pattern are also included in the `Content` item list.

To explicitly add a file to the publish list, add the file directly in the *.csproj* file as shown in the Include Files section.

When selecting the **Publish** button in Visual Studio or when publishing from the command line:

- The properties/items are computed (the files that are needed to build).
- **Visual Studio only**: NuGet packages are restored. (Restore needs to be explicit by the user on the CLI.)
- The project builds.
- The publish items are computed (the files that are needed to publish).
- The project is published (the computed files are copied to the publish destination).

When an ASP.NET Core project references `Microsoft.NET.Sdk.Web` in the project file, an *app_offline.htm* file is placed at the root of the web app directory. When the file is present, the ASP.NET Core Module gracefully shuts down the app and serves the *app_offline.htm* file during the deployment. For more information, see the ASP.NET Core Module configuration reference.

Basic command-line publishing

Command-line publishing works on all .NET Core-supported platforms and doesn't require Visual Studio. In the following examples, the .NET Core CLI's dotnet publish command is run from the project directory (which contains the *.csproj* file). If the project folder isn't the current working directory, explicitly pass in the project file path. For example:

```
dotnet publish C:\Webs\Web1
```

Run the following commands to create and publish a web app:

```
dotnet new mvc
dotnet publish
```

The `dotnet publish` command produces a variation of the following output:

```
C:\Webs\Web1>dotnet publish
Microsoft (R) Build Engine version {VERSION} for .NET Core
Copyright (C) Microsoft Corporation. All rights reserved.

  Restore completed in 36.81 ms for C:\Webs\Web1\Web1.csproj.
  Web1 -> C:\Webs\Web1\bin\Debug\{TARGET FRAMEWORK MONIKER}\Web1.dll
  Web1 -> C:\Webs\Web1\bin\Debug\{TARGET FRAMEWORK MONIKER}\Web1.Views.dll
  Web1 -> C:\Webs\Web1\bin\Debug\{TARGET FRAMEWORK MONIKER}\publish\
```

The default publish folder format is *bin\Debug\{TARGET FRAMEWORK MONIKER}\publish*. For example, *bin\Debug\netcoreapp2.2\publish*.

The following command specifies a `Release` build and the publishing directory:

```
dotnet publish -c Release -o C:\MyWebs\test
```

The `dotnet publish` command calls MSBuild, which invokes the `Publish` target. Any parameters passed to `dotnet publish` are passed to MSBuild. The `-c` and `-o` parameters map to MSBuild's `Configuration` and `OutputPath` properties, respectively.

MSBuild properties can be passed using either of the following formats:

- `p:<NAME>=<VALUE>`
- `/p:<NAME>=<VALUE>`

For example, the following command publishes a `Release` build to a network share. The network share is

specified with forward slashes (*//r8/*) and works on all .NET Core supported platforms.

```
dotnet publish -c Release /p:PublishDir=//r8/release/AdminWeb
```

Confirm that the published app for deployment isn't running. Files in the *publish* folder are locked when the app is running. Deployment can't occur because locked files can't be copied.

Publish profiles

This section uses Visual Studio 2019 or later to create a publishing profile. Once the profile is created, publishing from Visual Studio or the command line is available. Publish profiles can simplify the publishing process, and any number of profiles can exist.

Create a publish profile in Visual Studio by choosing one of the following paths:

- Right-click the project in **Solution Explorer** and select **Publish**.
- Select **Publish {PROJECT NAME}** from the **Build** menu.

The **Publish** tab of the app capabilities page is displayed. If the project lacks a publish profile, the **Pick a publish target** page is displayed. You're asked to select one of the following publish targets:

- Azure App Service
- Azure App Service on Linux
- Azure Virtual Machines
- Folder
- IIS, FTP, Web Deploy (for any web server)
- Import Profile

To determine the most appropriate publish target, see What publishing options are right for me.

When the **Folder** publish target is selected, specify a folder path to store the published assets. The default folder path is *bin\{PROJECT CONFIGURATION}\{TARGET FRAMEWORK MONIKER}\publish*. For example, *bin\Release\netcoreapp2.2\publish*. Select the **Create Profile** button to finish.

Once a publish profile is created, the **Publish** tab's content changes. The newly created profile appears in a drop-down list. Below the drop-down list, select **Create new profile** to create another new profile.

Visual Studio's publish tool produces a *Properties/PublishProfiles/{PROFILE NAME}.pubxml* MSBuild file describing the publish profile. The *.pubxml* file:

- Contains publish configuration settings and is consumed by the publishing process.
- Can be modified to customize the build and publish process.

When publishing to an Azure target, the *.pubxml* file contains your Azure subscription identifier. With that target type, adding this file to source control is discouraged. When publishing to a non-Azure target, it's safe to check in the *.pubxml* file.

Sensitive information (like the publish password) is encrypted on a per user/machine level. It's stored in the *Properties/PublishProfiles/{PROFILE NAME}.pubxml.user* file. Because this file can store sensitive information, it shouldn't be checked into source control.

For an overview of how to publish an ASP.NET Core web app, see Host and deploy ASP.NET Core. The MSBuild tasks and targets necessary to publish an ASP.NET Core web app are open-source in the dotnet/websdk repository.

The following commands can use folder, MSDeploy, and Kudu publish profiles. Because MSDeploy lacks cross-

platform support, the following MSDeploy options are supported only on Windows.

Folder (works cross-platform):

```
dotnet publish WebApplication.csproj /p:PublishProfile=<FolderProfileName>
```

```
dotnet build WebApplication.csproj /p:DeployOnBuild=true /p:PublishProfile=<FolderProfileName>
```

MSDeploy:

```
dotnet publish WebApplication.csproj /p:PublishProfile=<MsDeployProfileName> /p:Password=
<DeploymentPassword>
```

```
dotnet build WebApplication.csproj /p:DeployOnBuild=true /p:PublishProfile=<MsDeployProfileName>
/p:Password=<DeploymentPassword>
```

MSDeploy package:

```
dotnet publish WebApplication.csproj /p:PublishProfile=<MsDeployPackageProfileName>
```

```
dotnet build WebApplication.csproj /p:DeployOnBuild=true /p:PublishProfile=<MsDeployPackageProfileName>
```

In the preceding examples:

- `dotnet publish` and `dotnet build` support Kudu APIs to publish to Azure from any platform. Visual Studio publish supports the Kudu APIs, but it's supported by WebSDK for cross-platform publish to Azure.
- Don't pass `DeployOnBuild` to the `dotnet publish` command.

For more information, see Microsoft.NET.Sdk.Publish.

Add a publish profile to the project's *Properties/PublishProfiles* folder with the following content:

```
<Project>
  <PropertyGroup>
    <PublishProtocol>Kudu</PublishProtocol>
    <PublishSiteName>nodewebapp</PublishSiteName>
    <UserName>username</UserName>
    <Password>password</Password>
  </PropertyGroup>
</Project>
```

Folder publish example

When publishing with a profile named *FolderProfile*, use any of the following commands:

```
dotnet publish /p:Configuration=Release /p:PublishProfile=FolderProfile`
```

```
dotnet build /p:DeployOnBuild=true /p:PublishProfile=FolderProfile
```

```
msbuild /p:DeployOnBuild=true /p:PublishProfile=FolderProfile
```

The .NET Core CLI's dotnet build command calls `msbuild` to run the build and publish process. The `dotnet build` and `msbuild` commands are equivalent when passing in a folder profile. When calling `msbuild` directly on Windows, the .NET Framework version of MSBuild is used. Calling `dotnet build` on a non-folder profile:

- Invokes `msbuild`, which uses MSDeploy.
- Results in a failure (even when running on Windows). To publish with a non-folder profile, call `msbuild` directly.

The following folder publish profile was created with Visual Studio and publishes to a network share:

```
<?xml version="1.0" encoding="utf-8"?>
<!--
This file is used by the publish/package process of your Web project.
You can customize the behavior of this process by editing this
MSBuild file.
-->
<Project ToolsVersion="4.0" xmlns="http://schemas.microsoft.com/developer/msbuild/2003">
  <PropertyGroup>
    <WebPublishMethod>FileSystem</WebPublishMethod>
    <PublishProvider>FileSystem</PublishProvider>
    <LastUsedBuildConfiguration>Release</LastUsedBuildConfiguration>
    <LastUsedPlatform>Any CPU</LastUsedPlatform>
    <SiteUrlToLaunchAfterPublish />
    <LaunchSiteAfterPublish>True</LaunchSiteAfterPublish>
    <ExcludeApp_Data>False</ExcludeApp_Data>
    <PublishFramework>netcoreapp1.1</PublishFramework>
    <ProjectGuid>c30c453c-312e-40c4-aec9-394a145dee0b</ProjectGuid>
    <publishUrl>\\r8\Release\AdminWeb</publishUrl>
    <DeleteExistingFiles>False</DeleteExistingFiles>
  </PropertyGroup>
</Project>
```

In the preceding example:

- The `<ExcludeApp_Data>` property is present merely to satisfy an XML schema requirement. The `<ExcludeApp_Data>` property has no effect on the publish process, even if there's an *App_Data* folder in the project root. The *App_Data* folder doesn't receive special treatment as it does in ASP.NET 4.x projects.
- The `<LastUsedBuildConfiguration>` property is set to `Release`. When publishing from Visual Studio, the value of `<LastUsedBuildConfiguration>` is set using the value when the publish process is started. `<LastUsedBuildConfiguration>` is special and shouldn't be overridden in an imported MSBuild file. This property can, however, be overridden from the command line using one of the following approaches.
  - Using the .NET Core CLI:

    ```
    dotnet publish /p:Configuration=Release /p:PublishProfile=FolderProfile
    ```

    ```
    dotnet build -c Release /p:DeployOnBuild=true /p:PublishProfile=FolderProfile
    ```

  - Using MSBuild:

    ```
    msbuild /p:Configuration=Release /p:DeployOnBuild=true /p:PublishProfile=FolderProfile
    ```

For more information, see MSBuild: how to set the configuration property.

Publish to an MSDeploy endpoint from the command line

The following example uses an ASP.NET Core web app created by Visual Studio named *AzureWebApp*. An Azure Apps publish profile is added with Visual Studio. For more information on how to create a profile, see the Publish profiles section.

To deploy the app using a publish profile, execute the `msbuild` command from a Visual Studio **Developer Command Prompt**. The command prompt is available in the *Visual Studio* folder of the **Start** menu on the Windows taskbar. For easier access, you can add the command prompt to the **Tools** menu in Visual Studio. For more information, see Developer Command Prompt for Visual Studio.

MSBuild uses the following command syntax:

```
msbuild {PATH}
    /p:DeployOnBuild=true
    /p:PublishProfile={PROFILE}
    /p:Username={USERNAME}
    /p:Password={PASSWORD}
```

- `{PATH}`: Path to the app's project file.
- `{PROFILE}`: Name of the publish profile.
- `{USERNAME}`: MSDeploy username. The `{USERNAME}` can be found in the publish profile.
- `{PASSWORD}`: MSDeploy password. Obtain the `{PASSWORD}` from the *{PROFILE}.PublishSettings* file. Download the *.PublishSettings* file from either:
  - **Solution Explorer**: Select **View** > **Cloud Explorer**. Connect with your Azure subscription. Open **App Services**. Right-click the app. Select **Download Publish Profile**.
  - Azure portal: Select **Get publish profile** in the web app's **Overview** panel.

The following example uses a publish profile named *AzureWebApp - Web Deploy*:

```
msbuild "AzureWebApp.csproj"
    /p:DeployOnBuild=true
    /p:PublishProfile="AzureWebApp - Web Deploy"
    /p:Username="$AzureWebApp"
    /p:Password="........."
```

A publish profile can also be used with the .NET Core CLI's dotnet msbuild command from a Windows command shell:

```
dotnet msbuild "AzureWebApp.csproj"
    /p:DeployOnBuild=true
    /p:PublishProfile="AzureWebApp - Web Deploy"
    /p:Username="$AzureWebApp"
    /p:Password="........."
```

IMPORTANT

The `dotnet msbuild` command is a cross-platform command and can compile ASP.NET Core apps on macOS and Linux. However, MSBuild on macOS and Linux isn't capable of deploying an app to Azure or other MSDeploy endpoints.

Set the environment

Include the `<EnvironmentName>` property in the publish profile (*.pubxml*) or project file to set the app's environment:

```
<PropertyGroup>
  <EnvironmentName>Development</EnvironmentName>
</PropertyGroup>
```

If you require *web.config* transformations (for example, setting environment variables based on the configuration, profile, or environment), see Transform web.config.

Exclude files

When publishing ASP.NET Core web apps, the following assets are included:

- Build artifacts
- Folders and files matching the following globbing patterns:
  - `**\*.config` (for example, *web.config*)
  - `**\*.json` (for example, *appsettings.json*)
  - `wwwroot\**`

MSBuild supports globbing patterns. For example, the following `<Content>` element suppresses the copying of text (*.txt*) files in the *wwwroot\content* folder and its subfolders:

```
<ItemGroup>
  <Content Update="wwwroot/content/**/*.txt" CopyToPublishDirectory="Never" />
</ItemGroup>
```

The preceding markup can be added to a publish profile or the *.csproj* file. When added to the *.csproj* file, the rule is added to all publish profiles in the project.

The following `<MsDeploySkipRules>` element excludes all files from the *wwwroot\content* folder:

```
<ItemGroup>
  <MsDeploySkipRules Include="CustomSkipFolder">
    <ObjectName>dirPath</ObjectName>
    <AbsolutePath>wwwroot\\content</AbsolutePath>
  </MsDeploySkipRules>
</ItemGroup>
```

`<MsDeploySkipRules>` won't delete the *skip* targets from the deployment site. `<Content>` targeted files and folders are deleted from the deployment site. For example, suppose a deployed web app had the following files:

- *Views/Home/About1.cshtml*
- *Views/Home/About2.cshtml*
- *Views/Home/About3.cshtml*

If the following `<MsDeploySkipRules>` elements are added, those files wouldn't be deleted on the deployment site.

```
<ItemGroup>
  <MsDeploySkipRules Include="CustomSkipFile">
    <ObjectName>filePath</ObjectName>
    <AbsolutePath>Views\\Home\\About1.cshtml</AbsolutePath>
  </MsDeploySkipRules>

  <MsDeploySkipRules Include="CustomSkipFile">
    <ObjectName>filePath</ObjectName>
    <AbsolutePath>Views\\Home\\About2.cshtml</AbsolutePath>
  </MsDeploySkipRules>

  <MsDeploySkipRules Include="CustomSkipFile">
    <ObjectName>filePath</ObjectName>
    <AbsolutePath>Views\\Home\\About3.cshtml</AbsolutePath>
  </MsDeploySkipRules>
</ItemGroup>
```

The preceding `<MsDeploySkipRules>` elements prevent the *skipped* files from being deployed. It won't delete those files once they're deployed.

The following `<Content>` element deletes the targeted files at the deployment site:

```
<ItemGroup>
  <Content Update="Views/Home/About?.cshtml" CopyToPublishDirectory="Never" />
</ItemGroup>
```

Using command-line deployment with the preceding `<Content>` element yields a variation of the following output:

```
MSDeployPublish:
  Starting Web deployment task from source: manifest(C:\Webs\Web1\obj\Release\{TARGET FRAMEWORK
MONIKER}\PubTmp\Web1.SourceManifest.
  xml) to Destination: auto().
  Deleting file (Web11112\Views\Home\About1.cshtml).
  Deleting file (Web11112\Views\Home\About2.cshtml).
  Deleting file (Web11112\Views\Home\About3.cshtml).
  Updating file (Web11112\web.config).
  Updating file (Web11112\Web1.deps.json).
  Updating file (Web11112\Web1.dll).
  Updating file (Web11112\Web1.pdb).
  Updating file (Web11112\Web1.runtimeconfig.json).
  Successfully executed Web deployment task.
  Publish Succeeded.
Done Building Project "C:\Webs\Web1\Web1.csproj" (default targets).
```

Include files

The following sections outline different approaches for file inclusion at publish time. The General file inclusion section uses the `DotNetPublishFiles` item, which is provided by a publish targets file in the Web SDK. The Selective file inclusion section uses the `ResolvedFileToPublish` item, which is provided by a publish targets file in the .NET Core SDK. Because the Web SDK depends on the .NET Core SDK, either item can be used in an ASP.NET Core project.

General file inclusion

The following example's `<ItemGroup>` element demonstrates copying a folder located outside of the project directory to a folder of the published site. Any files added to the following markup's `<ItemGroup>` are included by default.

```
<ItemGroup>
  <_CustomFiles Include="$(MSBuildProjectDirectory)/../images/**/*" />
  <DotNetPublishFiles Include="@(_CustomFiles)">
    <DestinationRelativePath>wwwroot/images/%(RecursiveDir)%(Filename)%(Extension)
</DestinationRelativePath>
  </DotNetPublishFiles>
</ItemGroup>
```

The preceding markup:

- Can be added to the *.csproj* file or the publish profile. If it's added to the *.csproj* file, it's included in each publish profile in the project.
- Declares a `_CustomFiles` item to store files matching the `Include` attribute's globbing pattern. The *images* folder referenced in the pattern is located outside of the project directory. A reserved property, named `$(MSBuildProjectDirectory)`, resolves to the project file's absolute path.
- Provides a list of files to the `DotNetPublishFiles` item. By default, the item's `<DestinationRelativePath>` element is empty. The default value is overridden in the markup and uses well-known item metadata such as `%(RecursiveDir)`. The inner text represents the *wwwroot/images* folder of the published site.

Selective file inclusion

The highlighted markup in the following example demonstrates:

- Copying a file located outside of the project into the published site's *wwwroot* folder. The file name of *ReadMe2.md* is maintained.
- Excluding the *wwwroot\Content* folder.
- Excluding *Views\Home\About2.cshtml*.

```
<?xml version="1.0" encoding="utf-8"?>
<Project ToolsVersion="4.0"
         xmlns="http://schemas.microsoft.com/developer/msbuild/2003">
  <PropertyGroup>
    <WebPublishMethod>FileSystem</WebPublishMethod>
    <PublishProvider>FileSystem</PublishProvider>
    <LastUsedBuildConfiguration>Release</LastUsedBuildConfiguration>
    <LastUsedPlatform>Any CPU</LastUsedPlatform>
    <SiteUrlToLaunchAfterPublish />
    <LaunchSiteAfterPublish>True</LaunchSiteAfterPublish>
    <ExcludeApp_Data>False</ExcludeApp_Data>
    <PublishFramework />
    <ProjectGuid>afa9f185-7ce0-4935-9da1-ab676229d68a</ProjectGuid>
    <publishUrl>bin\Release\PublishOutput</publishUrl>
    <DeleteExistingFiles>False</DeleteExistingFiles>
  </PropertyGroup>
  <ItemGroup>
    <ResolvedFileToPublish Include="..\ReadMe2.md">
      <RelativePath>wwwroot\ReadMe2.md</RelativePath>
    </ResolvedFileToPublish>

    <Content Update="wwwroot\Content\**\*" CopyToPublishDirectory="Never" />
    <Content Update="Views\Home\About2.cshtml" CopyToPublishDirectory="Never" />
  </ItemGroup>
</Project>
```

The preceding example uses the `ResolvedFileToPublish` item, whose default behavior is to always copy the files provided in the `Include` attribute to the published site. Override the default behavior by including a `<CopyToPublishDirectory>` child element with inner text of either `Never` or `PreserveNewest`. For example:

```
<ResolvedFileToPublish Include="..\ReadMe2.md">
  <RelativePath>wwwroot\ReadMe2.md</RelativePath>
  <CopyToPublishDirectory>PreserveNewest</CopyToPublishDirectory>
</ResolvedFileToPublish>
```

For more deployment samples, see the Web SDK README file.

Run a target before or after publishing

The built-in `BeforePublish` and `AfterPublish` targets execute a target before or after the publish target. Add the following elements to the publish profile to log console messages both before and after publishing:

```
<Target Name="CustomActionsBeforePublish" BeforeTargets="BeforePublish">
    <Message Text="Inside BeforePublish" Importance="high" />
  </Target>
  <Target Name="CustomActionsAfterPublish" AfterTargets="AfterPublish">
    <Message Text="Inside AfterPublish" Importance="high" />
</Target>
```

Publish to a server using an untrusted certificate

Add the `<AllowUntrustedCertificate>` property with a value of `True` to the publish profile:

```
<PropertyGroup>
  <AllowUntrustedCertificate>True</AllowUntrustedCertificate>
</PropertyGroup>
```

The Kudu service

To view the files in an Azure App Service web app deployment, use the Kudu service. Append the `scm` token to the web app name. For example:

URL	RESULT
`http://mysite.azurewebsites.net/`	Web App
`http://mysite.scm.azurewebsites.net/`	Kudu service

Select the Debug Console menu item to view, edit, delete, or add files.

ASP.NET Core directory structure

9/22/2020 • 3 minutes to read • Edit Online

The *publish* directory contains the app's deployable assets produced by the dotnet publish command. The directory contains:

- Application files
- Configuration files
- Static assets
- Packages
- A runtime (self-contained deployment only)

APP TYPE	DIRECTORY STRUCTURE
Framework-dependent Executable (FDE)	• publish† ◦ Views† MVC apps; if views aren't precompiled ◦ Pages† MVC or Razor Pages apps, if pages aren't precompiled ◦ wwwroot† ◦ *.dll files ◦ {ASSEMBLY NAME}.deps.json ◦ {ASSEMBLY NAME}.dll ◦ {ASSEMBLY NAME}{.EXTENSION} .exe extension on Windows, no extension on macOS or Linux ◦ {ASSEMBLY NAME}.pdb ◦ {ASSEMBLY NAME}.Views.dll ◦ {ASSEMBLY NAME}.Views.pdb ◦ {ASSEMBLY NAME}.runtimeconfig.json ◦ web.config (IIS deployments) ◦ createdump (Linux createdump utility) ◦ *.so (Linux shared object library) ◦ *.a (macOS archive) ◦ *.dylib (macOS dynamic library)
Self-contained Deployment (SCD)	• publish† ◦ Views† MVC apps, if views aren't precompiled ◦ Pages† MVC or Razor Pages apps, if pages aren't precompiled ◦ wwwroot† ◦ *.dll files ◦ {ASSEMBLY NAME}.deps.json ◦ {ASSEMBLY NAME}.dll ◦ {ASSEMBLY NAME}.exe ◦ {ASSEMBLY NAME}.pdb ◦ {ASSEMBLY NAME}.Views.dll ◦ {ASSEMBLY NAME}.Views.pdb ◦ {ASSEMBLY NAME}.runtimeconfig.json ◦ web.config (IIS deployments)

†Indicates a directory

The *publish* directory represents the *content root path*, also called the *application base path*, of the deployment. Whatever name is given to the *publish* directory of the deployed app on the server, its location serves as the server's physical path to the hosted app.

The *wwwroot* directory, if present, only contains static assets.

†Indicates a directory

The *publish* directory represents the *content root path*, also called the *application base path*, of the deployment. Whatever name is given to the *publish* directory of the deployed app on the server, its location serves as the server's physical path to the hosted app.

The *wwwroot* directory, if present, only contains static assets.

Creating a *Logs* folder is useful for ASP.NET Core Module enhanced debug logging. Folders in the path provided to the `<handlerSetting>` value aren't created by the module automatically and should pre-exist in the deployment to allow the module to write the debug log.

A *Logs* directory can be created for the deployment using one of the following two approaches:

- Add the following `<Target>` element to the project file:

  ```
  <Target Name="CreateLogsFolder" AfterTargets="Publish">
     <MakeDir Directories="$(PublishDir)Logs"
              Condition="!Exists('$(PublishDir)Logs')" />
     <WriteLinesToFile File="$(PublishDir)Logs\.log"
                       Lines="Generated file"
                       Overwrite="True"
                       Condition="!Exists('$(PublishDir)Logs\.log')" />
  </Target>
  ```

  The `<MakeDir>` element creates an empty *Logs* folder in the published output. The element uses the `PublishDir` property to determine the target location for creating the folder. Several deployment methods, such as Web Deploy, skip empty folders during deployment. The `<WriteLinesToFile>` element generates a file in the *Logs* folder, which guarantees deployment of the folder to the server. Folder creation using this approach fails if the worker process doesn't have write access to the target folder.

- Physically create the *Logs* directory on the server in the deployment.

The deployment directory requires Read/Execute permissions. The *Logs* directory requires Read/Write permissions. Additional directories where files are written require Read/Write permissions.

Health checks in ASP.NET Core

9/22/2020 • 44 minutes to read • Edit Online

By Glenn Condron

ASP.NET Core offers Health Checks Middleware and libraries for reporting the health of app infrastructure components.

Health checks are exposed by an app as HTTP endpoints. Health check endpoints can be configured for a variety of real-time monitoring scenarios:

- Health probes can be used by container orchestrators and load balancers to check an app's status. For example, a container orchestrator may respond to a failing health check by halting a rolling deployment or restarting a container. A load balancer might react to an unhealthy app by routing traffic away from the failing instance to a healthy instance.
- Use of memory, disk, and other physical server resources can be monitored for healthy status.
- Health checks can test an app's dependencies, such as databases and external service endpoints, to confirm availability and normal functioning.

View or download sample code (how to download)

The sample app includes examples of the scenarios described in this topic. To run the sample app for a given scenario, use the dotnet run command from the project's folder in a command shell. See the sample app's *README.md* file and the scenario descriptions in this topic for details on how to use the sample app.

Prerequisites

Health checks are usually used with an external monitoring service or container orchestrator to check the status of an app. Before adding health checks to an app, decide on which monitoring system to use. The monitoring system dictates what types of health checks to create and how to configure their endpoints.

The Microsoft.AspNetCore.Diagnostics.HealthChecks package is referenced implicitly for ASP.NET Core apps. To perform health checks using Entity Framework Core, add a package reference to the Microsoft.Extensions.Diagnostics.HealthChecks.EntityFrameworkCore package.

The sample app provides startup code to demonstrate health checks for several scenarios. The database probe scenario checks the health of a database connection using AspNetCore.Diagnostics.HealthChecks. The DbContext probe scenario checks a database using an EF Core `DbContext`. To explore the database scenarios, the sample app:

- Creates a database and provides its connection string in the *appsettings.json* file.
- Has the following package references in its project file:
  - AspNetCore.HealthChecks.SqlServer
  - Microsoft.Extensions.Diagnostics.HealthChecks.EntityFrameworkCore

> **NOTE**
>
> AspNetCore.Diagnostics.HealthChecks isn't maintained or supported by Microsoft.

Another health check scenario demonstrates how to filter health checks to a management port. The sample app requires you to create a *Properties/launchSettings.json* file that includes the management URL and management

port. For more information, see the Filter by port section.

Basic health probe

For many apps, a basic health probe configuration that reports the app's availability to process requests (*liveness*) is sufficient to discover the status of the app.

The basic configuration registers health check services and calls the Health Checks Middleware to respond at a URL endpoint with a health response. By default, no specific health checks are registered to test any particular dependency or subsystem. The app is considered healthy if it's capable of responding at the health endpoint URL. The default response writer writes the status (HealthStatus) as a plaintext response back to the client, indicating either a HealthStatus.Healthy, HealthStatus.Degraded or HealthStatus.Unhealthy status.

Register health check services with AddHealthChecks in `Startup.ConfigureServices`. Create a health check endpoint by calling `MapHealthChecks` in `Startup.Configure`.

In the sample app, the health check endpoint is created at `/health` (*BasicStartup.cs*):

```
public class BasicStartup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddHealthChecks();
    }

    public void Configure(IApplicationBuilder app)
    {
        app.UseRouting();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapHealthChecks("/health");
        });
    }
}
```

To run the basic configuration scenario using the sample app, execute the following command from the project's folder in a command shell:

```
dotnet run --scenario basic
```

Docker example

Docker offers a built-in `HEALTHCHECK` directive that can be used to check the status of an app that uses the basic health check configuration:

```
HEALTHCHECK CMD curl --fail http://localhost:5000/health || exit
```

Create health checks

Health checks are created by implementing the IHealthCheck interface. The CheckHealthAsync method returns a HealthCheckResult that indicates the health as `Healthy`, `Degraded`, or `Unhealthy`. The result is written as a plaintext response with a configurable status code (configuration is described in the Health check options section). HealthCheckResult can also return optional key-value pairs.

The following `ExampleHealthCheck` class demonstrates the layout of a health check. The health checks logic is placed in the `CheckHealthAsync` method. The following example sets a dummy variable,

`healthCheckResultHealthy`, to `true`. If the value of `healthCheckResultHealthy` is set to `false`, the HealthCheckResult.Unhealthy status is returned.

```
public class ExampleHealthCheck : IHealthCheck
{
    public Task<HealthCheckResult> CheckHealthAsync(
        HealthCheckContext context,
        CancellationToken cancellationToken = default(CancellationToken))
    {
        var healthCheckResultHealthy = true;

        if (healthCheckResultHealthy)
        {
            return Task.FromResult(
                HealthCheckResult.Healthy("A healthy result."));
        }

        return Task.FromResult(
            HealthCheckResult.Unhealthy("An unhealthy result."));
    }
}
```

Register health check services

The `ExampleHealthCheck` type is added to health check services with AddCheck in `Startup.ConfigureServices`:

```
services.AddHealthChecks()
    .AddCheck<ExampleHealthCheck>("example_health_check");
```

The AddCheck overload shown in the following example sets the failure status (HealthStatus) to report when the health check reports a failure. If the failure status is set to `null` (default), HealthStatus.Unhealthy is reported. This overload is a useful scenario for library authors, where the failure status indicated by the library is enforced by the app when a health check failure occurs if the health check implementation honors the setting.

Tags can be used to filter health checks (described further in the Filter health checks section).

```
services.AddHealthChecks()
    .AddCheck<ExampleHealthCheck>(
        "example_health_check",
        failureStatus: HealthStatus.Degraded,
        tags: new[] { "example" });
```

AddCheck can also execute a lambda function. In the following example, the health check name is specified as `Example` and the check always returns a healthy state:

```
services.AddHealthChecks()
    .AddCheck("Example", () =>
        HealthCheckResult.Healthy("Example is OK!"), tags: new[] { "example" });
```

Call AddTypeActivatedCheck to pass arguments to a health check implementation. In the following example, `TestHealthCheckWithArgs` accepts an integer and a string for use when CheckHealthAsync is called:

```
private class TestHealthCheckWithArgs : IHealthCheck
{
    public TestHealthCheckWithArgs(int i, string s)
    {
        I = i;
        S = s;
    }

    public int I { get; set; }

    public string S { get; set; }

    public Task<HealthCheckResult> CheckHealthAsync(HealthCheckContext context,
        CancellationToken cancellationToken = default)
    {
        ...
    }
}
```

`TestHealthCheckWithArgs` is registered by calling `AddTypeActivatedCheck` with the integer and string passed to the implementation:

```
services.AddHealthChecks()
    .AddTypeActivatedCheck<TestHealthCheckWithArgs>(
        "test",
        failureStatus: HealthStatus.Degraded,
        tags: new[] { "example" },
        args: new object[] { 5, "string" });
```

Use Health Checks Routing

In `Startup.Configure`, call `MapHealthChecks` on the endpoint builder with the endpoint URL or relative path:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health");
});
```

Require host

Call `RequireHost` to specify one or more permitted hosts for the health check endpoint. Hosts should be Unicode rather than punycode and may include a port. If a collection isn't supplied, any host is accepted.

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health").RequireHost("www.contoso.com:5001");
});
```

For more information, see the Filter by port section.

Require authorization

Call `RequireAuthorization` to run Authorization Middleware on the health check request endpoint. A `RequireAuthorization` overload accepts one or more authorization policies. If a policy isn't provided, the default authorization policy is used.

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health").RequireAuthorization();
});
```

Enable Cross-Origin Requests (CORS)

Although performing health checks manually from a browser isn't a common use scenario, CORS Middleware can be enabled by calling `RequireCors` on health checks endpoints. A `RequireCors` overload accepts a CORS policy builder delegate (`CorsPolicyBuilder`) or a policy name. If a policy isn't provided, the default CORS policy is used. For more information, see Enable Cross-Origin Requests (CORS) in ASP.NET Core.

Health check options

HealthCheckOptions provide an opportunity to customize health check behavior:

- Filter health checks
- Customize the HTTP status code
- Suppress cache headers
- Customize output

Filter health checks

By default, Health Checks Middleware runs all registered health checks. To run a subset of health checks, provide a function that returns a boolean to the Predicate option. In the following example, the `Bar` health check is filtered out by its tag (`bar_tag`) in the function's conditional statement, where `true` is only returned if the health check's Tags property matches `foo_tag` or `baz_tag`:

In `Startup.ConfigureServices`:

```
services.AddHealthChecks()
    .AddCheck("Foo", () =>
        HealthCheckResult.Healthy("Foo is OK!"), tags: new[] { "foo_tag" })
    .AddCheck("Bar", () =>
        HealthCheckResult.Unhealthy("Bar is unhealthy!"), tags: new[] { "bar_tag" })
    .AddCheck("Baz", () =>
        HealthCheckResult.Healthy("Baz is OK!"), tags: new[] { "baz_tag" });
```

In `Startup.Configure`, the `Predicate` filters out the 'Bar' health check. Only Foo and Baz execute.:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health", new HealthCheckOptions()
    {
        Predicate = (check) => check.Tags.Contains("foo_tag") ||
            check.Tags.Contains("baz_tag")
    });
});
```

Customize the HTTP status code

Use ResultStatusCodes to customize the mapping of health status to HTTP status codes. The following StatusCodes assignments are the default values used by the middleware. Change the status code values to meet your requirements.

In `Startup.Configure`:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health", new HealthCheckOptions()
    {
        ResultStatusCodes =
        {
            [HealthStatus.Healthy] = StatusCodes.Status200OK,
            [HealthStatus.Degraded] = StatusCodes.Status200OK,
            [HealthStatus.Unhealthy] = StatusCodes.Status503ServiceUnavailable
        }
    });
});
```

Suppress cache headers

AllowCachingResponses controls whether the Health Checks Middleware adds HTTP headers to a probe response to prevent response caching. If the value is `false` (default), the middleware sets or overrides the `Cache-Control`, `Expires`, and `Pragma` headers to prevent response caching. If the value is `true`, the middleware doesn't modify the cache headers of the response.

In `Startup.Configure`:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health", new HealthCheckOptions()
    {
        AllowCachingResponses = false
    });
});
```

Customize output

In `Startup.Configure`, set the HealthCheckOptions.ResponseWriter option to a delegate for writing the response:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health", new HealthCheckOptions()
    {
        ResponseWriter = WriteResponse
    });
});
```

The default delegate writes a minimal plaintext response with the string value of HealthReport.Status. The following custom delegates output a custom JSON response.

The first example from the sample app demonstrates how to use System.Text.Json:

```
private static Task WriteResponse(HttpContext context, HealthReport result)
{
    context.Response.ContentType = "application/json; charset=utf-8";

    var options = new JsonWriterOptions
    {
        Indented = true
    };

    using (var stream = new MemoryStream())
    {
        using (var writer = new Utf8JsonWriter(stream, options))
        {
            writer.WriteStartObject();
            writer.WriteString("status", result.Status.ToString());
            writer.WriteStartObject("results");
            foreach (var entry in result.Entries)
            {
                writer.WriteStartObject(entry.Key);
                writer.WriteString("status", entry.Value.Status.ToString());
                writer.WriteString("description", entry.Value.Description);
                writer.WriteStartObject("data");
                foreach (var item in entry.Value.Data)
                {
                    writer.WritePropertyName(item.Key);
                    JsonSerializer.Serialize(
                        writer, item.Value, item.Value?.GetType() ??
                        typeof(object));
                }
                writer.WriteEndObject();
                writer.WriteEndObject();
            }
            writer.WriteEndObject();
            writer.WriteEndObject();
        }

        var json = Encoding.UTF8.GetString(stream.ToArray());

        return context.Response.WriteAsync(json);
    }
}
```

The second example demonstrates how to use Newtonsoft.Json:

```
private static Task WriteResponse(HttpContext context, HealthReport result)
{
    context.Response.ContentType = "application/json";

    var json = new JObject(
        new JProperty("status", result.Status.ToString()),
        new JProperty("results", new JObject(result.Entries.Select(pair =>
            new JProperty(pair.Key, new JObject(
                new JProperty("status", pair.Value.Status.ToString()),
                new JProperty("description", pair.Value.Description),
                new JProperty("data", new JObject(pair.Value.Data.Select(
                    p => new JProperty(p.Key, p.Value)))))))));

    return context.Response.WriteAsync(
        json.ToString(Formatting.Indented));
}
```

In the sample app, comment out the `SYSTEM_TEXT_JSON` preprocessor directive in *CustomWriterStartup.cs* to enable the `Newtonsoft.Json` version of `WriteResponse`.

The health checks API doesn't provide built-in support for complex JSON return formats because the format is specific to your choice of monitoring system. Customize the response in the preceding examples as needed. For more information on JSON serialization with `System.Text.Json`, see How to serialize and deserialize JSON in .NET.

Database probe

A health check can specify a database query to run as a boolean test to indicate if the database is responding normally.

The sample app uses AspNetCore.Diagnostics.HealthChecks, a health check library for ASP.NET Core apps, to perform a health check on a SQL Server database. `AspNetCore.Diagnostics.HealthChecks` executes a `SELECT 1` query against the database to confirm the connection to the database is healthy.

> **WARNING**
> When checking a database connection with a query, choose a query that returns quickly. The query approach runs the risk of overloading the database and degrading its performance. In most cases, running a test query isn't necessary. Merely making a successful connection to the database is sufficient. If you find it necessary to run a query, choose a simple SELECT query, such as `SELECT 1`.

Include a package reference to AspNetCore.HealthChecks.SqlServer.

Supply a valid database connection string in the *appsettings.json* file of the sample app. The app uses a SQL Server database named `HealthCheckSample`:

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=
(localdb)\\MSSQLLocalDB;Database=HealthCheckSample;Trusted_Connection=True;MultipleActiveResultSets=true;Con
nectRetryCount=0"
  },
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    },
    "Console": {
      "IncludeScopes": "true"
    }
  },
  "AllowedHosts": "*"
}
```

Register health check services with AddHealthChecks in `Startup.ConfigureServices`. The sample app calls the `AddSqlServer` method with the database's connection string (*DbHealthStartup.cs*):

```
services.AddHealthChecks()
    .AddSqlServer(Configuration["ConnectionStrings:DefaultConnection"]);
```

A health check endpoint is created by calling `MapHealthChecks` in `Startup.Configure`:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health");
}
```

To run the database probe scenario using the sample app, execute the following command from the project's folder in a command shell:

```
dotnet run --scenario db
```

> **NOTE**
> AspNetCore.Diagnostics.HealthChecks isn't maintained or supported by Microsoft.

Entity Framework Core DbContext probe

The `DbContext` check confirms that the app can communicate with the database configured for an EF Core `DbContext`. The `DbContext` check is supported in apps that:

- Use Entity Framework (EF) Core.
- Include a package reference to Microsoft.Extensions.Diagnostics.HealthChecks.EntityFrameworkCore.

`AddDbContextCheck<TContext>` registers a health check for a `DbContext`. The `DbContext` is supplied as the `TContext` to the method. An overload is available to configure the failure status, tags, and a custom test query.

By default:

- The `DbContextHealthCheck` calls EF Core's `CanConnectAsync` method. You can customize what operation is run when checking health using `AddDbContextCheck` method overloads.
- The name of the health check is the name of the `TContext` type.

In the sample app, `AppDbContext` is provided to `AddDbContextCheck` and registered as a service in `Startup.ConfigureServices` (*DbContextHealthStartup.cs*):

```
services.AddHealthChecks()
    .AddDbContextCheck<AppDbContext>();

services.AddDbContext<AppDbContext>(options =>
{
    options.UseSqlServer(
        Configuration["ConnectionStrings:DefaultConnection"]);
});
```

A health check endpoint is created by calling `MapHealthChecks` in `Startup.Configure`:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health");
}
```

To run the `DbContext` probe scenario using the sample app, confirm that the database specified by the connection string doesn't exist in the SQL Server instance. If the database exists, delete it.

Execute the following command from the project's folder in a command shell:

```
dotnet run --scenario dbcontext
```

After the app is running, check the health status by making a request to the `/health` endpoint in a browser. The database and `AppDbContext` don't exist, so app provides the following response:

```
Unhealthy
```

Trigger the sample app to create the database. Make a request to `/createdatabase`. The app responds:

```
Creating the database...
Done!
Navigate to /health to see the health status.
```

Make a request to the `/health` endpoint. The database and context exist, so app responds:

```
Healthy
```

Trigger the sample app to delete the database. Make a request to `/deletedatabase`. The app responds:

```
Deleting the database...
Done!
Navigate to /health to see the health status.
```

Make a request to the `/health` endpoint. The app provides an unhealthy response:

```
Unhealthy
```

Separate readiness and liveness probes

In some hosting scenarios, a pair of health checks are used that distinguish two app states:

- *Readiness* indicates if the app is running normally but isn't ready to receive requests.
- *Liveness* indicates if an app has crashed and must be restarted.

Consider the following example: An app must download a large configuration file before it's ready to process requests. We don't want the app to be restarted if the initial download fails because the app can retry downloading the file several times. We use a *liveness probe* to describe the liveness of the process, no additional checks are performed. We also want to prevent requests from being sent to the app before the configuration file download has succeeded. We use a *readiness probe* to indicate a "not ready" state until the download succeeds and the app is ready to receive requests.

The sample app contains a health check to report the completion of long-running startup task in a Hosted Service. The `StartupHostedServiceHealthCheck` exposes a property, `StartupTaskCompleted`, that the hosted service can set to `true` when its long-running task is finished (*StartupHostedServiceHealthCheck.cs*):

```
public class StartupHostedServiceHealthCheck : IHealthCheck
{
    private volatile bool _startupTaskCompleted = false;

    public string Name => "slow_dependency_check";

    public bool StartupTaskCompleted
    {
        get => _startupTaskCompleted;
        set => _startupTaskCompleted = value;
    }

    public Task<HealthCheckResult> CheckHealthAsync(
        HealthCheckContext context,
        CancellationToken cancellationToken = default(CancellationToken))
    {
        if (StartupTaskCompleted)
        {
            return Task.FromResult(
                HealthCheckResult.Healthy("The startup task is finished."));
        }

        return Task.FromResult(
            HealthCheckResult.Unhealthy("The startup task is still running."));
    }
}
```

The long-running background task is started by a Hosted Service (*Services/StartupHostedService*). At the conclusion of the task, `StartupHostedServiceHealthCheck.StartupTaskCompleted` is set to `true`:

```
public class StartupHostedService : IHostedService, IDisposable
{
    private readonly int _delaySeconds = 15;
    private readonly ILogger _logger;
    private readonly StartupHostedServiceHealthCheck _startupHostedServiceHealthCheck;

    public StartupHostedService(ILogger<StartupHostedService> logger,
        StartupHostedServiceHealthCheck startupHostedServiceHealthCheck)
    {
        _logger = logger;
        _startupHostedServiceHealthCheck = startupHostedServiceHealthCheck;
    }

    public Task StartAsync(CancellationToken cancellationToken)
    {
        _logger.LogInformation("Startup Background Service is starting.");

        // Simulate the effect of a long-running startup task.
        Task.Run(async () =>
        {
            await Task.Delay(_delaySeconds * 1000);

            _startupHostedServiceHealthCheck.StartupTaskCompleted = true;

            _logger.LogInformation("Startup Background Service has started.");
        });

        return Task.CompletedTask;
    }

    public Task StopAsync(CancellationToken cancellationToken)
    {
        _logger.LogInformation("Startup Background Service is stopping.");

        return Task.CompletedTask;
    }

    public void Dispose()
    {
    }
}
```

The health check is registered with AddCheck in `Startup.ConfigureServices` along with the hosted service. Because the hosted service must set the property on the health check, the health check is also registered in the service container (*LivenessProbeStartup.cs*):

```
services.AddHostedService<StartupHostedService>();
services.AddSingleton<StartupHostedServiceHealthCheck>();

services.AddHealthChecks()
    .AddCheck<StartupHostedServiceHealthCheck>(
        "hosted_service_startup",
        failureStatus: HealthStatus.Degraded,
        tags: new[] { "ready" });

services.Configure<HealthCheckPublisherOptions>(options =>
{
    options.Delay = TimeSpan.FromSeconds(2);
    options.Predicate = (check) => check.Tags.Contains("ready");
});

services.AddSingleton<IHealthCheckPublisher, ReadinessPublisher>();
```

A health check endpoint is created by calling `MapHealthChecks` in `Startup.Configure`. In the sample app, the

health check endpoints are created at:

- `/health/ready` for the readiness check. The readiness check filters health checks to the health check with the `ready` tag.
- `/health/live` for the liveness check. The liveness check filters out the `StartupHostedServiceHealthCheck` by returning `false` in the HealthCheckOptions.Predicate (for more information, see Filter health checks)

In the following example code:

- The readiness check uses all registered checks with the 'ready' tag.
- The `Predicate` excludes all checks and return a 200-Ok.

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health/ready", new HealthCheckOptions()
    {
        Predicate = (check) => check.Tags.Contains("ready"),
    });

    endpoints.MapHealthChecks("/health/live", new HealthCheckOptions()
    {
        Predicate = (_) => false
    });
}
```

To run the readiness/liveness configuration scenario using the sample app, execute the following command from the project's folder in a command shell:

```
dotnet run --scenario liveness
```

In a browser, visit `/health/ready` several times until 15 seconds have passed. The health check reports *Unhealthy* for the first 15 seconds. After 15 seconds, the endpoint reports *Healthy*, which reflects the completion of the long-running task by the hosted service.

This example also creates a Health Check Publisher (IHealthCheckPublisher implementation) that runs the first readiness check with a two second delay. For more information, see the Health Check Publisher section.

Kubernetes example

Using separate readiness and liveness checks is useful in an environment such as Kubernetes. In Kubernetes, an app might be required to perform time-consuming startup work before accepting requests, such as a test of the underlying database availability. Using separate checks allows the orchestrator to distinguish whether the app is functioning but not yet ready or if the app has failed to start. For more information on readiness and liveness probes in Kubernetes, see Configure Liveness and Readiness Probes in the Kubernetes documentation.

The following example demonstrates a Kubernetes readiness probe configuration:

```
spec:
  template:
  spec:
    readinessProbe:
      # an http probe
      httpGet:
        path: /health/ready
        port: 80
      # length of time to wait for a pod to initialize
      # after pod startup, before applying health checking
      initialDelaySeconds: 30
      timeoutSeconds: 1
    ports:
      - containerPort: 80
```

Metric-based probe with a custom response writer

The sample app demonstrates a memory health check with a custom response writer.

`MemoryHealthCheck` reports a degraded status if the app uses more than a given threshold of memory (1 GB in the sample app). The HealthCheckResult includes Garbage Collector (GC) information for the app (*MemoryHealthCheck.cs*):

```
public class MemoryHealthCheck : IHealthCheck
{
    private readonly IOptionsMonitor<MemoryCheckOptions> _options;

    public MemoryHealthCheck(IOptionsMonitor<MemoryCheckOptions> options)
    {
        _options = options;
    }

    public string Name => "memory_check";

    public Task<HealthCheckResult> CheckHealthAsync(
        HealthCheckContext context,
        CancellationToken cancellationToken = default(CancellationToken))
    {
        var options = _options.Get(context.Registration.Name);

        // Include GC information in the reported diagnostics.
        var allocated = GC.GetTotalMemory(forceFullCollection: false);
        var data = new Dictionary<string, object>()
        {
            { "AllocatedBytes", allocated },
            { "Gen0Collections", GC.CollectionCount(0) },
            { "Gen1Collections", GC.CollectionCount(1) },
            { "Gen2Collections", GC.CollectionCount(2) },
        };
        var status = (allocated < options.Threshold) ?
            HealthStatus.Healthy : context.Registration.FailureStatus;

        return Task.FromResult(new HealthCheckResult(
            status,
            description: "Reports degraded status if allocated bytes " +
                $">= {options.Threshold} bytes.",
            exception: null,
            data: data));
    }
}
```

Register health check services with AddHealthChecks in `Startup.ConfigureServices`. Instead of enabling the

health check by passing it to AddCheck, the `MemoryHealthCheck` is registered as a service. All IHealthCheck registered services are available to the health check services and middleware. We recommend registering health check services as Singleton services.

In *CustomWriterStartup.cs* of the sample app:

```
services.AddHealthChecks()
    .AddMemoryHealthCheck("memory");
```

A health check endpoint is created by calling `MapHealthChecks` in `Startup.Configure`. A `WriteResponse` delegate is provided to the <Microsoft.AspNetCore.Diagnostics.HealthChecks.HealthCheckOptions.ResponseWriter> property to output a custom JSON response when the health check executes:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health", new HealthCheckOptions()
    {
        ResponseWriter = WriteResponse
    });
}
```

The `WriteResponse` delegate formats the `CompositeHealthCheckResult` into a JSON object and yields JSON output for the health check response. For more information, see the Customize output section.

To run the metric-based probe with custom response writer output using the sample app, execute the following command from the project's folder in a command shell:

```
dotnet run --scenario writer
```

> **NOTE**
>
> AspNetCore.Diagnostics.HealthChecks includes metric-based health check scenarios, including disk storage and maximum value liveness checks.
>
> AspNetCore.Diagnostics.HealthChecks isn't maintained or supported by Microsoft.

Filter by port

Call `RequireHost` on `MapHealthChecks` with a URL pattern that specifies a port to restrict health check requests to the port specified. This is typically used in a container environment to expose a port for monitoring services.

The sample app configures the port using the Environment Variable Configuration Provider. The port is set in the *launchSettings.json* file and passed to the configuration provider via an environment variable. You must also configure the server to listen to requests on the management port.

To use the sample app to demonstrate management port configuration, create the *launchSettings.json* file in a *Properties* folder.

The following *Properties/launchSettings.json* file in the sample app isn't included in the sample app's project files and must be created manually:

```
{
  "profiles": {
    "SampleApp": {
      "commandName": "Project",
      "commandLineArgs": "",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development",
        "ASPNETCORE_URLS": "http://localhost:5000/;http://localhost:5001/",
        "ASPNETCORE_MANAGEMENTPORT": "5001"
      },
      "applicationUrl": "http://localhost:5000/"
    }
  }
}
```

Register health check services with AddHealthChecks in `Startup.ConfigureServices`. Create a health check endpoint by calling `MapHealthChecks` in `Startup.Configure`.

In the sample app, a call to `RequireHost` on the endpoint in `Startup.Configure` specifies the management port from configuration:

```
endpoints.MapHealthChecks("/health")
    .RequireHost($"*:{Configuration["ManagementPort"]}");
```

Endpoints are created in the sample app in `Startup.Configure`. In the following example code:

- The readiness check uses all registered checks with the 'ready' tag.
- The `Predicate` excludes all checks and return a 200-Ok.

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health/ready", new HealthCheckOptions()
    {
        Predicate = (check) => check.Tags.Contains("ready"),
    });

    endpoints.MapHealthChecks("/health/live", new HealthCheckOptions()
    {
        Predicate = (_) => false
    });
}
```

NOTE

You can avoid creating the *launchSettings.json* file in the sample app by setting the management port explicitly in code. In *Program.cs* where the HostBuilder is created, add a call to ListenAnyIP and provide the app's management port endpoint. In `Configure` of *ManagementPortStartup.cs*, specify the management port with `RequireHost`:

Program.cs:

```
return new HostBuilder()
    .ConfigureWebHostDefaults(webBuilder =>
    {
        webBuilder.UseKestrel()
            .ConfigureKestrel(serverOptions =>
            {
                serverOptions.ListenAnyIP(5001);
            })
            .UseStartup(startupType);
    })
    .Build();
```

ManagementPortStartup.cs:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health").RequireHost("*:5001");
});
```

To run the management port configuration scenario using the sample app, execute the following command from the project's folder in a command shell:

```
dotnet run --scenario port
```

Distribute a health check library

To distribute a health check as a library:

1. Write a health check that implements the IHealthCheck interface as a standalone class. The class can rely on dependency injection (DI), type activation, and named options to access configuration data.

   In the health checks logic of `CheckHealthAsync`:

   - `data1` and `data2` are used in the method to run the probe's health check logic.
   - `AccessViolationException` is handled.

   When an AccessViolationException occurs, the FailureStatus is returned with the HealthCheckResult to allow users to configure the health checks failure status.

```
using System;
using System.Threading;
using System.Threading.Tasks;
using Microsoft.Extensions.Diagnostics.HealthChecks;

namespace SampleApp
{
    public class ExampleHealthCheck : IHealthCheck
    {
        private readonly string _data1;
        private readonly int? _data2;

        public ExampleHealthCheck(string data1, int? data2)
        {
            _data1 = data1 ?? throw new ArgumentNullException(nameof(data1));
            _data2 = data2 ?? throw new ArgumentNullException(nameof(data2));
        }

        public async Task<HealthCheckResult> CheckHealthAsync(
            HealthCheckContext context, CancellationToken cancellationToken)
        {
            try
            {
                return HealthCheckResult.Healthy();
            }
            catch (AccessViolationException ex)
            {
                return new HealthCheckResult(
                    context.Registration.FailureStatus,
                    description: "An access violation occurred during the check.",
                    exception: ex,
                    data: null);
            }
        }
    }
}
```

2. Write an extension method with parameters that the consuming app calls in its `Startup.Configure` method. In the following example, assume the following health check method signature:

```
ExampleHealthCheck(string, string, int )
```

The preceding signature indicates that the `ExampleHealthCheck` requires additional data to process the health check probe logic. The data is provided to the delegate used to create the health check instance when the health check is registered with an extension method. In the following example, the caller specifies optional:

- health check name (`name`). If `null` , `example_health_check` is used.
- string data point for the health check (`data1`).
- integer data point for the health check (`data2`). If `null` , `1` is used.
- failure status (HealthStatus). The default is `null` . If `null` , HealthStatus.Unhealthy is reported for a failure status.
- tags (`IEnumerable<string>`).

```
using System.Collections.Generic;
using Microsoft.Extensions.Diagnostics.HealthChecks;

public static class ExampleHealthCheckBuilderExtensions
{
    const string DefaultName = "example_health_check";

    public static IHealthChecksBuilder AddExampleHealthCheck(
        this IHealthChecksBuilder builder,
        string name = default,
        string data1,
        int data2 = 1,
        HealthStatus? failureStatus = default,
        IEnumerable<string> tags = default)
    {
        return builder.Add(new HealthCheckRegistration(
            name ?? DefaultName,
            sp => new ExampleHealthCheck(data1, data2),
            failureStatus,
            tags));
    }
}
```

Health Check Publisher

When an IHealthCheckPublisher is added to the service container, the health check system periodically executes your health checks and calls `PublishAsync` with the result. This is useful in a push-based health monitoring system scenario that expects each process to call the monitoring system periodically in order to determine health.

The IHealthCheckPublisher interface has a single method:

```
Task PublishAsync(HealthReport report, CancellationToken cancellationToken);
```

HealthCheckPublisherOptions allow you to set:

- Delay: The initial delay applied after the app starts before executing IHealthCheckPublisher instances. The delay is applied once at startup and doesn't apply to subsequent iterations. The default value is five seconds.
- Period: The period of IHealthCheckPublisher execution. The default value is 30 seconds.
- Predicate: If Predicate is `null` (default), the health check publisher service runs all registered health checks. To run a subset of health checks, provide a function that filters the set of checks. The predicate is evaluated each period.
- Timeout: The timeout for executing the health checks for all IHealthCheckPublisher instances. Use InfiniteTimeSpan to execute without a timeout. The default value is 30 seconds.

In the sample app, `ReadinessPublisher` is an IHealthCheckPublisher implementation. The health check status is logged for each check at a log level of:

- Information (LogInformation) if the health checks status is Healthy.
- Error (LogError) if the status is either Degraded or Unhealthy.

```
public class ReadinessPublisher : IHealthCheckPublisher
{
    private readonly ILogger _logger;

    public ReadinessPublisher(ILogger<ReadinessPublisher> logger)
    {
        _logger = logger;
    }

    // The following example is for demonstration purposes only. Health Checks
    // Middleware already logs health checks results. A real-world readiness
    // check in a production app might perform a set of more expensive or
    // time-consuming checks to determine if other resources are responding
    // properly.
    public Task PublishAsync(HealthReport report,
        CancellationToken cancellationToken)
    {
        if (report.Status == HealthStatus.Healthy)
        {
            _logger.LogInformation("{Timestamp} Readiness Probe Status: {Result}",
                DateTime.UtcNow, report.Status);
        }
        else
        {
            _logger.LogError("{Timestamp} Readiness Probe Status: {Result}",
                DateTime.UtcNow, report.Status);
        }

        cancellationToken.ThrowIfCancellationRequested();

        return Task.CompletedTask;
    }
}
```

In the sample app's `LivenessProbeStartup` example, the `StartupHostedService` readiness check has a two second startup delay and runs the check every 30 seconds. To activate the IHealthCheckPublisher implementation, the sample registers `ReadinessPublisher` as a singleton service in the dependency injection (DI) container:

```
services.AddHostedService<StartupHostedService>();
services.AddSingleton<StartupHostedServiceHealthCheck>();

services.AddHealthChecks()
    .AddCheck<StartupHostedServiceHealthCheck>(
        "hosted_service_startup",
        failureStatus: HealthStatus.Degraded,
        tags: new[] { "ready" });

services.Configure<HealthCheckPublisherOptions>(options =>
{
    options.Delay = TimeSpan.FromSeconds(2);
    options.Predicate = (check) => check.Tags.Contains("ready");
});

services.AddSingleton<IHealthCheckPublisher, ReadinessPublisher>();
```

NOTE

AspNetCore.Diagnostics.HealthChecks includes publishers for several systems, including Application Insights.

AspNetCore.Diagnostics.HealthChecks isn't maintained or supported by Microsoft.

Restrict health checks with MapWhen

Use MapWhen to conditionally branch the request pipeline for health check endpoints.

In the following example, `MapWhen` branches the request pipeline to activate Health Checks Middleware if a GET request is received for the `api/HealthCheck` endpoint:

```
app.MapWhen(
    context => context.Request.Method == HttpMethod.Get.Method &&
        context.Request.Path.StartsWith("/api/HealthCheck"),
    builder => builder.UseHealthChecks());

app.UseEndpoints(endpoints =>
{
    endpoints.MapRazorPages();
});
```

For more information, see ASP.NET Core Middleware.

ASP.NET Core offers Health Checks Middleware and libraries for reporting the health of app infrastructure components.

Health checks are exposed by an app as HTTP endpoints. Health check endpoints can be configured for a variety of real-time monitoring scenarios:

- Health probes can be used by container orchestrators and load balancers to check an app's status. For example, a container orchestrator may respond to a failing health check by halting a rolling deployment or restarting a container. A load balancer might react to an unhealthy app by routing traffic away from the failing instance to a healthy instance.
- Use of memory, disk, and other physical server resources can be monitored for healthy status.
- Health checks can test an app's dependencies, such as databases and external service endpoints, to confirm availability and normal functioning.

View or download sample code (how to download)

The sample app includes examples of the scenarios described in this topic. To run the sample app for a given scenario, use the dotnet run command from the project's folder in a command shell. See the sample app's *README.md* file and the scenario descriptions in this topic for details on how to use the sample app.

Prerequisites

Health checks are usually used with an external monitoring service or container orchestrator to check the status of an app. Before adding health checks to an app, decide on which monitoring system to use. The monitoring system dictates what types of health checks to create and how to configure their endpoints.

Reference the Microsoft.AspNetCore.App metapackage or add a package reference to the Microsoft.AspNetCore.Diagnostics.HealthChecks package.

The sample app provides startup code to demonstrate health checks for several scenarios. The database probe scenario checks the health of a database connection using AspNetCore.Diagnostics.HealthChecks. The DbContext probe scenario checks a database using an EF Core `DbContext`. To explore the database scenarios, the sample app:

- Creates a database and provides its connection string in the *appsettings.json* file.
- Has the following package references in its project file:
  - AspNetCore.HealthChecks.SqlServer
  - Microsoft.Extensions.Diagnostics.HealthChecks.EntityFrameworkCore

> **NOTE**
> AspNetCore.Diagnostics.HealthChecks isn't maintained or supported by Microsoft.

Another health check scenario demonstrates how to filter health checks to a management port. The sample app requires you to create a *Properties/launchSettings.json* file that includes the management URL and management port. For more information, see the Filter by port section.

Basic health probe

For many apps, a basic health probe configuration that reports the app's availability to process requests (*liveness*) is sufficient to discover the status of the app.

The basic configuration registers health check services and calls the Health Checks Middleware to respond at a URL endpoint with a health response. By default, no specific health checks are registered to test any particular dependency or subsystem. The app is considered healthy if it's capable of responding at the health endpoint URL. The default response writer writes the status (HealthStatus) as a plaintext response back to the client, indicating either a HealthStatus.Healthy, HealthStatus.Degraded or HealthStatus.Unhealthy status.

Register health check services with AddHealthChecks in `Startup.ConfigureServices`. Add an endpoint for Health Checks Middleware with UseHealthChecks in the request processing pipeline of `Startup.Configure`.

In the sample app, the health check endpoint is created at `/health` (*BasicStartup.cs*):

```
public class BasicStartup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddHealthChecks();
    }

    public void Configure(IApplicationBuilder app)
    {
        app.UseHealthChecks("/health");
    }
}
```

To run the basic configuration scenario using the sample app, execute the following command from the project's folder in a command shell:

```
dotnet run --scenario basic
```

Docker example

Docker offers a built-in `HEALTHCHECK` directive that can be used to check the status of an app that uses the basic health check configuration:

```
HEALTHCHECK CMD curl --fail http://localhost:5000/health || exit
```

Create health checks

Health checks are created by implementing the IHealthCheck interface. The CheckHealthAsync method returns a HealthCheckResult that indicates the health as `Healthy`, `Degraded`, or `Unhealthy`. The result is written as a plaintext response with a configurable status code (configuration is described in the Health check options

section). HealthCheckResult can also return optional key-value pairs.

Example health check

The following `ExampleHealthCheck` class demonstrates the layout of a health check. The health checks logic is placed in the `CheckHealthAsync` method. The following example sets a dummy variable, `healthCheckResultHealthy`, to `true`. If the value of `healthCheckResultHealthy` is set to `false`, the HealthCheckResult.Unhealthy status is returned.

```
public class ExampleHealthCheck : IHealthCheck
{
    public Task<HealthCheckResult> CheckHealthAsync(
        HealthCheckContext context,
        CancellationToken cancellationToken = default(CancellationToken))
    {
        var healthCheckResultHealthy = true;

        if (healthCheckResultHealthy)
        {
            return Task.FromResult(
                HealthCheckResult.Healthy("The check indicates a healthy result."));
        }

        return Task.FromResult(
            HealthCheckResult.Unhealthy("The check indicates an unhealthy result."));
    }
}
```

Register health check services

The `ExampleHealthCheck` type is added to health check services in `Startup.ConfigureServices` with AddCheck:

```
services.AddHealthChecks()
    .AddCheck<ExampleHealthCheck>("example_health_check");
```

The AddCheck overload shown in the following example sets the failure status (HealthStatus) to report when the health check reports a failure. If the failure status is set to `null` (default), HealthStatus.Unhealthy is reported. This overload is a useful scenario for library authors, where the failure status indicated by the library is enforced by the app when a health check failure occurs if the health check implementation honors the setting.

Tags can be used to filter health checks (described further in the Filter health checks section).

```
services.AddHealthChecks()
    .AddCheck<ExampleHealthCheck>(
        "example_health_check",
        failureStatus: HealthStatus.Degraded,
        tags: new[] { "example" });
```

AddCheck can also execute a lambda function. In the following `Startup.ConfigureServices` example, the health check name is specified as `Example` and the check always returns a healthy state:

```
services.AddHealthChecks()
    .AddCheck("Example", () =>
        HealthCheckResult.Healthy("Example is OK!"), tags: new[] { "example" });
```

Use Health Checks Middleware

In `Startup.Configure`, call UseHealthChecks in the processing pipeline with the endpoint URL or relative path:

```
app.UseHealthChecks("/health");
```

If the health checks should listen on a specific port, use an overload of UseHealthChecks to set the port (described further in the Filter by port section):

```
app.UseHealthChecks("/health", port: 8000);
```

Health check options

HealthCheckOptions provide an opportunity to customize health check behavior:

- Filter health checks
- Customize the HTTP status code
- Suppress cache headers
- Customize output

Filter health checks

By default, Health Checks Middleware runs all registered health checks. To run a subset of health checks, provide a function that returns a boolean to the Predicate option. In the following example, the `Bar` health check is filtered out by its tag (`bar_tag`) in the function's conditional statement, where `true` is only returned if the health check's Tags property matches `foo_tag` or `baz_tag`:

```
using System.Threading.Tasks;
using Microsoft.AspNetCore.Diagnostics.HealthChecks;
using Microsoft.Extensions.Diagnostics.HealthChecks;

public void ConfigureServices(IServiceCollection services)
{
    services.AddHealthChecks()
        .AddCheck("Foo", () =>
            HealthCheckResult.Healthy("Foo is OK!"), tags: new[] { "foo_tag" })
        .AddCheck("Bar", () =>
            HealthCheckResult.Unhealthy("Bar is unhealthy!"),
                tags: new[] { "bar_tag" })
        .AddCheck("Baz", () =>
            HealthCheckResult.Healthy("Baz is OK!"), tags: new[] { "baz_tag" });
}

public void Configure(IApplicationBuilder app)
{
    app.UseHealthChecks("/health", new HealthCheckOptions()
    {
        Predicate = (check) => check.Tags.Contains("foo_tag") ||
            check.Tags.Contains("baz_tag")
    });
}
```

Customize the HTTP status code

Use ResultStatusCodes to customize the mapping of health status to HTTP status codes. The following StatusCodes assignments are the default values used by the middleware. Change the status code values to meet your requirements.

In `Startup.Configure`:

```
//using Microsoft.AspNetCore.Diagnostics.HealthChecks;
//using Microsoft.Extensions.Diagnostics.HealthChecks;

app.UseHealthChecks("/health", new HealthCheckOptions()
{
    ResultStatusCodes =
    {
        [HealthStatus.Healthy] = StatusCodes.Status200OK,
        [HealthStatus.Degraded] = StatusCodes.Status200OK,
        [HealthStatus.Unhealthy] = StatusCodes.Status503ServiceUnavailable
    }
});
```

Suppress cache headers

AllowCachingResponses controls whether the Health Checks Middleware adds HTTP headers to a probe response to prevent response caching. If the value is `false` (default), the middleware sets or overrides the `Cache-Control`, `Expires`, and `Pragma` headers to prevent response caching. If the value is `true`, the middleware doesn't modify the cache headers of the response.

In `Startup.Configure`:

```
//using Microsoft.AspNetCore.Diagnostics.HealthChecks;
//using Microsoft.Extensions.Diagnostics.HealthChecks;

app.UseHealthChecks("/health", new HealthCheckOptions()
{
    AllowCachingResponses = false
});
```

Customize output

The ResponseWriter option gets or sets a delegate used to write the response. The default delegate writes a minimal plaintext response with the string value of HealthReport.Status.

In `Startup.Configure`:

```
// using Microsoft.AspNetCore.Diagnostics.HealthChecks;
// using Microsoft.Extensions.Diagnostics.HealthChecks;

app.UseHealthChecks("/health", new HealthCheckOptions()
{
    ResponseWriter = WriteResponse
});
```

The default delegate writes a minimal plaintext response with the string value of HealthReport.Status. The following custom delegate, `WriteResponse`, outputs a custom JSON response:

```
private static Task WriteResponse(HttpContext httpContext, HealthReport result)
{
    httpContext.Response.ContentType = "application/json";

    var json = new JObject(
        new JProperty("status", result.Status.ToString()),
        new JProperty("results", new JObject(result.Entries.Select(pair =>
            new JProperty(pair.Key, new JObject(
                new JProperty("status", pair.Value.Status.ToString()),
                new JProperty("description", pair.Value.Description),
                new JProperty("data", new JObject(pair.Value.Data.Select(
                    p => new JProperty(p.Key, p.Value)))))))));
    return httpContext.Response.WriteAsync(
        json.ToString(Formatting.Indented));
}
```

The health checks system doesn't provide built-in support for complex JSON return formats because the format is specific to your choice of monitoring system. Feel free to customize the `JObject` in the preceding example as necessary to meet your needs.

Database probe

A health check can specify a database query to run as a boolean test to indicate if the database is responding normally.

The sample app uses AspNetCore.Diagnostics.HealthChecks, a health check library for ASP.NET Core apps, to perform a health check on a SQL Server database. `AspNetCore.Diagnostics.HealthChecks` executes a `SELECT 1` query against the database to confirm the connection to the database is healthy.

> **WARNING**
> When checking a database connection with a query, choose a query that returns quickly. The query approach runs the risk of overloading the database and degrading its performance. In most cases, running a test query isn't necessary. Merely making a successful connection to the database is sufficient. If you find it necessary to run a query, choose a simple SELECT query, such as `SELECT 1`.

Include a package reference to AspNetCore.HealthChecks.SqlServer.

Supply a valid database connection string in the *appsettings.json* file of the sample app. The app uses a SQL Server database named `HealthCheckSample`:

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=
(localdb)\\MSSQLLocalDB;Database=HealthCheckSample;Trusted_Connection=True;MultipleActiveResultSets=true;Con
nectRetryCount=0"
  },
  "Logging": {
    "LogLevel": {
      "Default": "Debug"
    },
    "Console": {
      "IncludeScopes": "true"
    }
  }
}
```

Register health check services with AddHealthChecks in `Startup.ConfigureServices`. The sample app calls the

`AddSqlServer` method with the database's connection string (*DbHealthStartup.cs*):

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddHealthChecks()
        .AddSqlServer(Configuration["ConnectionStrings:DefaultConnection"]);
}
```

Call Health Checks Middleware in the app processing pipeline in `Startup.Configure`:

```
app.UseHealthChecks("/health");
```

To run the database probe scenario using the sample app, execute the following command from the project's folder in a command shell:

```
dotnet run --scenario db
```

> **NOTE**
> AspNetCore.Diagnostics.HealthChecks isn't maintained or supported by Microsoft.

Entity Framework Core DbContext probe

The `DbContext` check confirms that the app can communicate with the database configured for an EF Core `DbContext`. The `DbContext` check is supported in apps that:

- Use Entity Framework (EF) Core.
- Include a package reference to Microsoft.Extensions.Diagnostics.HealthChecks.EntityFrameworkCore.

`AddDbContextCheck<TContext>` registers a health check for a `DbContext`. The `DbContext` is supplied as the `TContext` to the method. An overload is available to configure the failure status, tags, and a custom test query.

By default:

- The `DbContextHealthCheck` calls EF Core's `CanConnectAsync` method. You can customize what operation is run when checking health using `AddDbContextCheck` method overloads.
- The name of the health check is the name of the `TContext` type.

In the sample app, `AppDbContext` is provided to `AddDbContextCheck` and registered as a service in `Startup.ConfigureServices` (*DbContextHealthStartup.cs*):

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddHealthChecks()
        .AddDbContextCheck<AppDbContext>();

    services.AddDbContext<AppDbContext>(options =>
    {
        options.UseSqlServer(
            Configuration["ConnectionStrings:DefaultConnection"]);
    });
}
```

In the sample app, `UseHealthChecks` adds the Health Checks Middleware in `Startup.Configure`.

```
app.UseHealthChecks("/health");
```

To run the `DbContext` probe scenario using the sample app, confirm that the database specified by the connection string doesn't exist in the SQL Server instance. If the database exists, delete it.

Execute the following command from the project's folder in a command shell:

```
dotnet run --scenario dbcontext
```

After the app is running, check the health status by making a request to the `/health` endpoint in a browser. The database and `AppDbContext` don't exist, so app provides the following response:

```
Unhealthy
```

Trigger the sample app to create the database. Make a request to `/createdatabase`. The app responds:

```
Creating the database...
Done!
Navigate to /health to see the health status.
```

Make a request to the `/health` endpoint. The database and context exist, so app responds:

```
Healthy
```

Trigger the sample app to delete the database. Make a request to `/deletedatabase`. The app responds:

```
Deleting the database...
Done!
Navigate to /health to see the health status.
```

Make a request to the `/health` endpoint. The app provides an unhealthy response:

```
Unhealthy
```

Separate readiness and liveness probes

In some hosting scenarios, a pair of health checks are used that distinguish two app states:

- *Readiness* indicates if the app is running normally but isn't ready to receive requests.
- *Liveness* indicates if an app has crashed and must be restarted.

Consider the following example: An app must download a large configuration file before it's ready to process requests. We don't want the app to be restarted if the initial download fails because the app can retry downloading the file several times. We use a *liveness probe* to describe the liveness of the process, no additional checks are performed. We also want to prevent requests from being sent to the app before the configuration file download has succeeded. We use a *readiness probe* to indicate a "not ready" state until the download succeeds and the app is ready to receive requests.

The sample app contains a health check to report the completion of long-running startup task in a Hosted Service. The `StartupHostedServiceHealthCheck` exposes a property, `StartupTaskCompleted`, that the hosted service

can set to `true` when its long-running task is finished (*StartupHostedServiceHealthCheck.cs*):

```
public class StartupHostedServiceHealthCheck : IHealthCheck
{
    private volatile bool _startupTaskCompleted = false;

    public string Name => "slow_dependency_check";

    public bool StartupTaskCompleted
    {
        get => _startupTaskCompleted;
        set => _startupTaskCompleted = value;
    }

    public Task<HealthCheckResult> CheckHealthAsync(
        HealthCheckContext context,
        CancellationToken cancellationToken = default(CancellationToken))
    {
        if (StartupTaskCompleted)
        {
            return Task.FromResult(
                HealthCheckResult.Healthy("The startup task is finished."));
        }

        return Task.FromResult(
            HealthCheckResult.Unhealthy("The startup task is still running."));
    }
}
```

The long-running background task is started by a Hosted Service (*Services/StartupHostedService*). At the conclusion of the task, `StartupHostedServiceHealthCheck.StartupTaskCompleted` is set to `true`:

```
public class StartupHostedService : IHostedService, IDisposable
{
    private readonly int _delaySeconds = 15;
    private readonly ILogger _logger;
    private readonly StartupHostedServiceHealthCheck _startupHostedServiceHealthCheck;

    public StartupHostedService(ILogger<StartupHostedService> logger,
        StartupHostedServiceHealthCheck startupHostedServiceHealthCheck)
    {
        _logger = logger;
        _startupHostedServiceHealthCheck = startupHostedServiceHealthCheck;
    }

    public Task StartAsync(CancellationToken cancellationToken)
    {
        _logger.LogInformation("Startup Background Service is starting.");

        // Simulate the effect of a long-running startup task.
        Task.Run(async () =>
        {
            await Task.Delay(_delaySeconds * 1000);

            _startupHostedServiceHealthCheck.StartupTaskCompleted = true;

            _logger.LogInformation("Startup Background Service has started.");
        });

        return Task.CompletedTask;
    }

    public Task StopAsync(CancellationToken cancellationToken)
    {
        _logger.LogInformation("Startup Background Service is stopping.");

        return Task.CompletedTask;
    }

    public void Dispose()
    {
    }
}
```

The health check is registered with AddCheck in `Startup.ConfigureServices` along with the hosted service. Because the hosted service must set the property on the health check, the health check is also registered in the service container (*LivenessProbeStartup.cs*):

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddHostedService<StartupHostedService>();
    services.AddSingleton<StartupHostedServiceHealthCheck>();

    services.AddHealthChecks()
        .AddCheck<StartupHostedServiceHealthCheck>(
            "hosted_service_startup",
            failureStatus: HealthStatus.Degraded,
            tags: new[] { "ready" });

    services.Configure<HealthCheckPublisherOptions>(options =>
    {
        options.Delay = TimeSpan.FromSeconds(2);
        options.Predicate = (check) => check.Tags.Contains("ready");
    });

    // The following workaround permits adding an IHealthCheckPublisher
    // instance to the service container when one or more other hosted
    // services have already been added to the app. This workaround
    // won't be required with the release of ASP.NET Core 3.0. For more
    // information, see: https://github.com/aspnet/Extensions/issues/639.
    services.TryAddEnumerable(
        ServiceDescriptor.Singleton(typeof(IHostedService),
            typeof(HealthCheckPublisherOptions).Assembly
                .GetType(HealthCheckServiceAssembly)));

    services.AddSingleton<IHealthCheckPublisher, ReadinessPublisher>();
}
```

Call Health Checks Middleware in the app processing pipeline in `Startup.Configure`. In the sample app, the health check endpoints are created at `/health/ready` for the readiness check and `/health/live` for the liveness check. The readiness check filters health checks to the health check with the `ready` tag. The liveness check filters out the `StartupHostedServiceHealthCheck` by returning `false` in the HealthCheckOptions.Predicate (for more information, see Filter health checks):

```
app.UseHealthChecks("/health/ready", new HealthCheckOptions()
{
    Predicate = (check) => check.Tags.Contains("ready"),
});

app.UseHealthChecks("/health/live", new HealthCheckOptions()
{
    Predicate = (_) => false
});
```

To run the readiness/liveness configuration scenario using the sample app, execute the following command from the project's folder in a command shell:

```
dotnet run --scenario liveness
```

In a browser, visit `/health/ready` several times until 15 seconds have passed. The health check reports *Unhealthy* for the first 15 seconds. After 15 seconds, the endpoint reports *Healthy*, which reflects the completion of the long-running task by the hosted service.

This example also creates a Health Check Publisher (IHealthCheckPublisher implementation) that runs the first readiness check with a two second delay. For more information, see the Health Check Publisher section.

Kubernetes example

Using separate readiness and liveness checks is useful in an environment such as Kubernetes. In Kubernetes, an app might be required to perform time-consuming startup work before accepting requests, such as a test of the underlying database availability. Using separate checks allows the orchestrator to distinguish whether the app is functioning but not yet ready or if the app has failed to start. For more information on readiness and liveness probes in Kubernetes, see Configure Liveness and Readiness Probes in the Kubernetes documentation.

The following example demonstrates a Kubernetes readiness probe configuration:

```
spec:
  template:
  spec:
    readinessProbe:
      # an http probe
      httpGet:
        path: /health/ready
        port: 80
      # length of time to wait for a pod to initialize
      # after pod startup, before applying health checking
      initialDelaySeconds: 30
      timeoutSeconds: 1
    ports:
      - containerPort: 80
```

Metric-based probe with a custom response writer

The sample app demonstrates a memory health check with a custom response writer.

`MemoryHealthCheck` reports an unhealthy status if the app uses more than a given threshold of memory (1 GB in the sample app). The HealthCheckResult includes Garbage Collector (GC) information for the app (*MemoryHealthCheck.cs*):

```
public class MemoryHealthCheck : IHealthCheck
{
    private readonly IOptionsMonitor<MemoryCheckOptions> _options;

    public MemoryHealthCheck(IOptionsMonitor<MemoryCheckOptions> options)
    {
        _options = options;
    }

    public string Name => "memory_check";

    public Task<HealthCheckResult> CheckHealthAsync(
        HealthCheckContext context,
        CancellationToken cancellationToken = default(CancellationToken))
    {
        var options = _options.Get(context.Registration.Name);

        // Include GC information in the reported diagnostics.
        var allocated = GC.GetTotalMemory(forceFullCollection: false);
        var data = new Dictionary<string, object>()
        {
            { "AllocatedBytes", allocated },
            { "Gen0Collections", GC.CollectionCount(0) },
            { "Gen1Collections", GC.CollectionCount(1) },
            { "Gen2Collections", GC.CollectionCount(2) },
        };

        var status = (allocated < options.Threshold) ?
            HealthStatus.Healthy : HealthStatus.Unhealthy;

        return Task.FromResult(new HealthCheckResult(
            status,
            description: "Reports degraded status if allocated bytes " +
                $">= {options.Threshold} bytes.",
            exception: null,
            data: data));
    }
}
```

Register health check services with AddHealthChecks in `Startup.ConfigureServices`. Instead of enabling the health check by passing it to AddCheck, the `MemoryHealthCheck` is registered as a service. All IHealthCheck registered services are available to the health check services and middleware. We recommend registering health check services as Singleton services.

In the sample app (*CustomWriterStartup.cs*):

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddHealthChecks()
        .AddMemoryHealthCheck("memory");
}
```

Call Health Checks Middleware in the app processing pipeline in `Startup.Configure`. A `WriteResponse` delegate is provided to the `ResponseWriter` property to output a custom JSON response when the health check executes:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    app.UseHealthChecks("/health", new HealthCheckOptions()
    {
        // This custom writer formats the detailed status as JSON.
        ResponseWriter = WriteResponse
    });
}
```

The `WriteResponse` method formats the `CompositeHealthCheckResult` into a JSON object and yields JSON output for the health check response:

```
private static Task WriteResponse(HttpContext httpContext,
    HealthReport result)
{
    httpContext.Response.ContentType = "application/json; charset=utf-8";

    var json = new JObject(
        new JProperty("status", result.Status.ToString()),
        new JProperty("results", new JObject(result.Entries.Select(pair =>
            new JProperty(pair.Key, new JObject(
                new JProperty("status", pair.Value.Status.ToString()),
                new JProperty("description", pair.Value.Description),
                new JProperty("data", new JObject(pair.Value.Data.Select(
                    p => new JProperty(p.Key, p.Value)))))))));
    return httpContext.Response.WriteAsync(
        json.ToString(Formatting.Indented));
}
```

To run the metric-based probe with custom response writer output using the sample app, execute the following command from the project's folder in a command shell:

```
dotnet run --scenario writer
```

> **NOTE**
>
> AspNetCore.Diagnostics.HealthChecks includes metric-based health check scenarios, including disk storage and maximum value liveness checks.
>
> AspNetCore.Diagnostics.HealthChecks isn't maintained or supported by Microsoft.

Filter by port

Calling UseHealthChecks with a port restricts health check requests to the port specified. This is typically used in a container environment to expose a port for monitoring services.

The sample app configures the port using the Environment Variable Configuration Provider. The port is set in the *launchSettings.json* file and passed to the configuration provider via an environment variable. You must also configure the server to listen to requests on the management port.

To use the sample app to demonstrate management port configuration, create the *launchSettings.json* file in a *Properties* folder.

The following *Properties/launchSettings.json* file in the sample app isn't included in the sample app's project files and must be created manually:

```
{
  "profiles": {
    "SampleApp": {
      "commandName": "Project",
      "commandLineArgs": "",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development",
        "ASPNETCORE_URLS": "http://localhost:5000/;http://localhost:5001/",
        "ASPNETCORE_MANAGEMENTPORT": "5001"
      },
      "applicationUrl": "http://localhost:5000/"
    }
  }
}
```

Register health check services with AddHealthChecks in `Startup.ConfigureServices`. The call to UseHealthChecks specifies the management port (*ManagementPortStartup.cs*):

```
public class ManagementPortStartup
{
    public ManagementPortStartup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddHealthChecks();
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        app.UseHealthChecks("/health", port: Configuration["ManagementPort"]);

        app.Run(async (context) =>
        {
            await context.Response.WriteAsync(
                "Navigate to " +
                $"http://localhost:{Configuration["ManagementPort"]}/health " +
                "to see the health status.");
        });
    }
}
```

NOTE

You can avoid creating the *launchSettings.json* file in the sample app by setting the URLs and management port explicitly in code. In *Program.cs* where the WebHostBuilder is created, add a call to UseUrls and provide the app's normal response endpoint and the management port endpoint. In *ManagementPortStartup.cs* where UseHealthChecks is called, specify the management port explicitly.

Program.cs:

```
return new WebHostBuilder()
    .UseConfiguration(config)
    .UseUrls("http://localhost:5000/;http://localhost:5001/")
    .ConfigureLogging(builder =>
    {
        builder.SetMinimumLevel(LogLevel.Trace);
        builder.AddConfiguration(config);
        builder.AddConsole();
    })
    .UseKestrel()
    .UseStartup(startupType)
    .Build();
```

ManagementPortStartup.cs:

```
app.UseHealthChecks("/health", port: 5001);
```

To run the management port configuration scenario using the sample app, execute the following command from the project's folder in a command shell:

```
dotnet run --scenario port
```

Distribute a health check library

To distribute a health check as a library:

1. Write a health check that implements the IHealthCheck interface as a standalone class. The class can rely on dependency injection (DI), type activation, and named options to access configuration data.

   In the health checks logic of `CheckHealthAsync`:

   - `data1` and `data2` are used in the method to run the probe's health check logic.
   - `AccessViolationException` is handled.

   When an AccessViolationException occurs, the FailureStatus is returned with the HealthCheckResult to allow users to configure the health checks failure status.

```
using System;
using System.Threading;
using System.Threading.Tasks;
using Microsoft.Extensions.Diagnostics.HealthChecks;

public class ExampleHealthCheck : IHealthCheck
{
    private readonly string _data1;
    private readonly int? _data2;

    public ExampleHealthCheck(string data1, int? data2)
    {
        _data1 = data1 ?? throw new ArgumentNullException(nameof(data1));
        _data2 = data2 ?? throw new ArgumentNullException(nameof(data2));
    }

    public async Task<HealthCheckResult> CheckHealthAsync(
        HealthCheckContext context, CancellationToken cancellationToken)
    {
        try
        {
            return HealthCheckResult.Healthy();
        }
        catch (AccessViolationException ex)
        {
            return new HealthCheckResult(
                context.Registration.FailureStatus,
                description: "An access violation occurred during the check.",
                exception: ex,
                data: null);
        }
    }
}
```

2. Write an extension method with parameters that the consuming app calls in its `Startup.Configure` method. In the following example, assume the following health check method signature:

```
ExampleHealthCheck(string, string, int )
```

The preceding signature indicates that the `ExampleHealthCheck` requires additional data to process the health check probe logic. The data is provided to the delegate used to create the health check instance when the health check is registered with an extension method. In the following example, the caller specifies optional:

- health check name (`name`). If `null` , `example_health_check` is used.
- string data point for the health check (`data1`).
- integer data point for the health check (`data2`). If `null` , `1` is used.
- failure status (HealthStatus). The default is `null` . If `null` , HealthStatus.Unhealthy is reported for a failure status.
- tags (`IEnumerable<string>`).

```
using System.Collections.Generic;
using Microsoft.Extensions.Diagnostics.HealthChecks;

public static class ExampleHealthCheckBuilderExtensions
{
    const string DefaultName = "example_health_check";

    public static IHealthChecksBuilder AddExampleHealthCheck(
        this IHealthChecksBuilder builder,
        string name = default,
        string data1,
        int data2 = 1,
        HealthStatus? failureStatus = default,
        IEnumerable<string> tags = default)
    {
        return builder.Add(new HealthCheckRegistration(
            name ?? DefaultName,
            sp => new ExampleHealthCheck(data1, data2),
            failureStatus,
            tags));
    }
}
```

Health Check Publisher

When an IHealthCheckPublisher is added to the service container, the health check system periodically executes your health checks and calls `PublishAsync` with the result. This is useful in a push-based health monitoring system scenario that expects each process to call the monitoring system periodically in order to determine health.

The IHealthCheckPublisher interface has a single method:

```
Task PublishAsync(HealthReport report, CancellationToken cancellationToken);
```

HealthCheckPublisherOptions allow you to set:

- Delay: The initial delay applied after the app starts before executing IHealthCheckPublisher instances. The delay is applied once at startup and doesn't apply to subsequent iterations. The default value is five seconds.
- Period: The period of IHealthCheckPublisher execution. The default value is 30 seconds.
- Predicate: If Predicate is `null` (default), the health check publisher service runs all registered health checks. To run a subset of health checks, provide a function that filters the set of checks. The predicate is evaluated each period.
- Timeout: The timeout for executing the health checks for all IHealthCheckPublisher instances. Use InfiniteTimeSpan to execute without a timeout. The default value is 30 seconds.

> **WARNING**
> In the ASP.NET Core 2.2 release, setting Period isn't honored by the IHealthCheckPublisher implementation; it sets the value of Delay. This issue has been addressed in ASP.NET Core 3.0.

In the sample app, `ReadinessPublisher` is an IHealthCheckPublisher implementation. The health check status is logged for each check as either:

- Information (LogInformation) if the health checks status is Healthy.
- Error (LogError) if the status is either Degraded or Unhealthy.

```
public class ReadinessPublisher : IHealthCheckPublisher
{
    private readonly ILogger _logger;

    public ReadinessPublisher(ILogger<ReadinessPublisher> logger)
    {
        _logger = logger;
    }

    // The following example is for demonstration purposes only. Health Checks
    // Middleware already logs health checks results. A real-world readiness
    // check in a production app might perform a set of more expensive or
    // time-consuming checks to determine if other resources are responding
    // properly.
    public Task PublishAsync(HealthReport report,
        CancellationToken cancellationToken)
    {
        if (report.Status == HealthStatus.Healthy)
        {
            _logger.LogInformation("{Timestamp} Readiness Probe Status: {Result}",
                DateTime.UtcNow, report.Status);
        }
        else
        {
            _logger.LogError("{Timestamp} Readiness Probe Status: {Result}",
                DateTime.UtcNow, report.Status);
        }

        cancellationToken.ThrowIfCancellationRequested();

        return Task.CompletedTask;
    }
}
```

In the sample app's `LivenessProbeStartup` example, the `StartupHostedService` readiness check has a two second startup delay and runs the check every 30 seconds. To activate the IHealthCheckPublisher implementation, the sample registers `ReadinessPublisher` as a singleton service in the dependency injection (DI) container:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddHostedService<StartupHostedService>();
    services.AddSingleton<StartupHostedServiceHealthCheck>();

    services.AddHealthChecks()
        .AddCheck<StartupHostedServiceHealthCheck>(
            "hosted_service_startup",
            failureStatus: HealthStatus.Degraded,
            tags: new[] { "ready" });

    services.Configure<HealthCheckPublisherOptions>(options =>
    {
        options.Delay = TimeSpan.FromSeconds(2);
        options.Predicate = (check) => check.Tags.Contains("ready");
    });

    // The following workaround permits adding an IHealthCheckPublisher
    // instance to the service container when one or more other hosted
    // services have already been added to the app. This workaround
    // won't be required with the release of ASP.NET Core 3.0. For more
    // information, see: https://github.com/aspnet/Extensions/issues/639.
    services.TryAddEnumerable(
        ServiceDescriptor.Singleton(typeof(IHostedService),
            typeof(HealthCheckPublisherOptions).Assembly
                .GetType(HealthCheckServiceAssembly)));

    services.AddSingleton<IHealthCheckPublisher, ReadinessPublisher>();
}
```

NOTE

The following workaround permits adding an IHealthCheckPublisher instance to the service container when one or more other hosted services have already been added to the app. This workaround won't isn't required in ASP.NET Core 3.0.

```
private const string HealthCheckServiceAssembly =
    "Microsoft.Extensions.Diagnostics.HealthChecks.HealthCheckPublisherHostedService";

services.TryAddEnumerable(
    ServiceDescriptor.Singleton(typeof(IHostedService),
        typeof(HealthCheckPublisherOptions).Assembly
            .GetType(HealthCheckServiceAssembly)));
```

NOTE

AspNetCore.Diagnostics.HealthChecks includes publishers for several systems, including Application Insights.

AspNetCore.Diagnostics.HealthChecks isn't maintained or supported by Microsoft.

Restrict health checks with MapWhen

Use MapWhen to conditionally branch the request pipeline for health check endpoints.

In the following example, `MapWhen` branches the request pipeline to activate Health Checks Middleware if a GET request is received for the `api/HealthCheck` endpoint:

```
app.MapWhen(
    context => context.Request.Method == HttpMethod.Get.Method &&
        context.Request.Path.StartsWith("/api/HealthCheck"),
    builder => builder.UseHealthChecks());

app.UseMvc();
```

For more information, see ASP.NET Core Middleware.

Overview of ASP.NET Core Security

9/22/2020 • 2 minutes to read • Edit Online

ASP.NET Core enables developers to easily configure and manage security for their apps. ASP.NET Core contains features for managing authentication, authorization, data protection, HTTPS enforcement, app secrets, XSRF/CSRF prevention, and CORS management. These security features allow you to build robust yet secure ASP.NET Core apps.

ASP.NET Core security features

ASP.NET Core provides many tools and libraries to secure your apps including built-in identity providers, but you can use third-party identity services such as Facebook, Twitter, and LinkedIn. With ASP.NET Core, you can easily manage app secrets, which are a way to store and use confidential information without having to expose it in the code.

Authentication vs. Authorization

Authentication is a process in which a user provides credentials that are then compared to those stored in an operating system, database, app or resource. If they match, users authenticate successfully, and can then perform actions that they're authorized for, during an authorization process. The authorization refers to the process that determines what a user is allowed to do.

Another way to think of authentication is to consider it as a way to enter a space, such as a server, database, app or resource, while authorization is which actions the user can perform to which objects inside that space (server, database, or app).

Common Vulnerabilities in software

ASP.NET Core and EF contain features that help you secure your apps and prevent security breaches. The following list of links takes you to documentation detailing techniques to avoid the most common security vulnerabilities in web apps:

- Cross-Site Scripting (XSS) attacks
- SQL injection attacks
- Cross-Site Request Forgery (XSRF/CSRF) attacks
- Open redirect attacks

There are more vulnerabilities that you should be aware of. For more information, see the other articles in the **Security and Identity** section of the table of contents.

Overview of ASP.NET Core authentication

9/22/2020 • 4 minutes to read • Edit Online

By Mike Rousos

Authentication is the process of determining a user's identity. Authorization is the process of determining whether a user has access to a resource. In ASP.NET Core, authentication is handled by the `IAuthenticationService`, which is used by authentication middleware. The authentication service uses registered authentication handlers to complete authentication-related actions. Examples of authentication-related actions include:

- Authenticating a user.
- Responding when an unauthenticated user tries to access a restricted resource.

The registered authentication handlers and their configuration options are called "schemes".

Authentication schemes are specified by registering authentication services in `Startup.ConfigureServices`:

- By calling a scheme-specific extension method after a call to `services.AddAuthentication` (such as `AddJwtBearer` or `AddCookie`, for example). These extension methods use AuthenticationBuilder.AddScheme to register schemes with appropriate settings.
- Less commonly, by calling AuthenticationBuilder.AddScheme directly.

For example, the following code registers authentication services and handlers for cookie and JWT bearer authentication schemes:

```
services.AddAuthentication(JwtBearerDefaults.AuthenticationScheme)
    .AddJwtBearer(JwtBearerDefaults.AuthenticationScheme, options => Configuration.Bind("JwtSettings",
options))
    .AddCookie(CookieAuthenticationDefaults.AuthenticationScheme, options =>
Configuration.Bind("CookieSettings", options));
```

The `AddAuthentication` parameter `JwtBearerDefaults.AuthenticationScheme` is the name of the scheme to use by default when a specific scheme isn't requested.

If multiple schemes are used, authorization policies (or authorization attributes) can specify the authentication scheme (or schemes) they depend on to authenticate the user. In the example above, the cookie authentication scheme could be used by specifying its name (`CookieAuthenticationDefaults.AuthenticationScheme` by default, though a different name could be provided when calling `AddCookie`).

In some cases, the call to `AddAuthentication` is automatically made by other extension methods. For example, when using ASP.NET Core Identity, `AddAuthentication` is called internally.

The Authentication middleware is added in `Startup.Configure` by calling the UseAuthentication extension method on the app's `IApplicationBuilder`. Calling `UseAuthentication` registers the middleware which uses the previously registered authentication schemes. Call `UseAuthentication` before any middleware that depends on users being authenticated. When using endpoint routing, the call to `UseAuthentication` must go:

- After `UseRouting`, so that route information is available for authentication decisions.
- Before `UseEndpoints`, so that users are authenticated before accessing the endpoints.

Authentication Concepts

Authentication scheme

An authentication scheme is a name which corresponds to:

- An authentication handler.
- Options for configuring that specific instance of the handler.

Schemes are useful as a mechanism for referring to the authentication, challenge, and forbid behaviors of the associated handler. For example, an authorization policy can use scheme names to specify which authentication scheme (or schemes) should be used to authenticate the user. When configuring authentication, it's common to specify the default authentication scheme. The default scheme is used unless a resource requests a specific scheme. It's also possible to:

- Specify different default schemes to use for authenticate, challenge, and forbid actions.
- Combine multiple schemes into one using policy schemes.

Authentication handler

An authentication handler:

- Is a type that implements the behavior of a scheme.
- Is derived from IAuthenticationHandler or AuthenticationHandler<TOptions>.
- Has the primary responsibility to authenticate users.

Based on the authentication scheme's configuration and the incoming request context, authentication handlers:

- Construct AuthenticationTicket objects representing the user's identity if authentication is successful.
- Return 'no result' or 'failure' if authentication is unsuccessful.
- Have methods for challenge and forbid actions for when users attempt to access resources:
  - They are unauthorized to access (forbid).
  - When they are unauthenticated (challenge).

Authenticate

An authentication scheme's authenticate action is responsible for constructing the user's identity based on request context. It returns an AuthenticateResult indicating whether authentication was successful and, if so, the user's identity in an authentication ticket. See AuthenticateAsync. Authenticate examples include:

- A cookie authentication scheme constructing the user's identity from cookies.
- A JWT bearer scheme deserializing and validating a JWT bearer token to construct the user's identity.

Challenge

An authentication challenge is invoked by Authorization when an unauthenticated user requests an endpoint that requires authentication. An authentication challenge is issued, for example, when an anonymous user requests a restricted resource or clicks on a login link. Authorization invokes a challenge using the specified authentication scheme(s), or the default if none is specified. See ChallengeAsync. Authentication challenge examples include:

- A cookie authentication scheme redirecting the user to a login page.
- A JWT bearer scheme returning a 401 result with a `www-authenticate: bearer` header.

A challenge action should let the user know what authentication mechanism to use to access the requested resource.

Forbid

An authentication scheme's forbid action is called by Authorization when an authenticated user attempts to access a resource they are not permitted to access. See ForbidAsync. Authentication forbid examples include:

- A cookie authentication scheme redirecting the user to a page indicating access was forbidden.
- A JWT bearer scheme returning a 403 result.

- A custom authentication scheme redirecting to a page where the user can request access to the resource.

A forbid action can let the user know:

- They are authenticated.
- They aren't permitted to access the requested resource.

See the following links for differences between challenge and forbid:

- Challenge and forbid with an operational resource handler.
- Differences between challenge and forbid.

Authentication providers per tenant

ASP.NET Core framework does not have a built-in solution for multi-tenant authentication. While it's certainly possible for customers to write one, using the built-in features, we recommend customers to look into Orchard Core for this purpose.

Orchard Core is:

- An open-source modular and multi-tenant app framework built with ASP.NET Core.
- A content management system (CMS) built on top of that app framework.

See the Orchard Core source for an example of authentication providers per tenant.

Additional resources

- Authorize with a specific scheme in ASP.NET Core
- Policy schemes in ASP.NET Core
- Create an ASP.NET Core app with user data protected by authorization
- Globally require authenticated users

Introduction to Identity on ASP.NET Core

9/22/2020 • 17 minutes to read • Edit Online

By Rick Anderson

ASP.NET Core Identity:

- Is an API that supports user interface (UI) login functionality.
- Manages users, passwords, profile data, roles, claims, tokens, email confirmation, and more.

Users can create an account with the login information stored in Identity or they can use an external login provider. Supported external login providers include Facebook, Google, Microsoft Account, and Twitter.

For information on how to globally require all users to be authenticated, see Require authenticated users.

The Identity source code is available on GitHub. Scaffold Identity and view the generated files to review the template interaction with Identity.

Identity is typically configured using a SQL Server database to store user names, passwords, and profile data. Alternatively, another persistent store can be used, for example, Azure Table Storage.

In this topic, you learn how to use Identity to register, log in, and log out a user. Note: the templates treat username and email as the same for users. For more detailed instructions about creating apps that use Identity, see Next Steps.

Microsoft identity platform is:

- An evolution of the Azure Active Directory (Azure AD) developer platform.
- Unrelated to ASP.NET Core Identity.

ASP.NET Core Identity adds user interface (UI) login functionality to ASP.NET Core web apps. To secure web APIs and SPAs, use one of the following:

- Azure Active Directory
- Azure Active Directory B2C (Azure AD B2C)
- IdentityServer4

IdentityServer4 is an OpenID Connect and OAuth 2.0 framework for ASP.NET Core. IdentityServer4 enables the following security features:

- Authentication as a Service (AaaS)
- Single sign-on/off (SSO) over multiple application types
- Access control for APIs
- Federation Gateway

For more information, see Welcome to IdentityServer4.

View or download the sample code (how to download).

Create a Web app with authentication

Create an ASP.NET Core Web Application project with Individual User Accounts.

- Visual Studio

- .NET Core CLI

- Select **File** > **New** > **Project**.
- Select **ASP.NET Core Web Application**. Name the project **WebApp1** to have the same namespace as the project download. Click **OK**.
- Select an ASP.NET Core **Web Application**, then select **Change Authentication**.
- Select **Individual User Accounts** and click **OK**.

The generated project provides ASP.NET Core Identity as a Razor Class Library. The Identity Razor Class Library exposes endpoints with the `Identity` area. For example:

- /Identity/Account/Login
- /Identity/Account/Logout
- /Identity/Account/Manage

Apply migrations

Apply the migrations to initialize the database.

- Visual Studio
- .NET Core CLI

Run the following command in the Package Manager Console (PMC):

```
PM> Update-Database
```

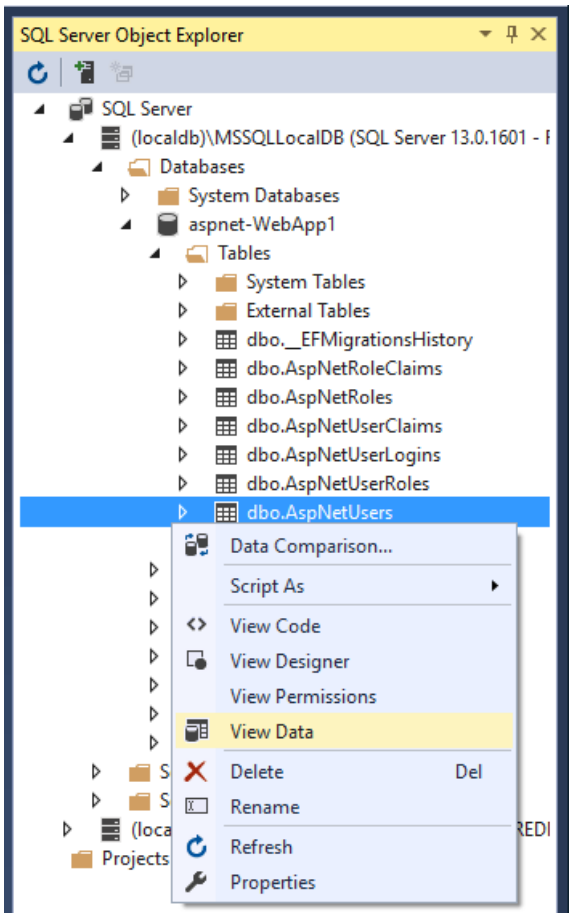
Test Register and Login

Run the app and register a user. Depending on your screen size, you might need to select the navigation toggle button to see the **Register** and **Login** links.

View the Identity database

- Visual Studio
- .NET Core CLI

- From the **View** menu, select **SQL Server Object Explorer** (SSOX).
- Navigate to **(localdb)MSSQLLocalDB(SQL Server 13)**. Right-click on **dbo.AspNetUsers** > **View Data**:



Configure Identity services

Services are added in `ConfigureServices`. The typical pattern is to call all the `Add{Service}` methods, and then call all the `services.Configure{Service}` methods.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
     // options.UseSqlite(
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>(options => options.SignIn.RequireConfirmedAccount =
true)
        .AddEntityFrameworkStores<ApplicationDbContext>();
    services.AddRazorPages();

    services.Configure<IdentityOptions>(options =>
    {
        // Password settings.
        options.Password.RequireDigit = true;
        options.Password.RequireLowercase = true;
        options.Password.RequireNonAlphanumeric = true;
        options.Password.RequireUppercase = true;
        options.Password.RequiredLength = 6;
        options.Password.RequiredUniqueChars = 1;

        // Lockout settings.
        options.Lockout.DefaultLockoutTimeSpan = TimeSpan.FromMinutes(5);
        options.Lockout.MaxFailedAccessAttempts = 5;
        options.Lockout.AllowedForNewUsers = true;

        // User settings.
        options.User.AllowedUserNameCharacters =
        "abcdefghijklmnopqrstuvwxyzABCDEFGHIJKLMNOPQRSTUVWXYZ0123456789-._@+";
        options.User.RequireUniqueEmail = false;
    });

    services.ConfigureApplicationCookie(options =>
    {
        // Cookie settings
        options.Cookie.HttpOnly = true;
        options.ExpireTimeSpan = TimeSpan.FromMinutes(5);

        options.LoginPath = "/Identity/Account/Login";
        options.AccessDeniedPath = "/Identity/Account/AccessDenied";
        options.SlidingExpiration = true;
    });
}
```

The preceding highlighted code configures Identity with default option values. Services are made available to the app through dependency injection.

Identity is enabled by calling UseAuthentication. `UseAuthentication` adds authentication middleware to the request pipeline.

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

The template-generated app doesn't use authorization. `app.UseAuthorization` is included to ensure it's added in the correct order should the app add authorization. `UseRouting`, `UseAuthentication`, `UseAuthorization`, and `UseEndpoints` must be called in the order shown in the preceding code.

For more information on `IdentityOptions` and `Startup`, see IdentityOptions and Application Startup.

Scaffold Register, Login, LogOut, and RegisterConfirmation

- Visual Studio
- .NET Core CLI

Add the `Register`, `Login`, `LogOut`, and `RegisterConfirmation` files. Follow the Scaffold identity into a Razor project with authorization instructions to generate the code shown in this section.

Examine Register

When a user clicks the **Register** button on the `Register` page, the `RegisterModel.OnPostAsync` action is invoked. The user is created by CreateAsync on the `_userManager` object:

```
public async Task<IActionResult> OnPostAsync(string returnUrl = null)
{
    returnUrl = returnUrl ?? Url.Content("~/");
    ExternalLogins = (await _signInManager.GetExternalAuthenticationSchemesAsync())
                                          .ToList();
    if (ModelState.IsValid)
    {
        var user = new IdentityUser { UserName = Input.Email, Email = Input.Email };
        var result = await _userManager.CreateAsync(user, Input.Password);
        if (result.Succeeded)
        {
            _logger.LogInformation("User created a new account with password.");

            var code = await _userManager.GenerateEmailConfirmationTokenAsync(user);
            code = WebEncoders.Base64UrlEncode(Encoding.UTF8.GetBytes(code));
            var callbackUrl = Url.Page(
                "/Account/ConfirmEmail",
                pageHandler: null,
                values: new { area = "Identity", userId = user.Id, code = code },
                protocol: Request.Scheme);

            await _emailSender.SendEmailAsync(Input.Email, "Confirm your email",
                $"Please confirm your account by <a
href='{HtmlEncoder.Default.Encode(callbackUrl)}'>clicking here</a>.");

            if (_userManager.Options.SignIn.RequireConfirmedAccount)
            {
                return RedirectToPage("RegisterConfirmation",
                                      new { email = Input.Email });
            }
            else
            {
                await _signInManager.SignInAsync(user, isPersistent: false);
                return LocalRedirect(returnUrl);
            }
        }
        foreach (var error in result.Errors)
        {
            ModelState.AddModelError(string.Empty, error.Description);
        }
    }

    // If we got this far, something failed, redisplay form
    return Page();
}
```

Disable default account verification

With the default templates, the user is redirected to the `Account.RegisterConfirmation` where they can select a link to have the account confirmed. The default `Account.RegisterConfirmation` is used ***only*** for testing, automatic account verification should be disabled in a production app.

To require a confirmed account and prevent immediate login at registration, set `DisplayConfirmAccountLink = false` in */Areas/Identity/Pages/Account/RegisterConfirmation.cshtml.cs*:

```
[AllowAnonymous]
public class RegisterConfirmationModel : PageModel
{
    private readonly UserManager<IdentityUser> _userManager;
    private readonly IEmailSender _sender;

    public RegisterConfirmationModel(UserManager<IdentityUser> userManager, IEmailSender sender)
    {
        _userManager = userManager;
        _sender = sender;
    }

    public string Email { get; set; }

    public bool DisplayConfirmAccountLink { get; set; }

    public string EmailConfirmationUrl { get; set; }

    public async Task<IActionResult> OnGetAsync(string email, string returnUrl = null)
    {
        if (email == null)
        {
            return RedirectToPage("/Index");
        }

        var user = await _userManager.FindByEmailAsync(email);
        if (user == null)
        {
            return NotFound($"Unable to load user with email '{email}'.");
        }

        Email = email;
        // Once you add a real email sender, you should remove this code that lets you confirm the
account
        DisplayConfirmAccountLink = false;
        if (DisplayConfirmAccountLink)
        {
            var userId = await _userManager.GetUserIdAsync(user);
            var code = await _userManager.GenerateEmailConfirmationTokenAsync(user);
            code = WebEncoders.Base64UrlEncode(Encoding.UTF8.GetBytes(code));
            EmailConfirmationUrl = Url.Page(
                "/Account/ConfirmEmail",
                pageHandler: null,
                values: new { area = "Identity", userId = userId, code = code, returnUrl = returnUrl
},
                protocol: Request.Scheme);
        }

        return Page();
    }
}
```

Log in

The Login form is displayed when:

- The **Log in** link is selected.
- A user attempts to access a restricted page that they aren't authorized to access **or** when they haven't been authenticated by the system.

When the form on the Login page is submitted, the `OnPostAsync` action is called. `PasswordSignInAsync` is called on the `_signInManager` object.

```
public async Task<IActionResult> OnPostAsync(string returnUrl = null)
{
    returnUrl = returnUrl ?? Url.Content("~/");

    if (ModelState.IsValid)
    {
        // This doesn't count login failures towards account lockout
        // To enable password failures to trigger account lockout,
        // set lockoutOnFailure: true
        var result = await _signInManager.PasswordSignInAsync(Input.Email,
                          Input.Password, Input.RememberMe, lockoutOnFailure: true);
        if (result.Succeeded)
        {
            _logger.LogInformation("User logged in.");
            return LocalRedirect(returnUrl);
        }
        if (result.RequiresTwoFactor)
        {
            return RedirectToPage("./LoginWith2fa", new
            {
                ReturnUrl = returnUrl,
                RememberMe = Input.RememberMe
            });
        }
        if (result.IsLockedOut)
        {
            _logger.LogWarning("User account locked out.");
            return RedirectToPage("./Lockout");
        }
        else
        {
            ModelState.AddModelError(string.Empty, "Invalid login attempt.");
            return Page();
        }
    }

    // If we got this far, something failed, redisplay form
    return Page();
}
```

For information on how to make authorization decisions, see Introduction to authorization in ASP.NET Core.

Log out

The **Log out** link invokes the `LogoutModel.OnPost` action.

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.Extensions.Logging;
using System.Threading.Tasks;

namespace WebApp1.Areas.Identity.Pages.Account
{
    [AllowAnonymous]
    public class LogoutModel : PageModel
    {
        private readonly SignInManager<IdentityUser> _signInManager;
        private readonly ILogger<LogoutModel> _logger;

        public LogoutModel(SignInManager<IdentityUser> signInManager, ILogger<LogoutModel> logger)
        {
            _signInManager = signInManager;
            _logger = logger;
        }

        public void OnGet()
        {
        }

        public async Task<IActionResult> OnPost(string returnUrl = null)
        {
            await _signInManager.SignOutAsync();
            _logger.LogInformation("User logged out.");
            if (returnUrl != null)
            {
                return LocalRedirect(returnUrl);
            }
            else
            {
                return RedirectToPage();
            }
        }
    }
}
```

In the preceding code, the code `return RedirectToPage();` needs to be a redirect so that the browser performs a new request and the identity for the user gets updated.

SignOutAsync clears the user's claims stored in a cookie.

Post is specified in the *Pages/Shared/_LoginPartial.cshtml*:

```
@using Microsoft.AspNetCore.Identity
@inject SignInManager<IdentityUser> SignInManager
@inject UserManager<IdentityUser> UserManager

<ul class="navbar-nav">
@if (SignInManager.IsSignedIn(User))
{
    <li class="nav-item">
        <a  class="nav-link text-dark" asp-area="Identity" asp-page="/Account/Manage/Index"
                                            title="Manage">Hello @User.Identity.Name!</a>
    </li>
    <li class="nav-item">
        <form class="form-inline" asp-area="Identity" asp-page="/Account/Logout"
                                  asp-route-returnUrl="@Url.Page("/", new { area = "" })"
                                  method="post" >
            <button  type="submit" class="nav-link btn btn-link text-dark">Logout</button>
        </form>
    </li>
}
else
{
    <li class="nav-item">
        <a class="nav-link text-dark" asp-area="Identity" asp-page="/Account/Register">Register</a>
    </li>
    <li class="nav-item">
        <a class="nav-link text-dark" asp-area="Identity" asp-page="/Account/Login">Login</a>
    </li>
}
</ul>
```

Test Identity

The default web project templates allow anonymous access to the home pages. To test Identity, add `[Authorize]`:

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.Extensions.Logging;

namespace WebApp1.Pages
{
    [Authorize]
    public class PrivacyModel : PageModel
    {
        private readonly ILogger<PrivacyModel> _logger;

        public PrivacyModel(ILogger<PrivacyModel> logger)
        {
            _logger = logger;
        }

        public void OnGet()
        {
        }
    }
}
```

If you are signed in, sign out. Run the app and select the **Privacy** link. You are redirected to the login page.

Explore Identity

To explore Identity in more detail:

- Create full identity UI source
- Examine the source of each page and step through the debugger.

Identity Components

All the Identity-dependent NuGet packages are included in the ASP.NET Core shared framework.

The primary package for Identity is Microsoft.AspNetCore.Identity. This package contains the core set of interfaces for ASP.NET Core Identity, and is included by `Microsoft.AspNetCore.Identity.EntityFrameworkCore`.

Migrating to ASP.NET Core Identity

For more information and guidance on migrating your existing Identity store, see Migrate Authentication and Identity.

Setting password strength

See Configuration for a sample that sets the minimum password requirements.

AddDefaultIdentity and AddIdentity

AddDefaultIdentity was introduced in ASP.NET Core 2.1. Calling `AddDefaultIdentity` is similar to calling the following:

- AddIdentity
- AddDefaultUI
- AddDefaultTokenProviders

See AddDefaultIdentity source for more information.

Prevent publish of static Identity assets

To prevent publishing static Identity assets (stylesheets and JavaScript files for Identity UI) to the web root, add the following `ResolveStaticWebAssetsInputsDependsOn` property and `RemoveIdentityAssets` target to the app's project file:

```
<PropertyGroup>
  <ResolveStaticWebAssetsInputsDependsOn>RemoveIdentityAssets</ResolveStaticWebAssetsInputsDependsOn>
</PropertyGroup>

<Target Name="RemoveIdentityAssets">
  <ItemGroup>
    <StaticWebAsset Remove="@(StaticWebAsset)" Condition="%(SourceId) ==
'Microsoft.AspNetCore.Identity.UI'" />
  </ItemGroup>
</Target>
```

Next Steps

- ASP.NET Core Identity source code
- See this GitHub issue for information on configuring Identity using SQLite.
- Configure Identity
- Create an ASP.NET Core app with user data protected by authorization
- Add, download, and delete user data to Identity in an ASP.NET Core project

- Enable QR Code generation for TOTP authenticator apps in ASP.NET Core
- Migrate Authentication and Identity to ASP.NET Core
- Account confirmation and password recovery in ASP.NET Core
- Two-factor authentication with SMS in ASP.NET Core
- Host ASP.NET Core in a web farm

By Rick Anderson

ASP.NET Core Identity is a membership system that adds login functionality to ASP.NET Core apps. Users can create an account with the login information stored in Identity or they can use an external login provider. Supported external login providers include Facebook, Google, Microsoft Account, and Twitter.

Identity can be configured using a SQL Server database to store user names, passwords, and profile data. Alternatively, another persistent store can be used, for example, Azure Table Storage.

View or download the sample code (how to download).

In this topic, you learn how to use Identity to register, log in, and log out a user. For more detailed instructions about creating apps that use Identity, see the Next Steps section at the end of this article.

AddDefaultIdentity and AddIdentity

AddDefaultIdentity was introduced in ASP.NET Core 2.1. Calling `AddDefaultIdentity` is similar to calling the following:

- AddIdentity
- AddDefaultUI
- AddDefaultTokenProviders

See AddDefaultIdentity source for more information.

Create a Web app with authentication

Create an ASP.NET Core Web Application project with Individual User Accounts.

- Visual Studio
- .NET Core CLI

- Select **File** > **New** > **Project**.
- Select **ASP.NET Core Web Application**. Name the project **WebApp1** to have the same namespace as the project download. Click **OK**.
- Select an ASP.NET Core **Web Application**, then select **Change Authentication**.
- Select **Individual User Accounts** and click **OK**.

The generated project provides ASP.NET Core Identity as a Razor Class Library. The Identity Razor Class Library exposes endpoints with the `Identity` area. For example:

- /Identity/Account/Login
- /Identity/Account/Logout
- /Identity/Account/Manage

Apply migrations

Apply the migrations to initialize the database.

- Visual Studio
- .NET Core CLI

Run the following command in the Package Manager Console (PMC):

```
Update-Database
```

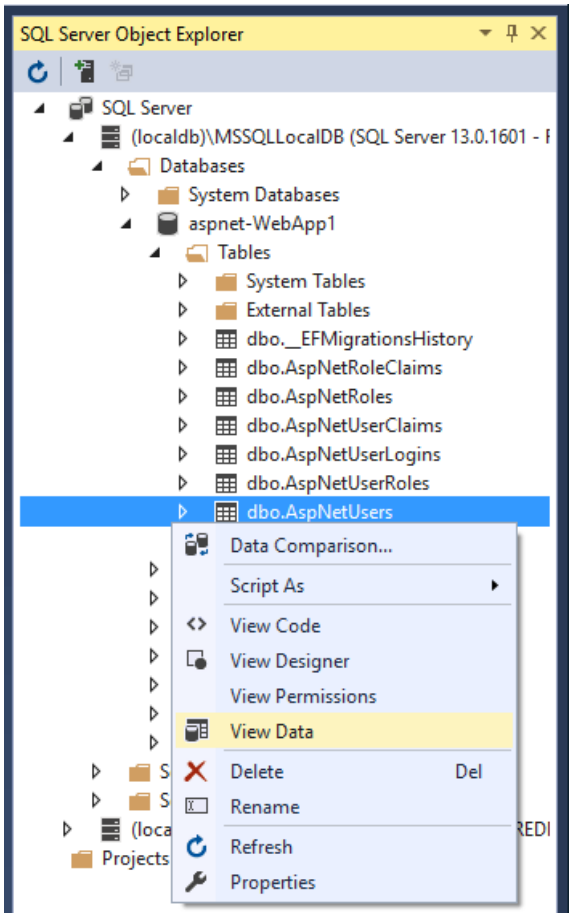
Test Register and Login

Run the app and register a user. Depending on your screen size, you might need to select the navigation toggle button to see the **Register** and **Login** links.

View the Identity database

- Visual Studio
- .NET Core CLI

- From the **View** menu, select **SQL Server Object Explorer** (SSOX).
- Navigate to **(localdb)MSSQLLocalDB(SQL Server 13)**. Right-click on **dbo.AspNetUsers** > **View Data**:



Configure Identity services

Services are added in `ConfigureServices`. The typical pattern is to call all the `Add{Service}` methods, and then call all the `services.Configure{Service}` methods.

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>()
        .AddDefaultUI(UIFramework.Bootstrap4)
        .AddEntityFrameworkStores<ApplicationDbContext>();

    services.Configure<IdentityOptions>(options =>
    {
        // Password settings.
        options.Password.RequireDigit = true;
        options.Password.RequireLowercase = true;
        options.Password.RequireNonAlphanumeric = true;
        options.Password.RequireUppercase = true;
        options.Password.RequiredLength = 6;
        options.Password.RequiredUniqueChars = 1;

        // Lockout settings.
        options.Lockout.DefaultLockoutTimeSpan = TimeSpan.FromMinutes(5);
        options.Lockout.MaxFailedAccessAttempts = 5;
        options.Lockout.AllowedForNewUsers = true;

        // User settings.
        options.User.AllowedUserNameCharacters =
        "abcdefghijklmnopqrstuvwxyzABCDEFGHIJKLMNOPQRSTUVWXYZ0123456789-._@+";
        options.User.RequireUniqueEmail = false;
    });

    services.ConfigureApplicationCookie(options =>
    {
        // Cookie settings
        options.Cookie.HttpOnly = true;
        options.ExpireTimeSpan = TimeSpan.FromMinutes(5);

        options.LoginPath = "/Identity/Account/Login";
        options.AccessDeniedPath = "/Identity/Account/AccessDenied";
        options.SlidingExpiration = true;
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

The preceding code configures Identity with default option values. Services are made available to the app through dependency injection.

Identity is enabled by calling UseAuthentication. `UseAuthentication` adds authentication middleware to the request pipeline.

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseCookiePolicy();

    app.UseAuthentication();

    app.UseMvc();
}
```

For more information, see the IdentityOptions Class and Application Startup.

Scaffold Register, Login, and LogOut

Follow the Scaffold identity into a Razor project with authorization instructions to generate the code shown in this section.

- Visual Studio
- .NET Core CLI

Add the Register, Login, and LogOut files.

Examine Register

When a user clicks the **Register** link, the `RegisterModel.OnPostAsync` action is invoked. The user is created by CreateAsync on the `_userManager` object:

```
public async Task<IActionResult> OnPostAsync(string returnUrl = null)
{
    returnUrl = returnUrl ?? Url.Content("~/");
    if (ModelState.IsValid)
    {
        var user = new IdentityUser { UserName = Input.Email, Email = Input.Email };
        var result = await _userManager.CreateAsync(user, Input.Password);
        if (result.Succeeded)
        {
            _logger.LogInformation("User created a new account with password.");

            var code = await _userManager.GenerateEmailConfirmationTokenAsync(user);
            var callbackUrl = Url.Page(
                "/Account/ConfirmEmail",
                pageHandler: null,
                values: new { userId = user.Id, code = code },
                protocol: Request.Scheme);

            await _emailSender.SendEmailAsync(Input.Email, "Confirm your email",
                $"Please confirm your account by <a
href='{HtmlEncoder.Default.Encode(callbackUrl)}'>clicking here</a>.");

            await _signInManager.SignInAsync(user, isPersistent: false);
            return LocalRedirect(returnUrl);
        }
        foreach (var error in result.Errors)
        {
            ModelState.AddModelError(string.Empty, error.Description);
        }
    }

    // If we got this far, something failed, redisplay form
    return Page();
}
```

If the user was created successfully, the user is logged in by the call to `_signInManager.SignInAsync`.

Note: See account confirmation for steps to prevent immediate login at registration.

Log in

The Login form is displayed when:

- The **Log in** link is selected.
- A user attempts to access a restricted page that they aren't authorized to access **or** when they haven't been authenticated by the system.

When the form on the Login page is submitted, the `OnPostAsync` action is called. `PasswordSignInAsync` is called on the `_signInManager` object.

```
public async Task<IActionResult> OnPostAsync(string returnUrl = null)
{
    returnUrl = returnUrl ?? Url.Content("~/");

    if (ModelState.IsValid)
    {
        // This doesn't count login failures towards account lockout
        // To enable password failures to trigger account lockout,
        // set lockoutOnFailure: true
        var result = await _signInManager.PasswordSignInAsync(Input.Email,
            Input.Password, Input.RememberMe, lockoutOnFailure: true);
        if (result.Succeeded)
        {
            _logger.LogInformation("User logged in.");
            return LocalRedirect(returnUrl);
        }
        if (result.RequiresTwoFactor)
        {
            return RedirectToPage("./LoginWith2fa", new { ReturnUrl = returnUrl, RememberMe =
Input.RememberMe });
        }
        if (result.IsLockedOut)
        {
            _logger.LogWarning("User account locked out.");
            return RedirectToPage("./Lockout");
        }
        else
        {
            ModelState.AddModelError(string.Empty, "Invalid login attempt.");
            return Page();
        }
    }

    // If we got this far, something failed, redisplay form
    return Page();
}
```

For information on how to make authorization decisions, see Introduction to authorization in ASP.NET Core.

Log out

The **Log out** link invokes the `LogoutModel.OnPost` action.

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.Extensions.Logging;
using System.Threading.Tasks;

namespace WebApp1.Areas.Identity.Pages.Account
{
    [AllowAnonymous]
    public class LogoutModel : PageModel
    {
        private readonly SignInManager<IdentityUser> _signInManager;
        private readonly ILogger<LogoutModel> _logger;

        public LogoutModel(SignInManager<IdentityUser> signInManager, ILogger<LogoutModel> logger)
        {
            _signInManager = signInManager;
            _logger = logger;
        }

        public void OnGet()
        {
        }

        public async Task<IActionResult> OnPost(string returnUrl = null)
        {
            await _signInManager.SignOutAsync();
            _logger.LogInformation("User logged out.");
            if (returnUrl != null)
            {
                return LocalRedirect(returnUrl);
            }
            else
            {
                // This needs to be a redirect so that the browser performs a new
                // request and the identity for the user gets updated.
                return RedirectToPage();
            }
        }
    }
}
```

SignOutAsync clears the user's claims stored in a cookie.

Post is specified in the *Pages/Shared/_LoginPartial.cshtml*:

```
@using Microsoft.AspNetCore.Identity
@inject SignInManager<IdentityUser> SignInManager
@inject UserManager<IdentityUser> UserManager

<ul class="navbar-nav">
    @if (SignInManager.IsSignedIn(User))
    {
        <li class="nav-item">
            <a class="nav-link text-dark" asp-area="Identity"
               asp-page="/Account/Manage/Index"
               title="Manage">Hello@User.Identity.Name!</a>
        </li>
        <li class="nav-item">
            <form class="form-inline" asp-area="Identity" asp-page="/Account/Logout"
                  asp-route-returnUrl="@Url.Page("/", new { area = "" })"
                  method="post">
                <button type="submit" class="nav-link btn btn-link text-dark">Logout</button>
            </form>
        </li>
    }
    else
    {
        <li class="nav-item">
            <a class="nav-link text-dark" asp-area="Identity" asp-
page="/Account/Register">Register</a>
        </li>
        <li class="nav-item">
            <a class="nav-link text-dark" asp-area="Identity" asp-page="/Account/Login">Login</a>
        </li>
    }
</ul>
```

Test Identity

The default web project templates allow anonymous access to the home pages. To test Identity, add `[Authorize]` to the Privacy page.

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace WebApp1.Pages
{
    [Authorize]
    public class PrivacyModel : PageModel
    {
        public void OnGet()
        {
        }
    }
}
```

If you are signed in, sign out. Run the app and select the **Privacy** link. You are redirected to the login page.

Explore Identity

To explore Identity in more detail:

- Create full identity UI source
- Examine the source of each page and step through the debugger.

Identity Components

All the Identity dependent NuGet packages are included in the Microsoft.AspNetCore.App metapackage.

The primary package for Identity is Microsoft.AspNetCore.Identity. This package contains the core set of interfaces for ASP.NET Core Identity, and is included by `Microsoft.AspNetCore.Identity.EntityFrameworkCore`.

Migrating to ASP.NET Core Identity

For more information and guidance on migrating your existing Identity store, see Migrate Authentication and Identity.

Setting password strength

See Configuration for a sample that sets the minimum password requirements.

Next Steps

- See this GitHub issue for information on configuring Identity using SQLite.
- Configure Identity
- Create an ASP.NET Core app with user data protected by authorization
- Add, download, and delete user data to Identity in an ASP.NET Core project
- Enable QR Code generation for TOTP authenticator apps in ASP.NET Core
- Migrate Authentication and Identity to ASP.NET Core
- Account confirmation and password recovery in ASP.NET Core
- Two-factor authentication with SMS in ASP.NET Core
- Host ASP.NET Core in a web farm

Authentication and authorization for SPAs

9/22/2020 • 11 minutes to read • Edit Online

ASP.NET Core 3.0 or later offers authentication in Single Page Apps (SPAs) using the support for API authorization. ASP.NET Core Identity for authenticating and storing users is combined with IdentityServer for implementing OpenID Connect.

An authentication parameter was added to the **Angular** and **React** project templates that is similar to the authentication parameter in the **Web Application (Model-View-Controller)** (MVC) and **Web Application** (Razor Pages) project templates. The allowed parameter values are **None** and **Individual**. The **React.js and Redux** project template doesn't support the authentication parameter at this time.

Create an app with API authorization support

User authentication and authorization can be used with both Angular and React SPAs. Open a command shell, and run the following command:

Angular:

```
dotnet new angular -o <output_directory_name> -au Individual
```

React:

```
dotnet new react -o <output_directory_name> -au Individual
```

The preceding command creates an ASP.NET Core app with a *ClientApp* directory containing the SPA.

General description of the ASP.NET Core components of the app

The following sections describe additions to the project when authentication support is included:

Startup class

The following code examples rely on the Microsoft.AspNetCore.ApiAuthorization.IdentityServer NuGet package. The examples configure API authentication and authorization using the AddApiAuthorization and AddIdentityServerJwt extension methods. Projects using the React or Angular SPA project templates with authentication include a reference to this package.

The `Startup` class has the following additions:

- Inside the `Startup.ConfigureServices` method:
  - Identity with the default UI:

    ```
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlite(Configuration.GetConnectionString("DefaultConnection")));

    services.AddDefaultIdentity<ApplicationUser>()
        .AddEntityFrameworkStores<ApplicationDbContext>();
    ```

  - IdentityServer with an additional `AddApiAuthorization` helper method that sets up some default ASP.NET Core conventions on top of IdentityServer:

```
services.AddIdentityServer()
    .AddApiAuthorization<ApplicationUser, ApplicationDbContext>();
```

- Authentication with an additional `AddIdentityServerJwt` helper method that configures the app to validate JWT tokens produced by IdentityServer:

```
services.AddAuthentication()
    .AddIdentityServerJwt();
```

- Inside the `Startup.Configure` method:
  - The authentication middleware that is responsible for validating the request credentials and setting the user on the request context:

```
app.UseAuthentication();
```

  - The IdentityServer middleware that exposes the OpenID Connect endpoints:

```
app.UseIdentityServer();
```

AddApiAuthorization

This helper method configures IdentityServer to use our supported configuration. IdentityServer is a powerful and extensible framework for handling app security concerns. At the same time, that exposes unnecessary complexity for the most common scenarios. Consequently, a set of conventions and configuration options is provided to you that are considered a good starting point. Once your authentication needs change, the full power of IdentityServer is still available to customize authentication to suit your needs.

AddIdentityServerJwt

This helper method configures a policy scheme for the app as the default authentication handler. The policy is configured to let Identity handle all requests routed to any subpath in the Identity URL space "/Identity". The `JwtBearerHandler` handles all other requests. Additionally, this method registers an `<<ApplicationName>>API` API resource with IdentityServer with a default scope of `<<ApplicationName>>API` and configures the JWT Bearer token middleware to validate tokens issued by IdentityServer for the app.

WeatherForecastController

In the *Controllers\WeatherForecastController.cs* file, notice the `[Authorize]` attribute applied to the class that indicates that the user needs to be authorized based on the default policy to access the resource. The default authorization policy happens to be configured to use the default authentication scheme, which is set up by `AddIdentityServerJwt` to the policy scheme that was mentioned above, making the `JwtBearerHandler` configured by such helper method the default handler for requests to the app.

ApplicationDbContext

In the *Data\ApplicationDbContext.cs* file, notice the same `DbContext` is used in Identity with the exception that it extends `ApiAuthorizationDbContext` (a more derived class from `IdentityDbContext`) to include the schema for IdentityServer.

To gain full control of the database schema, inherit from one of the available Identity `DbContext` classes and configure the context to include the Identity schema by calling `builder.ConfigurePersistedGrantContext(_operationalStoreOptions.Value)` on the `OnModelCreating` method.

OidcConfigurationController

In the *Controllers\OidcConfigurationController.cs* file, notice the endpoint that's provisioned to serve the OIDC

parameters that the client needs to use.

appsettings.json

In the *appsettings.json* file of the project root, there's a new `IdentityServer` section that describes the list of configured clients. In the following example, there's a single client. The client name corresponds to the app name and is mapped by convention to the OAuth `ClientId` parameter. The profile indicates the app type being configured. It's used internally to drive conventions that simplify the configuration process for the server. There are several profiles available, as explained in the Application profiles section.

```
"IdentityServer": {
  "Clients": {
    "angularindividualpreview3final": {
      "Profile": "IdentityServerSPA"
    }
  }
}
```

appsettings.Development.json

In the *appsettings.Development.json* file of the project root, there's an `IdentityServer` section that describes the key used to sign tokens. When deploying to production, a key needs to be provisioned and deployed alongside the app, as explained in the Deploy to production section.

```
"IdentityServer": {
  "Key": {
    "Type": "Development"
  }
}
```

General description of the Angular app

The authentication and API authorization support in the Angular template resides in its own Angular module in the *ClientApp\src\api-authorization* directory. The module is composed of the following elements:

- 3 components:
  - *login.component.ts*: Handles the app's login flow.
  - *logout.component.ts*: Handles the app's logout flow.
  - *login-menu.component.ts*: A widget that displays one of the following sets of links:
    - User profile management and log out links when the user is authenticated.
    - Registration and log in links when the user isn't authenticated.
- A route guard `AuthorizeGuard` that can be added to routes and requires a user to be authenticated before visiting the route.
- An HTTP interceptor `AuthorizeInterceptor` that attaches the access token to outgoing HTTP requests targeting the API when the user is authenticated.
- A service `AuthorizeService` that handles the lower-level details of the authentication process and exposes information about the authenticated user to the rest of the app for consumption.
- An Angular module that defines routes associated with the authentication parts of the app. It exposes the login menu component, the interceptor, the guard, and the service for consumption from the rest of the app.

General description of the React app

The support for authentication and API authorization in the React template resides in the *ClientApp\src\components\api-authorization* directory. It's composed of the following elements:

- 4 components:
  - *Login.js*: Handles the app's login flow.
  - *Logout.js*: Handles the app's logout flow.
  - *LoginMenu.js*: A widget that displays one of the following sets of links:
    - User profile management and log out links when the user is authenticated.
    - Registration and log in links when the user isn't authenticated.
  - *AuthorizeRoute.js*: A route component that requires a user to be authenticated before rendering the component indicated in the `Component` parameter.
- An exported `authService` instance of class `AuthorizeService` that handles the lower-level details of the authentication process and exposes information about the authenticated user to the rest of the app for consumption.

Now that you've seen the main components of the solution, you can take a deeper look at individual scenarios for the app.

Require authorization on a new API

By default, the system is configured to easily require authorization for new APIs. To do so, create a new controller and add the `[Authorize]` attribute to the controller class or to any action within the controller.

Customize the API authentication handler

To customize the configuration of the API's JWT handler, configure its JwtBearerOptions instance:

```
services.AddAuthentication()
    .AddIdentityServerJwt();

services.Configure<JwtBearerOptions>(
    IdentityServerJwtConstants.IdentityServerJwtBearerScheme,
    options =>
    {
        ...
    });
```

The API's JWT handler raises events that enable control over the authentication process using `JwtBearerEvents`. To provide support for API authorization, `AddIdentityServerJwt` registers its own event handlers.

To customize the handling of an event, wrap the existing event handler with additional logic as required. For example:

```
services.Configure<JwtBearerOptions>(
    IdentityServerJwtConstants.IdentityServerJwtBearerScheme,
    options =>
    {
        var onTokenValidated = options.Events.OnTokenValidated;

        options.Events.OnTokenValidated = async context =>
        {
            await onTokenValidated(context);
            ...
        }
    });
```

In the preceding code, the `OnTokenValidated` event handler is replaced with a custom implementation. This implementation:

1. Calls the original implementation provided by the API authorization support.
2. Run its own custom logic.

Protect a client-side route (Angular)

Protecting a client-side route is done by adding the authorize guard to the list of guards to run when configuring a route. As an example, you can see how the `fetch-data` route is configured within the main app Angular module:

```
RouterModule.forRoot([
  // ...
  { path: 'fetch-data', component: FetchDataComponent, canActivate: [AuthorizeGuard] },
])
```

It's important to mention that protecting a route doesn't protect the actual endpoint (which still requires an `[Authorize]` attribute applied to it) but that it only prevents the user from navigating to the given client-side route when it isn't authenticated.

Authenticate API requests (Angular)

Authenticating requests to APIs hosted alongside the app is done automatically through the use of the HTTP client interceptor defined by the app.

Protect a client-side route (React)

Protect a client-side route by using the `AuthorizeRoute` component instead of the plain `Route` component. For example, notice how the `fetch-data` route is configured within the `App` component:

```
<AuthorizeRoute path='/fetch-data' component={FetchData} />
```

Protecting a route:

- Doesn't protect the actual endpoint (which still requires an `[Authorize]` attribute applied to it).
- Only prevents the user from navigating to the given client-side route when it isn't authenticated.

Authenticate API requests (React)

Authenticating requests with React is done by first importing the `authService` instance from the `AuthorizeService` . The access token is retrieved from the `authService` and is attached to the request as shown below. In React components, this work is typically done in the `componentDidMount` lifecycle method or as the result from some user interaction.

Import the authService into your component

```
import authService from './api-authorization/AuthorizeService'
```

Retrieve and attach the access token to the response

```
async populateWeatherData() {
  const token = await authService.getAccessToken();
  const response = await fetch('api/SampleData/WeatherForecasts', {
    headers: !token ? {} : { 'Authorization': `Bearer ${token}` }
  });
  const data = await response.json();
  this.setState({ forecasts: data, loading: false });
}
```

Deploy to production

To deploy the app to production, the following resources need to be provisioned:

- A database to store the Identity user accounts and the IdentityServer grants.
- A production certificate to use for signing tokens.
  - There are no specific requirements for this certificate; it can be a self-signed certificate or a certificate provisioned through a CA authority.
  - It can be generated through standard tools like PowerShell or OpenSSL.
  - It can be installed into the certificate store on the target machines or deployed as a *.pfx* file with a strong password.

Example: Deploy to Azure App Service

This section describes deploying the app to Azure App Service using a certificate stored in the certificate store. To modify the app to load a certificate from the certificate store, a Standard tier service plan or better is required when you configure the app in the Azure portal in a later step.

In the app's *appsettings.json* file, modify the `IdentityServer` section to include the key details:

```
"IdentityServer": {
  "Key": {
    "Type": "Store",
    "StoreName": "My",
    "StoreLocation": "CurrentUser",
    "Name": "CN=MyApplication"
  }
}
```

- The store name represents the name of the certificate store where the certificate is stored. In this case, it points to the personal user store.
- The store location represents where to load the certificate from (`CurrentUser` or `LocalMachine`).
- The name property on certificate corresponds with the distinguished subject for the certificate.

To deploy to Azure App Service, follow the steps in Deploy the app to Azure, which explains how to create the necessary Azure resources and deploy the app to production.

After following the preceding instructions, the app is deployed to Azure but isn't yet functional. The certificate used by the app must be configured in the Azure portal. Locate the thumbprint for the certificate and follow the steps described in Load your certificates.

While these steps mention SSL, there's a **Private certificates** section in the Azure portal where you can upload the provisioned certificate to use with the app.

After configuring the app and the app's settings in the Azure portal, restart the app in the portal.

Other configuration options

The support for API authorization builds on top of IdentityServer with a set of conventions, default values, and enhancements to simplify the experience for SPAs. Needless to say, the full power of IdentityServer is available behind the scenes if the ASP.NET Core integrations don't cover your scenario. The ASP.NET Core support is focused on "first-party" apps, where all the apps are created and deployed by our organization. As such, support isn't offered for things like consent or federation. For those scenarios, use IdentityServer and follow their documentation.

Application profiles

Application profiles are predefined configurations for apps that further define their parameters. At this time, the following profiles are supported:

- `IdentityServerSPA`: Represents a SPA hosted alongside IdentityServer as a single unit.
  - The `redirect_uri` defaults to `/authentication/login-callback`.
  - The `post_logout_redirect_uri` defaults to `/authentication/logout-callback`.
  - The set of scopes includes the `openid`, `profile`, and every scope defined for the APIs in the app.
  - The set of allowed OIDC response types is `id_token token` or each of them individually (`id_token`, `token`).
  - The allowed response mode is `fragment`.
- `SPA`: Represents a SPA that isn't hosted with IdentityServer.
  - The set of scopes includes the `openid`, `profile`, and every scope defined for the APIs in the app.
  - The set of allowed OIDC response types is `id_token token` or each of them individually (`id_token`, `token`).
  - The allowed response mode is `fragment`.
- `IdentityServerJwt`: Represents an API that is hosted alongside with IdentityServer.
  - The app is configured to have a single scope that defaults to the app name.
- `API`: Represents an API that isn't hosted with IdentityServer.
  - The app is configured to have a single scope that defaults to the app name.

Configuration through AppSettings

Configure the apps through the configuration system by adding them to the list of `Clients` or `Resources`.

Configure each client's `redirect_uri` and `post_logout_redirect_uri` property, as shown in the following example:

```
"IdentityServer": {
  "Clients": {
    "MySPA": {
      "Profile": "SPA",
      "RedirectUri": "https://www.example.com/authentication/login-callback",
      "LogoutUri": "https://www.example.com/authentication/logout-callback"
    }
  }
}
```

When configuring resources, you can configure the scopes for the resource as shown below:

```
"IdentityServer": {
  "Resources": {
    "MyExternalApi": {
      "Profile": "API",
      "Scopes": "a b c"
    }
  }
}
```

Configuration through code

You can also configure the clients and resources through code using an overload of `AddApiAuthorization` that takes an action to configure options.

```
AddApiAuthorization<ApplicationUser, ApplicationDbContext>(options =>
{
    options.Clients.AddSPA(
        "My SPA", spa =>
        spa.WithRedirectUri("http://www.example.com/authentication/login-callback")
           .WithLogoutRedirectUri(
               "http://www.example.com/authentication/logout-callback"));

    options.ApiResources.AddApiResource("MyExternalApi", resource =>
        resource.WithScopes("a", "b", "c"));
});
```

Scaffold Identity in ASP.NET Core projects

9/22/2020 • 51 minutes to read • Edit Online

By Rick Anderson

ASP.NET Core provides ASP.NET Core Identity as a Razor Class Library. Applications that include Identity can apply the scaffolder to selectively add the source code contained in the Identity Razor Class Library (RCL). You might want to generate source code so you can modify the code and change the behavior. For example, you could instruct the scaffolder to generate the code used in registration. Generated code takes precedence over the same code in the Identity RCL. To gain full control of the UI and not use the default RCL, see the section Create full Identity UI source.

Applications that do **not** include authentication can apply the scaffolder to add the RCL Identity package. You have the option of selecting Identity code to be generated.

Although the scaffolder generates most of the necessary code, you need to update your project to complete the process. This document explains the steps needed to complete an Identity scaffolding update.

We recommend using a source control system that shows file differences and allows you to back out of changes. Inspect the changes after running the Identity scaffolder.

Services are required when using Two Factor Authentication, Account confirmation and password recovery, and other security features with Identity. Services or service stubs aren't generated when scaffolding Identity. Services to enable these features must be added manually. For example, see Require Email Confirmation.

When scaffolding Identity with a new data context into a project with existing individual accounts:

- In `Startup.ConfigureServices`, remove the calls to:
  - `AddDbContext`
  - `AddDefaultIdentity`

For example, `AddDbContext` and `AddDefaultIdentity` are commented out in the following code:

```
public void ConfigureServices(IServiceCollection services)
{
    //services.AddDbContext<ApplicationDbContext>(options =>
    //    options.UseSqlServer(
    //        Configuration.GetConnectionString("DefaultConnection")));
    //services.AddDefaultIdentity<IdentityUser>(options => options.SignIn.RequireConfirmedAccount = true)
    //    .AddEntityFrameworkStores<ApplicationDbContext>();
    services.AddControllersWithViews();
    services.AddRazorPages();
}
```

The preceeding code comments out the code that is duplicated in *Areas/Identity/IdentityHostingStartup.cs*

Typically, apps that were created with individual accounts should ***not*** create a new data context.

Scaffold Identity into an empty project

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add New Scaffolded Item** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
  - Select your existing layout page, or your layout file will be overwritten with incorrect markup:
    - `~/Pages/Shared/_Layout.cshtml` for Razor Pages
    - `~/Views/Shared/_Layout.cshtml` for MVC projects
    - Blazor Server apps created from the Blazor Server template (`blazorserver`) aren't configured for Razor Pages or MVC by default. Leave the layout page entry blank.
  - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
- Select **Add**.

Update the `Startup` class with code similar to the following:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddControllersWithViews();
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
            app.UseDatabaseErrorPage();
        }
        else
        {
            app.UseExceptionHandler("/Home/Error");
            app.UseHsts();
        }
        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthentication();
        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapControllerRoute(
                name: "default",
                pattern: "{controller=Home}/{action=Index}/{id?}");
            endpoints.MapRazorPages();
        });
    }
}
```

`UseHsts` is recommended but not required. For more information, see HTTP Strict Transport Security Protocol.

The generated Identity database code requires Entity Framework Core Migrations. Create a migration and update the database. For example, run the following commands:

- Visual Studio
- .NET Core CLI

In the Visual Studio **Package Manager Console**:

```
Install-Package Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore
Add-Migration CreateIdentitySchema
Update-Database
```

The "CreateIdentitySchema" name parameter for the `Add-Migration` command is arbitrary. `"CreateIdentitySchema"` describes the migration.

Scaffold Identity into a Razor project without existing authorization

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add New Scaffolded Item** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
  - Select your existing layout page, or your layout file will be overwritten with incorrect markup:
    - `~/Pages/Shared/_Layout.cshtml` for Razor Pages
    - `~/Views/Shared/_Layout.cshtml` for MVC projects
    - Blazor Server apps created from the Blazor Server template (`blazorserver`) aren't configured for Razor Pages or MVC by default. Leave the layout page entry blank.
  - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
- Select **Add**.

Identity is configured in *Areas/Identity/IdentityHostingStartup.cs*. For more information, see IHostingStartup.

Migrations, UseAuthentication, and layout

The generated Identity database code requires Entity Framework Core Migrations. Create a migration and update the database. For example, run the following commands:

- Visual Studio
- .NET Core CLI

In the Visual Studio **Package Manager Console**:

```
Install-Package Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore
Add-Migration CreateIdentitySchema
Update-Database
```

The "CreateIdentitySchema" name parameter for the `Add-Migration` command is arbitrary. `"CreateIdentitySchema"` describes the migration.

Enable authentication

Update the `Startup` class with code similar to the following:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
            app.UseDatabaseErrorPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthentication();
        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapRazorPages();
        });
    }
}
```

`UseHsts` is recommended but not required. For more information, see HTTP Strict Transport Security Protocol.

Layout changes

Optional: Add the login partial (`_LoginPartial`) to the layout file:

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - WebRP</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.min.css" />
    <link rel="stylesheet" href="~/css/site.css" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-light bg-white border-bottom box-
shadow mb-3">
            <div class="container">
                <a class="navbar-brand" asp-area="" asp-page="/Index">WebRP</a>
                <button class="navbar-toggler" type="button" data-toggle="collapse" data-target=".navbar-
collapse" aria-controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle navigation">
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex flex-sm-row-reverse">
                    <partial name="_LoginPartial" />
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-page="/Index">Home</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-page="/Privacy">Privacy</a>
                        </li>
                    </ul>
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2019 - WebRP - <a asp-area="" asp-page="/Privacy">Privacy</a>
        </div>
    </footer>

    <script src="~/lib/jquery/dist/jquery.min.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.min.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>

    @RenderSection("Scripts", required: false)
</body>
</html>
```

Scaffold Identity into a Razor project with authorization

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add Scaffold** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.

    - Select your existing layout page so your layout file isn't overwritten with incorrect markup. When an existing *_Layout.cshtml* file is selected, it is **not** overwritten. For example:
        - `~/Pages/Shared/_Layout.cshtml` for Razor Pages or Blazor Server projects with existing Razor Pages infrastructure
        - `~/Views/Shared/_Layout.cshtml` for MVC projects or Blazor Server projects with existing MVC infrastructure
- To use your existing data context, select at least one file to override. You must select at least one file to add your data context.
    - Select your data context class.
    - Select **Add**.
- To create a new user context and possibly create a custom user class for Identity:
    - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
    - Select **Add**.

Note: If you're creating a new user context, you don't have to select a file to override.

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add Scaffold** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
    - Select your existing layout page, or your layout file will be overwritten with incorrect markup. When an existing *_Layout.cshtml* file is selected, it is **not** overwritten. For example:
        - `~/Pages/Shared/_Layout.cshtml` for Razor Pages
        - `~/Views/Shared/_Layout.cshtml` for MVC projects
- To use your existing data context, select at least one file to override. You must select at least one file to add your data context.
    - Select your data context class.
    - Select **Add**.
- To create a new user context and possibly create a custom user class for Identity:
    - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
    - Select **Add**.

Note: If you're creating a new user context, you don't have to select a file to override.

Some Identity options are configured in *Areas/Identity/IdentityHostingStartup.cs*. For more information, see IHostingStartup.

Scaffold Identity into an MVC project without existing authorization

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add New Scaffolded Item** dialog, select **Identity** > **Add**.

- In the **Add Identity** dialog, select the options you want.
  - Select your existing layout page, or your layout file will be overwritten with incorrect markup:
    - `~/Pages/Shared/_Layout.cshtml` for Razor Pages
    - `~/Views/Shared/_Layout.cshtml` for MVC projects
    - Blazor Server apps created from the Blazor Server template (`blazorserver`) aren't configured for Razor Pages or MVC by default. Leave the layout page entry blank.
  - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
- Select **Add**.

Optional: Add the login partial (`_LoginPartial`) to the *Views/Shared/_Layout.cshtml* file:

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - WebRP</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.min.css" />
    <link rel="stylesheet" href="~/css/site.css" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-light bg-white border-bottom box-
shadow mb-3">
            <div class="container">
                <a class="navbar-brand" asp-area="" asp-page="/Index">WebRP</a>
                <button class="navbar-toggler" type="button" data-toggle="collapse" data-target=".navbar-
collapse" aria-controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle navigation">
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex flex-sm-row-reverse">
                    <partial name="_LoginPartial" />
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-page="/Index">Home</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-page="/Privacy">Privacy</a>
                        </li>
                    </ul>
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2019 - WebRP - <a asp-area="" asp-page="/Privacy">Privacy</a>
        </div>
    </footer>

    <script src="~/lib/jquery/dist/jquery.min.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.min.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>

    @RenderSection("Scripts", required: false)
</body>
</html>
```

- Move the *Pages/Shared/_LoginPartial.cshtml* file to *Views/Shared/_LoginPartial.cshtml*

Identity is configured in *Areas/Identity/IdentityHostingStartup.cs*. For more information, see IHostingStartup.

The generated Identity database code requires Entity Framework Core Migrations. Create a migration and update the database. For example, run the following commands:

- Visual Studio
- .NET Core CLI

In the Visual Studio **Package Manager Console**:

```
Install-Package Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore
Add-Migration CreateIdentitySchema
Update-Database
```

The "CreateIdentitySchema" name parameter for the `Add-Migration` command is arbitrary. `"CreateIdentitySchema"` describes the migration.

Update the `Startup` class with code similar to the following:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddControllersWithViews();
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
            app.UseDatabaseErrorPage();
        }
        else
        {
            app.UseExceptionHandler("/Home/Error");
            app.UseHsts();
        }
        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthentication();
        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapControllerRoute(
                name: "default",
                pattern: "{controller=Home}/{action=Index}/{id?}");
            endpoints.MapRazorPages();
        });
    }
}
```

`UseHsts` is recommended but not required. For more information, see HTTP Strict Transport Security Protocol.

Scaffold Identity into an MVC project with authorization

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add Scaffold** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
  - Select your existing layout page so your layout file isn't overwritten with incorrect markup. When an existing *_Layout.cshtml* file is selected, it is **not** overwritten. For example:
    - `~/Pages/Shared/_Layout.cshtml` for Razor Pages or Blazor Server projects with existing Razor Pages infrastructure
    - `~/Views/Shared/_Layout.cshtml` for MVC projects or Blazor Server projects with existing MVC infrastructure
- To use your existing data context, select at least one file to override. You must select at least one file to add your data context.
  - Select your data context class.
  - Select **Add**.
- To create a new user context and possibly create a custom user class for Identity:
  - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
  - Select **Add**.

Note: If you're creating a new user context, you don't have to select a file to override.

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add Scaffold** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
  - Select your existing layout page, or your layout file will be overwritten with incorrect markup. When an existing *_Layout.cshtml* file is selected, it is **not** overwritten. For example:
    - `~/Pages/Shared/_Layout.cshtml` for Razor Pages
    - `~/Views/Shared/_Layout.cshtml` for MVC projects
- To use your existing data context, select at least one file to override. You must select at least one file to add your data context.
  - Select your data context class.
  - Select **Add**.
- To create a new user context and possibly create a custom user class for Identity:
  - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
  - Select **Add**.

Note: If you're creating a new user context, you don't have to select a file to override.

Scaffold Identity into a Blazor Server project without existing authorization

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add New Scaffolded Item** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
  - Select your existing layout page, or your layout file will be overwritten with incorrect markup:
    - `~/Pages/Shared/_Layout.cshtml` for Razor Pages
    - `~/Views/Shared/_Layout.cshtml` for MVC projects
    - Blazor Server apps created from the Blazor Server template (`blazorserver`) aren't configured for Razor Pages or MVC by default. Leave the layout page entry blank.
  - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
- Select **Add**.

Identity is configured in *Areas/Identity/IdentityHostingStartup.cs*. For more information, see IHostingStartup.

Migrations

The generated Identity database code requires Entity Framework Core Migrations. Create a migration and update the database. For example, run the following commands:

- Visual Studio
- .NET Core CLI

In the Visual Studio **Package Manager Console**:

```
Install-Package Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore
Add-Migration CreateIdentitySchema
Update-Database
```

The "CreateIdentitySchema" name parameter for the `Add-Migration` command is arbitrary. `"CreateIdentitySchema"` describes the migration.

Pass an XSRF token to the app

Tokens can be passed to components:

- When authentication tokens are provisioned and saved to the authentication cookie, they can be passed to components.
- Razor components can't use `HttpContext` directly, so there's no way to obtain an anti-request forgery (XSRF) token to POST to Identity's logout endpoint at `/Identity/Account/Logout`. An XSRF token can be passed to components.

For more information, see ASP.NET Core Blazor Server additional security scenarios.

In the *Pages/_Host.cshtml* file, establish the token after adding it to the `InitialApplicationState` and `TokenProvider` classes:

```
@inject Microsoft.AspNetCore.Antiforgery.IAntiforgery Xsrf

...

var tokens = new InitialApplicationState
{
    ...

    XsrfToken = Xsrf.GetAndStoreTokens(HttpContext).RequestToken
};
```

Update the `App` component (*App.razor*) to assign the `InitialState.XsrfToken`:

```
@inject TokenProvider TokenProvider

...

TokenProvider.XsrfToken = InitialState.XsrfToken;
```

The `TokenProvider` service demonstrated in the topic is used in the `LoginDisplay` component in the following Layout and authentication flow changes section.

Enable authentication

In the `Startup` class:

- Confirm that Razor Pages services are added in `Startup.ConfigureServices`.
- If using the TokenProvider, register the service.
- Call `UseDatabaseErrorPage` on the application builder in `Startup.Configure` for the Development environment.
- Call `UseAuthentication` and `UseAuthorization` after `UseRouting`.
- Add an endpoint for Razor Pages.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();
    services.AddServerSideBlazor();
    services.AddSingleton<WeatherForecastService>();
    services.AddScoped<TokenProvider>();
}

public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
        endpoints.MapBlazorHub();
        endpoints.MapFallbackToPage("/_Host");
    });
}
```

`UseHsts` is recommended but not required. For more information, see HTTP Strict Transport Security Protocol.

Layout and authentication flow changes

Add a `RedirectToLogin` component (*RedirectToLogin.razor*) to the app's *Shared* folder in the project root:

```
@inject NavigationManager Navigation
@code {
    protected override void OnInitialized()
    {
        Navigation.NavigateTo("Identity/Account/Login?returnUrl=" +
            Uri.EscapeDataString(Navigation.Uri), true);
    }
}
```

Add a `LoginDisplay` component (*LoginDisplay.razor*) to the app's *Shared* folder. The TokenProvider service provides the XSRF token for the HTML form that POSTs to Identity's logout endpoint:

```
@using Microsoft.AspNetCore.Components.Authorization
@inject NavigationManager Navigation
@inject TokenProvider TokenProvider

<AuthorizeView>
    <Authorized>
        <a href="Identity/Account/Manage/Index">
            Hello, @context.User.Identity.Name!
        </a>
        <form action="/Identity/Account/Logout?returnUrl=%2F" method="post">
            <button class="nav-link btn btn-link" type="submit">Logout</button>
            <input name="__RequestVerificationToken" type="hidden"
                value="@TokenProvider.XsrfToken">
        </form>
    </Authorized>
    <NotAuthorized>
        <a href="Identity/Account/Register">Register</a>
        <a href="Identity/Account/Login">Login</a>
    </NotAuthorized>
</AuthorizeView>
```

In the `MainLayout` component (*Shared/MainLayout.razor*), add the `LoginDisplay` component to the top-row `<div>` element's content:

```
<div class="top-row px-4 auth">
    <LoginDisplay />
    <a href="https://docs.microsoft.com/aspnet/" target="_blank">About</a>
</div>
```

Style authentication endpoints

Because Blazor Server uses Razor Pages Identity pages, the styling of the UI changes when a visitor navigates between Identity pages and components. You have two options to address the incongruous styles:

Build Identity components

An approach to using components for Identity instead of pages is to build Identity components. Because `SignInManager` and `UserManager` aren't supported in Razor components, use API endpoints in the Blazor Server app to process user account actions.

Use a custom layout with Blazor app styles

The Identity pages layout and styles can be modified to produce pages that use the default Blazor theme.

> **NOTE**
>
> The example in this section is merely a starting point for customization. Additional work is likely required for the best user experience.

Create a new `NavMenu_IdentityLayout` component (*Shared/NavMenu_IdentityLayout.razor*). For the markup and code of the component, use the same content of the app's `NavMenu` component (*Shared/NavMenu.razor*). Strip out any `NavLink` s to components that can't be reached anonymously because automatic redirects in the `RedirectToLogin` component fail for components requiring authentication or authorization.

In the *Pages/Shared/Layout.cshtml* file, make the following changes:

- Add Razor directives to the top of the file to use Tag Helpers and the app's components in the *Shared* folder:

  ```
  @addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
  @using {APPLICATION ASSEMBLY}.Shared
  ```

  Replace `{APPLICATION ASSEMBLY}` with the app's assembly name.

- Add a `<base>` tag and Blazor stylesheet `<link>` to the `<head>` content:

  ```
  <base href="~/" />
  <link rel="stylesheet" href="~/css/site.css" />
  ```

- Change the content of the `<body>` tag to the following:

```
<div class="sidebar" style="float:left">
    <component type="typeof(NavMenu_IdentityLayout)"
        render-mode="ServerPrerendered" />
</div>

<div class="main" style="padding-left:250px">
    <div class="top-row px-4">
        @{
            var result = Engine.FindView(ViewContext, "_LoginPartial",
                isMainPage: false);
        }
        @if (result.Success)
        {
            await Html.RenderPartialAsync("_LoginPartial");
        }
        else
        {
            throw new InvalidOperationException("The default Identity UI " +
                "layout requires a partial view '_LoginPartial'.");
        }
        <a href="https://docs.microsoft.com/aspnet/" target="_blank">About</a>
    </div>

    <div class="content px-4">
        @RenderBody()
    </div>
</div>

<script src="~/Identity/lib/jquery/dist/jquery.min.js"></script>
<script src="~/Identity/lib/bootstrap/dist/js/bootstrap.bundle.min.js"></script>
<script src="~/Identity/js/site.js" asp-append-version="true"></script>
@RenderSection("Scripts", required: false)
<script src="_framework/blazor.server.js"></script>
```

Scaffold Identity into a Blazor Server project with authorization

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add Scaffold** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
  - Select your existing layout page so your layout file isn't overwritten with incorrect markup. When an existing *_Layout.cshtml* file is selected, it is **not** overwritten. For example:
    - `~/Pages/Shared/_Layout.cshtml` for Razor Pages or Blazor Server projects with existing Razor Pages infrastructure
    - `~/Views/Shared/_Layout.cshtml` for MVC projects or Blazor Server projects with existing MVC infrastructure
- To use your existing data context, select at least one file to override. You must select at least one file to add your data context.
  - Select your data context class.
  - Select **Add**.
- To create a new user context and possibly create a custom user class for Identity:
  - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
  - Select **Add**.

Note: If you're creating a new user context, you don't have to select a file to override.

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add Scaffold** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
  - Select your existing layout page, or your layout file will be overwritten with incorrect markup. When an existing *_Layout.cshtml* file is selected, it is **not** overwritten. For example:
    - `~/Pages/Shared/_Layout.cshtml` for Razor Pages
    - `~/Views/Shared/_Layout.cshtml` for MVC projects
- To use your existing data context, select at least one file to override. You must select at least one file to add your data context.
  - Select your data context class.
  - Select **Add**.
- To create a new user context and possibly create a custom user class for Identity:
  - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
  - Select **Add**.

Note: If you're creating a new user context, you don't have to select a file to override.

Some Identity options are configured in *Areas/Identity/IdentityHostingStartup.cs*. For more information, see IHostingStartup.

Create full Identity UI source

To maintain full control of the Identity UI, run the Identity scaffolder and select **Override all files**.

The following highlighted code shows the changes to replace the default Identity UI with Identity in an ASP.NET Core 2.1 web app. You might want to do this to have full control of the Identity UI.

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));

    services.AddIdentity<IdentityUser, IdentityRole>()
        // services.AddDefaultIdentity<IdentityUser>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultTokenProviders();

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1)
        .AddRazorPagesOptions(options =>
        {
            options.AllowAreas = true;
            options.Conventions.AuthorizeAreaFolder("Identity", "/Account/Manage");
            options.Conventions.AuthorizeAreaPage("Identity", "/Account/Logout");
        });

    services.ConfigureApplicationCookie(options =>
    {
        options.LoginPath = $"/Identity/Account/Login";
        options.LogoutPath = $"/Identity/Account/Logout";
        options.AccessDeniedPath = $"/Identity/Account/AccessDenied";
    });

    // using Microsoft.AspNetCore.Identity.UI.Services;
    services.AddSingleton<IEmailSender, EmailSender>();
}
```

The default Identity is replaced in the following code:

```
services.AddIdentity<IdentityUser, IdentityRole>()
    // services.AddDefaultIdentity<IdentityUser>()
    .AddEntityFrameworkStores<ApplicationDbContext>()
    .AddDefaultTokenProviders();
```

The following code sets the LoginPath, LogoutPath, and AccessDeniedPath:

```
services.ConfigureApplicationCookie(options =>
{
    options.LoginPath = $"/Identity/Account/Login";
    options.LogoutPath = $"/Identity/Account/Logout";
    options.AccessDeniedPath = $"/Identity/Account/AccessDenied";
});
```

Register an `IEmailSender` implementation, for example:

```
// using Microsoft.AspNetCore.Identity.UI.Services;
services.AddSingleton<IEmailSender, EmailSender>();
```

```
public class EmailSender : IEmailSender
{
    public Task SendEmailAsync(string email, string subject, string message)
    {
        return Task.CompletedTask;
    }
}
```

Password configuration

If PasswordOptions are configured in `Startup.ConfigureServices`, `[StringLength]` attribute configuration might be required for the `Password` property in scaffolded Identity pages. `InputModel` `Password` properties are found in the following files:

- `Areas/Identity/Pages/Account/Register.cshtml.cs`
- `Areas/Identity/Pages/Account/ResetPassword.cshtml.cs`

Disable a page

This sections show how to disable the register page but the approach can be used to disable any page.

To disable user registration:

- Scaffold Identity. Include Account.Register, Account.Login, and Account.RegisterConfirmation. For example:

  ```
  dotnet aspnet-codegenerator identity -dc RPauth.Data.ApplicationDbContext --files
  "Account.Register;Account.Login;Account.RegisterConfirmation"
  ```

- Update *Areas/Identity/Pages/Account/Register.cshtml.cs* so users can't register from this endpoint:

  ```
  public class RegisterModel : PageModel
  {
      public IActionResult OnGet()
      {
          return RedirectToPage("Login");
      }

      public IActionResult OnPost()
      {
          return RedirectToPage("Login");
      }
  }
  ```

- Update *Areas/Identity/Pages/Account/Register.cshtml* to be consistent with the preceding changes:

  ```
  @page
  @model RegisterModel
  @{
      ViewData["Title"] = "Go to Login";
  }

  <h1>@ViewData["Title"]</h1>

  <li class="nav-item">
      <a class="nav-link text-dark" asp-area="Identity" asp-page="/Account/Login">Login</a>
  </li>
  ```

- Comment out or remove the registration link from *Areas/Identity/Pages/Account/Login.cshtml*

```
@*
<p>
    <a asp-page="./Register" asp-route-returnUrl="@Model.ReturnUrl">Register as a new user</a>
</p>
*@
```

- Update the *Areas/Identity/Pages/Account/RegisterConfirmation* page.
  - Remove the code and links from the cshtml file.
  - Remove the confirmation code from the `PageModel`:

```
[AllowAnonymous]
  public class RegisterConfirmationModel : PageModel
  {
      public IActionResult OnGet()
      {
          return Page();
      }
  }
```

Use another app to add users

Provide a mechanism to add users outside the web app. Options to add users include:

- A dedicated admin web app.
- A console app.

The following code outlines one approach to adding users:

- A list of users is read into memory.
- A strong unique password is generated for each user.
- The user is added to the Identity database.
- The user is notified and told to change the password.

```
public class Program
{
    public static void Main(string[] args)
    {
        var host = CreateHostBuilder(args).Build();

        using (var scope = host.Services.CreateScope())
        {
            var services = scope.ServiceProvider;

            try
            {
                var context = services.GetRequiredService<AppDbCntx>();
                context.Database.Migrate();

                var config = host.Services.GetRequiredService<IConfiguration>();
                var userList = config.GetSection("userList").Get<List<string>>();

                SeedData.Initialize(services, userList).Wait();
            }
            catch (Exception ex)
            {
                var logger = services.GetRequiredService<ILogger<Program>>();
                logger.LogError(ex, "An error occurred adding users.");
            }
        }

        host.Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The following code outlines adding a user:

```
public static async Task Initialize(IServiceProvider serviceProvider,
                                    List<string> userList)
{
    var userManager = serviceProvider.GetService<UserManager<IdentityUser>>();

    foreach (var userName in userList)
    {
        var userPassword = GenerateSecurePassword();
        var userId = await EnsureUser(userManager, userName, userPassword);

        NotifyUser(userName, userPassword);
    }
}

private static async Task<string> EnsureUser(UserManager<IdentityUser> userManager,
                                             string userName, string userPassword)
{
    var user = await userManager.FindByNameAsync(userName);

    if (user == null)
    {
        user = new IdentityUser(userName)
        {
            EmailConfirmed = true
        };
        await userManager.CreateAsync(user, userPassword);
    }

    return user.Id;
}
```

A similar approach can be followed for production scenarios.

Prevent publish of static Identity assets

To prevent publishing static Identity assets to the web root, see Introduction to Identity on ASP.NET Core.

Additional resources

- Changes to authentication code to ASP.NET Core 2.1 and later

ASP.NET Core 2.1 and later provides ASP.NET Core Identity as a Razor Class Library. Applications that include Identity can apply the scaffolder to selectively add the source code contained in the Identity Razor Class Library (RCL). You might want to generate source code so you can modify the code and change the behavior. For example, you could instruct the scaffolder to generate the code used in registration. Generated code takes precedence over the same code in the Identity RCL. To gain full control of the UI and not use the default RCL, see the section Create full identity UI source.

Applications that do **not** include authentication can apply the scaffolder to add the RCL Identity package. You have the option of selecting Identity code to be generated.

Although the scaffolder generates most of the necessary code, you'll have to update your project to complete the process. This document explains the steps needed to complete an Identity scaffolding update.

When the Identity scaffolder is run, a *ScaffoldingReadme.txt* file is created in the project directory. The *ScaffoldingReadme.txt* file contains general instructions on what's needed to complete the Identity scaffolding update. This document contains more complete instructions than the *ScaffoldingReadme.txt* file.

We recommend using a source control system that shows file differences and allows you to back out of changes. Inspect the changes after running the Identity scaffolder.

> **NOTE**
>
> Services are required when using Two Factor Authentication, Account confirmation and password recovery, and other security features with Identity. Services or service stubs aren't generated when scaffolding Identity. Services to enable these features must be added manually. For example, see Require Email Confirmation.

Scaffold Identity into an empty project

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add New Scaffolded Item** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
  - Select your existing layout page, or your layout file will be overwritten with incorrect markup:
    - `~/Pages/Shared/_Layout.cshtml` for Razor Pages
    - `~/Views/Shared/_Layout.cshtml` for MVC projects
    - Blazor Server apps created from the Blazor Server template (`blazorserver`) aren't configured for Razor Pages or MVC by default. Leave the layout page entry blank.
  - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
- Select **Add**.

Add the following highlighted calls to the `Startup` class:

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddMvc();
    }

    // This method gets called by the runtime. Use this method to configure the HTTP request pipeline.
    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseAuthentication();
        app.UseMvc();
    }
}
```

`UseHsts` is recommended but not required. For more information, see HTTP Strict Transport Security Protocol.

The generated Identity database code requires Entity Framework Core Migrations. Create a migration and update the database. For example, run the following commands:

- Visual Studio
- .NET Core CLI

In the Visual Studio **Package Manager Console**:

```
Install-Package Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore
Add-Migration CreateIdentitySchema
Update-Database
```

The "CreateIdentitySchema" name parameter for the `Add-Migration` command is arbitrary. `"CreateIdentitySchema"` describes the migration.

Scaffold Identity into a Razor project without existing authorization

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add New Scaffolded Item** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
  - Select your existing layout page, or your layout file will be overwritten with incorrect markup:
    - `~/Pages/Shared/_Layout.cshtml` for Razor Pages
    - `~/Views/Shared/_Layout.cshtml` for MVC projects
    - Blazor Server apps created from the Blazor Server template (`blazorserver`) aren't configured for Razor Pages or MVC by default. Leave the layout page entry blank.
  - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
- Select **Add**.

Identity is configured in *Areas/Identity/IdentityHostingStartup.cs*. For more information, see IHostingStartup.

Migrations, UseAuthentication, and layout

The generated Identity database code requires Entity Framework Core Migrations. Create a migration and update the database. For example, run the following commands:

- Visual Studio
- .NET Core CLI

In the Visual Studio **Package Manager Console**:

```
Install-Package Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore
Add-Migration CreateIdentitySchema
Update-Database
```

The "CreateIdentitySchema" name parameter for the `Add-Migration` command is arbitrary. `"CreateIdentitySchema"` describes the migration.

Enable authentication

In the `Configure` method of the `Startup` class, call UseAuthentication after `UseStaticFiles`:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddMvc();
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseAuthentication();

        app.UseMvc();
    }
}
```

`UseHsts` is recommended but not required. For more information, see HTTP Strict Transport Security Protocol.

Layout changes

Optional: Add the login partial (`_LoginPartial`) to the layout file:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - RazorNoAuth8</title>

    <environment include="Development">
        <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
        <link rel="stylesheet" href="~/css/site.css" />
    </environment>
    <environment exclude="Development">
        <link rel="stylesheet" href="https://ajax.aspnetcdn.com/ajax/bootstrap/3.3.7/css/bootstrap.min.css"
              asp-fallback-href="~/lib/bootstrap/dist/css/bootstrap.min.css"
              asp-fallback-test-class="sr-only" asp-fallback-test-property="position" asp-fallback-test-
value="absolute" />
        <link rel="stylesheet" href="~/css/site.min.css" asp-append-version="true" />
    </environment>
</head>
<body>
    <nav class="navbar navbar-inverse navbar-fixed-top">
        <div class="container">
            <div class="navbar-header">
                <button type="button" class="navbar-toggle" data-toggle="collapse" data-target=".navbar-
collapse">
                    <span class="sr-only">Toggle navigation</span>
```

```
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                </button>
                <a asp-page="/Index" class="navbar-brand">RazorNoAuth8</a>
            </div>
            <div class="navbar-collapse collapse">
                <ul class="nav navbar-nav">
                    <li><a asp-page="/Index">Home</a></li>
                    <li><a asp-page="/About">About</a></li>
                    <li><a asp-page="/Contact">Contact</a></li>
                </ul>
                <partial name="_LoginPartial" />
            </div>
        </div>
    </nav>

    <partial name="_CookieConsentPartial" />

    <div class="container body-content">
        @RenderBody()
        <hr />
        <footer>

    </environment>

    @RenderSection("Scripts", required: false)
</body>
</html>
```

Scaffold Identity into a Razor project with authorization

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add Scaffold** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
  - Select your existing layout page so your layout file isn't overwritten with incorrect markup. When an existing *_Layout.cshtml* file is selected, it is **not** overwritten. For example:

    - `~/Pages/Shared/_Layout.cshtml` for Razor Pages or Blazor Server projects with existing Razor Pages infrastructure
    - `~/Views/Shared/_Layout.cshtml` for MVC projects or Blazor Server projects with existing MVC infrastructure
- To use your existing data context, select at least one file to override. You must select at least one file to add your data context.
    - Select your data context class.
    - Select **Add**.
- To create a new user context and possibly create a custom user class for Identity:
    - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
    - Select **Add**.

Note: If you're creating a new user context, you don't have to select a file to override.

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add Scaffold** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
    - Select your existing layout page, or your layout file will be overwritten with incorrect markup. When an existing *_Layout.cshtml* file is selected, it is **not** overwritten. For example:
        - `~/Pages/Shared/_Layout.cshtml` for Razor Pages
        - `~/Views/Shared/_Layout.cshtml` for MVC projects
- To use your existing data context, select at least one file to override. You must select at least one file to add your data context.
    - Select your data context class.
    - Select **Add**.
- To create a new user context and possibly create a custom user class for Identity:
    - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
    - Select **Add**.

Note: If you're creating a new user context, you don't have to select a file to override.

Some Identity options are configured in *Areas/Identity/IdentityHostingStartup.cs*. For more information, see IHostingStartup.

Scaffold Identity into an MVC project without existing authorization

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add New Scaffolded Item** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
    - Select your existing layout page, or your layout file will be overwritten with incorrect markup:

    - `~/Pages/Shared/_Layout.cshtml` for Razor Pages
    - `~/Views/Shared/_Layout.cshtml` for MVC projects
    - Blazor Server apps created from the Blazor Server template (`blazorserver`) aren't configured for Razor Pages or MVC by default. Leave the layout page entry blank.
  - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
- Select **Add**.

Optional: Add the login partial (`_LoginPartial`) to the *Views/Shared/_Layout.cshtml* file:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - MvcNoAuth3</title>

    <environment include="Development">
        <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
        <link rel="stylesheet" href="~/css/site.css" />
    </environment>
    <environment exclude="Development">
        <link rel="stylesheet" href="https://ajax.aspnetcdn.com/ajax/bootstrap/3.3.7/css/bootstrap.min.css"
              asp-fallback-href="~/lib/bootstrap/dist/css/bootstrap.min.css"
              asp-fallback-test-class="sr-only" asp-fallback-test-property="position" asp-fallback-test-
value="absolute" />
        <link rel="stylesheet" href="~/css/site.min.css" asp-append-version="true" />
    </environment>
</head>
<body>
    <nav class="navbar navbar-inverse navbar-fixed-top">
        <div class="container">
            <div class="navbar-header">
                <button type="button" class="navbar-toggle" data-toggle="collapse" data-target=".navbar-
collapse">
                    <span class="sr-only">Toggle navigation</span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                </button>
                <a asp-area="" asp-controller="Home" asp-action="Index" class="navbar-brand">MvcNoAuth3</a>
            </div>
            <div class="navbar-collapse collapse">
                <ul class="nav navbar-nav">
                    <li><a asp-area="" asp-controller="Home" asp-action="Index">Home</a></li>
                    <li><a asp-area="" asp-controller="Home" asp-action="About">About</a></li>
                    <li><a asp-area="" asp-controller="Home" asp-action="Contact">Contact</a></li>
                </ul>
                <partial name="_LoginPartial" />
            </div>
        </div>
    </nav>

    <partial name="_CookieConsentPartial" />

    <div class="container body-content">
        @RenderBody()
        <hr />
        <footer>
            <p>&copy; 2018 - MvcNoAuth3</p>
        </footer>
    </div>

    <environment include="Development">
        <script src="~/lib/jquery/dist/jquery.js"></script>
```

```
        <script src="~/lib/bootstrap/dist/js/bootstrap.js"></script>
        <script src="~/js/site.js" asp-append-version="true"></script>
    </environment>
    <environment exclude="Development">
        <script src="https://ajax.aspnetcdn.com/ajax/jquery/jquery-3.3.1.min.js"
                asp-fallback-src="~/lib/jquery/dist/jquery.min.js"
                asp-fallback-test="window.jQuery"
                crossorigin="anonymous"
                integrity="sha384-K+ctZQ+LL8q6tP7I94W+qzQsfRV2a+AfHIi9k8z8l9ggpc8X+Ytst4yBo/hH+8Fk">
        </script>
        <script src="https://ajax.aspnetcdn.com/ajax/bootstrap/3.3.7/bootstrap.min.js"
                asp-fallback-src="~/lib/bootstrap/dist/js/bootstrap.min.js"
                asp-fallback-test="window.jQuery && window.jQuery.fn && window.jQuery.fn.modal"
                crossorigin="anonymous"
                integrity="sha384-Tc5IQib027qvyjSMfHjOMaLkfuWVxZxUPnCJA7l2mCWNIpG9mGCD8wGNIcPD7Txa">
        </script>
        <script src="~/js/site.min.js" asp-append-version="true"></script>
    </environment>

    @RenderSection("Scripts", required: false)
</body>
</html>
```

- Move the *Pages/Shared/_LoginPartial.cshtml* file to *Views/Shared/_LoginPartial.cshtml*

Identity is configured in *Areas/Identity/IdentityHostingStartup.cs*. For more information, see IHostingStartup.

The generated Identity database code requires Entity Framework Core Migrations. Create a migration and update the database. For example, run the following commands:

- Visual Studio
- .NET Core CLI

In the Visual Studio **Package Manager Console**:

```
Install-Package Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore
Add-Migration CreateIdentitySchema
Update-Database
```

The "CreateIdentitySchema" name parameter for the `Add-Migration` command is arbitrary. `"CreateIdentitySchema"` describes the migration.

Call UseAuthentication after `UseStaticFiles`:

```
public class Startup
{

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddMvc();
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Home/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseAuthentication();
        app.UseMvcWithDefaultRoute();
    }
}
```

`UseHsts` is recommended but not required. For more information, see HTTP Strict Transport Security Protocol.

Scaffold Identity into an MVC project with authorization

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add Scaffold** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
  - Select your existing layout page so your layout file isn't overwritten with incorrect markup. When an existing *_Layout.cshtml* file is selected, it is **not** overwritten. For example:
    - `~/Pages/Shared/_Layout.cshtml` for Razor Pages or Blazor Server projects with existing Razor Pages infrastructure
    - `~/Views/Shared/_Layout.cshtml` for MVC projects or Blazor Server projects with existing MVC infrastructure
- To use your existing data context, select at least one file to override. You must select at least one file to add your data context.
  - Select your data context class.
  - Select **Add**.
- To create a new user context and possibly create a custom user class for Identity:
  - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
  - Select **Add**.

Note: If you're creating a new user context, you don't have to select a file to override.

Run the Identity scaffolder:

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add Scaffold** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, select the options you want.
  - Select your existing layout page, or your layout file will be overwritten with incorrect markup. When an existing *_Layout.cshtml* file is selected, it is **not** overwritten. For example:
    - `~/Pages/Shared/_Layout.cshtml` for Razor Pages
    - `~/Views/Shared/_Layout.cshtml` for MVC projects
- To use your existing data context, select at least one file to override. You must select at least one file to add your data context.
  - Select your data context class.
  - Select **Add**.
- To create a new user context and possibly create a custom user class for Identity:
  - Select the **+** button to create a new **Data context class**. Accept the default value or specify a class (for example, `MyApplication.Data.ApplicationDbContext`).
  - Select **Add**.

Note: If you're creating a new user context, you don't have to select a file to override.

Delete the *Pages/Shared* folder and the files in that folder.

Create full Identity UI source

To maintain full control of the Identity UI, run the Identity scaffolder and select **Override all files**.

The following highlighted code shows the changes to replace the default Identity UI with Identity in an ASP.NET Core 2.1 web app. You might want to do this to have full control of the Identity UI.

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));

    services.AddIdentity<IdentityUser, IdentityRole>()
        // services.AddDefaultIdentity<IdentityUser>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultTokenProviders();

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1)
        .AddRazorPagesOptions(options =>
        {
            options.AllowAreas = true;
            options.Conventions.AuthorizeAreaFolder("Identity", "/Account/Manage");
            options.Conventions.AuthorizeAreaPage("Identity", "/Account/Logout");
        });

    services.ConfigureApplicationCookie(options =>
    {
        options.LoginPath = $"/Identity/Account/Login";
        options.LogoutPath = $"/Identity/Account/Logout";
        options.AccessDeniedPath = $"/Identity/Account/AccessDenied";
    });

    // using Microsoft.AspNetCore.Identity.UI.Services;
    services.AddSingleton<IEmailSender, EmailSender>();
}
```

The default Identity is replaced in the following code:

```
services.AddIdentity<IdentityUser, IdentityRole>()
    // services.AddDefaultIdentity<IdentityUser>()
    .AddEntityFrameworkStores<ApplicationDbContext>()
    .AddDefaultTokenProviders();
```

The following code sets the LoginPath, LogoutPath, and AccessDeniedPath:

```
services.ConfigureApplicationCookie(options =>
{
    options.LoginPath = $"/Identity/Account/Login";
    options.LogoutPath = $"/Identity/Account/Logout";
    options.AccessDeniedPath = $"/Identity/Account/AccessDenied";
});
```

Register an `IEmailSender` implementation, for example:

```
// using Microsoft.AspNetCore.Identity.UI.Services;
services.AddSingleton<IEmailSender, EmailSender>();
```

```
public class EmailSender : IEmailSender
{
    public Task SendEmailAsync(string email, string subject, string message)
    {
        return Task.CompletedTask;
    }
}
```

Password configuration

If PasswordOptions are configured in `Startup.ConfigureServices`, `[StringLength]` attribute configuration might be required for the `Password` property in scaffolded Identity pages. `InputModel` `Password` properties are found in the following files:

- `Areas/Identity/Pages/Account/Register.cshtml.cs`
- `Areas/Identity/Pages/Account/ResetPassword.cshtml.cs`

Disable register page

To disable user registration:

- Scaffold Identity. Include Account.Register, Account.Login, and Account.RegisterConfirmation. For example:

```
dotnet aspnet-codegenerator identity -dc RPauth.Data.ApplicationDbContext --files
"Account.Register;Account.Login;Account.RegisterConfirmation"
```

- Update *Areas/Identity/Pages/Account/Register.cshtml.cs* so users can't register from this endpoint:

```
public class RegisterModel : PageModel
{
    public IActionResult OnGet()
    {
        return RedirectToPage("Login");
    }

    public IActionResult OnPost()
    {
        return RedirectToPage("Login");
    }
}
```

- Update *Areas/Identity/Pages/Account/Register.cshtml* to be consistent with the preceding changes:

```
@page
@model RegisterModel
@{
    ViewData["Title"] = "Go to Login";
}

<h1>@ViewData["Title"]</h1>

<li class="nav-item">
    <a class="nav-link text-dark" asp-area="Identity" asp-page="/Account/Login">Login</a>
</li>
```

- Comment out or remove the registration link from *Areas/Identity/Pages/Account/Login.cshtml*

```
@*
<p>
    <a asp-page="./Register" asp-route-returnUrl="@Model.ReturnUrl">Register as a new user</a>
</p>
*@
```

- Update the *Areas/Identity/Pages/Account/RegisterConfirmation* page.
  - Remove the code and links from the cshtml file.
  - Remove the confirmation code from the `PageModel`:

```
[AllowAnonymous]
  public class RegisterConfirmationModel : PageModel
  {
      public IActionResult OnGet()
      {
          return Page();
      }
  }
```

Use another app to add users

Provide a mechanism to add users outside the web app. Options to add users include:

- A dedicated admin web app.
- A console app.

The following code outlines one approach to adding users:

- A list of users is read into memory.
- A strong unique password is generated for each user.
- The user is added to the Identity database.
- The user is notified and told to change the password.

```
public class Program
{
    public static void Main(string[] args)
    {
        var host = CreateHostBuilder(args).Build();

        using (var scope = host.Services.CreateScope())
        {
            var services = scope.ServiceProvider;

            try
            {
                var context = services.GetRequiredService<AppDbCntx>();
                context.Database.Migrate();

                var config = host.Services.GetRequiredService<IConfiguration>();
                var userList = config.GetSection("userList").Get<List<string>>();

                SeedData.Initialize(services, userList).Wait();
            }
            catch (Exception ex)
            {
                var logger = services.GetRequiredService<ILogger<Program>>();
                logger.LogError(ex, "An error occurred adding users.");
            }
        }

        host.Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The following code outlines adding a user:

```
public static async Task Initialize(IServiceProvider serviceProvider,
                                    List<string> userList)
{
    var userManager = serviceProvider.GetService<UserManager<IdentityUser>>();

    foreach (var userName in userList)
    {
        var userPassword = GenerateSecurePassword();
        var userId = await EnsureUser(userManager, userName, userPassword);

        NotifyUser(userName, userPassword);
    }
}

private static async Task<string> EnsureUser(UserManager<IdentityUser> userManager,
                                             string userName, string userPassword)
{
    var user = await userManager.FindByNameAsync(userName);

    if (user == null)
    {
        user = new IdentityUser(userName)
        {
            EmailConfirmed = true
        };
        await userManager.CreateAsync(user, userPassword);
    }

    return user.Id;
}
```

A similar approach can be followed for production scenarios.

Add, download, and delete custom user data to Identity in an ASP.NET Core project

9/22/2020 • 13 minutes to read • Edit Online

By Rick Anderson

This article shows how to:

- Add custom user data to an ASP.NET Core web app.
- Mark the custom user data model with the PersonalDataAttribute attribute so it's automatically available for download and deletion. Making the data able to be downloaded and deleted helps meet GDPR requirements.

The project sample is created from a Razor Pages web app, but the instructions are similar for a ASP.NET Core MVC web app.

View or download sample code (how to download)

Prerequisites

.NET Core 3.0 SDK or later

.NET Core 2.2 SDK or later

Create a Razor web app

- Visual Studio
- .NET Core CLI

- From the Visual Studio **File** menu, select **New** > **Project**. Name the project **WebApp1** if you want to it match the namespace of the download sample code.
- Select **ASP.NET Core Web Application** > **OK**
- Select **ASP.NET Core 3.0** in the dropdown
- Select **Web Application** > **OK**
- Build and run the project.

- From the Visual Studio **File** menu, select **New** > **Project**. Name the project **WebApp1** if you want to it match the namespace of the download sample code.
- Select **ASP.NET Core Web Application** > **OK**
- Select **ASP.NET Core 2.2** in the dropdown
- Select **Web Application** > **OK**
- Build and run the project.

Run the Identity scaffolder

- Visual Studio
- .NET Core CLI

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add Scaffold** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, the following options:

    - Select the existing layout file *~/Pages/Shared/_Layout.cshtml*
    - Select the following files to override:
        - **Account/Register**
        - **Account/Manage/Index**
    - Select the **+** button to create a new **Data context class**. Accept the type (**WebApp1.Models.WebApp1Context** if the project is named **WebApp1**).
    - Select the **+** button to create a new **User class**. Accept the type (**WebApp1User** if the project is named **WebApp1**) > **Add**.
- Select **Add**.

Follow the instruction in Migrations, UseAuthentication, and layout to perform the following steps:

- Create a migration and update the database.
- Add `UseAuthentication` to `Startup.Configure`.
- Add `<partial name="_LoginPartial" />` to the layout file.
- Test the app:
    - Register a user
    - Select the new user name (next to the **Logout** link). You might need to expand the window or select the navigation bar icon to show the user name and other links.
    - Select the **Personal Data** tab.
    - Select the **Download** button and examined the *PersonalData.json* file.
    - Test the **Delete** button, which deletes the logged on user.

Add custom user data to the Identity DB

Update the `IdentityUser` derived class with custom properties. If you named the project WebApp1, the file is named *Areas/Identity/Data/WebApp1User.cs*. Update the file with the following code:

```
using System;
using Microsoft.AspNetCore.Identity;

namespace WebApp1.Areas.Identity.Data
{
    public class WebApp1User : IdentityUser
    {
        [PersonalData]
        public string Name { get; set; }
        [PersonalData]
        public DateTime DOB { get; set; }
    }
}
```

```
using Microsoft.AspNetCore.Identity;
using System;

namespace WebApp1.Areas.Identity.Data
{
    public class WebApp1User : IdentityUser
    {
        [PersonalData]
        public string Name { get; set; }
        [PersonalData]
        public DateTime DOB { get; set; }
    }
}
```

Properties with the PersonalData attribute are:

- Deleted when the *Areas/Identity/Pages/Account/Manage/DeletePersonalData.cshtml* Razor Page calls `UserManager.Delete`.
- Included in the downloaded data by the *Areas/Identity/Pages/Account/Manage/DownloadPersonalData.cshtml* Razor Page.

Update the Account/Manage/Index.cshtml page

Update the `InputModel` in *Areas/Identity/Pages/Account/Manage/Index.cshtml.cs* with the following highlighted code:

```
public partial class IndexModel : PageModel
{
    private readonly UserManager<WebApp1User> _userManager;
    private readonly SignInManager<WebApp1User> _signInManager;

    public IndexModel(
        UserManager<WebApp1User> userManager,
        SignInManager<WebApp1User> signInManager)
    {
        _userManager = userManager;
        _signInManager = signInManager;
    }

    public string Username { get; set; }

    [TempData]
    public string StatusMessage { get; set; }

    [BindProperty]
    public InputModel Input { get; set; }

    public class InputModel
    {
        [Required]
        [DataType(DataType.Text)]
        [Display(Name = "Full name")]
        public string Name { get; set; }

        [Required]
        [Display(Name = "Birth Date")]
        [DataType(DataType.Date)]
        public DateTime DOB { get; set; }

        [Phone]
        [Display(Name = "Phone number")]
        public string PhoneNumber { get; set; }
    }

    private async Task LoadAsync(WebApp1User user)
    {
        var userName = await _userManager.GetUserNameAsync(user);
        var phoneNumber = await _userManager.GetPhoneNumberAsync(user);

        Username = userName;

        Input = new InputModel
        {
            Name = user.Name,
            DOB = user.DOB,
            PhoneNumber = phoneNumber
        };
    }

    public async Task<IActionResult> OnGetAsync()
    {
```

```
    {
        var user = await _userManager.GetUserAsync(User);
        if (user == null)
        {
            return NotFound(
                $"Unable to load user with ID '{_userManager.GetUserId(User)}'.");
        }

        await LoadAsync(user);
        return Page();
    }

    public async Task<IActionResult> OnPostAsync()
    {
        var user = await _userManager.GetUserAsync(User);
        if (user == null)
        {
            return NotFound(
                $"Unable to load user with ID '{_userManager.GetUserId(User)}'.");
        }

        if (!ModelState.IsValid)
        {
            await LoadAsync(user);
            return Page();
        }

        var phoneNumber = await _userManager.GetPhoneNumberAsync(user);
        if (Input.PhoneNumber != phoneNumber)
        {
            var setPhoneResult = await _userManager.SetPhoneNumberAsync(user,
                Input.PhoneNumber);

            if (!setPhoneResult.Succeeded)
            {
                var userId = await _userManager.GetUserIdAsync(user);
                throw new InvalidOperationException(
                    $"Unexpected error occurred setting phone number for user with ID '{userId}'.");
            }
        }

        if (Input.Name != user.Name)
        {
            user.Name = Input.Name;
        }

        if (Input.DOB != user.DOB)
        {
            user.DOB = Input.DOB;
        }

        await _userManager.UpdateAsync(user);

        await _signInManager.RefreshSignInAsync(user);
        StatusMessage = "Your profile has been updated";
        return RedirectToPage();
    }
}
```

Update the *Areas/Identity/Pages/Account/Manage/Index.cshtml* with the following highlighted markup:

```
@page
@model IndexModel
@{
    ViewData["Title"] = "Profile";
    ViewData["ActivePage"] = ManageNavPages.Index;
}

<h4>@ViewData["Title"]</h4>
<partial name="_StatusMessage" model="Model.StatusMessage" />
<div class="row">
    <div class="col-md-6">
        <form id="profile-form" method="post">
            <div asp-validation-summary="All" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Username"></label>
                <input asp-for="Username" class="form-control" disabled />
            </div>
            <div class="form-group">
                <label asp-for="Input.Name"></label>
                <input asp-for="Input.Name" class="form-control" />
            </div>
            <div class="form-group">
                <label asp-for="Input.DOB"></label>
                <input asp-for="Input.DOB" class="form-control" />
            </div>
            <div class="form-group">
                <label asp-for="Input.PhoneNumber"></label>
                <input asp-for="Input.PhoneNumber" class="form-control" />
                <span asp-validation-for="Input.PhoneNumber"
                    class="text-danger"></span>
            </div>
            <button id="update-profile-button" type="submit"
                class="btn btn-primary">Save</button>
        </form>
    </div>
</div>

@section Scripts {
    <partial name="_ValidationScriptsPartial" />
}
```

@section Scripts {
    <partial name="_ValidationScriptsPartial" />
}
```

Build the project.

Add a migration for the custom user data

- Visual Studio
- .NET Core CLI

In the Visual Studio **Package Manager Console**:

```
Add-Migration CustomUserData
Update-Database
```

Test create, view, download, delete custom user data

Test the app:

- Register a new user.
- View the custom user data on the `/Identity/Account/Manage` page.
- Download and view the users personal data from the `/Identity/Account/Manage/PersonalData` page.

Add claims to Identity using IUserClaimsPrincipalFactory

> **NOTE**
>
> This section isn't an extension of the previous tutorial. To apply the following steps to the app built using the tutorial, see this GitHub issue.

Additional claims can be added to ASP.NET Core Identity by using the `IUserClaimsPrincipalFactory<T>` interface. This class can be added to the app in the `Startup.ConfigureServices` method. Add the custom implementation of the class as follows:

```
public void ConfigureServices(IServiceCollection services)
{
 services.AddIdentity<ApplicationUser, IdentityRole>()
  .AddEntityFrameworkStores<ApplicationDbContext>()
  .AddDefaultTokenProviders();

 services.AddScoped<IUserClaimsPrincipalFactory<ApplicationUser>,
  AdditionalUserClaimsPrincipalFactory>();
```

The demo code uses the `ApplicationUser` class. This class adds an `IsAdmin` property which is used to add the additional claim.

```
public class ApplicationUser : IdentityUser
{
 public bool IsAdmin { get; set; }
}
```

The `AdditionalUserClaimsPrincipalFactory` implements the `UserClaimsPrincipalFactory` interface. A new role claim is added to the `ClaimsPrincipal`.

```
public class AdditionalUserClaimsPrincipalFactory
  : UserClaimsPrincipalFactory<ApplicationUser, IdentityRole>
{
 public AdditionalUserClaimsPrincipalFactory(
  UserManager<ApplicationUser> userManager,
  RoleManager<IdentityRole> roleManager,
  IOptions<IdentityOptions> optionsAccessor)
  : base(userManager, roleManager, optionsAccessor)
 {}

 public async override Task<ClaimsPrincipal> CreateAsync(ApplicationUser user)
 {
  var principal = await base.CreateAsync(user);
  var identity = (ClaimsIdentity)principal.Identity;

  var claims = new List<Claim>();
  if (user.IsAdmin)
  {
   claims.Add(new Claim(JwtClaimTypes.Role, "admin"));
  }
  else
  {
   claims.Add(new Claim(JwtClaimTypes.Role, "user"));
  }

  identity.AddClaims(claims);
  return principal;
 }
}
```

The additional claim can then be used in the app. In a Razor Page, the `IAuthorizationService` instance can be used to access the claim value.

```
@using Microsoft.AspNetCore.Authorization
@inject IAuthorizationService AuthorizationService

@if ((await AuthorizationService.AuthorizeAsync(User, "IsAdmin")).Succeeded)
{
 <ul class="mr-auto navbar-nav">
  <li class="nav-item">
   <a class="nav-link" asp-controller="Admin" asp-action="Index">ADMIN</a>
  </li>
 </ul>
}
```

Authentication samples for ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

By Rick Anderson

The ASP.NET Core repository contains the following authentication samples in the *AspNetCore/src/Security/samples* folder:

- Claims transformation
- Cookie authentication
- Custom policy provider - IAuthorizationPolicyProvider
- Dynamic authentication schemes and options
- External claims
- Selecting between cookie and another authentication scheme based on the request
- Restricts access to static files

Run the samples

- Select a branch. For example, `release/3.1`
- Clone or download the ASP.NET Core repository.
- Verify you have installed the .NET Core SDK version matching the clone of the ASP.NET Core repository.
- Navigate to a sample in *AspNetCore/src/Security/samples* and run the sample with `dotnet run`.

Identity model customization in ASP.NET Core

9/22/2020 • 19 minutes to read • Edit Online

By Arthur Vickers

ASP.NET Core Identity provides a framework for managing and storing user accounts in ASP.NET Core apps. Identity is added to your project when **Individual User Accounts** is selected as the authentication mechanism. By default, Identity makes use of an Entity Framework (EF) Core data model. This article describes how to customize the Identity model.

Identity and EF Core Migrations

Before examining the model, it's useful to understand how Identity works with EF Core Migrations to create and update a database. At the top level, the process is:

1. Define or update a data model in code.
2. Add a Migration to translate this model into changes that can be applied to the database.
3. Check that the Migration correctly represents your intentions.
4. Apply the Migration to update the database to be in sync with the model.
5. Repeat steps 1 through 4 to further refine the model and keep the database in sync.

Use one of the following approaches to add and apply Migrations:

- The **Package Manager Console** (PMC) window if using Visual Studio. For more information, see EF Core PMC tools.
- The .NET Core CLI if using the command line. For more information, see EF Core .NET command line tools.
- Clicking the **Apply Migrations** button on the error page when the app is run.

ASP.NET Core has a development-time error page handler. The handler can apply migrations when the app is run. Production apps typically generate SQL scripts from the migrations and deploy database changes as part of a controlled app and database deployment.

When a new app using Identity is created, steps 1 and 2 above have already been completed. That is, the initial data model already exists, and the initial migration has been added to the project. The initial migration still needs to be applied to the database. The initial migration can be applied via one of the following approaches:

- Run `Update-Database` in PMC.
- Run `dotnet ef database update` in a command shell.
- Click the **Apply Migrations** button on the error page when the app is run.

Repeat the preceding steps as changes are made to the model.

The Identity model

Entity types

The Identity model consists of the following entity types.

ENTITY TYPE	DESCRIPTION
`User`	Represents the user.

ENTITY TYPE	DESCRIPTION
`Role`	Represents a role.
`UserClaim`	Represents a claim that a user possesses.
`UserToken`	Represents an authentication token for a user.
`UserLogin`	Associates a user with a login.
`RoleClaim`	Represents a claim that's granted to all users within a role.
`UserRole`	A join entity that associates users and roles.

Entity type relationships

The entity types are related to each other in the following ways:

- Each `User` can have many `UserClaims`.
- Each `User` can have many `UserLogins`.
- Each `User` can have many `UserTokens`.
- Each `Role` can have many associated `RoleClaims`.
- Each `User` can have many associated `Roles`, and each `Role` can be associated with many `Users`. This is a many-to-many relationship that requires a join table in the database. The join table is represented by the `UserRole` entity.

Default model configuration

Identity defines many *context classes* that inherit from DbContext to configure and use the model. This configuration is done using the EF Core Code First Fluent API in the OnModelCreating method of the context class. The default configuration is:

```
builder.Entity<TUser>(b =>
{
    // Primary key
    b.HasKey(u => u.Id);

    // Indexes for "normalized" username and email, to allow efficient lookups
    b.HasIndex(u => u.NormalizedUserName).HasName("UserNameIndex").IsUnique();
    b.HasIndex(u => u.NormalizedEmail).HasName("EmailIndex");

    // Maps to the AspNetUsers table
    b.ToTable("AspNetUsers");

    // A concurrency token for use with the optimistic concurrency checking
    b.Property(u => u.ConcurrencyStamp).IsConcurrencyToken();

    // Limit the size of columns to use efficient database types
    b.Property(u => u.UserName).HasMaxLength(256);
    b.Property(u => u.NormalizedUserName).HasMaxLength(256);
    b.Property(u => u.Email).HasMaxLength(256);
    b.Property(u => u.NormalizedEmail).HasMaxLength(256);

    // The relationships between User and other entity types
    // Note that these relationships are configured with no navigation properties

    // Each User can have many UserClaims
    b.HasMany<TUserClaim>().WithOne().HasForeignKey(uc => uc.UserId).IsRequired();

    // Each User can have many UserLogins
```

```
    b.HasMany<TUserLogin>().WithOne().HasForeignKey(ul => ul.UserId).IsRequired();

    // Each User can have many UserTokens
    b.HasMany<TUserToken>().WithOne().HasForeignKey(ut => ut.UserId).IsRequired();

    // Each User can have many entries in the UserRole join table
    b.HasMany<TUserRole>().WithOne().HasForeignKey(ur => ur.UserId).IsRequired();
});

builder.Entity<TUserClaim>(b =>
{
    // Primary key
    b.HasKey(uc => uc.Id);

    // Maps to the AspNetUserClaims table
    b.ToTable("AspNetUserClaims");
});

builder.Entity<TUserLogin>(b =>
{
    // Composite primary key consisting of the LoginProvider and the key to use
    // with that provider
    b.HasKey(l => new { l.LoginProvider, l.ProviderKey });

    // Limit the size of the composite key columns due to common DB restrictions
    b.Property(l => l.LoginProvider).HasMaxLength(128);
    b.Property(l => l.ProviderKey).HasMaxLength(128);

    // Maps to the AspNetUserLogins table
    b.ToTable("AspNetUserLogins");
});

builder.Entity<TUserToken>(b =>
{
    // Composite primary key consisting of the UserId, LoginProvider and Name
    b.HasKey(t => new { t.UserId, t.LoginProvider, t.Name });

    // Limit the size of the composite key columns due to common DB restrictions
    b.Property(t => t.LoginProvider).HasMaxLength(maxKeyLength);
    b.Property(t => t.Name).HasMaxLength(maxKeyLength);

    // Maps to the AspNetUserTokens table
    b.ToTable("AspNetUserTokens");
});

builder.Entity<TRole>(b =>
{
    // Primary key
    b.HasKey(r => r.Id);

    // Index for "normalized" role name to allow efficient lookups
    b.HasIndex(r => r.NormalizedName).HasName("RoleNameIndex").IsUnique();

    // Maps to the AspNetRoles table
    b.ToTable("AspNetRoles");

    // A concurrency token for use with the optimistic concurrency checking
    b.Property(r => r.ConcurrencyStamp).IsConcurrencyToken();

    // Limit the size of columns to use efficient database types
    b.Property(u => u.Name).HasMaxLength(256);
    b.Property(u => u.NormalizedName).HasMaxLength(256);

    // The relationships between Role and other entity types
    // Note that these relationships are configured with no navigation properties

    // Each Role can have many entries in the UserRole join table
    b.HasMany<TUserRole>().WithOne().HasForeignKey(ur => ur.RoleId).IsRequired();
```

```
    // Each Role can have many associated RoleClaims
    b.HasMany<TRoleClaim>().WithOne().HasForeignKey(rc => rc.RoleId).IsRequired();
});

builder.Entity<TRoleClaim>(b =>
{
    // Primary key
    b.HasKey(rc => rc.Id);

    // Maps to the AspNetRoleClaims table
    b.ToTable("AspNetRoleClaims");
});

builder.Entity<TUserRole>(b =>
{
    // Primary key
    b.HasKey(r => new { r.UserId, r.RoleId });

    // Maps to the AspNetUserRoles table
    b.ToTable("AspNetUserRoles");
});
```

Model generic types

Identity defines default Common Language Runtime (CLR) types for each of the entity types listed above. These types are all prefixed with *Identity*:

- `IdentityUser`
- `IdentityRole`
- `IdentityUserClaim`
- `IdentityUserToken`
- `IdentityUserLogin`
- `IdentityRoleClaim`
- `IdentityUserRole`

Rather than using these types directly, the types can be used as base classes for the app's own types. The `DbContext` classes defined by Identity are generic, such that different CLR types can be used for one or more of the entity types in the model. These generic types also allow the `User` primary key (PK) data type to be changed.

When using Identity with support for roles, an IdentityDbContext class should be used. For example:

```
// Uses all the built-in Identity types
// Uses `string` as the key type
public class IdentityDbContext
    : IdentityDbContext<IdentityUser, IdentityRole, string>
{
}

// Uses the built-in Identity types except with a custom User type
// Uses `string` as the key type
public class IdentityDbContext<TUser>
    : IdentityDbContext<TUser, IdentityRole, string>
        where TUser : IdentityUser
{
}

// Uses the built-in Identity types except with custom User and Role types
// The key type is defined by TKey
public class IdentityDbContext<TUser, TRole, TKey> : IdentityDbContext<
    TUser, TRole, TKey, IdentityUserClaim<TKey>, IdentityUserRole<TKey>,
    IdentityUserLogin<TKey>, IdentityRoleClaim<TKey>, IdentityUserToken<TKey>>
        where TUser : IdentityUser<TKey>
        where TRole : IdentityRole<TKey>
        where TKey : IEquatable<TKey>
{
}

// No built-in Identity types are used; all are specified by generic arguments
// The key type is defined by TKey
public abstract class IdentityDbContext<
    TUser, TRole, TKey, TUserClaim, TUserRole, TUserLogin, TRoleClaim, TUserToken>
    : IdentityUserContext<TUser, TKey, TUserClaim, TUserLogin, TUserToken>
         where TUser : IdentityUser<TKey>
         where TRole : IdentityRole<TKey>
         where TKey : IEquatable<TKey>
         where TUserClaim : IdentityUserClaim<TKey>
         where TUserRole : IdentityUserRole<TKey>
         where TUserLogin : IdentityUserLogin<TKey>
         where TRoleClaim : IdentityRoleClaim<TKey>
         where TUserToken : IdentityUserToken<TKey>
```

It's also possible to use Identity without roles (only claims), in which case an IdentityUserContext<TUser> class should be used:

```
// Uses the built-in non-role Identity types except with a custom User type
// Uses `string` as the key type
public class IdentityUserContext<TUser>
    : IdentityUserContext<TUser, string>
        where TUser : IdentityUser
{
}

// Uses the built-in non-role Identity types except with a custom User type
// The key type is defined by TKey
public class IdentityUserContext<TUser, TKey> : IdentityUserContext<
    TUser, TKey, IdentityUserClaim<TKey>, IdentityUserLogin<TKey>,
    IdentityUserToken<TKey>>
        where TUser : IdentityUser<TKey>
        where TKey : IEquatable<TKey>
{
}

// No built-in Identity types are used; all are specified by generic arguments, with no roles
// The key type is defined by TKey
public abstract class IdentityUserContext<
    TUser, TKey, TUserClaim, TUserLogin, TUserToken> : DbContext
        where TUser : IdentityUser<TKey>
        where TKey : IEquatable<TKey>
        where TUserClaim : IdentityUserClaim<TKey>
        where TUserLogin : IdentityUserLogin<TKey>
        where TUserToken : IdentityUserToken<TKey>
{
}
```

Customize the model

The starting point for model customization is to derive from the appropriate context type. See the Model generic types section. This context type is customarily called `ApplicationDbContext` and is created by the ASP.NET Core templates.

The context is used to configure the model in two ways:

- Supplying entity and key types for the generic type parameters.
- Overriding `OnModelCreating` to modify the mapping of these types.

When overriding `OnModelCreating`, `base.OnModelCreating` should be called first; the overriding configuration should be called next. EF Core generally has a last-one-wins policy for configuration. For example, if the `ToTable` method for an entity type is called first with one table name and then again later with a different table name, the table name in the second call is used.

Custom user data

Custom user data is supported by inheriting from `IdentityUser`. It's customary to name this type `ApplicationUser`:

```
public class ApplicationUser : IdentityUser
{
    public string CustomTag { get; set; }
}
```

Use the `ApplicationUser` type as a generic argument for the context:

```
public class ApplicationDbContext : IdentityDbContext<ApplicationUser>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext> options)
        : base(options)
    {
    }

    protected override void OnModelCreating(ModelBuilder builder)
    {
        base.OnModelCreating(builder);
    }
}
```

There's no need to override `OnModelCreating` in the `ApplicationDbContext` class. EF Core maps the `CustomTag` property by convention. However, the database needs to be updated to create a new `CustomTag` column. To create the column, add a migration, and then update the database as described in Identity and EF Core Migrations.

Update *Pages/Shared/_LoginPartial.cshtml* and replace `IdentityUser` with `ApplicationUser`:

```
@using Microsoft.AspNetCore.Identity
@using WebApp1.Areas.Identity.Data
@inject SignInManager<ApplicationUser> SignInManager
@inject UserManager<ApplicationUser> UserManager
```

Update *Areas/Identity/IdentityHostingStartup.cs* or `Startup.ConfigureServices` and replace `IdentityUser` with `ApplicationUser`.

```
services.AddIdentity<ApplicationUser>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultUI();
```

In ASP.NET Core 2.1 or later, Identity is provided as a Razor Class Library. For more information, see Scaffold Identity in ASP.NET Core projects. Consequently, the preceding code requires a call to AddDefaultUI. If the Identity scaffolder was used to add Identity files to the project, remove the call to `AddDefaultUI`. For more information, see:

- Scaffold Identity
- Add, download, and delete custom user data to Identity

Change the primary key type

A change to the PK column's data type after the database has been created is problematic on many database systems. Changing the PK typically involves dropping and re-creating the table. Therefore, key types should be specified in the initial migration when the database is created.

Follow these steps to change the PK type:

1. If the database was created before the PK change, run `Drop-Database` (PMC) or `dotnet ef database drop` (.NET Core CLI) to delete it.
2. After confirming deletion of the database, remove the initial migration with `Remove-Migration` (PMC) or `dotnet ef migrations remove` (.NET Core CLI).
3. Update the `ApplicationDbContext` class to derive from IdentityDbContext<TUser,TRole,TKey>. Specify the new key type for `TKey`. For example, to use a `Guid` key type:

```
public class ApplicationDbContext
    : IdentityDbContext<IdentityUser<Guid>, IdentityRole<Guid>, Guid>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext> options)
        : base(options)
    {
    }
}
```

In the preceding code, the generic classes IdentityUser<TKey> and IdentityRole<TKey> must be specified to use the new key type.

In the preceding code, the generic classes IdentityUser<TKey> and IdentityRole<TKey> must be specified to use the new key type.

`Startup.ConfigureServices` must be updated to use the generic user:

```
services.AddDefaultIdentity<IdentityUser<Guid>>()
        .AddEntityFrameworkStores<ApplicationDbContext>();
```

```
services.AddIdentity<IdentityUser<Guid>, IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultTokenProviders();
```

```
services.AddIdentity<IdentityUser<Guid>, IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext, Guid>()
        .AddDefaultTokenProviders();
```

4. If a custom `ApplicationUser` class is being used, update the class to inherit from `IdentityUser`. For example:

```
using System;
using Microsoft.AspNetCore.Identity.EntityFrameworkCore;

public class ApplicationUser : IdentityUser<Guid>
{
    public string CustomTag { get; set; }
}
```

```
using System;
using Microsoft.AspNetCore.Identity;

public class ApplicationUser : IdentityUser<Guid>
{
    public string CustomTag { get; set; }
}
```

Update `ApplicationDbContext` to reference the custom `ApplicationUser` class:

```
public class ApplicationDbContext
    : IdentityDbContext<ApplicationUser, IdentityRole<Guid>, Guid>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext> options)
        : base(options)
    {
    }
}
```

Register the custom database context class when adding the Identity service in `Startup.ConfigureServices`:

```
services.AddIdentity<ApplicationUser>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultUI()
        .AddDefaultTokenProviders();
```

The primary key's data type is inferred by analyzing the DbContext object.

In ASP.NET Core 2.1 or later, Identity is provided as a Razor Class Library. For more information, see Scaffold Identity in ASP.NET Core projects. Consequently, the preceding code requires a call to AddDefaultUI. If the Identity scaffolder was used to add Identity files to the project, remove the call to `AddDefaultUI`.

```
services.AddIdentity<ApplicationUser, IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultTokenProviders();
```

The primary key's data type is inferred by analyzing the DbContext object.

```
services.AddIdentity<ApplicationUser, IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext, Guid>()
        .AddDefaultTokenProviders();
```

The AddEntityFrameworkStores method accepts a `TKey` type indicating the primary key's data type.

5. If a custom `ApplicationRole` class is being used, update the class to inherit from `IdentityRole<TKey>`. For example:

```
using System;
using Microsoft.AspNetCore.Identity;

public class ApplicationRole : IdentityRole<Guid>
{
    public string Description { get; set; }
}
```

Update `ApplicationDbContext` to reference the custom `ApplicationRole` class. For example, the following class references a custom `ApplicationUser` and a custom `ApplicationRole`:

```
using System;
using Microsoft.AspNetCore.Identity.EntityFrameworkCore;
using Microsoft.EntityFrameworkCore;

public class ApplicationDbContext :
    IdentityDbContext<ApplicationUser, ApplicationRole, Guid>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext> options)
        : base(options)
    {
    }
}
```

Register the custom database context class when adding the Identity service in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));

    services.AddIdentity<ApplicationUser, ApplicationRole>()
            .AddEntityFrameworkStores<ApplicationDbContext>()
            .AddDefaultUI()
            .AddDefaultTokenProviders();

    services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
}
```

The primary key's data type is inferred by analyzing the DbContext object.

In ASP.NET Core 2.1 or later, Identity is provided as a Razor Class Library. For more information, see Scaffold Identity in ASP.NET Core projects. Consequently, the preceding code requires a call to AddDefaultUI. If the Identity scaffolder was used to add Identity files to the project, remove the call to `AddDefaultUI`.

```
using System;
using Microsoft.AspNetCore.Identity.EntityFrameworkCore;
using Microsoft.EntityFrameworkCore;

public class ApplicationDbContext :
    IdentityDbContext<ApplicationUser, ApplicationRole, Guid>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext> options)
        : base(options)
    {
    }
}
```

Register the custom database context class when adding the Identity service in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));

    services.AddIdentity<ApplicationUser, ApplicationRole>()
            .AddEntityFrameworkStores<ApplicationDbContext>()
            .AddDefaultTokenProviders();

    services.AddMvc()
        .AddRazorPagesOptions(options =>
        {
            options.Conventions.AuthorizeFolder("/Account/Manage");
            options.Conventions.AuthorizePage("/Account/Logout");
        });

    services.AddSingleton<IEmailSender, EmailSender>();
}
```

The primary key's data type is inferred by analyzing the DbContext object.

```
using System;
using Microsoft.AspNetCore.Identity.EntityFrameworkCore;
using Microsoft.EntityFrameworkCore;

public class ApplicationDbContext :
    IdentityDbContext<ApplicationUser, ApplicationRole, Guid>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext> options)
        : base(options)
    {
    }
}
```

Register the custom database context class when adding the Identity service in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));

    services.AddIdentity<ApplicationUser, ApplicationRole>()
            .AddEntityFrameworkStores<ApplicationDbContext, Guid>()
            .AddDefaultTokenProviders();

    services.AddMvc();

    services.AddTransient<IEmailSender, AuthMessageSender>();
    services.AddTransient<ISmsSender, AuthMessageSender>();
}
```

The AddEntityFrameworkStores method accepts a `TKey` type indicating the primary key's data type.

Add navigation properties

Changing the model configuration for relationships can be more difficult than making other changes. Care must be taken to replace the existing relationships rather than create new, additional relationships. In particular, the changed relationship must specify the same foreign key (FK) property as the existing relationship. For example, the relationship between `Users` and `UserClaims` is, by default, specified as follows:

```
builder.Entity<TUser>(b =>
{
    // Each User can have many UserClaims
    b.HasMany<TUserClaim>()
     .WithOne()
     .HasForeignKey(uc => uc.UserId)
     .IsRequired();
});
```

The FK for this relationship is specified as the `UserClaim.UserId` property. `HasMany` and `WithOne` are called without arguments to create the relationship without navigation properties.

Add a navigation property to `ApplicationUser` that allows associated `UserClaims` to be referenced from the user:

```
public class ApplicationUser : IdentityUser
{
    public virtual ICollection<IdentityUserClaim<string>> Claims { get; set; }
}
```

The `TKey` for `IdentityUserClaim<TKey>` is the type specified for the PK of users. In this case, `TKey` is `string` because the defaults are being used. It's **not** the PK type for the `UserClaim` entity type.

Now that the navigation property exists, it must be configured in `OnModelCreating`:

```
public class ApplicationDbContext : IdentityDbContext<ApplicationUser>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext> options)
        : base(options)
    {
    }

    protected override void OnModelCreating(ModelBuilder modelBuilder)
    {
        base.OnModelCreating(modelBuilder);

        modelBuilder.Entity<ApplicationUser>(b =>
        {
            // Each User can have many UserClaims
            b.HasMany(e => e.Claims)
                .WithOne()
                .HasForeignKey(uc => uc.UserId)
                .IsRequired();
        });
    }
}
```

Notice that relationship is configured exactly as it was before, only with a navigation property specified in the call to `HasMany`.

The navigation properties only exist in the EF model, not the database. Because the FK for the relationship hasn't changed, this kind of model change doesn't require the database to be updated. This can be checked by adding a migration after making the change. The `Up` and `Down` methods are empty.

Add all User navigation properties

Using the section above as guidance, the following example configures unidirectional navigation properties for all relationships on User:

```
public class ApplicationUser : IdentityUser
{
    public virtual ICollection<IdentityUserClaim<string>> Claims { get; set; }
    public virtual ICollection<IdentityUserLogin<string>> Logins { get; set; }
    public virtual ICollection<IdentityUserToken<string>> Tokens { get; set; }
    public virtual ICollection<IdentityUserRole<string>> UserRoles { get; set; }
}
```

```
public class ApplicationDbContext : IdentityDbContext<ApplicationUser>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext> options)
        : base(options)
    {
    }

    protected override void OnModelCreating(ModelBuilder modelBuilder)
    {
        base.OnModelCreating(modelBuilder);

        modelBuilder.Entity<ApplicationUser>(b =>
        {
            // Each User can have many UserClaims
            b.HasMany(e => e.Claims)
                .WithOne()
                .HasForeignKey(uc => uc.UserId)
                .IsRequired();

            // Each User can have many UserLogins
            b.HasMany(e => e.Logins)
                .WithOne()
                .HasForeignKey(ul => ul.UserId)
                .IsRequired();

            // Each User can have many UserTokens
            b.HasMany(e => e.Tokens)
                .WithOne()
                .HasForeignKey(ut => ut.UserId)
                .IsRequired();

            // Each User can have many entries in the UserRole join table
            b.HasMany(e => e.UserRoles)
                .WithOne()
                .HasForeignKey(ur => ur.UserId)
                .IsRequired();
        });
    }
}
```

Add User and Role navigation properties

Using the section above as guidance, the following example configures navigation properties for all relationships on User and Role:

```
public class ApplicationUser : IdentityUser
{
    public virtual ICollection<IdentityUserClaim<string>> Claims { get; set; }
    public virtual ICollection<IdentityUserLogin<string>> Logins { get; set; }
    public virtual ICollection<IdentityUserToken<string>> Tokens { get; set; }
    public virtual ICollection<ApplicationUserRole> UserRoles { get; set; }
}

public class ApplicationRole : IdentityRole
{
    public virtual ICollection<ApplicationUserRole> UserRoles { get; set; }
}

public class ApplicationUserRole : IdentityUserRole<string>
{
    public virtual ApplicationUser User { get; set; }
    public virtual ApplicationRole Role { get; set; }
}
```

```
public class ApplicationDbContext
    : IdentityDbContext<
        ApplicationUser, ApplicationRole, string,
        IdentityUserClaim<string>, ApplicationUserRole, IdentityUserLogin<string>,
        IdentityRoleClaim<string>, IdentityUserToken<string>>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext> options)
        : base(options)
    {
    }

    protected override void OnModelCreating(ModelBuilder modelBuilder)
    {
        base.OnModelCreating(modelBuilder);

        modelBuilder.Entity<ApplicationUser>(b =>
        {
            // Each User can have many UserClaims
            b.HasMany(e => e.Claims)
                .WithOne()
                .HasForeignKey(uc => uc.UserId)
                .IsRequired();

            // Each User can have many UserLogins
            b.HasMany(e => e.Logins)
                .WithOne()
                .HasForeignKey(ul => ul.UserId)
                .IsRequired();

            // Each User can have many UserTokens
            b.HasMany(e => e.Tokens)
                .WithOne()
                .HasForeignKey(ut => ut.UserId)
                .IsRequired();

            // Each User can have many entries in the UserRole join table
            b.HasMany(e => e.UserRoles)
                .WithOne(e => e.User)
                .HasForeignKey(ur => ur.UserId)
                .IsRequired();
        });

        modelBuilder.Entity<ApplicationRole>(b =>
        {
            // Each Role can have many entries in the UserRole join table
            b.HasMany(e => e.UserRoles)
                .WithOne(e => e.Role)
                .HasForeignKey(ur => ur.RoleId)
                .IsRequired();
        });

    }
}
```

Notes:

- This example also includes the `UserRole` join entity, which is needed to navigate the many-to-many relationship from Users to Roles.
- Remember to change the types of the navigation properties to reflect that `Application{...}` types are now being used instead of `Identity{...}` types.
- Remember to use the `Application{...}` in the generic `ApplicationContext` definition.

Add all navigation properties

Using the section above as guidance, the following example configures navigation properties for all relationships

on all entity types:

```
public class ApplicationUser : IdentityUser
{
    public virtual ICollection<ApplicationUserClaim> Claims { get; set; }
    public virtual ICollection<ApplicationUserLogin> Logins { get; set; }
    public virtual ICollection<ApplicationUserToken> Tokens { get; set; }
    public virtual ICollection<ApplicationUserRole> UserRoles { get; set; }
}

public class ApplicationRole : IdentityRole
{
    public virtual ICollection<ApplicationUserRole> UserRoles { get; set; }
    public virtual ICollection<ApplicationRoleClaim> RoleClaims { get; set; }
}

public class ApplicationUserRole : IdentityUserRole<string>
{
    public virtual ApplicationUser User { get; set; }
    public virtual ApplicationRole Role { get; set; }
}

public class ApplicationUserClaim : IdentityUserClaim<string>
{
    public virtual ApplicationUser User { get; set; }
}

public class ApplicationUserLogin : IdentityUserLogin<string>
{
    public virtual ApplicationUser User { get; set; }
}

public class ApplicationRoleClaim : IdentityRoleClaim<string>
{
    public virtual ApplicationRole Role { get; set; }
}

public class ApplicationUserToken : IdentityUserToken<string>
{
    public virtual ApplicationUser User { get; set; }
}
```

```
public class ApplicationDbContext
    : IdentityDbContext<
        ApplicationUser, ApplicationRole, string,
        ApplicationUserClaim, ApplicationUserRole, ApplicationUserLogin,
        ApplicationRoleClaim, ApplicationUserToken>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext> options)
        : base(options)
    {
    }

    protected override void OnModelCreating(ModelBuilder modelBuilder)
    {
        base.OnModelCreating(modelBuilder);

        modelBuilder.Entity<ApplicationUser>(b =>
        {
            // Each User can have many UserClaims
            b.HasMany(e => e.Claims)
                .WithOne(e => e.User)
                .HasForeignKey(uc => uc.UserId)
                .IsRequired();

            // Each User can have many UserLogins
            b.HasMany(e => e.Logins)
                .WithOne(e => e.User)
                .HasForeignKey(ul => ul.UserId)
                .IsRequired();

            // Each User can have many UserTokens
            b.HasMany(e => e.Tokens)
                .WithOne(e => e.User)
                .HasForeignKey(ut => ut.UserId)
                .IsRequired();

            // Each User can have many entries in the UserRole join table
            b.HasMany(e => e.UserRoles)
                .WithOne(e => e.User)
                .HasForeignKey(ur => ur.UserId)
                .IsRequired();
        });

        modelBuilder.Entity<ApplicationRole>(b =>
        {
            // Each Role can have many entries in the UserRole join table
            b.HasMany(e => e.UserRoles)
                .WithOne(e => e.Role)
                .HasForeignKey(ur => ur.RoleId)
                .IsRequired();

            // Each Role can have many associated RoleClaims
            b.HasMany(e => e.RoleClaims)
                .WithOne(e => e.Role)
                .HasForeignKey(rc => rc.RoleId)
                .IsRequired();
        });
    }
}
```

Use composite keys

The preceding sections demonstrated changing the type of key used in the Identity model. Changing the Identity key model to use composite keys isn't supported or recommended. Using a composite key with Identity involves changing how the Identity manager code interacts with the model. This customization is beyond the scope of this document.

Change table/column names and facets

To change the names of tables and columns, call `base.OnModelCreating`. Then, add configuration to override any of the defaults. For example, to change the name of all the Identity tables:

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    base.OnModelCreating(modelBuilder);

    modelBuilder.Entity<IdentityUser>(b =>
    {
        b.ToTable("MyUsers");
    });

    modelBuilder.Entity<IdentityUserClaim<string>>(b =>
    {
        b.ToTable("MyUserClaims");
    });

    modelBuilder.Entity<IdentityUserLogin<string>>(b =>
    {
        b.ToTable("MyUserLogins");
    });

    modelBuilder.Entity<IdentityUserToken<string>>(b =>
    {
        b.ToTable("MyUserTokens");
    });

    modelBuilder.Entity<IdentityRole>(b =>
    {
        b.ToTable("MyRoles");
    });

    modelBuilder.Entity<IdentityRoleClaim<string>>(b =>
    {
        b.ToTable("MyRoleClaims");
    });

    modelBuilder.Entity<IdentityUserRole<string>>(b =>
    {
        b.ToTable("MyUserRoles");
    });
}
```

These examples use the default Identity types. If using an app type such as `ApplicationUser`, configure that type instead of the default type.

The following example changes some column names:

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    base.OnModelCreating(modelBuilder);

    modelBuilder.Entity<IdentityUser>(b =>
    {
        b.Property(e => e.Email).HasColumnName("EMail");
    });

    modelBuilder.Entity<IdentityUserClaim<string>>(b =>
    {
        b.Property(e => e.ClaimType).HasColumnName("CType");
        b.Property(e => e.ClaimValue).HasColumnName("CValue");
    });
}
```

Some types of database columns can be configured with certain *facets* (for example, the maximum `string` length allowed). The following example sets column maximum lengths for several `string` properties in the model:

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    base.OnModelCreating(modelBuilder);

    modelBuilder.Entity<IdentityUser>(b =>
    {
        b.Property(u => u.UserName).HasMaxLength(128);
        b.Property(u => u.NormalizedUserName).HasMaxLength(128);
        b.Property(u => u.Email).HasMaxLength(128);
        b.Property(u => u.NormalizedEmail).HasMaxLength(128);
    });

    modelBuilder.Entity<IdentityUserToken<string>>(b =>
    {
        b.Property(t => t.LoginProvider).HasMaxLength(128);
        b.Property(t => t.Name).HasMaxLength(128);
    });
}
```

Map to a different schema

Schemas can behave differently across database providers. For SQL Server, the default is to create all tables in the *dbo* schema. The tables can be created in a different schema. For example:

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    base.OnModelCreating(modelBuilder);

    modelBuilder.HasDefaultSchema("notdbo");
}
```

Lazy loading

In this section, support for lazy-loading proxies in the Identity model is added. Lazy-loading is useful since it allows navigation properties to be used without first ensuring they're loaded.

Entity types can be made suitable for lazy-loading in several ways, as described in the EF Core documentation. For simplicity, use lazy-loading proxies, which requires:

- Installation of the Microsoft.EntityFrameworkCore.Proxies package.
- A call to UseLazyLoadingProxies inside AddDbContext<TContext>.
- Public entity types with `public virtual` navigation properties.

The following example demonstrates calling `UseLazyLoadingProxies` in `Startup.ConfigureServices`:

```
services
    .AddDbContext<ApplicationDbContext>(
        b => b.UseSqlServer(connectionString)
              .UseLazyLoadingProxies())
    .AddDefaultIdentity<ApplicationUser>()
    .AddEntityFrameworkStores<ApplicationDbContext>();
```

Refer to the preceding examples for guidance on adding navigation properties to the entity types.

Community OSS authentication options for ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

This page contains community-provided, open source authentication options for ASP.NET Core. This page is periodically updated as new providers become available.

OSS authentication providers

The list below is sorted alphabetically.

NAME	DESCRIPTION
AspNet.Security.OpenIdConnect.Server (ASOS)	ASOS is a low-level, protocol-first OpenID Connect server framework for ASP.NET Core and OWIN/Katana.
Gluu Server	Enterprise ready, open source software for identity, access management (IAM), and single sign-on (SSO). For more information, see the Gluu Product Documentation.
IdentityServer	IdentityServer is an OpenID Connect and OAuth 2.0 framework for ASP.NET Core, officially certified by the OpenID Foundation and under governance of the .NET Foundation. For more information, see Welcome to IdentityServer4 (Documentation).
OpenIddict	OpenIddict is an easy-to-use OpenID Connect server for ASP.NET Core.

To add a provider, edit this page.

Configure ASP.NET Core Identity

9/22/2020 • 4 minutes to read • Edit Online

ASP.NET Core Identity uses default values for settings such as password policy, lockout, and cookie configuration. These settings can be overridden in the `Startup` class.

Identity options

The IdentityOptions class represents the options that can be used to configure the Identity system. `IdentityOptions` must be set **after** calling `AddIdentity` or `AddDefaultIdentity`.

Claims Identity

IdentityOptions.ClaimsIdentity specifies the ClaimsIdentityOptions with the properties shown in the following table.

PROPERTY	DESCRIPTION	DEFAULT
RoleClaimType	Gets or sets the claim type used for a role claim.	ClaimTypes.Role
SecurityStampClaimType	Gets or sets the claim type used for the security stamp claim.	`AspNet.Identity.SecurityStamp`
UserIdClaimType	Gets or sets the claim type used for the user identifier claim.	ClaimTypes.NameIdentifier
UserNameClaimType	Gets or sets the claim type used for the user name claim.	ClaimTypes.Name

Lockout

Lockout is set in the PasswordSignInAsync method:

```
public async Task<IActionResult> OnPostAsync(string returnUrl = null)
{
    returnUrl = returnUrl ?? Url.Content("~/");

    if (ModelState.IsValid)
    {
        var result = await _signInManager.PasswordSignInAsync(Input.Email,
            Input.Password, Input.RememberMe,
            lockoutOnFailure: false);
        if (result.Succeeded)
        {
            _logger.LogInformation("User logged in.");
            return LocalRedirect(returnUrl);
        }
        if (result.RequiresTwoFactor)
        {
            return RedirectToPage("./LoginWith2fa", new { ReturnUrl = returnUrl,
                Input.RememberMe });
        }
        if (result.IsLockedOut)
        {
            _logger.LogWarning("User account locked out.");
            return RedirectToPage("./Lockout");
        }
        else
        {
            ModelState.AddModelError(string.Empty, "Invalid login attempt.");
            return Page();
        }
    }

    // If we got this far, something failed, redisplay form
    return Page();
}
```

The preceding code is based on the `Login` Identity template.

Lockout options are set in `StartUp.ConfigureServices`:

```
services.Configure<IdentityOptions>(options =>
{
    // Default Lockout settings.
    options.Lockout.DefaultLockoutTimeSpan = TimeSpan.FromMinutes(5);
    options.Lockout.MaxFailedAccessAttempts = 5;
    options.Lockout.AllowedForNewUsers = true;
});
```

The preceding code sets the IdentityOptions LockoutOptions with default values.

A successful authentication resets the failed access attempts count and resets the clock.

IdentityOptions.Lockout specifies the LockoutOptions with the properties shown in the table.

PROPERTY	DESCRIPTION	DEFAULT
AllowedForNewUsers	Determines if a new user can be locked out.	`true`
DefaultLockoutTimeSpan	The amount of time a user is locked out when a lockout occurs.	5 minutes

PROPERTY	DESCRIPTION	DEFAULT
MaxFailedAccessAttempts	The number of failed access attempts until a user is locked out, if lockout is enabled.	5

Password

By default, Identity requires that passwords contain an uppercase character, lowercase character, a digit, and a non-alphanumeric character. Passwords must be at least six characters long.

Passwords are configured with:

- PasswordOptions in `Startup.ConfigureServices`.
- `[StringLength]` attributes of `Password` properties if Identity is scaffolded into the app. `InputModel` `Password` properties are found in the following files:
  - `Areas/Identity/Pages/Account/Register.cshtml.cs`
  - `Areas/Identity/Pages/Account/ResetPassword.cshtml.cs`

```
services.Configure<IdentityOptions>(options =>
{
    // Default Password settings.
    options.Password.RequireDigit = true;
    options.Password.RequireLowercase = true;
    options.Password.RequireNonAlphanumeric = true;
    options.Password.RequireUppercase = true;
    options.Password.RequiredLength = 6;
    options.Password.RequiredUniqueChars = 1;
});
```

IdentityOptions.Password specifies the PasswordOptions with the properties shown in the table.

PROPERTY	DESCRIPTION	DEFAULT
RequireDigit	Requires a number between 0-9 in the password.	`true`
RequiredLength	The minimum length of the password.	6
RequireLowercase	Requires a lowercase character in the password.	`true`
RequireNonAlphanumeric	Requires a non-alphanumeric character in the password.	`true`
RequiredUniqueChars	Only applies to ASP.NET Core 2.0 or later. Requires the number of distinct characters in the password.	1
RequireUppercase	Requires an uppercase character in the password.	`true`

Sign-in

The following code sets `SignIn` settings (to default values):

```
services.Configure<IdentityOptions>(options =>
{
    // Default SignIn settings.
    options.SignIn.RequireConfirmedEmail = false;
    options.SignIn.RequireConfirmedPhoneNumber = false;
});
```

IdentityOptions.SignIn specifies the SignInOptions with the properties shown in the table.

PROPERTY	DESCRIPTION	DEFAULT
RequireConfirmedEmail	Requires a confirmed email to sign in.	`false`
RequireConfirmedPhoneNumber	Requires a confirmed phone number to sign in.	`false`

Tokens

IdentityOptions.Tokens specifies the TokenOptions with the properties shown in the table.

PROPERTY	DESCRIPTION
AuthenticatorTokenProvider	Gets or sets the `AuthenticatorTokenProvider` used to validate two-factor sign-ins with an authenticator.
ChangeEmailTokenProvider	Gets or sets the `ChangeEmailTokenProvider` used to generate tokens used in email change confirmation emails.
ChangePhoneNumberTokenProvider	Gets or sets the `ChangePhoneNumberTokenProvider` used to generate tokens used when changing phone numbers.
EmailConfirmationTokenProvider	Gets or sets the token provider used to generate tokens used in account confirmation emails.
PasswordResetTokenProvider	Gets or sets the IUserTwoFactorTokenProvider<TUser> used to generate tokens used in password reset emails.
ProviderMap	Used to construct a User Token Provider with the key used as the provider's name.

User

```
services.Configure<IdentityOptions>(options =>
{
    // Default User settings.
    options.User.AllowedUserNameCharacters =
            "abcdefghijklmnopqrstuvwxyzABCDEFGHIJKLMNOPQRSTUVWXYZ0123456789-._@+";
    options.User.RequireUniqueEmail = false;

});
```

IdentityOptions.User specifies the UserOptions with the properties shown in the table.

PROPERTY	DESCRIPTION	DEFAULT

PROPERTY	DESCRIPTION	DEFAULT
AllowedUserNameCharacters	Allowed characters in the username.	abcdefghijklmnopqrstuvwxyz ABCDEFGHIJKLMNOPQRSTUVWXYZ 0123456789 -._@+
RequireUniqueEmail	Requires each user to have a unique email.	`false`

Cookie settings

Configure the app's cookie in `Startup.ConfigureServices`. ConfigureApplicationCookie must be called **after** calling `AddIdentity` or `AddDefaultIdentity`.

```
services.ConfigureApplicationCookie(options =>
{
    options.AccessDeniedPath = "/Identity/Account/AccessDenied";
    options.Cookie.Name = "YourAppCookieName";
    options.Cookie.HttpOnly = true;
    options.ExpireTimeSpan = TimeSpan.FromMinutes(60);
    options.LoginPath = "/Identity/Account/Login";
    // ReturnUrlParameter requires
    //using Microsoft.AspNetCore.Authentication.Cookies;
    options.ReturnUrlParameter = CookieAuthenticationDefaults.ReturnUrlParameter;
    options.SlidingExpiration = true;
});
```

For more information, see CookieAuthenticationOptions.

Password Hasher options

PasswordHasherOptions gets and sets options for password hashing.

OPTION	DESCRIPTION
CompatibilityMode	The compatibility mode used when hashing new passwords. Defaults to IdentityV3. The first byte of a hashed password, called a *format marker*, specifies the version of the hashing algorithm used to hash the password. When verifying a password against a hash, the VerifyHashedPassword method selects the correct algorithm based on the first byte. A client is able to authenticate regardless of which version of the algorithm was used to hash the password. Setting the compatibility mode affects the hashing of *new passwords*.
IterationCount	The number of iterations used when hashing passwords using PBKDF2. This value is only used when the CompatibilityMode is set to IdentityV3. The value must be a positive integer and defaults to `10000`.

In the following example, the IterationCount is set to `12000` in `Startup.ConfigureServices`:

```
// using Microsoft.AspNetCore.Identity;

services.Configure<PasswordHasherOptions>(option =>
{
    option.IterationCount = 12000;
});
```

Globally require all users to be authenticated

For information on how to globally require all users to be authenticated, see Require authenticated users.

Configure Windows Authentication in ASP.NET Core

9/22/2020 • 10 minutes to read • Edit Online

By Scott Addie

Windows Authentication (also known as Negotiate, Kerberos, or NTLM authentication) can be configured for ASP.NET Core apps hosted with IIS, Kestrel, or HTTP.sys.

Windows Authentication (also known as Negotiate, Kerberos, or NTLM authentication) can be configured for ASP.NET Core apps hosted with IIS or HTTP.sys.

Windows Authentication relies on the operating system to authenticate users of ASP.NET Core apps. You can use Windows Authentication when your server runs on a corporate network using Active Directory domain identities or Windows accounts to identify users. Windows Authentication is best suited to intranet environments where users, client apps, and web servers belong to the same Windows domain.

> **NOTE**
> Windows Authentication isn't supported with HTTP/2. Authentication challenges can be sent on HTTP/2 responses, but the client must downgrade to HTTP/1.1 before authenticating.

Proxy and load balancer scenarios

Windows Authentication is a stateful scenario primarily used in an intranet, where a proxy or load balancer doesn't usually handle traffic between clients and servers. If a proxy or load balancer is used, Windows Authentication only works if the proxy or load balancer:

- Handles the authentication.
- Passes the user authentication information to the app (for example, in a request header), which acts on the authentication information.

An alternative to Windows Authentication in environments where proxies and load balancers are used is Active Directory Federated Services (ADFS) with OpenID Connect (OIDC).

IIS/IIS Express

Add authentication services by invoking AddAuthentication (Microsoft.AspNetCore.Server.IISIntegration namespace) in `Startup.ConfigureServices`:

```
services.AddAuthentication(IISDefaults.AuthenticationScheme);
```

Launch settings (debugger)

Configuration for launch settings only affects the *Properties/launchSettings.json* file for IIS Express and doesn't configure IIS for Windows Authentication. Server configuration is explained in the IIS section.

The **Web Application** template available via Visual Studio or the .NET Core CLI can be configured to support Windows Authentication, which updates the *Properties/launchSettings.json* file automatically.

- Visual Studio

- .NET Core CLI

New project

1. Create a new project.
2. Select **ASP.NET Core Web Application**. Select **Next**.
3. Provide a name in the **Project name** field. Confirm the **Location** entry is correct or provide a location for the project. Select **Create**.
4. Select **Change** under **Authentication**.
5. In the **Change Authentication** window, select **Windows Authentication**. Select **OK**.
6. Select **Web Application**.
7. Select **Create**.

Run the app. The username appears in the rendered app's user interface.

Existing project

The project's properties enable Windows Authentication and disable Anonymous Authentication:

1. Right-click the project in **Solution Explorer** and select **Properties**.
2. Select the **Debug** tab.
3. Clear the check box for **Enable Anonymous Authentication**.
4. Select the check box for **Enable Windows Authentication**.
5. Save and close the property page.

Alternatively, the properties can be configured in the `iisSettings` node of the *launchSettings.json* file:

```
"iisSettings": {
    "windowsAuthentication": true,
    "anonymousAuthentication": false,
    "iisExpress": {
        "applicationUrl": "http://localhost:52171/",
        "sslPort": 44308
    }
}
```

When modifying an existing project, confirm that the project file includes a package reference for the Microsoft.AspNetCore.App metapackage **or** the Microsoft.AspNetCore.Authentication NuGet package.

IIS

IIS uses the ASP.NET Core Module to host ASP.NET Core apps. Windows Authentication is configured for IIS via the *web.config* file. The following sections show how to:

- Provide a local *web.config* file that activates Windows Authentication on the server when the app is deployed.
- Use the IIS Manager to configure the *web.config* file of an ASP.NET Core app that has already been deployed to the server.

If you haven't already done so, enable IIS to host ASP.NET Core apps. For more information, see Host ASP.NET Core on Windows with IIS.

Enable the IIS Role Service for Windows Authentication. For more information, see Enable Windows Authentication in IIS Role Services (see Step 2).

IIS Integration Middleware is configured to automatically authenticate requests by default. For more information, see Host ASP.NET Core on Windows with IIS: IIS options (AutomaticAuthentication).

The ASP.NET Core Module is configured to forward the Windows Authentication token to the app by default. For more information, see ASP.NET Core Module configuration reference: Attributes of the aspNetCore element.

Use **either** of the following approaches:

- **Before publishing and deploying the project,** add the following *web.config* file to the project root:

  ```
  <?xml version="1.0" encoding="utf-8"?>
  <configuration>
    <location path="." inheritInChildApplications="false">
      <system.webServer>
        <security>
          <authentication>
            <anonymousAuthentication enabled="false" />
            <windowsAuthentication enabled="true" />
          </authentication>
        </security>
      </system.webServer>
    </location>
  </configuration>
  ```

  When the project is published by the .NET Core SDK (without the `<IsTransformWebConfigDisabled>` property set to `true` in the project file), the published *web.config* file includes the `<location><system.webServer><security><authentication>` section. For more information on the `<IsTransformWebConfigDisabled>` property, see Host ASP.NET Core on Windows with IIS.

- **After publishing and deploying the project,** perform server-side configuration with the IIS Manager:

  1. In IIS Manager, select the IIS site under the **Sites** node of the **Connections** sidebar.
  2. Double-click **Authentication** in the **IIS** area.
  3. Select **Anonymous Authentication**. Select **Disable** in the **Actions** sidebar.
  4. Select **Windows Authentication**. Select **Enable** in the **Actions** sidebar.

  When these actions are taken, IIS Manager modifies the app's *web.config* file. A `<system.webServer><security><authentication>` node is added with updated settings for `anonymousAuthentication` and `windowsAuthentication`:

  ```
  <system.webServer>
    <security>
      <authentication>
        <anonymousAuthentication enabled="false" />
        <windowsAuthentication enabled="true" />
      </authentication>
    </security>
  </system.webServer>
  ```

  The `<system.webServer>` section added to the *web.config* file by IIS Manager is outside of the app's `<location>` section added by the .NET Core SDK when the app is published. Because the section is added outside of the `<location>` node, the settings are inherited by any sub-apps to the current app. To prevent inheritance, move the added `<security>` section inside of the `<location><system.webServer>` section that the .NET Core SDK provided.

  When IIS Manager is used to add the IIS configuration, it only affects the app's *web.config* file on the server. A subsequent deployment of the app may overwrite the settings on the server if the server's copy of *web.config* is replaced by the project's *web.config* file. Use **either** of the following

approaches to manage the settings:

- Use IIS Manager to reset the settings in the *web.config* file after the file is overwritten on deployment.
- Add a *web.config file* to the app locally with the settings.

Kestrel

The Microsoft.AspNetCore.Authentication.Negotiate NuGet package can be used with Kestrel to support Windows Authentication using Negotiate and Kerberos on Windows, Linux, and macOS.

> **WARNING**
>
> Credentials can be persisted across requests on a connection. *Negotiate authentication must not be used with proxies unless the proxy maintains a 1:1 connection affinity (a persistent connection) with Kestrel.*

> **NOTE**
>
> The Negotiate handler detects if the underlying server supports Windows Authentication natively and if it's enabled. If the server supports Windows Authentication but it's disabled, an error is thrown asking you to enable the server implementation. When Windows Authentication is enabled in the server, the Negotiate handler transparently forwards to it.

Add authentication services by invoking AddAuthentication and AddNegotiate in `Startup.ConfigureServices`:

```
// using Microsoft.AspNetCore.Authentication.Negotiate;
// using Microsoft.Extensions.DependencyInjection;

services.AddAuthentication(NegotiateDefaults.AuthenticationScheme)
   .AddNegotiate();
```

Add Authentication Middleware by calling UseAuthentication in `Startup.Configure`:

```
app.UseAuthentication();
```

For more information on middleware, see ASP.NET Core Middleware.

Anonymous requests are allowed. Use ASP.NET Core Authorization to challenge anonymous requests for authentication.

Windows environment configuration

The Microsoft.AspNetCore.Authentication.Negotiate component performs User Mode authentication. Service Principal Names (SPNs) must be added to the user account running the service, not the machine account. Execute `setspn -S HTTP/myservername.mydomain.com myuser` in an administrative command shell.

Linux and macOS environment configuration

Instructions for joining a Linux or macOS machine to a Windows domain are available in the Connect Azure Data Studio to your SQL Server using Windows authentication - Kerberos article. The instructions create a machine account for the Linux machine on the domain. SPNs must be added to that machine account.

> **NOTE**
>
> When following the guidance in the Connect Azure Data Studio to your SQL Server using Windows authentication - Kerberos article, replace `python-software-properties` with `python3-software-properties` if needed.

Once the Linux or macOS machine is joined to the domain, additional steps are required to provide a keytab file with the SPNs:

- On the domain controller, add new web service SPNs to the machine account:
  - `setspn -S HTTP/mywebservice.mydomain.com mymachine`
  - `setspn -S HTTP/mywebservice@MYDOMAIN.COM mymachine`
- Use ktpass to generate a keytab file:
  - ```
    ktpass -princ HTTP/mywebservice.mydomain.com@MYDOMAIN.COM -pass myKeyTabFilePassword -mapuser
    MYDOMAIN\mymachine$ -pType KRB5_NT_PRINCIPAL -out c:\temp\mymachine.HTTP.keytab -crypto
    AES256-SHA1
    ```
  - Some fields must be specified in uppercase as indicated.
- Copy the keytab file to the Linux or macOS machine.
- Select the keytab file via an environment variable: `export KRB5_KTNAME=/tmp/mymachine.HTTP.keytab`
- Invoke `klist` to show the SPNs currently available for use.

> **NOTE**
>
> A keytab file contains domain access credentials and must be protected accordingly.

HTTP.sys

HTTP.sys supports Kernel Mode Windows Authentication using Negotiate, NTLM, or Basic authentication.

Add authentication services by invoking AddAuthentication (Microsoft.AspNetCore.Server.HttpSys namespace) in `Startup.ConfigureServices`:

```
services.AddAuthentication(HttpSysDefaults.AuthenticationScheme);
```

Configure the app's web host to use HTTP.sys with Windows Authentication (*Program.cs*). UseHttpSys is in the Microsoft.AspNetCore.Server.HttpSys namespace.
```

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>()
                    .UseHttpSys(options =>
                    {
                        options.Authentication.Schemes =
                            AuthenticationSchemes.NTLM |
                            AuthenticationSchemes.Negotiate;
                        options.Authentication.AllowAnonymous = false;
                    });
            });
}
```

```
public class Program
{
    public static void Main(string[] args) =>
        BuildWebHost(args).Run();

    public static IWebHost BuildWebHost(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>()
            .UseHttpSys(options =>
            {
                options.Authentication.Schemes =
                    AuthenticationSchemes.NTLM |
                    AuthenticationSchemes.Negotiate;
                options.Authentication.AllowAnonymous = false;
            })
            .Build();
}
```

NOTE

HTTP.sys delegates to Kernel Mode authentication with the Kerberos authentication protocol. User Mode authentication isn't supported with Kerberos and HTTP.sys. The machine account must be used to decrypt the Kerberos token/ticket that's obtained from Active Directory and forwarded by the client to the server to authenticate the user. Register the Service Principal Name (SPN) for the host, not the user of the app.

NOTE

HTTP.sys isn't supported on Nano Server version 1709 or later. To use Windows Authentication and HTTP.sys with Nano Server, use a Server Core (microsoft/windowsservercore) container. For more information on Server Core, see What is the Server Core installation option in Windows Server?.

Authorize users

The configuration state of anonymous access determines the way in which the `[Authorize]` and `[AllowAnonymous]` attributes are used in the app. The following two sections explain how to handle the disallowed and allowed configuration states of anonymous access.

Disallow anonymous access

When Windows Authentication is enabled and anonymous access is disabled, the `[Authorize]` and `[AllowAnonymous]` attributes have no effect. If an IIS site is configured to disallow anonymous access, the request never reaches the app. For this reason, the `[AllowAnonymous]` attribute isn't applicable.

Allow anonymous access

When both Windows Authentication and anonymous access are enabled, use the `[Authorize]` and `[AllowAnonymous]` attributes. The `[Authorize]` attribute allows you to secure endpoints of the app which require authentication. The `[AllowAnonymous]` attribute overrides the `[Authorize]` attribute in apps that allow anonymous access. For attribute usage details, see Simple authorization in ASP.NET Core.

> **NOTE**
>
> By default, users who lack authorization to access a page are presented with an empty HTTP 403 response. The StatusCodePages Middleware can be configured to provide users with a better "Access Denied" experience.

Impersonation

ASP.NET Core doesn't implement impersonation. Apps run with the app's identity for all requests, using app pool or process identity. If the app should perform an action on behalf of a user, use WindowsIdentity.RunImpersonated in a terminal inline middleware in `Startup.Configure`. Run a single action in this context and then close the context.

```
app.Run(async (context) =>
{
    try
    {
        var user = (WindowsIdentity)context.User.Identity;

        await context.Response
            .WriteAsync($"User: {user.Name}\tState: {user.ImpersonationLevel}\n");

        WindowsIdentity.RunImpersonated(user.AccessToken, () =>
        {
            var impersonatedUser = WindowsIdentity.GetCurrent();
            var message =
                $"User: {impersonatedUser.Name}\t" +
                $"State: {impersonatedUser.ImpersonationLevel}";

            var bytes = Encoding.UTF8.GetBytes(message);
            context.Response.Body.Write(bytes, 0, bytes.Length);
        });
    }
    catch (Exception e)
    {
        await context.Response.WriteAsync(e.ToString());
    }
});
```

`RunImpersonated` doesn't support asynchronous operations and shouldn't be used for complex scenarios. For example, wrapping entire requests or middleware chains isn't supported or recommended.

While the Microsoft.AspNetCore.Authentication.Negotiate package enables authentication on Windows, Linux, and macOS, impersonation is only supported on Windows.

Claims transformations

When hosting with IIS, AuthenticateAsync isn't called internally to initialize a user. Therefore, an IClaimsTransformation implementation used to transform claims after every authentication isn't activated by default. For more information and a code example that activates claims transformations, see ASP.NET Core Module.

When hosting with IIS in-process mode, AuthenticateAsync isn't called internally to initialize a user. Therefore, an IClaimsTransformation implementation used to transform claims after every authentication isn't activated by default. For more information and a code example that activates claims transformations when hosting in-process, see ASP.NET Core Module.

Custom storage providers for ASP.NET Core Identity

9/22/2020 • 9 minutes to read • Edit Online

By Steve Smith

ASP.NET Core Identity is an extensible system which enables you to create a custom storage provider and connect it to your app. This topic describes how to create a customized storage provider for ASP.NET Core Identity. It covers the important concepts for creating your own storage provider, but isn't a step-by-step walkthrough.

View or download sample from GitHub.

Introduction

By default, the ASP.NET Core Identity system stores user information in a SQL Server database using Entity Framework Core. For many apps, this approach works well. However, you may prefer to use a different persistence mechanism or data schema. For example:

- You use Azure Table Storage or another data store.
- Your database tables have a different structure.
- You may wish to use a different data access approach, such as Dapper.

In each of these cases, you can write a customized provider for your storage mechanism and plug that provider into your app.

ASP.NET Core Identity is included in project templates in Visual Studio with the "Individual User Accounts" option.

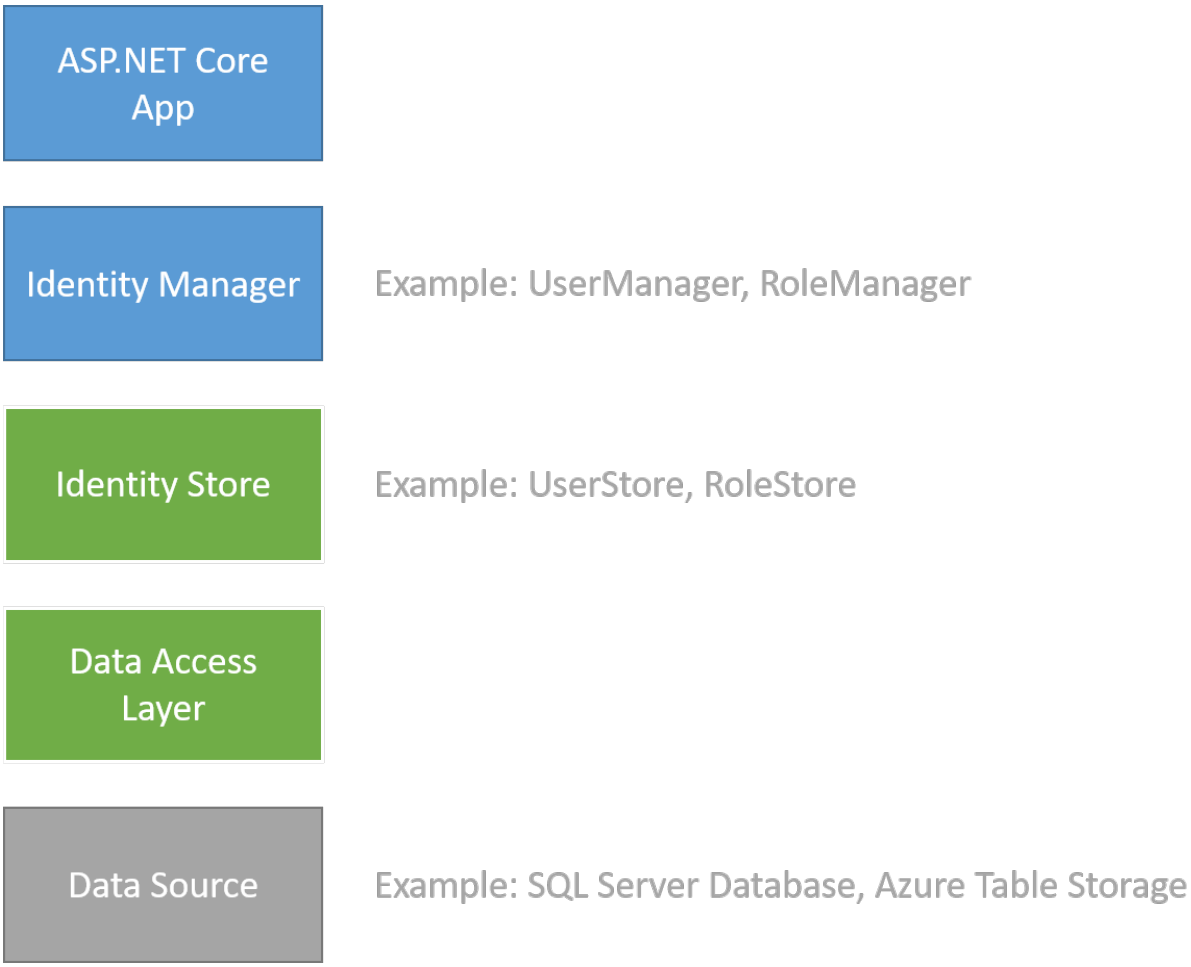
When using the .NET Core CLI, add `-au Individual`:

```
dotnet new mvc -au Individual
```

The ASP.NET Core Identity architecture

ASP.NET Core Identity consists of classes called managers and stores. *Managers* are high-level classes which an app developer uses to perform operations, such as creating an Identity user. *Stores* are lower-level classes that specify how entities, such as users and roles, are persisted. Stores follow the repository pattern and are closely coupled with the persistence mechanism. Managers are decoupled from stores, which means you can replace the persistence mechanism without changing your application code (except for configuration).

The following diagram shows how a web app interacts with the managers, while stores interact with the data access layer.



To create a custom storage provider, create the data source, the data access layer, and the store classes that interact with this data access layer (the green and grey boxes in the diagram above). You don't need to customize the managers or your app code that interacts with them (the blue boxes above).

When creating a new instance of `UserManager` or `RoleManager` you provide the type of the user class and pass an instance of the store class as an argument. This approach enables you to plug your customized classes into ASP.NET Core.

Reconfigure app to use new storage provider shows how to instantiate `UserManager` and `RoleManager` with a customized store.

ASP.NET Core Identity stores data types

ASP.NET Core Identity data types are detailed in the following sections:

Users

Registered users of your web site. The IdentityUser type may be extended or used as an example for your own custom type. You don't need to inherit from a particular type to implement your own custom identity storage solution.

User Claims

A set of statements (or Claims) about the user that represent the user's identity. Can enable greater expression of the user's identity than can be achieved through roles.

User Logins

Information about the external authentication provider (like Facebook or a Microsoft account) to use when logging in a user. Example

Roles

Authorization groups for your site. Includes the role Id and role name (like "Admin" or "Employee"). Example

The data access layer

This topic assumes you are familiar with the persistence mechanism that you are going to use and how to create entities for that mechanism. This topic doesn't provide details about how to create the repositories or data access classes; it provides some suggestions about design decisions when working with ASP.NET Core Identity.

You have a lot of freedom when designing the data access layer for a customized store provider. You only need to create persistence mechanisms for features that you intend to use in your app. For example, if you are not using roles in your app, you don't need to create storage for roles or user role associations. Your technology and existing infrastructure may require a structure that's very different from the default implementation of ASP.NET Core Identity. In your data access layer, you provide the logic to work with the structure of your storage implementation.

The data access layer provides the logic to save the data from ASP.NET Core Identity to a data source. The data access layer for your customized storage provider might include the following classes to store user and role information.

Context class

Encapsulates the information to connect to your persistence mechanism and execute queries. Several data classes require an instance of this class, typically provided through dependency injection. Example.

User Storage

Stores and retrieves user information (such as user name and password hash). Example

Role Storage

Stores and retrieves role information (such as the role name). Example

UserClaims Storage

Stores and retrieves user claim information (such as the claim type and value). Example

UserLogins Storage

Stores and retrieves user login information (such as an external authentication provider). Example

UserRole Storage

Stores and retrieves which roles are assigned to which users. Example

TIP: Only implement the classes you intend to use in your app.

In the data access classes, provide code to perform data operations for your persistence mechanism. For example, within a custom provider, you might have the following code to create a new user in the *store* class:

```
public async Task<IdentityResult> CreateAsync(ApplicationUser user,
    CancellationToken cancellationToken = default(CancellationToken))
{
    cancellationToken.ThrowIfCancellationRequested();
    if (user == null) throw new ArgumentNullException(nameof(user));

    return await _usersTable.CreateAsync(user);
}
```

The implementation logic for creating the user is in the `_usersTable.CreateAsync` method, shown below.

Customize the user class

When implementing a storage provider, create a user class which is equivalent to the IdentityUser class.

At a minimum, your user class must include an `Id` and a `UserName` property.

The `IdentityUser` class defines the properties that the `UserManager` calls when performing requested operations. The default type of the `Id` property is a string, but you can inherit from `IdentityUser<TKey, TUserClaim, TUserRole, TUserLogin, TUserToken>` and specify a different type. The framework expects the storage implementation to handle data type conversions.

Customize the user store

Create a `UserStore` class that provides the methods for all data operations on the user. This class is equivalent to the UserStore<TUser> class. In your `UserStore` class, implement `IUserStore<TUser>` and the optional interfaces required. You select which optional interfaces to implement based on the functionality provided in your app.

Optional interfaces

- IUserRoleStore
- IUserClaimStore
- IUserPasswordStore
- IUserSecurityStampStore
- IUserEmailStore
- IUserPhoneNumberStore
- IQueryableUserStore
- IUserLoginStore
- IUserTwoFactorStore
- IUserLockoutStore

The optional interfaces inherit from `IUserStore<TUser>`. You can see a partially implemented sample user store in the sample app.

Within the `UserStore` class, you use the data access classes that you created to perform operations. These are passed in using dependency injection. For example, in the SQL Server with Dapper implementation, the `UserStore` class has the `CreateAsync` method which uses an instance of `DapperUsersTable` to insert a new record:

```
public async Task<IdentityResult> CreateAsync(ApplicationUser user)
{
    string sql = "INSERT INTO dbo.CustomUser " +
        "VALUES (@id, @Email, @EmailConfirmed, @PasswordHash, @UserName)";

    int rows = await _connection.ExecuteAsync(sql, new { user.Id, user.Email, user.EmailConfirmed,
user.PasswordHash, user.UserName });

    if(rows > 0)
    {
        return IdentityResult.Success;
    }
    return IdentityResult.Failed(new IdentityError { Description = $"Could not insert user {user.Email}." });
}
```

Interfaces to implement when customizing user store

- **IUserStore**
  The IUserStore<TUser> interface is the only interface you must implement in the user store. It defines methods for creating, updating, deleting, and retrieving users.
- **IUserClaimStore**
  The IUserClaimStore<TUser> interface defines the methods you implement to enable user claims. It contains methods for adding, removing and retrieving user claims.

- **IUserLoginStore**
  The IUserLoginStore<TUser> defines the methods you implement to enable external authentication providers. It contains methods for adding, removing and retrieving user logins, and a method for retrieving a user based on the login information.
- **IUserRoleStore**
  The IUserRoleStore<TUser> interface defines the methods you implement to map a user to a role. It contains methods to add, remove, and retrieve a user's roles, and a method to check if a user is assigned to a role.
- **IUserPasswordStore**
  The IUserPasswordStore<TUser> interface defines the methods you implement to persist hashed passwords. It contains methods for getting and setting the hashed password, and a method that indicates whether the user has set a password.
- **IUserSecurityStampStore**
  The IUserSecurityStampStore<TUser> interface defines the methods you implement to use a security stamp for indicating whether the user's account information has changed. This stamp is updated when a user changes the password, or adds or removes logins. It contains methods for getting and setting the security stamp.
- **IUserTwoFactorStore**
  The IUserTwoFactorStore<TUser> interface defines the methods you implement to support two factor authentication. It contains methods for getting and setting whether two factor authentication is enabled for a user.
- **IUserPhoneNumberStore**
  The IUserPhoneNumberStore<TUser> interface defines the methods you implement to store user phone numbers. It contains methods for getting and setting the phone number and whether the phone number is confirmed.
- **IUserEmailStore**
  The IUserEmailStore<TUser> interface defines the methods you implement to store user email addresses. It contains methods for getting and setting the email address and whether the email is confirmed.
- **IUserLockoutStore**
  The IUserLockoutStore<TUser> interface defines the methods you implement to store information about locking an account. It contains methods for tracking failed access attempts and lockouts.
- **IQueryableUserStore**
  The IQueryableUserStore<TUser> interface defines the members you implement to provide a queryable user store.

You implement only the interfaces that are needed in your app. For example:

```
public class UserStore : IUserStore<IdentityUser>,
                         IUserClaimStore<IdentityUser>,
                         IUserLoginStore<IdentityUser>,
                         IUserRoleStore<IdentityUser>,
                         IUserPasswordStore<IdentityUser>,
                         IUserSecurityStampStore<IdentityUser>
{
    // interface implementations not shown
}
```

IdentityUserClaim, IdentityUserLogin, and IdentityUserRole

The `Microsoft.AspNet.Identity.EntityFramework` namespace contains implementations of the IdentityUserClaim, IdentityUserLogin, and IdentityUserRole classes. If you are using these features, you may want to create your own versions of these classes and define the properties for your app. However, sometimes it's more efficient to not load these entities into memory when performing basic operations (such as adding or removing a user's claim). Instead, the backend store classes can execute these operations directly on the data source. For example, the `UserStore.GetClaimsAsync` method can call the `userClaimTable.FindByUserId(user.Id)` method to execute a query

on that table directly and return a list of claims.

Customize the role class

When implementing a role storage provider, you can create a custom role type. It need not implement a particular interface, but it must have an `Id` and typically it will have a `Name` property.

The following is an example role class:

```
using System;

namespace CustomIdentityProviderSample.CustomProvider
{
    public class ApplicationRole
    {
        public Guid Id { get; set; } = Guid.NewGuid();
        public string Name { get; set; }
    }
}
```

Customize the role store

You can create a `RoleStore` class that provides the methods for all data operations on roles. This class is equivalent to the RoleStore<TRole> class. In the `RoleStore` class, you implement the `IRoleStore<TRole>` and optionally the `IQueryableRoleStore<TRole>` interface.

- **IRoleStore<TRole>**
  The IRoleStore<TRole> interface defines the methods to implement in the role store class. It contains methods for creating, updating, deleting, and retrieving roles.
- **RoleStore<TRole>**
  To customize `RoleStore`, create a class that implements the `IRoleStore<TRole>` interface.

Reconfigure app to use a new storage provider

Once you have implemented a storage provider, you configure your app to use it. If your app used the default provider, replace it with your custom provider.

1. Remove the `Microsoft.AspNetCore.EntityFramework.Identity` NuGet package.
2. If the storage provider resides in a separate project or package, add a reference to it.
3. Replace all references to `Microsoft.AspNetCore.EntityFramework.Identity` with a using statement for the namespace of your storage provider.
4. In the `ConfigureServices` method, change the `AddIdentity` method to use your custom types. You can create your own extension methods for this purpose. See IdentityServiceCollectionExtensions for an example.
5. If you are using Roles, update the `RoleManager` to use your `RoleStore` class.
6. Update the connection string and credentials to your app's configuration.

Example:

```
public void ConfigureServices(IServiceCollection services)
{
    // Add identity types
    services.AddIdentity<ApplicationUser, ApplicationRole>()
        .AddDefaultTokenProviders();

    // Identity Services
    services.AddTransient<IUserStore<ApplicationUser>, CustomUserStore>();
    services.AddTransient<IRoleStore<ApplicationRole>, CustomRoleStore>();
    string connectionString = Configuration.GetConnectionString("DefaultConnection");
    services.AddTransient<SqlConnection>(e => new SqlConnection(connectionString));
    services.AddTransient<DapperUsersTable>();

    // additional configuration
}
```

Facebook, Google, and external provider authentication in ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

By Valeriy Novytskyy and Rick Anderson

This tutorial demonstrates how to build an ASP.NET Core 3.0 app that enables users to sign in using OAuth 2.0 with credentials from external authentication providers.

Facebook, Twitter, Google, and Microsoft providers are covered in the following sections and use the starter project created in this article. Other providers are available in third-party packages such as AspNet.Security.OAuth.Providers and AspNet.Security.OpenId.Providers.

Enabling users to sign in with their existing credentials:

- Is convenient for the users.
- Shifts many of the complexities of managing the sign-in process onto a third party.

For examples of how social logins can drive traffic and customer conversions, see case studies by Facebook and Twitter.

Create a New ASP.NET Core Project

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Create a new project.
- Select **ASP.NET Core Web Application** and **Next**.
- Provide a **Project name** and confirm or change the **Location**. Select **Create**.
- Select the latest version of ASP.NET Core in the drop-down (**ASP.NET Core {X.Y}**), and then select **Web Application**.
- Under **Authentication**, select **Change** and set the authentication to **Individual User Accounts**. Select **OK**.
- In the **Create a new ASP.NET Core Web Application** window, select **Create**.

Apply migrations

- Run the app and select the **Register** link.
- Enter the email and password for the new account, and then select **Register**.
- Follow the instructions to apply migrations.

Forward request information with a proxy or load balancer

If the app is deployed behind a proxy server or load balancer, some of the original request information might be forwarded to the app in request headers. This information usually includes the secure request scheme (`https`), host, and client IP address. Apps don't automatically read these request headers to discover and use the original request information.

The scheme is used in link generation that affects the authentication flow with external providers. Losing the secure scheme (`https`) results in the app generating incorrect insecure redirect URLs.

Use Forwarded Headers Middleware to make the original request information available to the app for request processing.

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Use SecretManager to store tokens assigned by login providers

Social login providers assign **Application Id** and **Application Secret** tokens during the registration process. The exact token names vary by provider. These tokens represent the credentials your app uses to access their API. The tokens constitute the "secrets" that can be linked to your app configuration with the help of Secret Manager. Secret Manager is a more secure alternative to storing the tokens in a configuration file, such as *appsettings.json*.

> **IMPORTANT**
> Secret Manager is for development purposes only. You can store and protect Azure test and production secrets with the Azure Key Vault configuration provider.

Follow the steps in Safe storage of app secrets in development in ASP.NET Core topic to store tokens assigned by each login provider below.

Setup login providers required by your application

Use the following topics to configure your application to use the respective providers:

- Facebook instructions
- Twitter instructions
- Google instructions
- Microsoft instructions
- Other provider instructions

Multiple authentication providers

When the app requires multiple providers, chain the provider extension methods behind AddAuthentication:

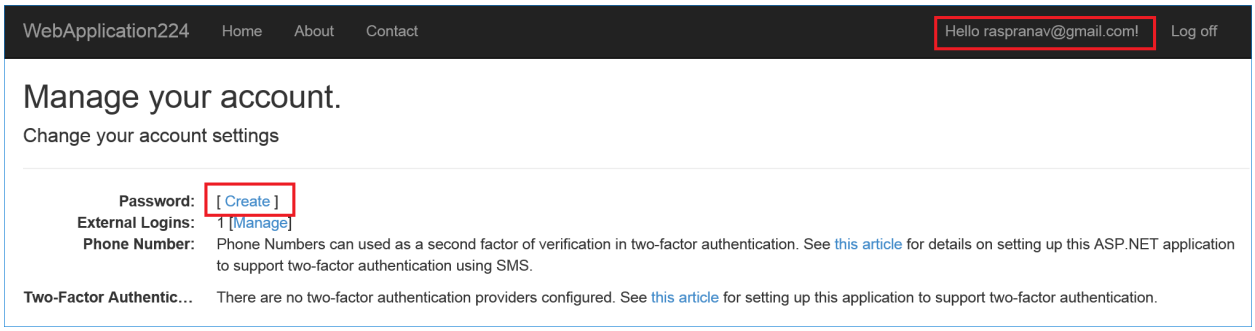
```
services.AddAuthentication()
    .AddMicrosoftAccount(microsoftOptions => { ... })
    .AddGoogle(googleOptions => { ... })
    .AddTwitter(twitterOptions => { ... })
    .AddFacebook(facebookOptions => { ... });
```

Optionally set password

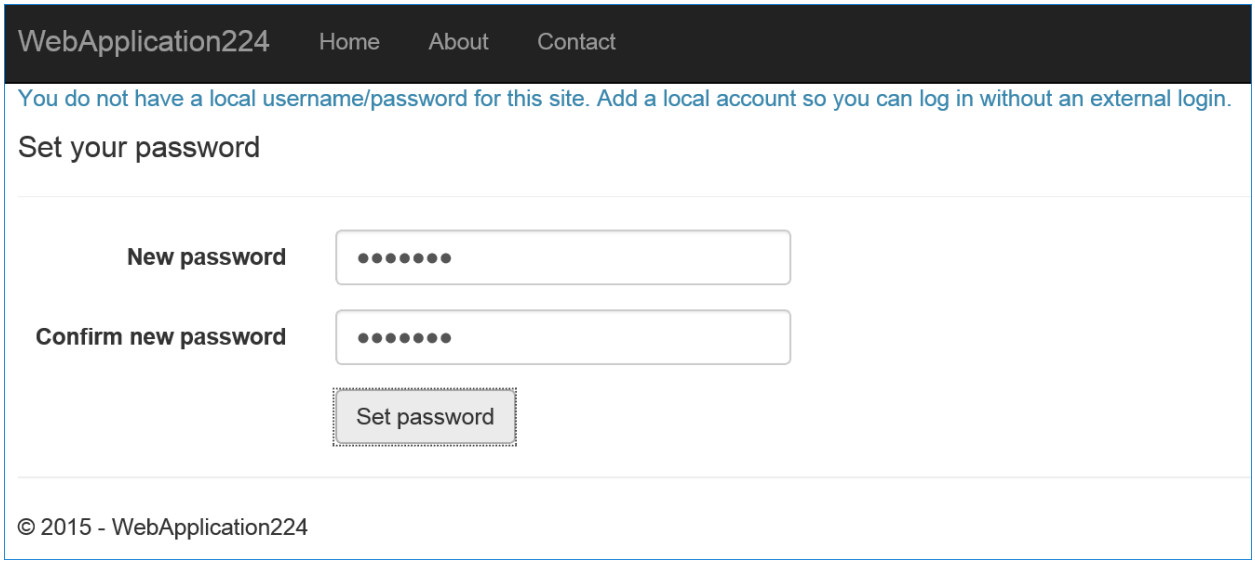
When you register with an external login provider, you don't have a password registered with the app. This alleviates you from creating and remembering a password for the site, but it also makes you dependent on the external login provider. If the external login provider is unavailable, you won't be able to sign in to the web site.

To create a password and sign in using your email that you set during the sign in process with external providers:

- Select the **Hello <email alias>** link at the top-right corner to navigate to the **Manage** view.



- Select **Create**



- Set a valid password and you can use this to sign in with your email.

Next steps

- See this GitHub issue for information on how to customize the login buttons.
- This article introduced external authentication and explained the prerequisites required to add external logins to your ASP.NET Core app.
- Reference provider-specific pages to configure logins for the providers required by your app.
- You may want to persist additional data about the user and their access and refresh tokens. For more information, see Persist additional claims and tokens from external providers in ASP.NET Core.

Google external login setup in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

By Valeriy Novytskyy and Rick Anderson

This tutorial shows you how to enable users to sign in with their Google account using the ASP.NET Core 3.0 project created on the previous page.

Create a Google API Console project and client ID

- Install Microsoft.AspNetCore.Authentication.Google.
- Navigate to Integrating Google Sign-In into your web app and select **Configure a project**.
- In the **Configure your OAuth client** dialog, select **Web server**.
- In the **Authorized redirect URIs** text entry box, set the redirect URI. For example, `https://localhost:44312/signin-google`
- Save the **Client ID** and **Client Secret**.
- When deploying the site, register the new public url from the **Google Console**.

Store the Google client ID and secret

Store sensitive settings such as the Google client ID and secret values with Secret Manager. For this sample, use the following steps:

1. Initialize the project for secret storage per the instructions at Enable secret storage.
2. Store the sensitive settings in the local secret store with the secret keys `Authentication:Google:ClientId` and `Authentication:Google:ClientSecret`:

```
dotnet user-secrets set "Authentication:Google:ClientId" "<client-id>"
dotnet user-secrets set "Authentication:Google:ClientSecret" "<client-secret>"
```

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. `__`, the double underscore, is:

- Supported by all platforms. For example, the `:` separator is not supported by Bash, but `__` is.
- Automatically replaced by a `:`

You can manage your API credentials and usage in the API Console.

Configure Google authentication

Add the Google service to `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>(options =>
        options.SignIn.RequireConfirmedAccount = true)
            .AddEntityFrameworkStores<ApplicationDbContext>();
    services.AddRazorPages();

    services.AddAuthentication()
        .AddGoogle(options =>
        {
            IConfigurationSection googleAuthNSection =
                Configuration.GetSection("Authentication:Google");

            options.ClientId = googleAuthNSection["ClientId"];
            options.ClientSecret = googleAuthNSection["ClientSecret"];
        });
}
```

The call to AddIdentity configures the default scheme settings. The AddAuthentication(String) overload sets the DefaultScheme property. The AddAuthentication(Action<AuthenticationOptions>) overload allows configuring authentication options, which can be used to set up default authentication schemes for different purposes. Subsequent calls to `AddAuthentication` override previously configured AuthenticationOptions properties.

AuthenticationBuilder extension methods that register an authentication handler may only be called once per authentication scheme. Overloads exist that allow configuring the scheme properties, scheme name, and display name.

Sign in with Google

- Run the app and click **Log in**. An option to sign in with Google appears.
- Click the **Google** button, which redirects to Google for authentication.
- After entering your Google credentials, you are redirected back to the web site.

Forward request information with a proxy or load balancer

If the app is deployed behind a proxy server or load balancer, some of the original request information might be forwarded to the app in request headers. This information usually includes the secure request scheme (`https`), host, and client IP address. Apps don't automatically read these request headers to discover and use the original request information.

The scheme is used in link generation that affects the authentication flow with external providers. Losing the secure scheme (`https`) results in the app generating incorrect insecure redirect URLs.

Use Forwarded Headers Middleware to make the original request information available to the app for request processing.

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Multiple authentication providers

When the app requires multiple providers, chain the provider extension methods behind AddAuthentication:

```
services.AddAuthentication()
    .AddMicrosoftAccount(microsoftOptions => { ... })
    .AddGoogle(googleOptions => { ... })
    .AddTwitter(twitterOptions => { ... })
    .AddFacebook(facebookOptions => { ... });
```

See the GoogleOptions API reference for more information on configuration options supported by Google authentication. This can be used to request different information about the user.

Change the default callback URI

The URI segment `/signin-google` is set as the default callback of the Google authentication provider. You can change the default callback URI while configuring the Google authentication middleware via the inherited RemoteAuthenticationOptions.CallbackPath property of the GoogleOptions class.

Troubleshooting

- If the sign-in doesn't work and you aren't getting any errors, switch to development mode to make the issue easier to debug.
- If Identity isn't configured by calling `services.AddIdentity` in `ConfigureServices`, attempting to authenticate results in *ArgumentException: The 'SignInScheme' option must be provided*. The project template used in this tutorial ensures that this is done.
- If the site database has not been created by applying the initial migration, you get *A database operation failed while processing the request* error. Select **Apply Migrations** to create the database, and refresh the page to continue past the error.

Next steps

- This article showed how you can authenticate with Google. You can follow a similar approach to authenticate with other providers listed on the previous page.
- Once you publish the app to Azure, reset the `ClientSecret` in the Google API Console.
- Set the `Authentication:Google:ClientId` and `Authentication:Google:ClientSecret` as application settings in the Azure portal. The configuration system is set up to read keys from environment variables.

Facebook external login setup in ASP.NET Core

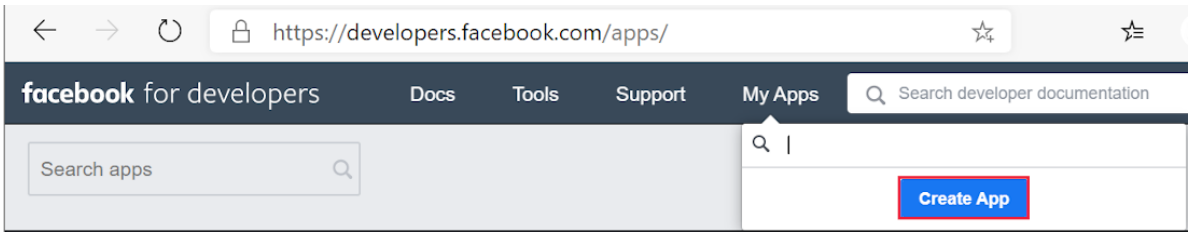
9/22/2020 • 5 minutes to read • Edit Online

By Valeriy Novytskyy and Rick Anderson

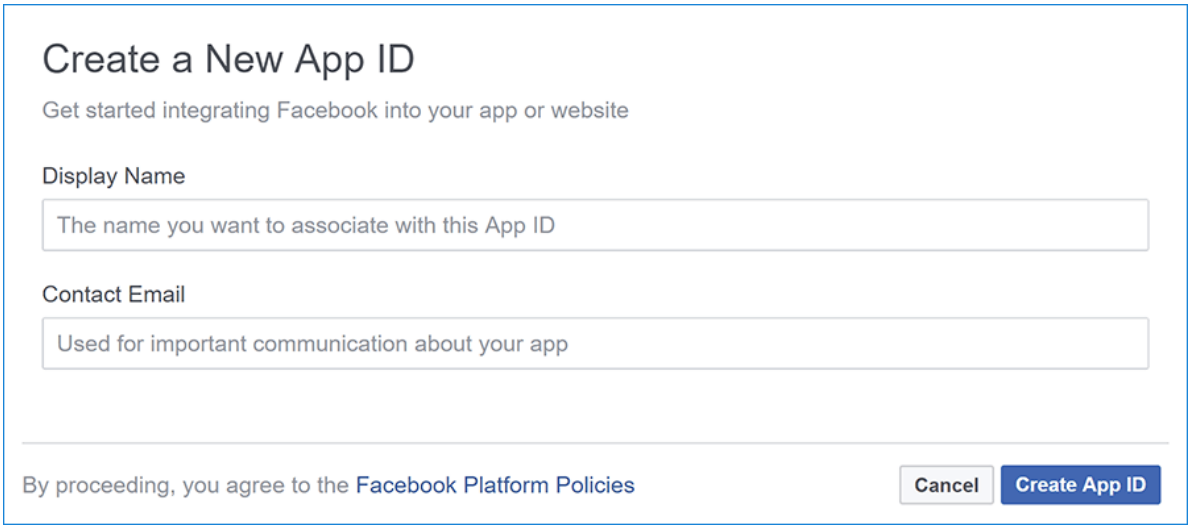
This tutorial with code examples shows how to enable your users to sign in with their Facebook account using a sample ASP.NET Core 3.0 project created on the previous page. We start by creating a Facebook App ID by following the official steps.

Create the app in Facebook

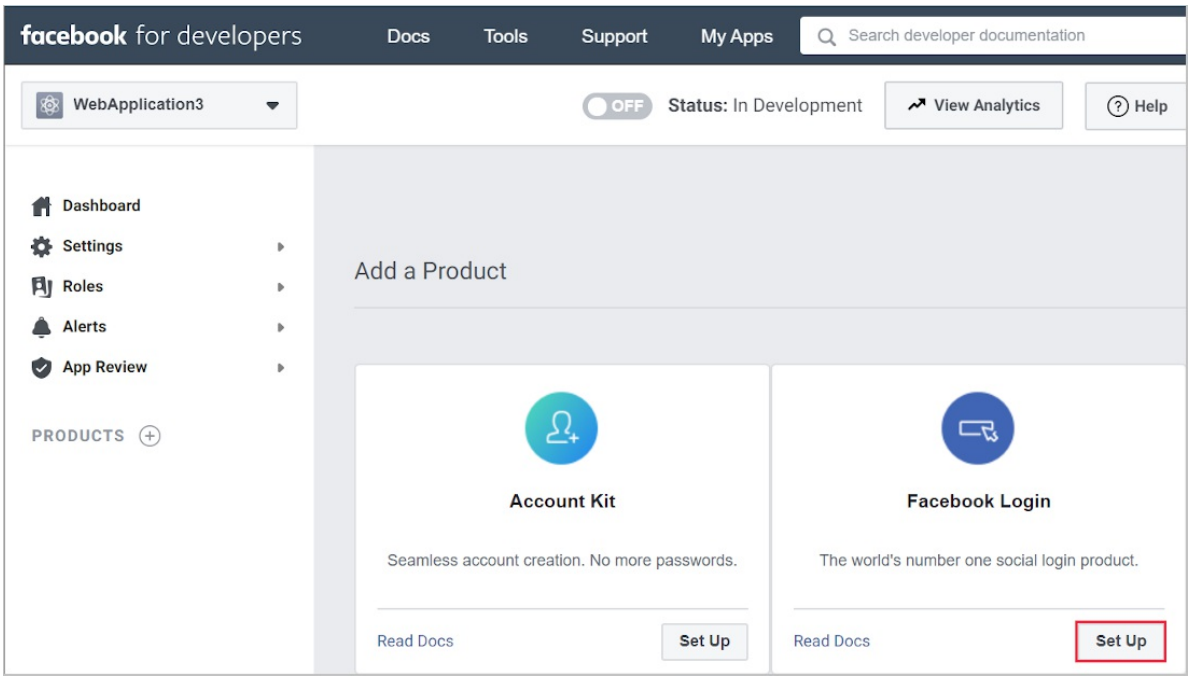
- Add the Microsoft.AspNetCore.Authentication.Facebook NuGet package to the project.
- Navigate to the Facebook Developers app page and sign in. If you don't already have a Facebook account, use the **Sign up for Facebook** link on the login page to create one. Once you have a Facebook account, follow the instructions to register as a Facebook Developer.
- From the **My Apps** menu select **Create App** to create a new App ID.



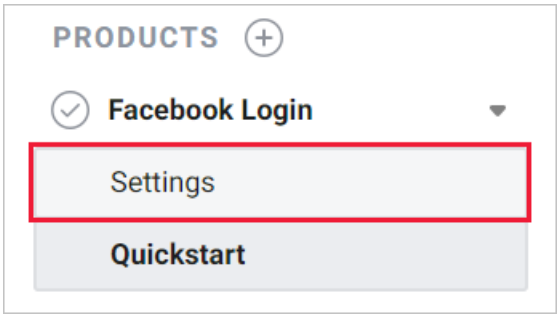
- Fill out the form and tap the **Create App ID** button.



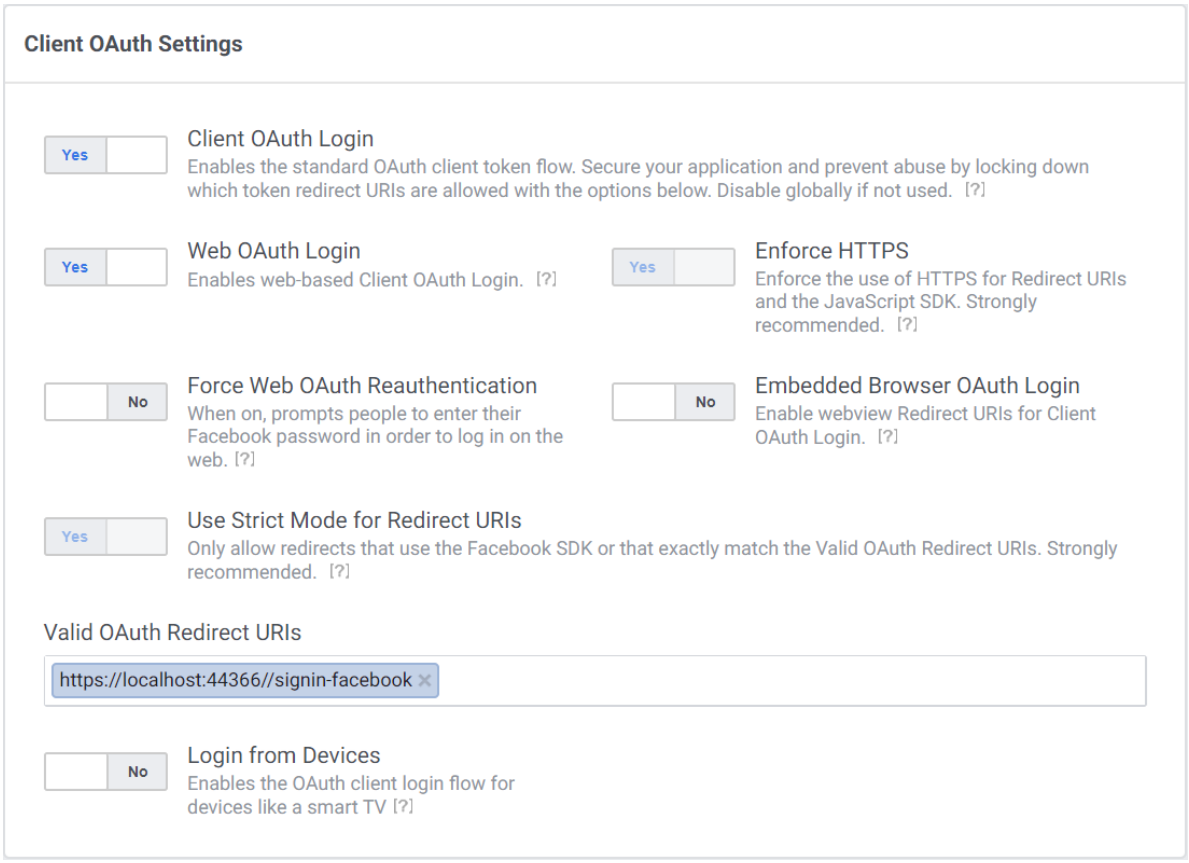
- On the new App card, select **Add a Product**. On the **Facebook Login** card, click **Set Up**



- The **Quickstart** wizard launches with **Choose a Platform** as the first page. Bypass the wizard for now by clicking the **FaceBook Login Settings** link in the menu on the lower left:



- You are presented with the **Client OAuth Settings** page:



- Enter your development URI with */signin-facebook* appended into the **Valid OAuth Redirect URIs** field (for example: `https://localhost:44320/signin-facebook`). The Facebook authentication configured later in this tutorial will automatically handle requests at */signin-facebook* route to implement the OAuth flow.

> **NOTE**
> The URI */signin-facebook* is set as the default callback of the Facebook authentication provider. You can change the default callback URI while configuring the Facebook authentication middleware via the inherited RemoteAuthenticationOptions.CallbackPath property of the FacebookOptions class.

- Click **Save Changes**.
- Click **Settings** > **Basic** link in the left navigation.

  On this page, make a note of your `App ID` and your `App Secret`. You will add both into your ASP.NET Core application in the next section:
- When deploying the site you need to revisit the **Facebook Login** setup page and register a new public URI.

Store the Facebook app ID and secret

Store sensitive settings such as the Facebook app ID and secret values with Secret Manager. For this sample, use the following steps:

1. Initialize the project for secret storage per the instructions at Enable secret storage.
2. Store the sensitive settings in the local secret store with the secret keys `Authentication:Facebook:AppId` and `Authentication:Facebook:AppSecret`:

```
dotnet user-secrets set "Authentication:Facebook:AppId" "<app-id>"
dotnet user-secrets set "Authentication:Facebook:AppSecret" "<app-secret>"
```

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. `__`, the double underscore, is:

- Supported by all platforms. For example, the `:` separator is not supported by Bash, but `__` is.
- Automatically replaced by a `:`

Configure Facebook Authentication

Add the Facebook service in the `ConfigureServices` method in the *Startup.cs* file:

```
services.AddAuthentication().AddFacebook(facebookOptions =>
{
    facebookOptions.AppId = Configuration["Authentication:Facebook:AppId"];
    facebookOptions.AppSecret = Configuration["Authentication:Facebook:AppSecret"];
});
```

The AddAuthentication(String) overload sets the DefaultScheme property. The AddAuthentication(Action<AuthenticationOptions>) overload allows configuring authentication options, which can be used to set up default authentication schemes for different purposes. Subsequent calls to `AddAuthentication` override previously configured AuthenticationOptions properties.

AuthenticationBuilder extension methods that register an authentication handler may only be called once per

authentication scheme. Overloads exist that allow configuring the scheme properties, scheme name, and display name.

Sign in with Facebook

- Run the app and select **Log in**.
- Under **Use another service to log in.**, select Facebook.
- You are redirected to **Facebook** for authentication.
- Enter your Facebook credentials.
- You are redirected back to your site where you can set your email.

You are now logged in using your Facebook credentials:

React to cancel authorize external sign-in

AccessDeniedPath can provide a redirect path to the user agent when the user doesn't approve the requested authorization demand.

The following code sets the `AccessDeniedPath` to `"/AccessDeniedPathInfo"`:

```
services.AddAuthentication().AddFacebook(options =>
{
    options.AppId = Configuration["Authentication:Facebook:AppId"];
    options.AppSecret = Configuration["Authentication:Facebook:AppSecret"];
    options.AccessDeniedPath = "/AccessDeniedPathInfo";
});
```

We recommend the `AccessDeniedPath` page contain the following information:

- Remote authentication was canceled.
- This app requires authentication.
- To try sign-in again, select the Login link.

Test AccessDeniedPath

- Navigate to facebook.com
- If you are signed in, you must sign out.
- Run the app and select Facebook sign-in.
- Select **Not now**. You are redirected to the specified `AccessDeniedPath` page.

Forward request information with a proxy or load balancer

If the app is deployed behind a proxy server or load balancer, some of the original request information might be forwarded to the app in request headers. This information usually includes the secure request scheme (`https`), host, and client IP address. Apps don't automatically read these request headers to discover and use the original request information.

The scheme is used in link generation that affects the authentication flow with external providers. Losing the secure scheme (`https`) results in the app generating incorrect insecure redirect URLs.

Use Forwarded Headers Middleware to make the original request information available to the app for request processing.

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Multiple authentication providers

When the app requires multiple providers, chain the provider extension methods behind AddAuthentication:

```
services.AddAuthentication()
    .AddMicrosoftAccount(microsoftOptions => { ... })
    .AddGoogle(googleOptions => { ... })
    .AddTwitter(twitterOptions => { ... })
    .AddFacebook(facebookOptions => { ... });
```

See the FacebookOptions API reference for more information on configuration options supported by Facebook authentication. Configuration options can be used to:

- Request different information about the user.
- Add query string arguments to customize the login experience.

Troubleshooting

- **ASP.NET Core 2.x only:** If Identity isn't configured by calling `services.AddIdentity` in `ConfigureServices`, attempting to authenticate will result in *ArgumentException: The 'SignInScheme' option must be provided*. The project template used in this tutorial ensures that this is done.
- If the site database has not been created by applying the initial migration, you get *A database operation failed while processing the request* error. Tap **Apply Migrations** to create the database and refresh to continue past the error.

Next steps

- This article showed how you can authenticate with Facebook. You can follow a similar approach to authenticate with other providers listed on the previous page.
- Once you publish your web site to Azure web app, you should reset the `AppSecret` in the Facebook developer portal.
- Set the `Authentication:Facebook:AppId` and `Authentication:Facebook:AppSecret` as application settings in the Azure portal. The configuration system is set up to read keys from environment variables.

Microsoft Account external login setup with ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

By Valeriy Novytskyy and Rick Anderson

This sample shows you how to enable users to sign in with their work, school, or personal Microsoft account using the ASP.NET Core 3.0 project created on the previous page.

Create the app in Microsoft Developer Portal

- Add the Microsoft.AspNetCore.Authentication.MicrosoftAccount NuGet package to the project.
- Navigate to the Azure portal - App registrations page and create or sign into a Microsoft account:

If you don't have a Microsoft account, select **Create one**. After signing in, you are redirected to the **App registrations** page:

- Select **New registration**
- Enter a **Name**.
- Select an option for **Supported account types**.
  - The `MicrosoftAccount` package supports App Registrations created using "Accounts in any organizational directory" or "Accounts in any organizational directory and Microsoft accounts" options by default.
  - To use other options, set `AuthorizationEndpoint` and `TokenEndpoint` members of `MicrosoftAccountOptions` used to initialize the Microsoft Account authentication to the URLs displayed on **Endpoints** page of the App Registration after it is created (available by clicking Endpoints on the **Overview** page).
- Under **Redirect URI**, enter your development URL with `/signin-microsoft` appended. For example, `https://localhost:5001/signin-microsoft`. The Microsoft authentication scheme configured later in this sample will automatically handle requests at `/signin-microsoft` route to implement the OAuth flow.
- Select **Register**

Create client secret

- In the left pane, select **Certificates & secrets**.
- Under **Client secrets**, select **New client secret**
  - Add a description for the client secret.
  - Select the **Add** button.
- Under **Client secrets**, copy the value of the client secret.

The URI segment `/signin-microsoft` is set as the default callback of the Microsoft authentication provider. You can change the default callback URI while configuring the Microsoft authentication middleware via the inherited RemoteAuthenticationOptions.CallbackPath property of the MicrosoftAccountOptions class.

Store the Microsoft client ID and secret

Store sensitive settings such as the Microsoft client ID and secret values with Secret Manager. For this sample, use the following steps:

1. Initialize the project for secret storage per the instructions at Enable secret storage.
2. Store the sensitive settings in the local secret store with the secret keys `Authentication:Microsoft:ClientId` and `Authentication:Microsoft:ClientSecret`:

```
dotnet user-secrets set "Authentication:Microsoft:ClientId" "<client-id>"
dotnet user-secrets set "Authentication:Microsoft:ClientSecret" "<client-secret>"
```

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. `__`, the double underscore, is:

- Supported by all platforms. For example, the `:` separator is not supported by Bash, but `__` is.
- Automatically replaced by a `:`

Configure Microsoft Account Authentication

Add the Microsoft Account service to the `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>(options => options.SignIn.RequireConfirmedAccount = true)
        .AddEntityFrameworkStores<ApplicationDbContext>();
    services.AddRazorPages();

    services.AddAuthentication().AddMicrosoftAccount(microsoftOptions =>
    {
        microsoftOptions.ClientId = Configuration["Authentication:Microsoft:ClientId"];
        microsoftOptions.ClientSecret = Configuration["Authentication:Microsoft:ClientSecret"];
    });
}
```

The AddAuthentication(String) overload sets the DefaultScheme property. The AddAuthentication(Action<AuthenticationOptions>) overload allows configuring authentication options, which can be used to set up default authentication schemes for different purposes. Subsequent calls to `AddAuthentication` override previously configured AuthenticationOptions properties.

AuthenticationBuilder extension methods that register an authentication handler may only be called once per authentication scheme. Overloads exist that allow configuring the scheme properties, scheme name, and display name.

For more information about configuration options supported by Microsoft Account authentication, see the MicrosoftAccountOptions API reference. This can be used to request different information about the user.

Sign in with Microsoft Account

Run the app and click **Log in**. An option to sign in with Microsoft appears. When you click on Microsoft, you are redirected to Microsoft for authentication. After signing in with your Microsoft Account, you will be prompted to let the app access your info:

Tap **Yes** and you will be redirected back to the web site where you can set your email.

You are now logged in using your Microsoft credentials:

Multiple authentication providers

When the app requires multiple providers, chain the provider extension methods behind AddAuthentication:

```
services.AddAuthentication()
    .AddMicrosoftAccount(microsoftOptions => { ... })
    .AddGoogle(googleOptions => { ... })
    .AddTwitter(twitterOptions => { ... })
    .AddFacebook(facebookOptions => { ... });
```

Forward request information with a proxy or load balancer

If the app is deployed behind a proxy server or load balancer, some of the original request information might be forwarded to the app in request headers. This information usually includes the secure request scheme (`https`), host, and client IP address. Apps don't automatically read these request headers to discover and use the original request information.

The scheme is used in link generation that affects the authentication flow with external providers. Losing the secure scheme (`https`) results in the app generating incorrect insecure redirect URLs.

Use Forwarded Headers Middleware to make the original request information available to the app for request processing.

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Troubleshooting

- If the Microsoft Account provider redirects you to a sign in error page, note the error title and description query string parameters directly following the `#` (hashtag) in the Uri.

  Although the error message seems to indicate a problem with Microsoft authentication, the most common cause is your application Uri not matching any of the **Redirect URIs** specified for the **Web** platform.

- If Identity isn't configured by calling `services.AddIdentity` in `ConfigureServices`, attempting to authenticate will result in *ArgumentException: The 'SignInScheme' option must be provided*. The project template used in this sample ensures that this is done.

- If the site database has not been created by applying the initial migration, you will get *A database operation failed while processing the request* error. Tap **Apply Migrations** to create the database and refresh to continue past the error.

Next steps

- This article showed how you can authenticate with Microsoft. You can follow a similar approach to authenticate with other providers listed on the previous page.

- Once you publish your web site to Azure web app, create a new client secrets in the Microsoft Developer Portal.

- Set the `Authentication:Microsoft:ClientId` and `Authentication:Microsoft:ClientSecret` as application settings in the Azure portal. The configuration system is set up to read keys from environment variables.

Twitter external sign-in setup with ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

By Valeriy Novytskyy and Rick Anderson

This sample shows how to enable users to sign in with their Twitter account using a sample ASP.NET Core 3.0 project created on the previous page.

Create the app in Twitter

- Add the Microsoft.AspNetCore.Authentication.Twitter NuGet package to the project.
- Navigate to https://apps.twitter.com/ and sign in. If you don't already have a Twitter account, use the **Sign up now** link to create one.
- Select **Create an app**. Fill out the **App name**, **Application description** and public **Website** URI (this can be temporary until you register the domain name):
- Check the box next to **Enable Sign in with Twitter**
- Microsoft.AspNetCore.Identity requires users to have an email address by default. Go to the **Permissions** tab, click the **Edit** button and check the box next to **Request email address from users**.
- Enter your development URI with `/signin-twitter` appended into the **Callback URLs** field (for example: `https://webapp128.azurewebsites.net/signin-twitter`). The Twitter authentication scheme configured later in this sample will automatically handle requests at `/signin-twitter` route to implement the OAuth flow.

  > **NOTE**
  > The URI segment `/signin-twitter` is set as the default callback of the Twitter authentication provider. You can change the default callback URI while configuring the Twitter authentication middleware via the inherited RemoteAuthenticationOptions.CallbackPath property of the TwitterOptions class.

- Fill out the rest of the form and select **Create**. New application details are displayed:

Store the Twitter consumer API key and secret

Store sensitive settings such as the Twitter consumer API key and secret with Secret Manager. For this sample, use the following steps:

1. Initialize the project for secret storage per the instructions at Enable secret storage.
2. Store the sensitive settings in the local secret store with the secrets keys `Authentication:Twitter:ConsumerKey` and `Authentication:Twitter:ConsumerSecret`:

```
dotnet user-secrets set "Authentication:Twitter:ConsumerAPIKey" "<consumer-api-key>"
dotnet user-secrets set "Authentication:Twitter:ConsumerSecret" "<consumer-secret>"
```

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. `__`, the double underscore, is:

- Supported by all platforms. For example, the `:` separator is not supported by Bash, but `__` is.

- Automatically replaced by a `:`

These tokens can be found on the **Keys and Access Tokens** tab after creating a new Twitter application:

Configure Twitter Authentication

Add the Twitter service in the `ConfigureServices` method in *Startup.cs* file:

```
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>(options =>
        options.SignIn.RequireConfirmedAccount = true)
            .AddEntityFrameworkStores<ApplicationDbContext>();
    services.AddRazorPages();

    services.AddAuthentication().AddTwitter(twitterOptions =>
    {
        twitterOptions.ConsumerKey = Configuration["Authentication:Twitter:ConsumerAPIKey"];
        twitterOptions.ConsumerSecret = Configuration["Authentication:Twitter:ConsumerSecret"];
        twitterOptions.RetrieveUserDetails = true;
    });

}
```

The AddAuthentication(String) overload sets the DefaultScheme property. The AddAuthentication(Action<AuthenticationOptions>) overload allows configuring authentication options, which can be used to set up default authentication schemes for different purposes. Subsequent calls to `AddAuthentication` override previously configured AuthenticationOptions properties.

AuthenticationBuilder extension methods that register an authentication handler may only be called once per authentication scheme. Overloads exist that allow configuring the scheme properties, scheme name, and display name.

Multiple authentication providers

When the app requires multiple providers, chain the provider extension methods behind AddAuthentication:

```
services.AddAuthentication()
    .AddMicrosoftAccount(microsoftOptions => { ... })
    .AddGoogle(googleOptions => { ... })
    .AddTwitter(twitterOptions => { ... })
    .AddFacebook(facebookOptions => { ... });
```

See the TwitterOptions API reference for more information on configuration options supported by Twitter authentication. This can be used to request different information about the user.

Sign in with Twitter

Run the app and select **Log in**. An option to sign in with Twitter appears:

Clicking on **Twitter** redirects to Twitter for authentication:

After entering your Twitter credentials, you are redirected back to the web site where you can set your email.

You are now logged in using your Twitter credentials:

Forward request information with a proxy or load balancer

If the app is deployed behind a proxy server or load balancer, some of the original request information might be forwarded to the app in request headers. This information usually includes the secure request scheme (`https`), host, and client IP address. Apps don't automatically read these request headers to discover and use the original request information.

The scheme is used in link generation that affects the authentication flow with external providers. Losing the secure scheme (`https`) results in the app generating incorrect insecure redirect URLs.

Use Forwarded Headers Middleware to make the original request information available to the app for request processing.

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Troubleshooting

- **ASP.NET Core 2.x only:** If Identity isn't configured by calling `services.AddIdentity` in `ConfigureServices` , attempting to authenticate will result in *ArgumentException: The 'SignInScheme' option must be provided.* The project template used in this sample ensures that this is done.
- If the site database has not been created by applying the initial migration, you will get *A database operation failed while processing the request* error. Tap **Apply Migrations** to create the database and refresh to continue past the error.

Next steps

- This article showed how you can authenticate with Twitter. You can follow a similar approach to authenticate with other providers listed on the previous page.
- Once you publish your web site to Azure web app, you should reset the `ConsumerSecret` in the Twitter developer portal.
- Set the `Authentication:Twitter:ConsumerKey` and `Authentication:Twitter:ConsumerSecret` as application settings in the Azure portal. The configuration system is set up to read keys from environment variables.

External OAuth authentication providers

9/22/2020 • 2 minutes to read • Edit Online

By Rick Anderson, Pranav Rastogi, and Valeriy Novytskyy

The following list includes common external OAuth authentication providers that work with ASP.NET Core apps. Third-party NuGet packages, such as the ones maintained by aspnet-contrib, can be used to complement the authentication providers implemented by the ASP.NET Core team.

- LinkedIn (Instructions)
- Instagram (Instructions)
- Reddit (Instructions)
- Github (Instructions)
- Yahoo (Instructions)
- Tumblr (Instructions)
- Pinterest (Instructions)
- Pocket (Instructions)
- Flickr (Instructions)
- Dribble (Instructions)
- Vimeo (Instructions)
- SoundCloud (Instructions)
- VK (Instructions)

Multiple authentication providers

When the app requires multiple providers, chain the provider extension methods behind AddAuthentication:

```
services.AddAuthentication()
    .AddMicrosoftAccount(microsoftOptions => { ... })
    .AddGoogle(googleOptions => { ... })
    .AddTwitter(twitterOptions => { ... })
    .AddFacebook(facebookOptions => { ... });
```

Forward request information with a proxy or load balancer

If the app is deployed behind a proxy server or load balancer, some of the original request information might be forwarded to the app in request headers. This information usually includes the secure request scheme (`https`), host, and client IP address. Apps don't automatically read these request headers to discover and use the original request information.

The scheme is used in link generation that affects the authentication flow with external providers. Losing the secure scheme (`https`) results in the app generating incorrect insecure redirect URLs.

Use Forwarded Headers Middleware to make the original request information available to the app for request

processing.

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Persist additional claims and tokens from external providers in ASP.NET Core

9/22/2020 • 16 minutes to read • Edit Online

An ASP.NET Core app can establish additional claims and tokens from external authentication providers, such as Facebook, Google, Microsoft, and Twitter. Each provider reveals different information about users on its platform, but the pattern for receiving and transforming user data into additional claims is the same.

View or download sample code (how to download)

Prerequisites

Decide which external authentication providers to support in the app. For each provider, register the app and obtain a client ID and client secret. For more information, see Facebook, Google, and external provider authentication in ASP.NET Core. The sample app uses the Google authentication provider.

Set the client ID and client secret

The OAuth authentication provider establishes a trust relationship with an app using a client ID and client secret. Client ID and client secret values are created for the app by the external authentication provider when the app is registered with the provider. Each external provider that the app uses must be configured independently with the provider's client ID and client secret. For more information, see the external authentication provider topics that apply to your scenario:

- Facebook authentication
- Google authentication
- Microsoft authentication
- Twitter authentication
- Other authentication providers
- OpenIdConnect

The sample app configures the Google authentication provider with a client ID and client secret provided by Google:

```
services.AddAuthentication().AddGoogle(options =>
{
    // Provide the Google Client ID
    options.ClientId = "XXXXXXXXXXXXXXX.apps.googleusercontent.com";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientId" "{Client ID}"

    // Provide the Google Client Secret
    options.ClientSecret = "{Client Secret}";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientSecret" "{Client Secret}"

    options.ClaimActions.MapJsonKey("urn:google:picture", "picture", "url");
    options.ClaimActions.MapJsonKey("urn:google:locale", "locale", "string");
    options.SaveTokens = true;

    options.Events.OnCreatingTicket = ctx =>
    {
        List<AuthenticationToken> tokens = ctx.Properties.GetTokens().ToList();

        tokens.Add(new AuthenticationToken()
        {
            Name = "TicketCreated",
            Value = DateTime.UtcNow.ToString()
        });

        ctx.Properties.StoreTokens(tokens);

        return Task.CompletedTask;
    };
});
```

Establish the authentication scope

Specify the list of permissions to retrieve from the provider by specifying the Scope. Authentication scopes for common external providers appear in the following table.

PROVIDER	SCOPE
Facebook	`https://www.facebook.com/dialog/oauth`
Google	`https://www.googleapis.com/auth/userinfo.profile`
Microsoft	`https://login.microsoftonline.com/common/oauth2/v2.0/authorize`
Twitter	`https://api.twitter.com/oauth/authenticate`

In the sample app, Google's `userinfo.profile` scope is automatically added by the framework when AddGoogle is called on the AuthenticationBuilder. If the app requires additional scopes, add them to the options. In the following example, the Google `https://www.googleapis.com/auth/user.birthday.read` scope is added in order to retrieve a user's birthday:

```
options.Scope.Add("https://www.googleapis.com/auth/user.birthday.read");
```

Map user data keys and create claims

In the provider's options, specify a MapJsonKey or MapJsonSubKey for each key/subkey in the external provider's JSON user data for the app identity to read on sign in. For more information on claim types, see ClaimTypes.

The sample app creates locale (`urn:google:locale`) and picture (`urn:google:picture`) claims from the `locale` and `picture` keys in Google user data:

```
services.AddAuthentication().AddGoogle(options =>
{
    // Provide the Google Client ID
    options.ClientId = "XXXXXXXXXXXXXXX.apps.googleusercontent.com";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientId" "{Client ID}"

    // Provide the Google Client Secret
    options.ClientSecret = "{Client Secret}";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientSecret" "{Client Secret}"

    options.ClaimActions.MapJsonKey("urn:google:picture", "picture", "url");
    options.ClaimActions.MapJsonKey("urn:google:locale", "locale", "string");
    options.SaveTokens = true;

    options.Events.OnCreatingTicket = ctx =>
    {
        List<AuthenticationToken> tokens = ctx.Properties.GetTokens().ToList();

        tokens.Add(new AuthenticationToken()
        {
            Name = "TicketCreated",
            Value = DateTime.UtcNow.ToString()
        });

        ctx.Properties.StoreTokens(tokens);

        return Task.CompletedTask;
    };
});
```

In `Microsoft.AspNetCore.Identity.UI.Pages.Account.Internal.ExternalLoginModel.OnPostConfirmationAsync`, an IdentityUser (`ApplicationUser`) is signed into the app with SignInAsync. During the sign in process, the UserManager<TUser> can store an `ApplicationUser` claims for user data available from the Principal.

In the sample app, `OnPostConfirmationAsync` (*Account/ExternalLogin.cshtml.cs*) establishes the locale (`urn:google:locale`) and picture (`urn:google:picture`) claims for the signed in `ApplicationUser`, including a claim for GivenName:

```
public async Task<IActionResult> OnPostConfirmationAsync(string returnUrl = null)
{
    returnUrl = returnUrl ?? Url.Content("~/");
    // Get the information about the user from the external login provider
    var info = await _signInManager.GetExternalLoginInfoAsync();

    if (info == null)
    {
        ErrorMessage =
            "Error loading external login information during confirmation.";

        return RedirectToPage("./Login", new { ReturnUrl = returnUrl });
    }

    if (ModelState.IsValid)
    {
        var user = new IdentityUser
        {
            UserName = Input.Email,
            Email = Input.Email
        };
```

```
        var result = await _userManager.CreateAsync(user);

        if (result.Succeeded)
        {
            result = await _userManager.AddLoginAsync(user, info);

            if (result.Succeeded)
            {
                // If they exist, add claims to the user for:
                //    Given (first) name
                //    Locale
                //    Picture
                if (info.Principal.HasClaim(c => c.Type == ClaimTypes.GivenName))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst(ClaimTypes.GivenName));
                }

                if (info.Principal.HasClaim(c => c.Type == "urn:google:locale"))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst("urn:google:locale"));
                }

                if (info.Principal.HasClaim(c => c.Type == "urn:google:picture"))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst("urn:google:picture"));
                }

                // Include the access token in the properties
                var props = new AuthenticationProperties();
                props.StoreTokens(info.AuthenticationTokens);
                props.IsPersistent = true;

                await _signInManager.SignInAsync(user, props);

                _logger.LogInformation(
                    "User created an account using {Name} provider.",
                    info.LoginProvider);

                return LocalRedirect(returnUrl);
            }
        }

        foreach (var error in result.Errors)
        {
            ModelState.AddModelError(string.Empty, error.Description);
        }
    }

    LoginProvider = info.LoginProvider;
    ReturnUrl = returnUrl;
    return Page();
}
```

By default, a user's claims are stored in the authentication cookie. If the authentication cookie is too large, it can cause the app to fail because:

- The browser detects that the cookie header is too long.
- The overall size of the request is too large.

If a large amount of user data is required for processing user requests:

- Limit the number and size of user claims for request processing to only what the app requires.
- Use a custom ITicketStore for the Cookie Authentication Middleware's SessionStore to store identity across requests. Preserve large quantities of identity information on the server while only sending a small session

identifier key to the client.

Save the access token

SaveTokens defines whether access and refresh tokens should be stored in the AuthenticationProperties after a successful authorization. `SaveTokens` is set to `false` by default to reduce the size of the final authentication cookie.

The sample app sets the value of `SaveTokens` to `true` in GoogleOptions:

```
services.AddAuthentication().AddGoogle(options =>
{
    // Provide the Google Client ID
    options.ClientId = "XXXXXXXXXXXXXXX.apps.googleusercontent.com";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientId" "{Client ID}"

    // Provide the Google Client Secret
    options.ClientSecret = "{Client Secret}";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientSecret" "{Client Secret}"

    options.ClaimActions.MapJsonKey("urn:google:picture", "picture", "url");
    options.ClaimActions.MapJsonKey("urn:google:locale", "locale", "string");
    options.SaveTokens = true;

    options.Events.OnCreatingTicket = ctx =>
    {
        List<AuthenticationToken> tokens = ctx.Properties.GetTokens().ToList();

        tokens.Add(new AuthenticationToken()
        {
            Name = "TicketCreated",
            Value = DateTime.UtcNow.ToString()
        });

        ctx.Properties.StoreTokens(tokens);

        return Task.CompletedTask;
    };
});
```

When `OnPostConfirmationAsync` executes, store the access token (ExternalLoginInfo.AuthenticationTokens) from the external provider in the `ApplicationUser`'s `AuthenticationProperties`.

The sample app saves the access token in `OnPostConfirmationAsync` (new user registration) and `OnGetCallbackAsync` (previously registered user) in *Account/ExternalLogin.cshtml.cs*:

```
public async Task<IActionResult> OnPostConfirmationAsync(string returnUrl = null)
{
    returnUrl = returnUrl ?? Url.Content("~/");
    // Get the information about the user from the external login provider
    var info = await _signInManager.GetExternalLoginInfoAsync();

    if (info == null)
    {
        ErrorMessage =
            "Error loading external login information during confirmation.";

        return RedirectToPage("./Login", new { ReturnUrl = returnUrl });
    }

    if (ModelState.IsValid)
    {
        var user = new IdentityUser
        {
```

```
            UserName = Input.Email,
            Email = Input.Email
        };

        var result = await _userManager.CreateAsync(user);

        if (result.Succeeded)
        {
            result = await _userManager.AddLoginAsync(user, info);

            if (result.Succeeded)
            {
                // If they exist, add claims to the user for:
                //    Given (first) name
                //    Locale
                //    Picture
                if (info.Principal.HasClaim(c => c.Type == ClaimTypes.GivenName))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst(ClaimTypes.GivenName));
                }

                if (info.Principal.HasClaim(c => c.Type == "urn:google:locale"))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst("urn:google:locale"));
                }

                if (info.Principal.HasClaim(c => c.Type == "urn:google:picture"))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst("urn:google:picture"));
                }

                // Include the access token in the properties
                var props = new AuthenticationProperties();
                props.StoreTokens(info.AuthenticationTokens);
                props.IsPersistent = true;

                await _signInManager.SignInAsync(user, props);

                _logger.LogInformation(
                    "User created an account using {Name} provider.",
                    info.LoginProvider);

                return LocalRedirect(returnUrl);
            }
        }

        foreach (var error in result.Errors)
        {
            ModelState.AddModelError(string.Empty, error.Description);
        }
    }

    LoginProvider = info.LoginProvider;
    ReturnUrl = returnUrl;
    return Page();
}
```

How to add additional custom tokens

To demonstrate how to add a custom token, which is stored as part of `SaveTokens`, the sample app adds an AuthenticationToken with the current DateTime for an AuthenticationToken.Name of `TicketCreated`:

```
services.AddAuthentication().AddGoogle(options =>
{
    // Provide the Google Client ID
    options.ClientId = "XXXXXXXXXXXXXXX.apps.googleusercontent.com";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientId" "{Client ID}"

    // Provide the Google Client Secret
    options.ClientSecret = "{Client Secret}";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientSecret" "{Client Secret}"

    options.ClaimActions.MapJsonKey("urn:google:picture", "picture", "url");
    options.ClaimActions.MapJsonKey("urn:google:locale", "locale", "string");
    options.SaveTokens = true;

    options.Events.OnCreatingTicket = ctx =>
    {
        List<AuthenticationToken> tokens = ctx.Properties.GetTokens().ToList();

        tokens.Add(new AuthenticationToken()
        {
            Name = "TicketCreated",
            Value = DateTime.UtcNow.ToString()
        });

        ctx.Properties.StoreTokens(tokens);

        return Task.CompletedTask;
    };
});
```

Creating and adding claims

The framework provides common actions and extension methods for creating and adding claims to the collection. For more information, see the ClaimActionCollectionMapExtensions and ClaimActionCollectionUniqueExtensions.

Users can define custom actions by deriving from ClaimAction and implementing the abstract Run method.

For more information, see Microsoft.AspNetCore.Authentication.OAuth.Claims.

Removal of claim actions and claims

ClaimActionCollection.Remove(String) removes all claim actions for the given ClaimType from the collection. ClaimActionCollectionMapExtensions.DeleteClaim(ClaimActionCollection, String) deletes a claim of the given ClaimType from the identity. DeleteClaim is primarily used with OpenID Connect (OIDC) to remove protocol-generated claims.

Sample app output

Forward request information with a proxy or load balancer

If the app is deployed behind a proxy server or load balancer, some of the original request information might be forwarded to the app in request headers. This information usually includes the secure request scheme (`https`), host, and client IP address. Apps don't automatically read these request headers to discover and use the original request information.

The scheme is used in link generation that affects the authentication flow with external providers. Losing the secure scheme (`https`) results in the app generating incorrect insecure redirect URLs.

Use Forwarded Headers Middleware to make the original request information available to the app for request processing.

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

An ASP.NET Core app can establish additional claims and tokens from external authentication providers, such as Facebook, Google, Microsoft, and Twitter. Each provider reveals different information about users on its platform, but the pattern for receiving and transforming user data into additional claims is the same.

View or download sample code (how to download)

Prerequisites

Decide which external authentication providers to support in the app. For each provider, register the app and obtain a client ID and client secret. For more information, see Facebook, Google, and external provider authentication in ASP.NET Core. The sample app uses the Google authentication provider.

Set the client ID and client secret

The OAuth authentication provider establishes a trust relationship with an app using a client ID and client secret. Client ID and client secret values are created for the app by the external authentication provider when the app is registered with the provider. Each external provider that the app uses must be configured independently with the provider's client ID and client secret. For more information, see the external authentication provider topics that apply to your scenario:

- Facebook authentication
- Google authentication
- Microsoft authentication
- Twitter authentication
- Other authentication providers
- OpenIdConnect

The sample app configures the Google authentication provider with a client ID and client secret provided by Google:

```
services.AddAuthentication().AddGoogle(options =>
{
    // Provide the Google Client ID
    options.ClientId = "XXXXXXXXXXXXXXX.apps.googleusercontent.com";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientId" "{Client ID}"

    // Provide the Google Client Secret
    options.ClientSecret = "{Client Secret}";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientSecret" "{Client Secret}"

    options.ClaimActions.MapJsonKey("urn:google:picture", "picture", "url");
    options.ClaimActions.MapJsonKey("urn:google:locale", "locale", "string");
    options.SaveTokens = true;

    options.Events.OnCreatingTicket = ctx =>
    {
        List<AuthenticationToken> tokens = ctx.Properties.GetTokens().ToList();

        tokens.Add(new AuthenticationToken()
        {
            Name = "TicketCreated",
            Value = DateTime.UtcNow.ToString()
        });

        ctx.Properties.StoreTokens(tokens);

        return Task.CompletedTask;
    };
});
```

Establish the authentication scope

Specify the list of permissions to retrieve from the provider by specifying the Scope. Authentication scopes for common external providers appear in the following table.

PROVIDER	SCOPE
Facebook	`https://www.facebook.com/dialog/oauth`
Google	`https://www.googleapis.com/auth/userinfo.profile`

PROVIDER	SCOPE
Microsoft	`https://login.microsoftonline.com/common/oauth2/v2.0/authorize`
Twitter	`https://api.twitter.com/oauth/authenticate`

In the sample app, Google's `userinfo.profile` scope is automatically added by the framework when AddGoogle is called on the AuthenticationBuilder. If the app requires additional scopes, add them to the options. In the following example, the Google `https://www.googleapis.com/auth/user.birthday.read` scope is added in order to retrieve a user's birthday:

```
options.Scope.Add("https://www.googleapis.com/auth/user.birthday.read");
```

Map user data keys and create claims

In the provider's options, specify a MapJsonKey or MapJsonSubKey for each key/subkey in the external provider's JSON user data for the app identity to read on sign in. For more information on claim types, see ClaimTypes.

The sample app creates locale (`urn:google:locale`) and picture (`urn:google:picture`) claims from the `locale` and `picture` keys in Google user data:

```
services.AddAuthentication().AddGoogle(options =>
{
    // Provide the Google Client ID
    options.ClientId = "XXXXXXXXXXXXXX.apps.googleusercontent.com";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientId" "{Client ID}"

    // Provide the Google Client Secret
    options.ClientSecret = "{Client Secret}";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientSecret" "{Client Secret}"

    options.ClaimActions.MapJsonKey("urn:google:picture", "picture", "url");
    options.ClaimActions.MapJsonKey("urn:google:locale", "locale", "string");
    options.SaveTokens = true;

    options.Events.OnCreatingTicket = ctx =>
    {
        List<AuthenticationToken> tokens = ctx.Properties.GetTokens().ToList();

        tokens.Add(new AuthenticationToken()
        {
            Name = "TicketCreated",
            Value = DateTime.UtcNow.ToString()
        });

        ctx.Properties.StoreTokens(tokens);

        return Task.CompletedTask;
    };
});
```

In `Microsoft.AspNetCore.Identity.UI.Pages.Account.Internal.ExternalLoginModel.OnPostConfirmationAsync` , an IdentityUser (`ApplicationUser`) is signed into the app with SignInAsync. During the sign in process, the UserManager<TUser> can store an `ApplicationUser` claims for user data available from the Principal.

In the sample app, `OnPostConfirmationAsync` (*Account/ExternalLogin.cshtml.cs*) establishes the locale (`urn:google:locale`) and picture (`urn:google:picture`) claims for the signed in `ApplicationUser` , including a claim for

GivenName:

```
public async Task<IActionResult> OnPostConfirmationAsync(string returnUrl = null)
{
    returnUrl = returnUrl ?? Url.Content("~/");
    // Get the information about the user from the external login provider
    var info = await _signInManager.GetExternalLoginInfoAsync();

    if (info == null)
    {
        ErrorMessage =
            "Error loading external login information during confirmation.";

        return RedirectToPage("./Login", new { ReturnUrl = returnUrl });
    }

    if (ModelState.IsValid)
    {
        var user = new IdentityUser
        {
            UserName = Input.Email,
            Email = Input.Email
        };

        var result = await _userManager.CreateAsync(user);

        if (result.Succeeded)
        {
            result = await _userManager.AddLoginAsync(user, info);

            if (result.Succeeded)
            {
                // If they exist, add claims to the user for:
                //    Given (first) name
                //    Locale
                //    Picture
                if (info.Principal.HasClaim(c => c.Type == ClaimTypes.GivenName))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst(ClaimTypes.GivenName));
                }

                if (info.Principal.HasClaim(c => c.Type == "urn:google:locale"))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst("urn:google:locale"));
                }

                if (info.Principal.HasClaim(c => c.Type == "urn:google:picture"))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst("urn:google:picture"));
                }

                // Include the access token in the properties
                var props = new AuthenticationProperties();
                props.StoreTokens(info.AuthenticationTokens);
                props.IsPersistent = true;

                await _signInManager.SignInAsync(user, props);

                _logger.LogInformation(
                    "User created an account using {Name} provider.",
                    info.LoginProvider);

                return LocalRedirect(returnUrl);
            }
        }
```

```
        foreach (var error in result.Errors)
        {
            ModelState.AddModelError(string.Empty, error.Description);
        }
    }

    LoginProvider = info.LoginProvider;
    ReturnUrl = returnUrl;
    return Page();
}
```

By default, a user's claims are stored in the authentication cookie. If the authentication cookie is too large, it can cause the app to fail because:

- The browser detects that the cookie header is too long.
- The overall size of the request is too large.

If a large amount of user data is required for processing user requests:

- Limit the number and size of user claims for request processing to only what the app requires.
- Use a custom ITicketStore for the Cookie Authentication Middleware's SessionStore to store identity across requests. Preserve large quantities of identity information on the server while only sending a small session identifier key to the client.

Save the access token

SaveTokens defines whether access and refresh tokens should be stored in the AuthenticationProperties after a successful authorization. `SaveTokens` is set to `false` by default to reduce the size of the final authentication cookie.

The sample app sets the value of `SaveTokens` to `true` in GoogleOptions:

```
services.AddAuthentication().AddGoogle(options =>
{
    // Provide the Google Client ID
    options.ClientId = "XXXXXXXXXXXXXX.apps.googleusercontent.com";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientId" "{Client ID}"

    // Provide the Google Client Secret
    options.ClientSecret = "{Client Secret}";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientSecret" "{Client Secret}"

    options.ClaimActions.MapJsonKey("urn:google:picture", "picture", "url");
    options.ClaimActions.MapJsonKey("urn:google:locale", "locale", "string");
    options.SaveTokens = true;

    options.Events.OnCreatingTicket = ctx =>
    {
        List<AuthenticationToken> tokens = ctx.Properties.GetTokens().ToList();

        tokens.Add(new AuthenticationToken()
        {
            Name = "TicketCreated",
            Value = DateTime.UtcNow.ToString()
        });

        ctx.Properties.StoreTokens(tokens);

        return Task.CompletedTask;
    };
});
```

When `OnPostConfirmationAsync` executes, store the access token (ExternalLoginInfo.AuthenticationTokens) from the external provider in the `ApplicationUser`'s `AuthenticationProperties`.

The sample app saves the access token in `OnPostConfirmationAsync` (new user registration) and `OnGetCallbackAsync` (previously registered user) in *Account/ExternalLogin.cshtml.cs*:

```
public async Task<IActionResult> OnPostConfirmationAsync(string returnUrl = null)
{
    returnUrl = returnUrl ?? Url.Content("~/");
    // Get the information about the user from the external login provider
    var info = await _signInManager.GetExternalLoginInfoAsync();

    if (info == null)
    {
        ErrorMessage =
            "Error loading external login information during confirmation.";

        return RedirectToPage("./Login", new { ReturnUrl = returnUrl });
    }

    if (ModelState.IsValid)
    {
        var user = new IdentityUser
        {
            UserName = Input.Email,
            Email = Input.Email
        };

        var result = await _userManager.CreateAsync(user);

        if (result.Succeeded)
        {
            result = await _userManager.AddLoginAsync(user, info);

            if (result.Succeeded)
            {
                // If they exist, add claims to the user for:
                //    Given (first) name
                //    Locale
                //    Picture
                if (info.Principal.HasClaim(c => c.Type == ClaimTypes.GivenName))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst(ClaimTypes.GivenName));
                }

                if (info.Principal.HasClaim(c => c.Type == "urn:google:locale"))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst("urn:google:locale"));
                }

                if (info.Principal.HasClaim(c => c.Type == "urn:google:picture"))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst("urn:google:picture"));
                }

                // Include the access token in the properties
                var props = new AuthenticationProperties();
                props.StoreTokens(info.AuthenticationTokens);
                props.IsPersistent = true;

                await _signInManager.SignInAsync(user, props);

                _logger.LogInformation(
                    "User created an account using {Name} provider.",
                    info.LoginProvider);
```

```
                return LocalRedirect(returnUrl);
            }
        }

        foreach (var error in result.Errors)
        {
            ModelState.AddModelError(string.Empty, error.Description);
        }
    }

    LoginProvider = info.LoginProvider;
    ReturnUrl = returnUrl;
    return Page();
}
```

How to add additional custom tokens

To demonstrate how to add a custom token, which is stored as part of `SaveTokens`, the sample app adds an AuthenticationToken with the current DateTime for an AuthenticationToken.Name of `TicketCreated`:

```
services.AddAuthentication().AddGoogle(options =>
{
    // Provide the Google Client ID
    options.ClientId = "XXXXXXXXXXXXXXX.apps.googleusercontent.com";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientId" "{Client ID}"

    // Provide the Google Client Secret
    options.ClientSecret = "{Client Secret}";
    // Register with User Secrets using:
    // dotnet user-secrets set "Authentication:Google:ClientSecret" "{Client Secret}"

    options.ClaimActions.MapJsonKey("urn:google:picture", "picture", "url");
    options.ClaimActions.MapJsonKey("urn:google:locale", "locale", "string");
    options.SaveTokens = true;

    options.Events.OnCreatingTicket = ctx =>
    {
        List<AuthenticationToken> tokens = ctx.Properties.GetTokens().ToList();

        tokens.Add(new AuthenticationToken()
        {
            Name = "TicketCreated",
            Value = DateTime.UtcNow.ToString()
        });

        ctx.Properties.StoreTokens(tokens);

        return Task.CompletedTask;
    };
});
```

Creating and adding claims

The framework provides common actions and extension methods for creating and adding claims to the collection. For more information, see the ClaimActionCollectionMapExtensions and ClaimActionCollectionUniqueExtensions.

Users can define custom actions by deriving from ClaimAction and implementing the abstract Run method.

For more information, see Microsoft.AspNetCore.Authentication.OAuth.Claims.

Removal of claim actions and claims

ClaimActionCollection.Remove(String) removes all claim actions for the given ClaimType from the collection. ClaimActionCollectionMapExtensions.DeleteClaim(ClaimActionCollection, String) deletes a claim of the given ClaimType from the identity. DeleteClaim is primarily used with OpenID Connect (OIDC) to remove protocol-generated claims.

Policy schemes in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

Authentication policy schemes make it easier to have a single logical authentication scheme potentially use multiple approaches. For example, a policy scheme might use Google authentication for challenges, and cookie authentication for everything else. Authentication policy schemes make it:

- Easy to forward any authentication action to another scheme.
- Forward dynamically based on the request.

All authentication schemes that use derived AuthenticationSchemeOptions and the associated AuthenticationHandler<TOptions>:

- Are automatically policy schemes in ASP.NET Core 2.1 and later.
- Can be enabled via configuring the scheme's options.

```
public class AuthenticationSchemeOptions
{
    /// <summary>
    /// If set, this specifies a default scheme that authentication handlers should
    /// forward all authentication operations to, by default. The default forwarding
    /// logic checks in this order:
    /// 1. The most specific ForwardAuthenticate/Challenge/Forbid/SignIn/SignOut
    /// 2. The ForwardDefaultSelector
    /// 3. ForwardDefault
    /// The first non null result is used as the target scheme to forward to.
    /// </summary>
    public string ForwardDefault { get; set; }

    /// <summary>
    /// If set, this specifies the target scheme that this scheme should forward
    /// AuthenticateAsync calls to. For example:
    /// Context.AuthenticateAsync("ThisScheme") =>
    ///               Context.AuthenticateAsync("ForwardAuthenticateValue");
    /// Set the target to the current scheme to disable forwarding and allow
    /// normal processing.
    /// </summary>
    public string ForwardAuthenticate { get; set; }

    /// <summary>
    /// If set, this specifies the target scheme that this scheme should forward
    /// ChallengeAsync calls to. For example:
    /// Context.ChallengeAsync("ThisScheme") =>
    ///                         Context.ChallengeAsync("ForwardChallengeValue");
    /// Set the target to the current scheme to disable forwarding and allow normal
    /// processing.
    /// </summary>
    public string ForwardChallenge { get; set; }

    /// <summary>
    /// If set, this specifies the target scheme that this scheme should forward
    /// ForbidAsync calls to.For example:
    /// Context.ForbidAsync("ThisScheme")
    ///                               => Context.ForbidAsync("ForwardForbidValue");
    /// Set the target to the current scheme to disable forwarding and allow normal
    /// processing.
    /// </summary>
    public string ForwardForbid { get; set; }

    /// <summary>
```

```
    /// If set, this specifies the target scheme that this scheme should forward
    /// SignInAsync calls to. For example:
    /// Context.SignInAsync("ThisScheme") =>
    ///                               Context.SignInAsync("ForwardSignInValue");
    /// Set the target to the current scheme to disable forwarding and allow normal
    /// processing.
    /// </summary>
    public string ForwardSignIn { get; set; }

    /// <summary>
    /// If set, this specifies the target scheme that this scheme should forward
    /// SignOutAsync calls to. For example:
    /// Context.SignOutAsync("ThisScheme") =>
    ///                             Context.SignOutAsync("ForwardSignOutValue");
    /// Set the target to the current scheme to disable forwarding and allow normal
    /// processing.
    /// </summary>
    public string ForwardSignOut { get; set; }

    /// <summary>
    /// Used to select a default scheme for the current request that authentication
    /// handlers should forward all authentication operations to by default. The
    /// default forwarding checks in this order:
    /// 1. The most specific ForwardAuthenticate/Challenge/Forbid/SignIn/SignOut
    /// 2. The ForwardDefaultSelector
    /// 3. ForwardDefault.
    /// The first non null result will be used as the target scheme to forward to.
    /// </summary>
    public Func<HttpContext, string> ForwardDefaultSelector { get; set; }
}
```

Examples

The following example shows a higher level scheme that combines lower level schemes. Google authentication is used for challenges, and cookie authentication is used for everything else:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
       .AddCookie(options => options.ForwardChallenge = "Google")
       .AddGoogle(options => { });
}
```

The following example enables dynamic selection of schemes on a per request basis. That is, how to mix cookies and API authentication:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
        .AddCookie(options =>
        {
            // For example, can foward any requests that start with /api
            // to the api scheme.
            options.ForwardDefaultSelector = ctx =>
               ctx.Request.Path.StartsWithSegments("/api") ? "Api" : null;
        })
        .AddYourApiAuth("Api");
}
```

Authenticate users with WS-Federation in ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

This tutorial demonstrates how to enable users to sign in with a WS-Federation authentication provider like Active Directory Federation Services (ADFS) or Azure Active Directory (AAD). It uses the ASP.NET Core sample app described in Facebook, Google, and external provider authentication.

For ASP.NET Core apps, WS-Federation support is provided by Microsoft.AspNetCore.Authentication.WsFederation. This component is ported from Microsoft.Owin.Security.WsFederation and shares many of that component's mechanics. However, the components differ in a couple of important ways.

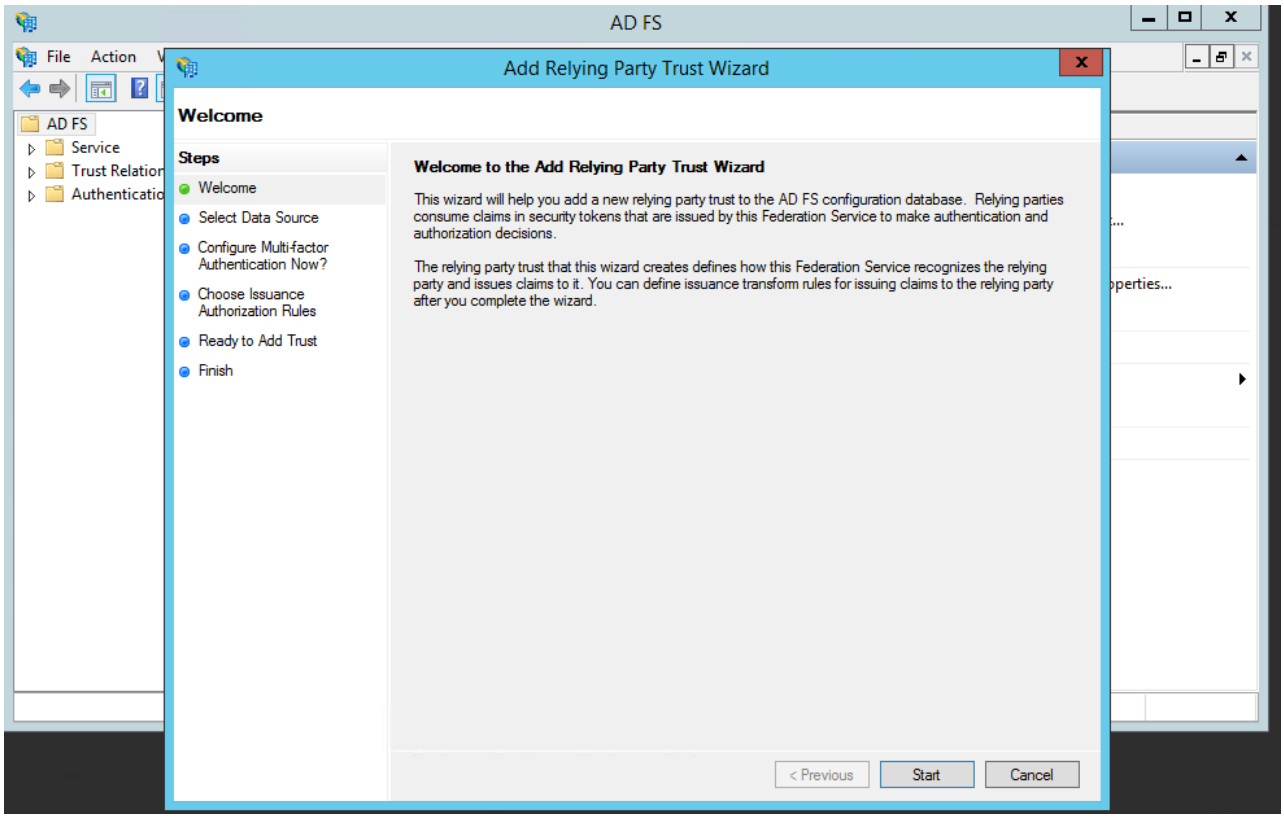
By default, the new middleware:

- Doesn't allow unsolicited logins. This feature of the WS-Federation protocol is vulnerable to XSRF attacks. However, it can be enabled with the `AllowUnsolicitedLogins` option.
- Doesn't check every form post for sign-in messages. Only requests to the `CallbackPath` are checked for sign-ins. `CallbackPath` defaults to `/signin-wsfed` but can be changed via the inherited RemoteAuthenticationOptions.CallbackPath property of the WsFederationOptions class. This path can be shared with other authentication providers by enabling the SkipUnrecognizedRequests option.

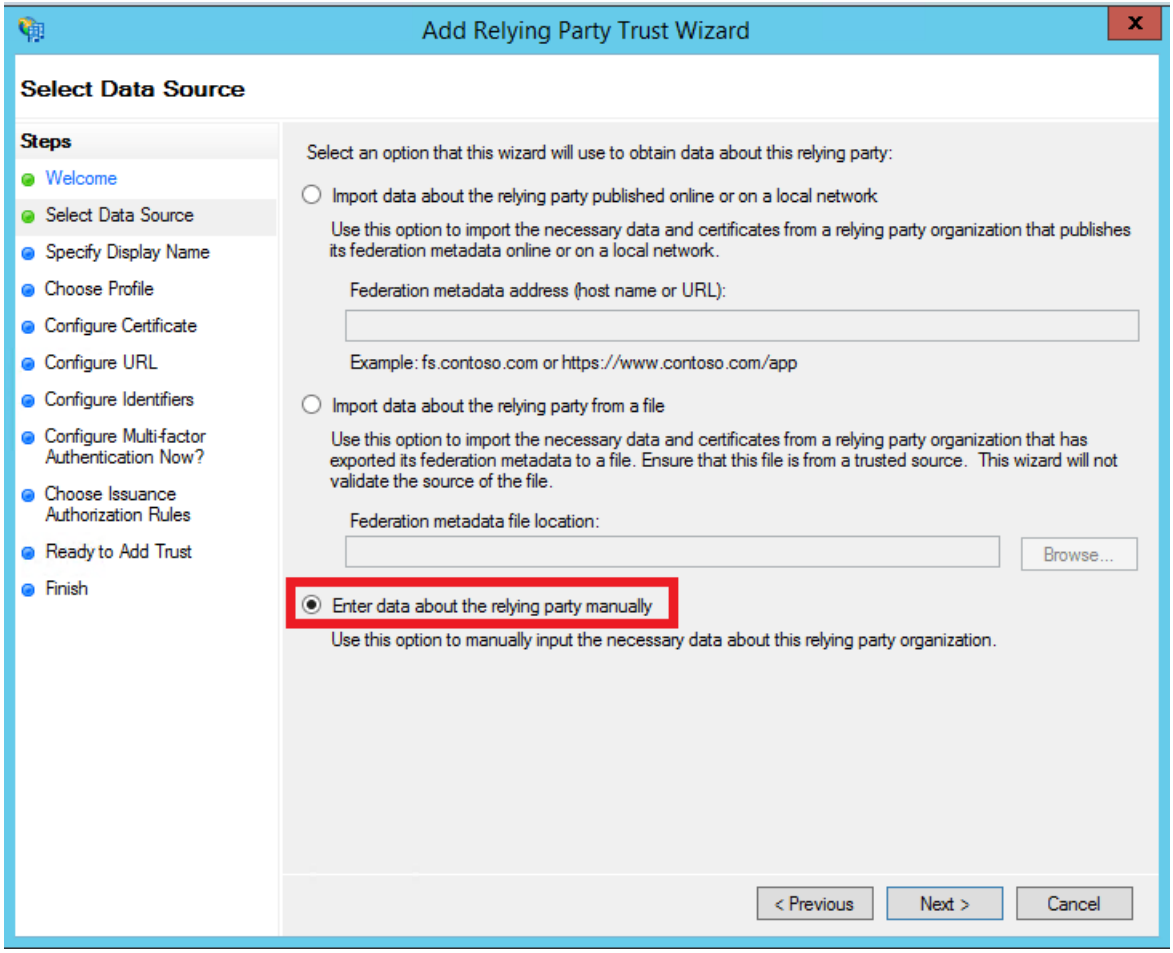
Register the app with Active Directory

Active Directory Federation Services

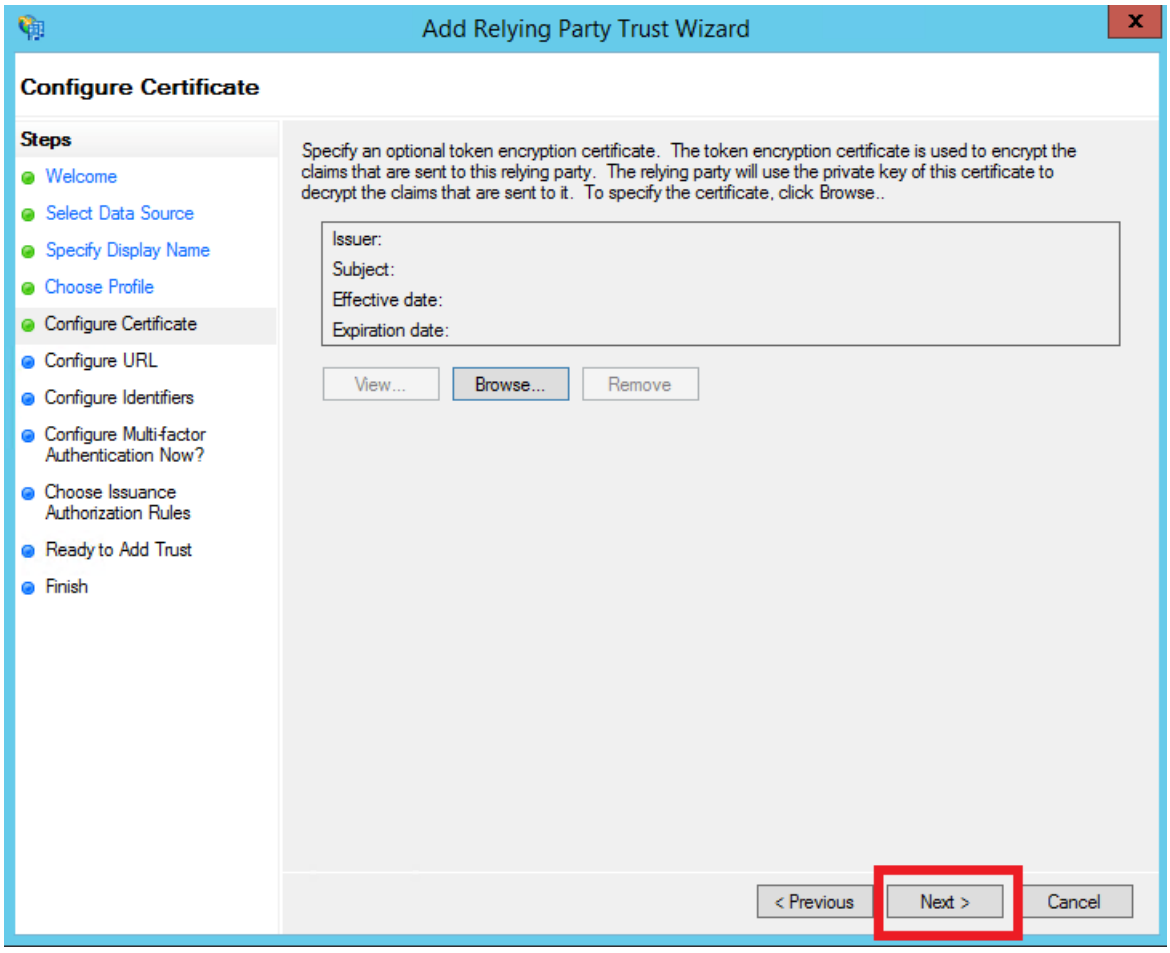
- Open the server's **Add Relying Party Trust Wizard** from the ADFS Management console:



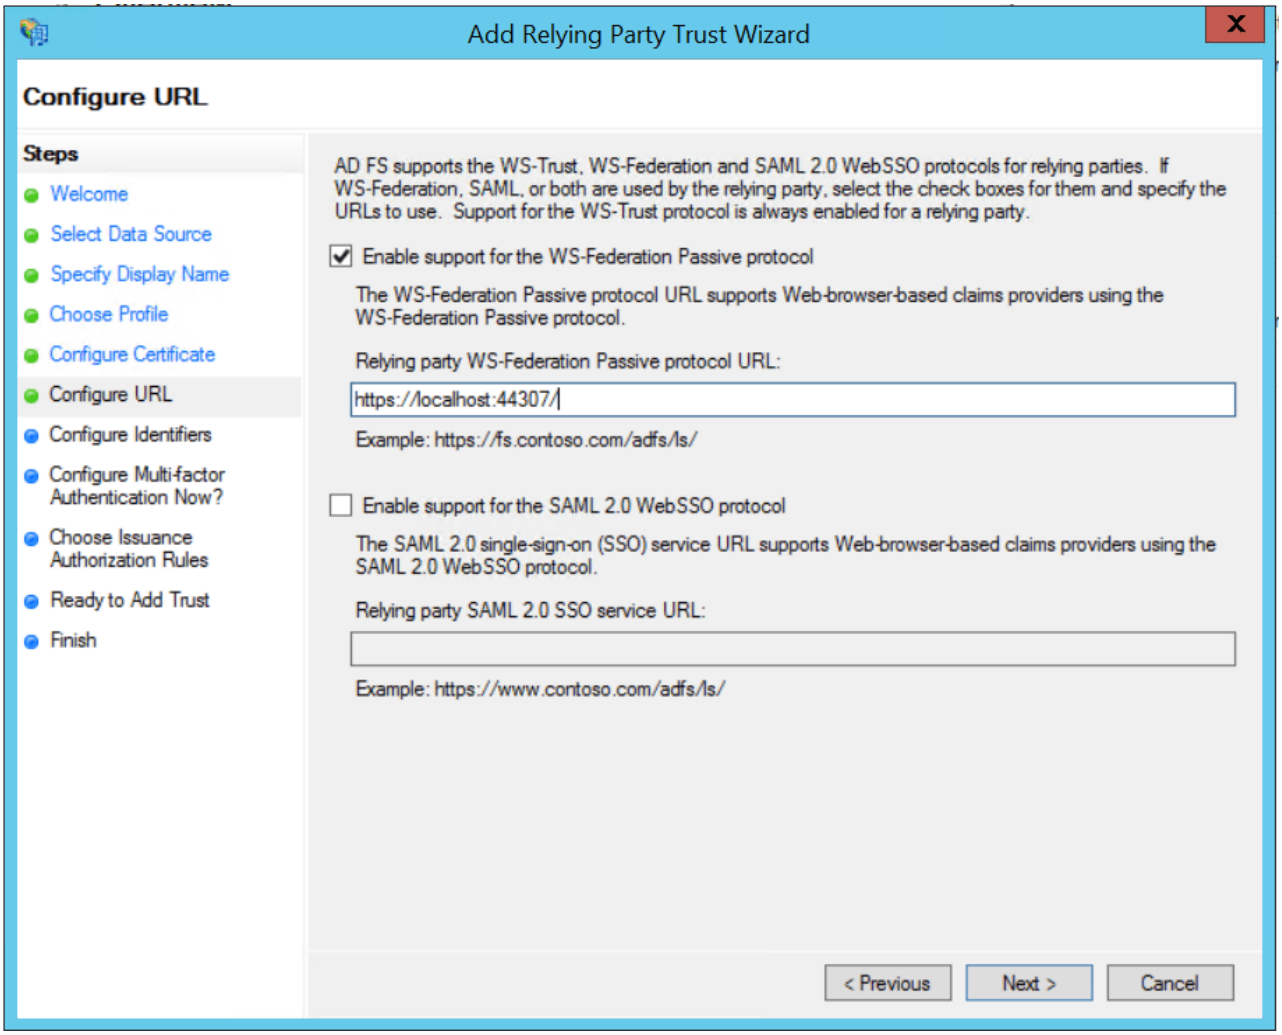
- Choose to enter data manually:



- Enter a display name for the relying party. The name isn't important to the ASP.NET Core app.
- Microsoft.AspNetCore.Authentication.WsFederation lacks support for token encryption, so don't configure a token encryption certificate:

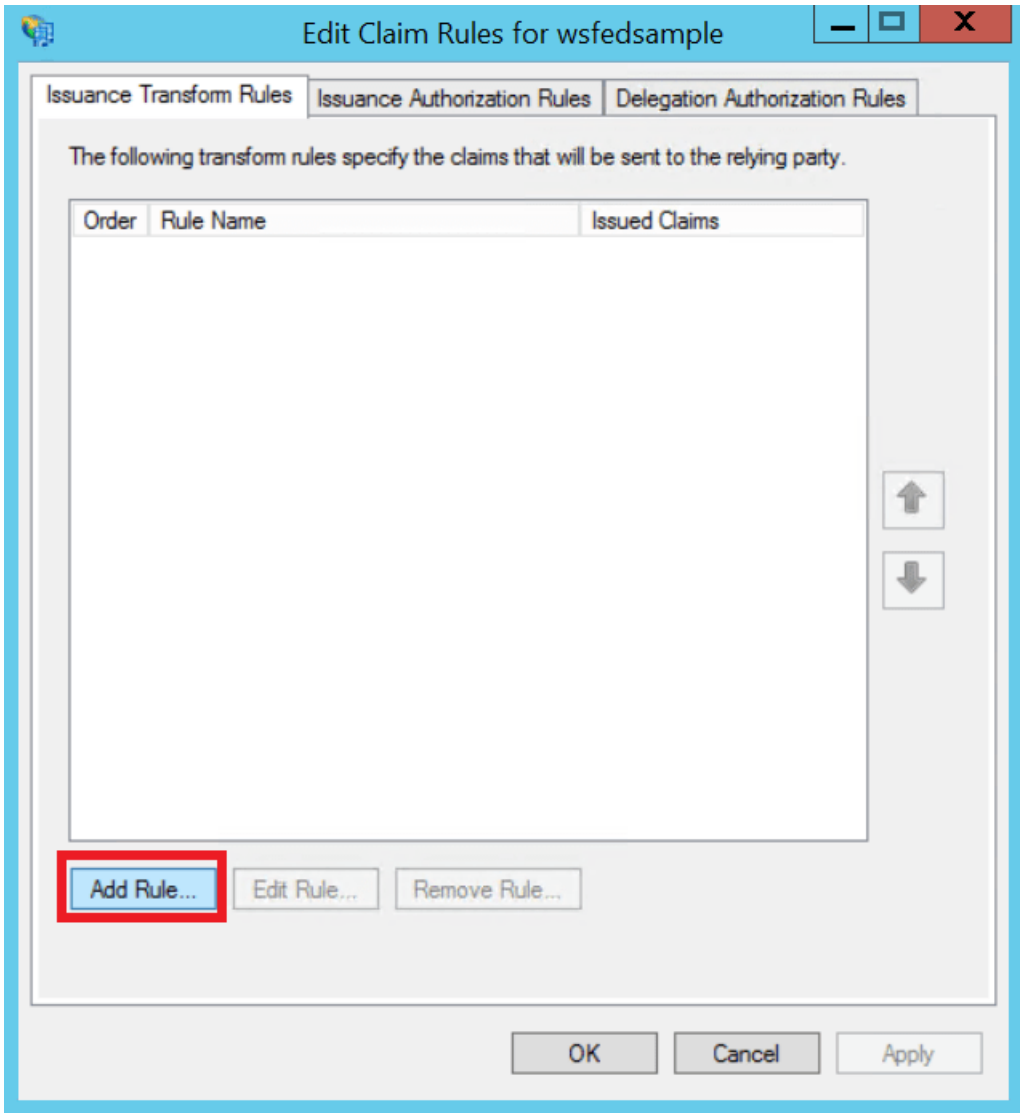


- Enable support for WS-Federation Passive protocol, using the app's URL. Verify the port is correct for the app:

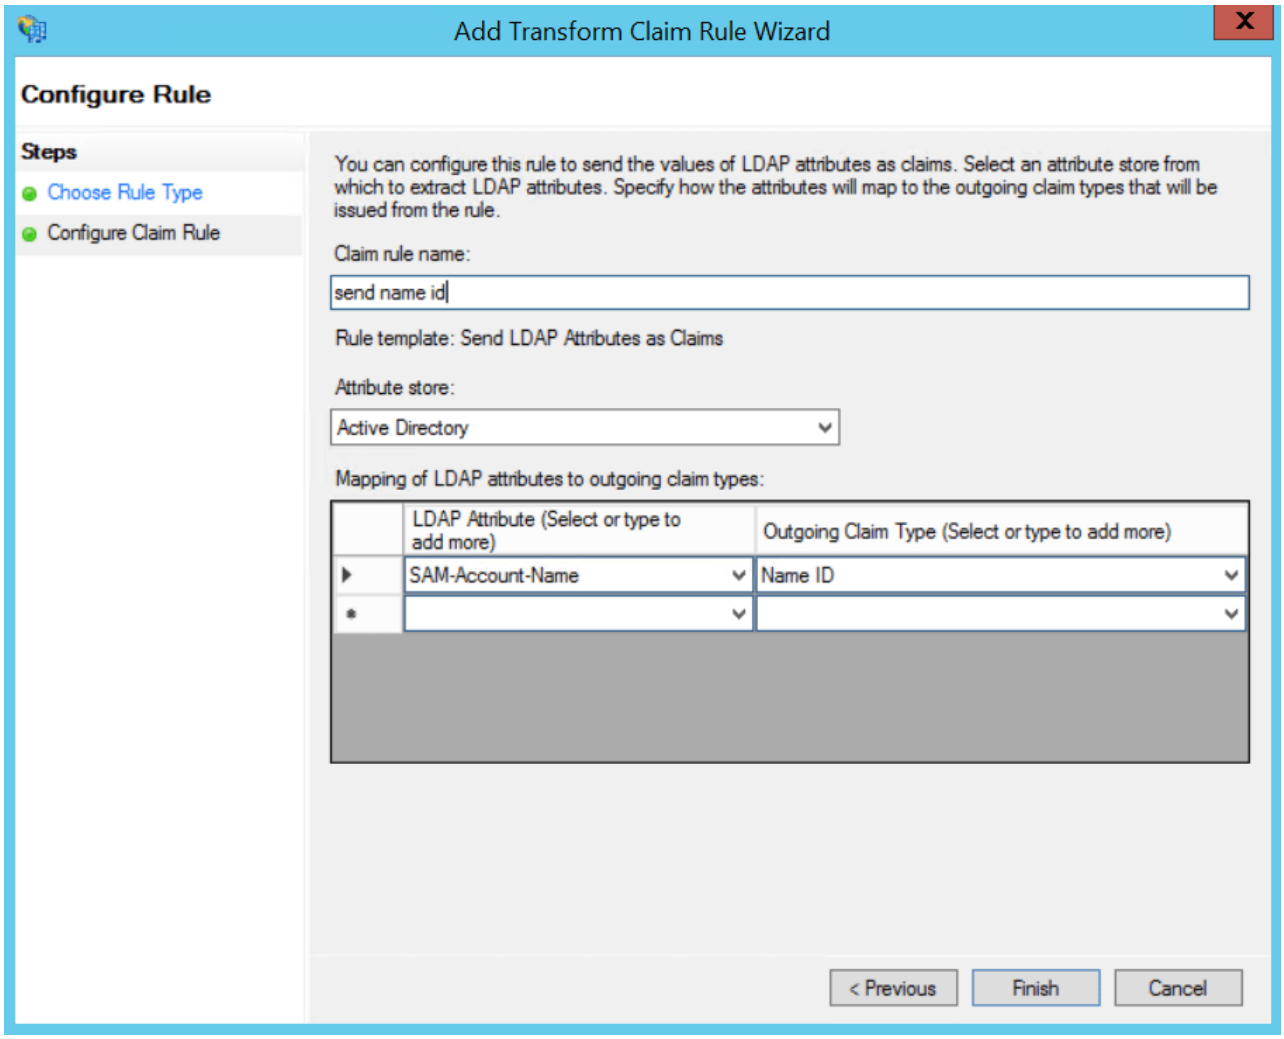


> **NOTE**
>
> This must be an HTTPS URL. IIS Express can provide a self-signed certificate when hosting the app during development. Kestrel requires manual certificate configuration. See the Kestrel documentation for more details.

- Click **Next** through the rest of the wizard and **Close** at the end.
- ASP.NET Core Identity requires a **Name ID** claim. Add one from the **Edit Claim Rules** dialog:



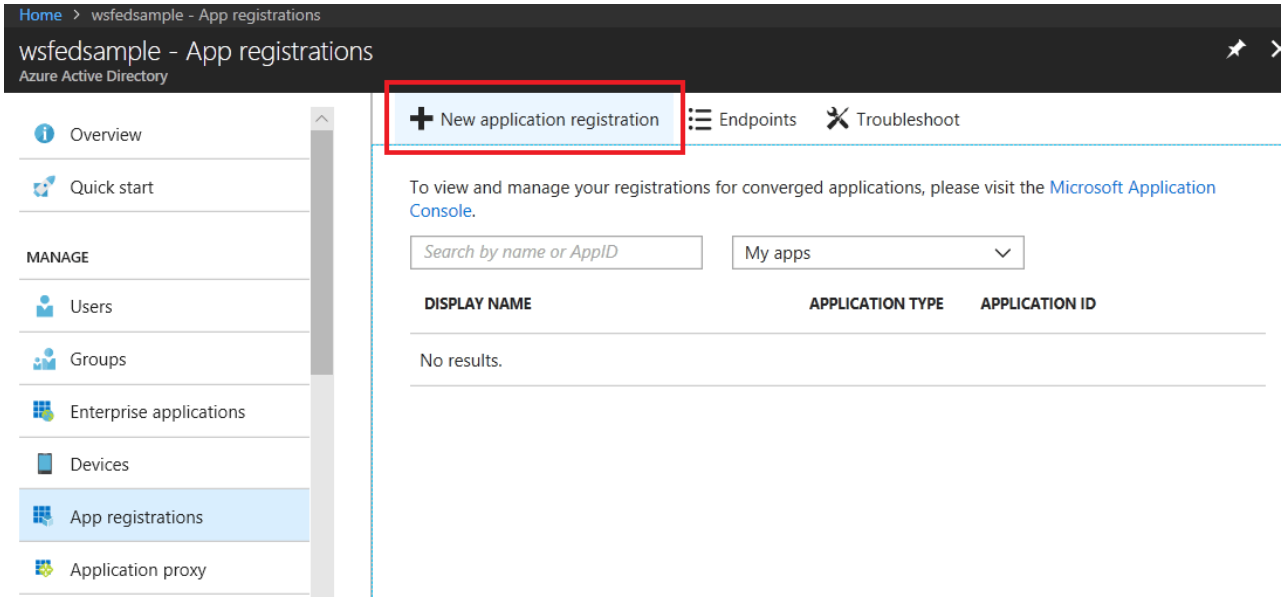
- In the **Add Transform Claim Rule Wizard**, leave the default **Send LDAP Attributes as Claims** template selected, and click **Next**. Add a rule mapping the **SAM-Account-Name** LDAP attribute to the **Name ID** outgoing claim:



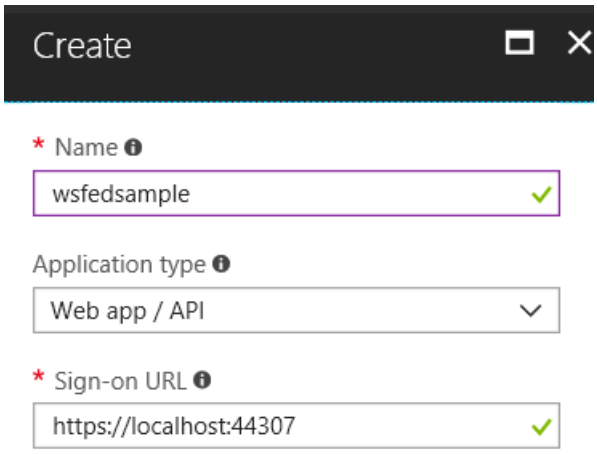
- Click **Finish** > **OK** in the **Edit Claim Rules** window.

Azure Active Directory

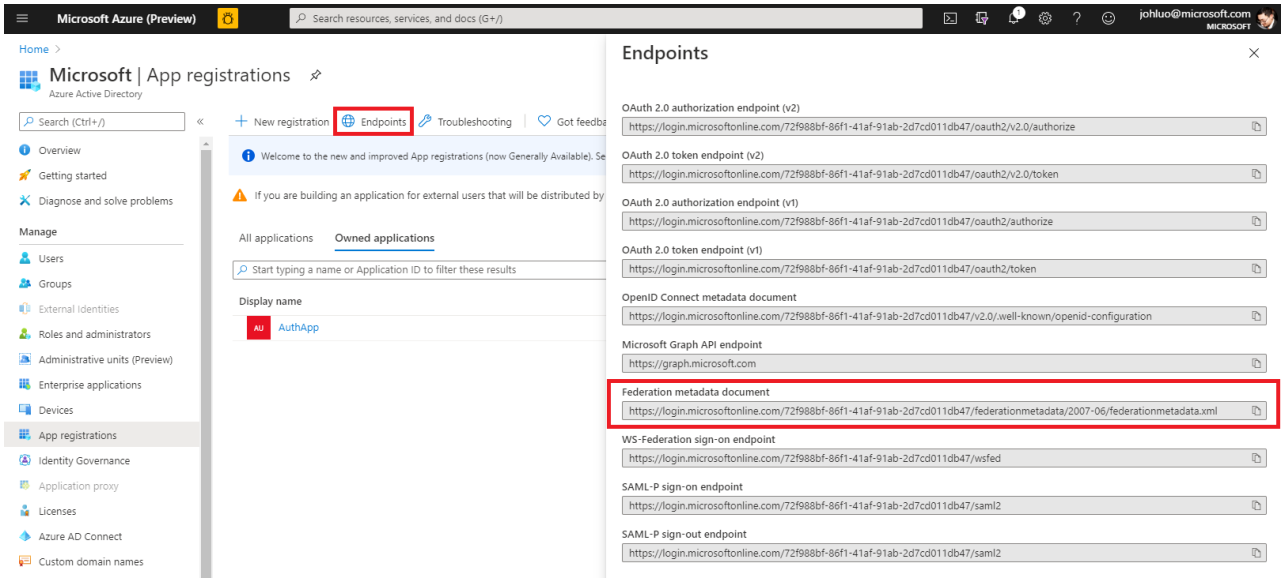
- Navigate to the AAD tenant's app registrations blade. Click **New application registration**:



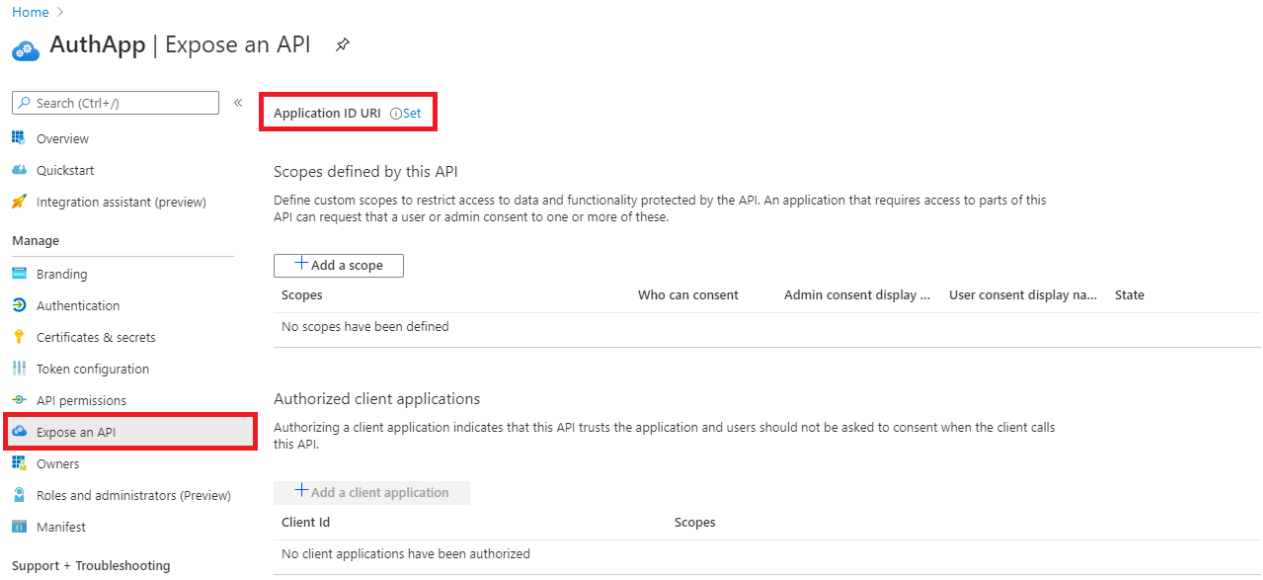
- Enter a name for the app registration. This isn't important to the ASP.NET Core app.
- Enter the URL the app listens on as the **Sign-on URL**:



- Click **Endpoints** and note the **Federation Metadata Document** URL. This is the WS-Federation middleware's `MetadataAddress`:



- Navigate to the new app registration. Click **Expose an API**. Click Application ID URI **Set** > **Save**. Make note of the **Application ID URI**. This is the WS-Federation middleware's `Wtrealm`:



Use WS-Federation without ASP.NET Core Identity

The WS-Federation middleware can be used without Identity. For example:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddAuthentication(sharedOptions =>
    {
        sharedOptions.DefaultScheme = CookieAuthenticationDefaults.AuthenticationScheme;
        sharedOptions.DefaultChallengeScheme = WsFederationDefaults.AuthenticationScheme;
    })
     .AddWsFederation(options =>
     {
         options.Wtrealm = Configuration["wsfed:realm"];
         options.MetadataAddress = Configuration["wsfed:metadata"];
     })
     .AddCookie();

    services.AddControllersWithViews();
    services.AddRazorPages();
}

public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }
    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllerRoute(
            name: "default",
            pattern: "{controller=Home}/{action=Index}/{id?}");
        endpoints.MapRazorPages();
    });
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddAuthentication(sharedOptions =>
    {
        sharedOptions.DefaultScheme = CookieAuthenticationDefaults.AuthenticationScheme;
        sharedOptions.DefaultSignInScheme = CookieAuthenticationDefaults.AuthenticationScheme;
        sharedOptions.DefaultChallengeScheme = WsFederationDefaults.AuthenticationScheme;
    })
    .AddWsFederation(options =>
    {
        options.Wtrealm = Configuration["wsfed:realm"];
        options.MetadataAddress = Configuration["wsfed:metadata"];
    })
    .AddCookie();

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
}

public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseCookiePolicy();

    app.UseAuthentication();

    app.UseMvc(routes =>
    {
        routes.MapRoute(
            name: "default",
            template: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

Add WS-Federation as an external login provider for ASP.NET Core Identity

- Add a dependency on Microsoft.AspNetCore.Authentication.WsFederation to the project.
- Add WS-Federation to `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>(options => options.SignIn.RequireConfirmedAccount = true)
        .AddEntityFrameworkStores<ApplicationDbContext>();

    services.AddAuthentication()
        .AddWsFederation(options =>
        {
            // MetadataAddress represents the Active Directory instance used to authenticate users.
            options.MetadataAddress = "https://<ADFS FQDN or AAD tenant>/FederationMetadata/2007-
06/FederationMetadata.xml";

            // Wtrealm is the app's identifier in the Active Directory instance.
            // For ADFS, use the relying party's identifier, its WS-Federation Passive protocol URL:
            options.Wtrealm = "https://localhost:44307/";

            // For AAD, use the Application ID URI from the app registration's Overview blade:
            options.Wtrealm = "api://bbd35166-7c13-49f3-8041-9551f2847b69";
        });

    services.AddControllersWithViews();
    services.AddRazorPages();
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>()
        .AddEntityFrameworkStores<ApplicationDbContext>();

    services.AddAuthentication()
        .AddWsFederation(options =>
        {
            // MetadataAddress represents the Active Directory instance used to authenticate users.
            options.MetadataAddress = "https://<ADFS FQDN or AAD tenant>/FederationMetadata/2007-
06/FederationMetadata.xml";

            // Wtrealm is the app's identifier in the Active Directory instance.
            // For ADFS, use the relying party's identifier, its WS-Federation Passive protocol URL:
            options.Wtrealm = "https://localhost:44307/";

            // For AAD, use the Application ID URI from the app registration's Overview blade:
            options.Wtrealm = "api://bbd35166-7c13-49f3-8041-9551f2847b69";
        });

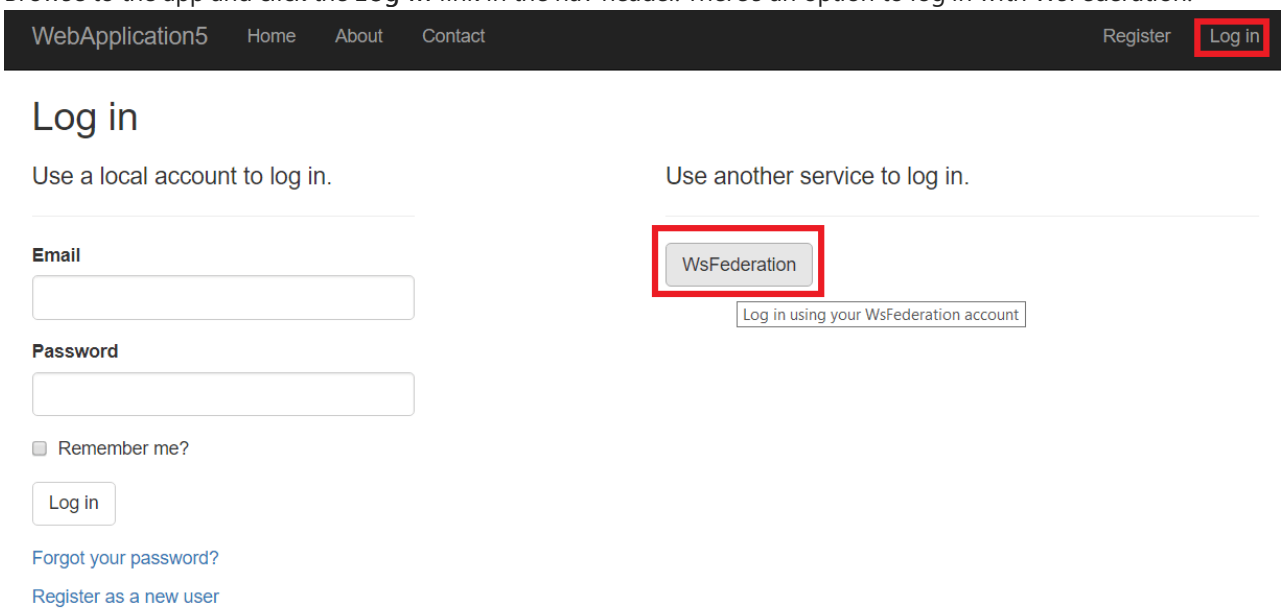
    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
}
```

The AddAuthentication(String) overload sets the DefaultScheme property. The AddAuthentication(Action<AuthenticationOptions>) overload allows configuring authentication options, which can be used to set up default authentication schemes for different purposes. Subsequent calls to `AddAuthentication` override previously configured AuthenticationOptions properties.

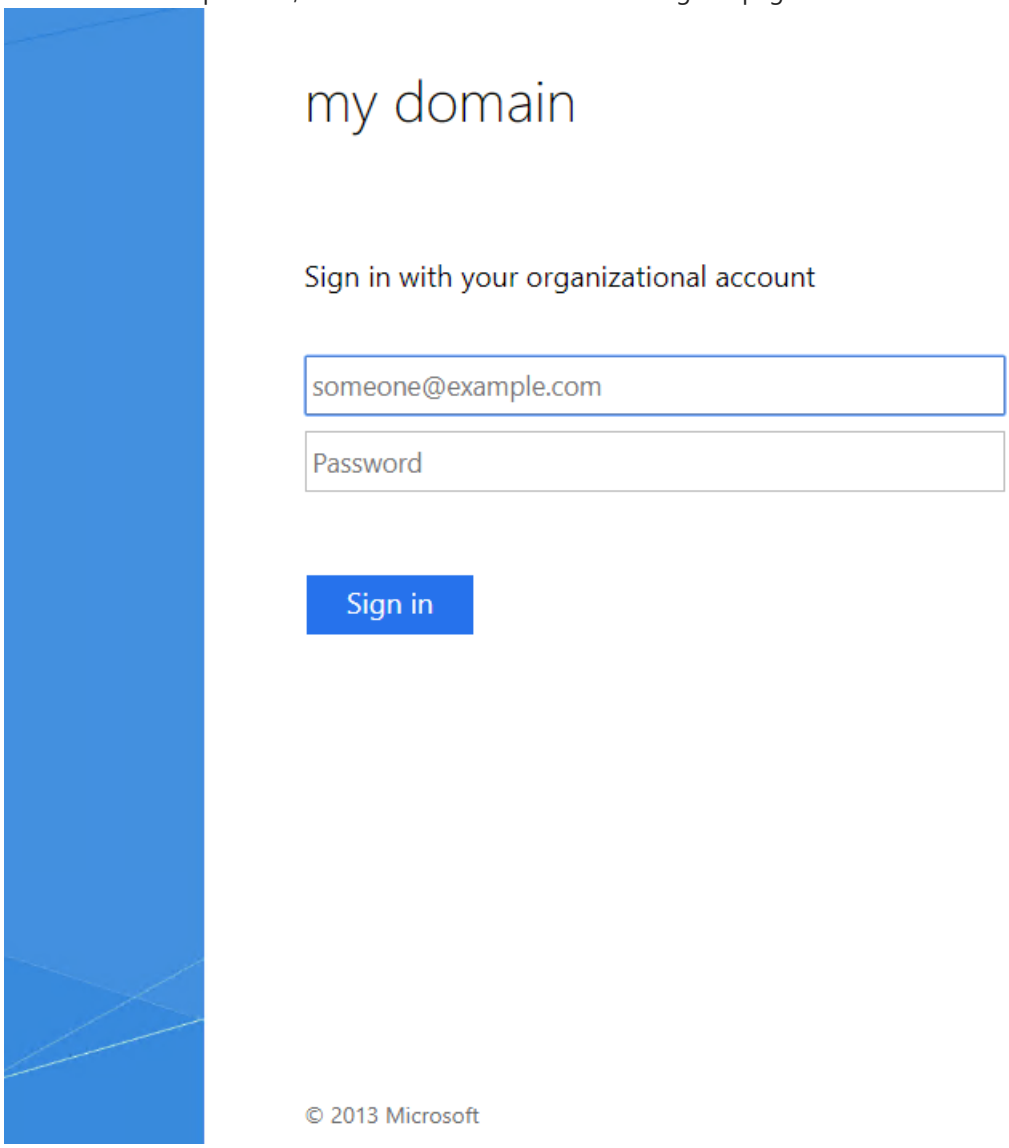
AuthenticationBuilder extension methods that register an authentication handler may only be called once per authentication scheme. Overloads exist that allow configuring the scheme properties, scheme name, and display name.

Log in with WS-Federation

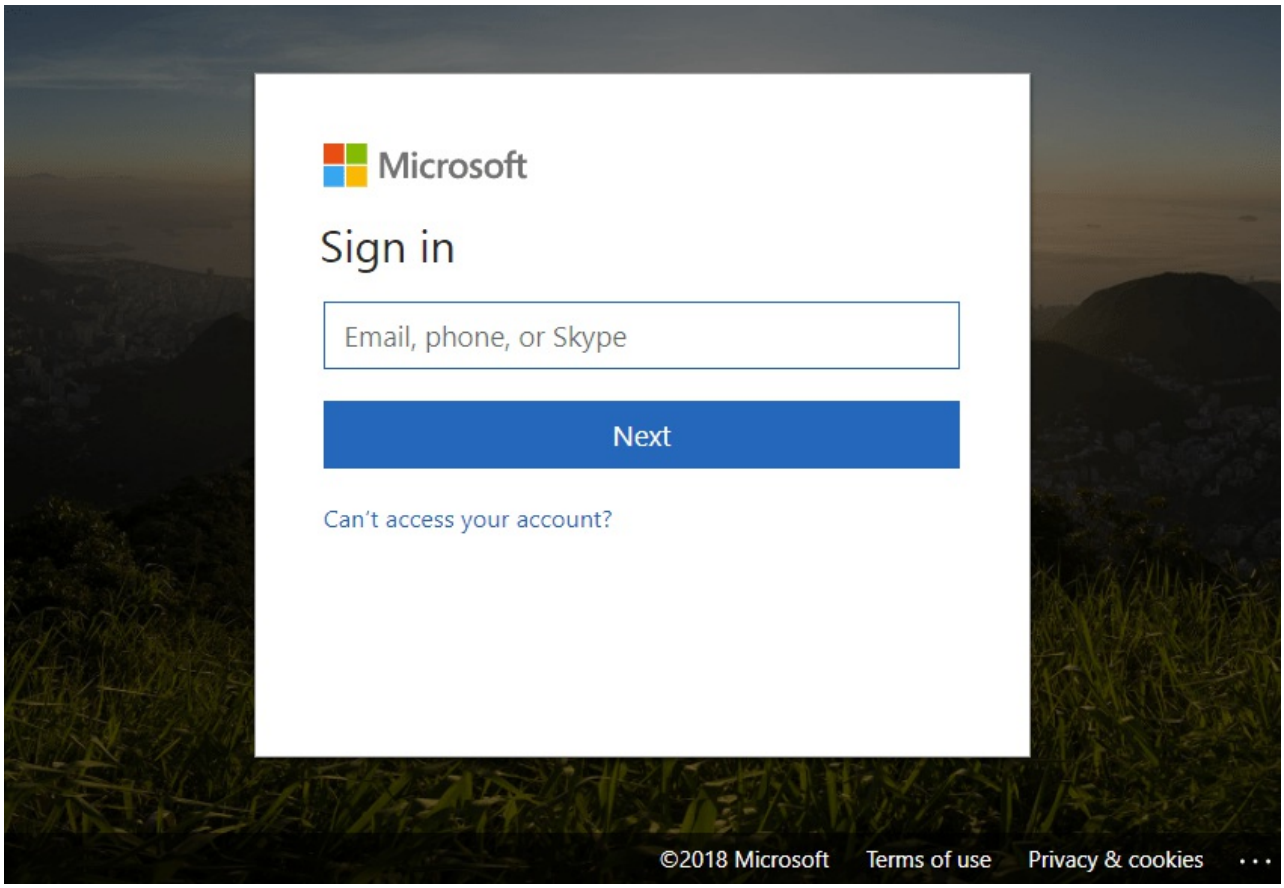
Browse to the app and click the **Log in** link in the nav header. There's an option to log in with WsFederation:



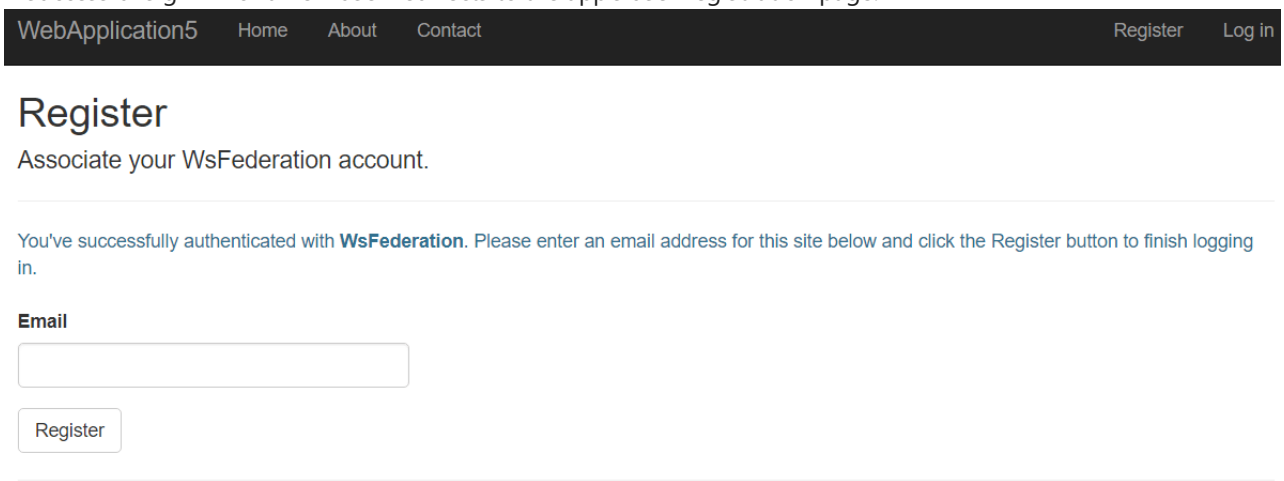
With ADFS as the provider, the button redirects to an ADFS sign-in page:



With Azure Active Directory as the provider, the button redirects to an AAD sign-in page:



A successful sign-in for a new user redirects to the app's user registration page:



Account confirmation and password recovery in ASP.NET Core

9/22/2020 • 15 minutes to read • Edit Online

By Rick Anderson, Ponant, and Joe Audette

This tutorial shows how to build an ASP.NET Core app with email confirmation and password reset. This tutorial is **not** a beginning topic. You should be familiar with:

- ASP.NET Core
- Authentication
- Entity Framework Core

Prerequisites

.NET Core 3.0 SDK or later

Create and test a web app with authentication

Run the following commands to create a web app with authentication.

```
dotnet new webapp -au Individual -uld -o WebPWrecover
cd WebPWrecover
dotnet run
```

Run the app, select the **Register** link, and register a user. Once registered, you are redirected to the to `/Identity/Account/RegisterConfirmation` page which contains a link to simulate email confirmation:

- Select the `Click here to confirm your account` link.
- Select the **Login** link and sign-in with the same credentials.
- Select the `Hello YourEmail@provider.com!` link, which redirects you to the `/Identity/Account/Manage/PersonalData` page.
- Select the **Personal data** tab on the left, and then select **Delete**.

Configure an email provider

In this tutorial, SendGrid is used to send email. You need a SendGrid account and key to send email. You can use other email providers. We recommend you use SendGrid or another email service to send email. SMTP is difficult to secure and set up correctly.

The SendGrid account may require adding a Sender.

Create a class to fetch the secure email key. For this sample, create *Services/AuthMessageSenderOptions.cs*:

```
public class AuthMessageSenderOptions
{
    public string SendGridUser { get; set; }
    public string SendGridKey { get; set; }
}
```

Configure SendGrid user secrets

Set the `SendGridUser` and `SendGridKey` with the secret-manager tool. For example:

```
dotnet user-secrets set SendGridUser RickAndMSFT
dotnet user-secrets set SendGridKey <key>

Successfully saved SendGridUser = RickAndMSFT to the secret store.
```

On Windows, Secret Manager stores keys/value pairs in a *secrets.json* file in the `%APPDATA%/Microsoft/UserSecrets/<WebAppName-userSecretsId>` directory.

The contents of the *secrets.json* file aren't encrypted. The following markup shows the *secrets.json* file. The `SendGridKey` value has been removed.

```
{
  "SendGridUser": "RickAndMSFT",
  "SendGridKey": "<key removed>"
}
```

For more information, see the Options pattern and configuration.

Install SendGrid

This tutorial shows how to add email notifications through SendGrid, but you can send email using SMTP and other mechanisms.

Install the `SendGrid` NuGet package:

- Visual Studio
- .NET Core CLI

From the Package Manager Console, enter the following command:

```
Install-Package SendGrid
```

See Get Started with SendGrid for Free to register for a free SendGrid account.

Implement IEmailSender

To Implement `IEmailSender`, create *Services/EmailSender.cs* with code similar to the following:

```
using Microsoft.AspNetCore.Identity.UI.Services;
using Microsoft.Extensions.Options;
using SendGrid;
using SendGrid.Helpers.Mail;
using System.Threading.Tasks;

namespace WebPWrecover.Services
{
    public class EmailSender : IEmailSender
    {
        public EmailSender(IOptions<AuthMessageSenderOptions> optionsAccessor)
        {
            Options = optionsAccessor.Value;
        }

        public AuthMessageSenderOptions Options { get; } //set only via Secret Manager

        public Task SendEmailAsync(string email, string subject, string message)
        {
            return Execute(Options.SendGridKey, subject, message, email);
        }

        public Task Execute(string apiKey, string subject, string message, string email)
        {
            var client = new SendGridClient(apiKey);
            var msg = new SendGridMessage()
            {
                From = new EmailAddress("Joe@contoso.com", Options.SendGridUser),
                Subject = subject,
                PlainTextContent = message,
                HtmlContent = message
            };
            msg.AddTo(new EmailAddress(email));

            // Disable click tracking.
            // See https://sendgrid.com/docs/User_Guide/Settings/tracking.html
            msg.SetClickTracking(false, false);

            return client.SendEmailAsync(msg);
        }
    }
}
```

Configure startup to support email

Add the following code to the `ConfigureServices` method in the *Startup.cs* file:

- Add `EmailSender` as a transient service.
- Register the `AuthMessageSenderOptions` configuration instance.

```
public void ConfigureServices(IServiceCollection services)
{

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>(
                options => options.SignIn.RequireConfirmedAccount = true)
        .AddEntityFrameworkStores<ApplicationDbContext>();

    // requires
    // using Microsoft.AspNetCore.Identity.UI.Services;
    // using WebPWrecover.Services;
    services.AddTransient<IEmailSender, EmailSender>();
    services.Configure<AuthMessageSenderOptions>(Configuration);

    services.AddRazorPages();
}
```

Scaffold RegisterConfirmation

Follow the instructions for Scaffold Identity and scaffold `RegisterConfirmation`.

Disable default account verification

With the default templates, the user is redirected to the `Account.RegisterConfirmation` where they can select a link to have the account confirmed. The default `Account.RegisterConfirmation` is used ***only*** for testing, automatic account verification should be disabled in a production app.

To require a confirmed account and prevent immediate login at registration, set `DisplayConfirmAccountLink = false` in */Areas/Identity/Pages/Account/RegisterConfirmation.cshtml.cs*:

```
[AllowAnonymous]
public class RegisterConfirmationModel : PageModel
{
    private readonly UserManager<IdentityUser> _userManager;
    private readonly IEmailSender _sender;

    public RegisterConfirmationModel(UserManager<IdentityUser> userManager, IEmailSender sender)
    {
        _userManager = userManager;
        _sender = sender;
    }

    public string Email { get; set; }

    public bool DisplayConfirmAccountLink { get; set; }

    public string EmailConfirmationUrl { get; set; }

    public async Task<IActionResult> OnGetAsync(string email, string returnUrl = null)
    {
        if (email == null)
        {
            return RedirectToPage("/Index");
        }

        var user = await _userManager.FindByEmailAsync(email);
        if (user == null)
        {
            return NotFound($"Unable to load user with email '{email}'.");
        }

        Email = email;
        // Once you add a real email sender, you should remove this code that lets you confirm the account
        DisplayConfirmAccountLink = false;
        if (DisplayConfirmAccountLink)
        {
            var userId = await _userManager.GetUserIdAsync(user);
            var code = await _userManager.GenerateEmailConfirmationTokenAsync(user);
            code = WebEncoders.Base64UrlEncode(Encoding.UTF8.GetBytes(code));
            EmailConfirmationUrl = Url.Page(
                "/Account/ConfirmEmail",
                pageHandler: null,
                values: new { area = "Identity", userId = userId, code = code, returnUrl = returnUrl },
                protocol: Request.Scheme);
        }

        return Page();
    }
}
```

Register, confirm email, and reset password

Run the web app, and test the account confirmation and password recovery flow.

- Run the app and register a new user
- Check your email for the account confirmation link. See Debug email if you don't get the email.
- Click the link to confirm your email.
- Sign in with your email and password.
- Sign out.

Test password reset

- If you're signed in, select **Logout**.

- Select the **Log in** link and select the **Forgot your password?** link.
- Enter the email you used to register the account.
- An email with a link to reset your password is sent. Check your email and click the link to reset your password. After your password has been successfully reset, you can sign in with your email and new password.

Resend email confirmation

In ASP.NET Core 5.0 and later, select the **Resend email confirmation** link on the **Login** page.

Change email and activity timeout

The default inactivity timeout is 14 days. The following code sets the inactivity timeout to 5 days:

```
services.ConfigureApplicationCookie(o => {
    o.ExpireTimeSpan = TimeSpan.FromDays(5);
    o.SlidingExpiration = true;
});
```

Change all data protection token lifespans

The following code changes all data protection tokens timeout period to 3 hours:

```
public void ConfigureServices(IServiceCollection services)
{

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>(
                  options => options.SignIn.RequireConfirmedAccount = true)
        .AddEntityFrameworkStores<ApplicationDbContext>();

    services.Configure<DataProtectionTokenProviderOptions>(o =>
       o.TokenLifespan = TimeSpan.FromHours(3));

    services.AddTransient<IEmailSender, EmailSender>();
    services.Configure<AuthMessageSenderOptions>(Configuration);

    services.AddRazorPages();
}
```

The built in Identity user tokens (see AspNetCore/src/Identity/Extensions.Core/src/TokenOptions.cs)have a one day timeout.

Change the email token lifespan

The default token lifespan of the Identity user tokens is one day. This section shows how to change the email token lifespan.

Add a custom DataProtectorTokenProvider<TUser> and DataProtectionTokenProviderOptions:

```
public class CustomEmailConfirmationTokenProvider<TUser>
                                     : DataProtectorTokenProvider<TUser> where TUser : class
{
    public CustomEmailConfirmationTokenProvider(IDataProtectionProvider dataProtectionProvider,
        IOptions<EmailConfirmationTokenProviderOptions> options,
        ILogger<DataProtectorTokenProvider<TUser>> logger)
                                       : base(dataProtectionProvider, options, logger)
    {

    }
}
public class EmailConfirmationTokenProviderOptions : DataProtectionTokenProviderOptions
{
    public EmailConfirmationTokenProviderOptions()
    {
        Name = "EmailDataProtectorTokenProvider";
        TokenLifespan = TimeSpan.FromHours(4);
    }
}
```

Add the custom provider to the service container:

```
public void ConfigureServices(IServiceCollection services)
{

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>(config =>
    {
        config.SignIn.RequireConfirmedEmail = true;
        config.Tokens.ProviderMap.Add("CustomEmailConfirmation",
            new TokenProviderDescriptor(
                typeof(CustomEmailConfirmationTokenProvider<IdentityUser>)));
        config.Tokens.EmailConfirmationTokenProvider = "CustomEmailConfirmation";
      }).AddEntityFrameworkStores<ApplicationDbContext>();

    services.AddTransient<CustomEmailConfirmationTokenProvider<IdentityUser>>();

    services.AddTransient<IEmailSender, EmailSender>();
    services.Configure<AuthMessageSenderOptions>(Configuration);

    services.AddRazorPages();
}
```

Debug email

If you can't get email working:

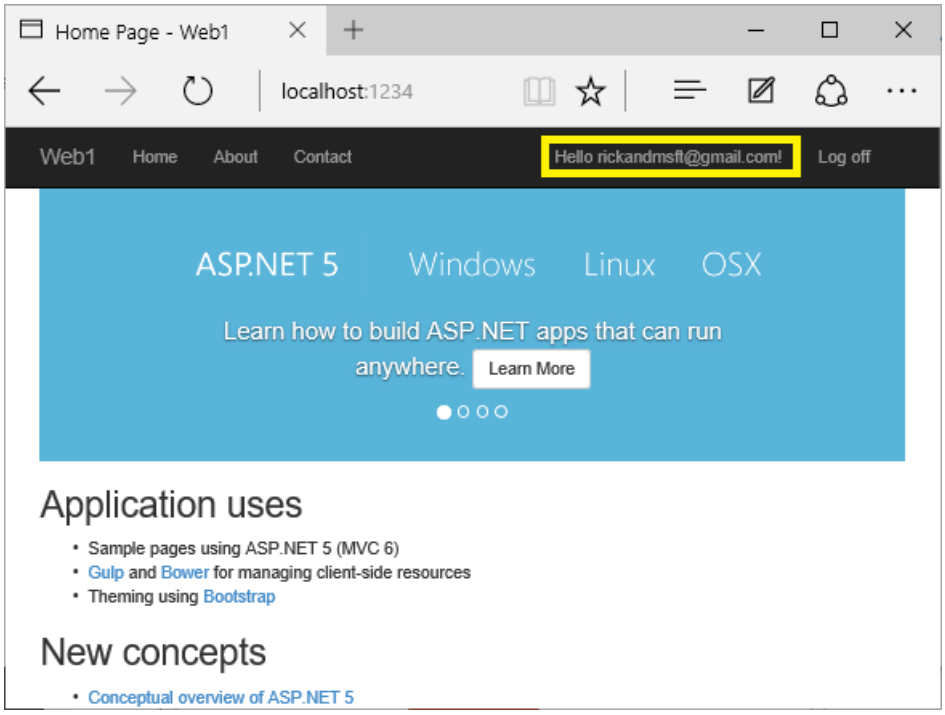
- Set a breakpoint in `EmailSender.Execute` to verify `SendGridClient.SendEmailAsync` is called.
- Create a console app to send email using similar code to `EmailSender.Execute`.
- Review the Email Activity page.
- Check your spam folder.
- Try another email alias on a different email provider (Microsoft, Yahoo, Gmail, etc.)
- Try sending to different email accounts.

A security best practice is to **not** use production secrets in test and development. If you publish the app to Azure, set the SendGrid secrets as application settings in the Azure Web App portal. The configuration system is set up to read keys from environment variables.

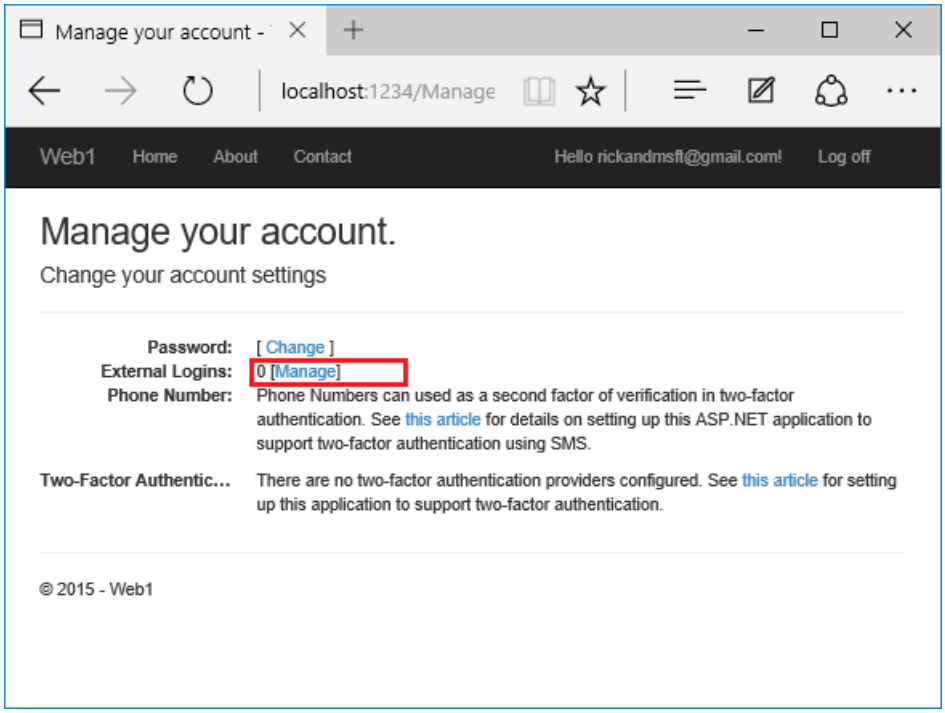
Combine social and local login accounts

To complete this section, you must first enable an external authentication provider. See Facebook, Google, and external provider authentication.

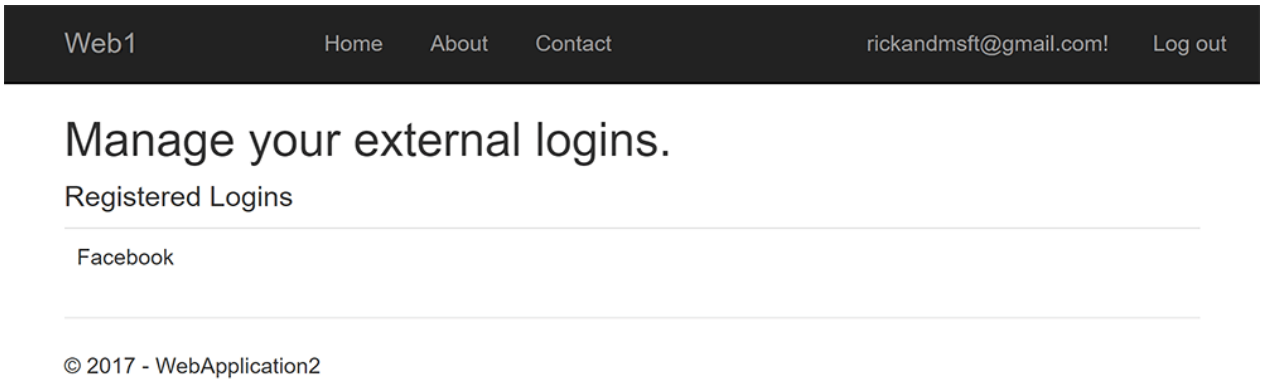
You can combine local and social accounts by clicking on your email link. In the following sequence, "RickAndMSFT@gmail.com" is first created as a local login; however, you can create the account as a social login first, then add a local login.



Click on the **Manage** link. Note the 0 external (social logins) associated with this account.



Click the link to another login service and accept the app requests. In the following image, Facebook is the external authentication provider:



The two accounts have been combined. You are able to sign in with either account. You might want your users to add local accounts in case their social login authentication service is down, or more likely they've lost access to their social account.

Enable account confirmation after a site has users

Enabling account confirmation on a site with users locks out all the existing users. Existing users are locked out because their accounts aren't confirmed. To work around existing user lockout, use one of the following approaches:

- Update the database to mark all existing users as being confirmed.
- Confirm existing users. For example, batch-send emails with confirmation links.

Prerequisites

.NET Core 2.2 SDK or later

Create a web app and scaffold Identity

Run the following commands to create a web app with authentication.

```
dotnet new webapp -au Individual -uld -o WebPWrecover
cd WebPWrecover
dotnet add package Microsoft.VisualStudio.Web.CodeGeneration.Design
dotnet tool install -g dotnet-aspnet-codegenerator
dotnet aspnet-codegenerator identity -dc WebPWrecover.Data.ApplicationDbContext --files
"Account.Register;Account.Login;Account.Logout;Account.ConfirmEmail"
dotnet ef database drop -f
dotnet ef database update
dotnet run
```

NOTE

If PasswordOptions are configured in `Startup.ConfigureServices`, `[StringLength]` attribute configuration might be required for the `Password` property in scaffolded Identity pages. An `InputModel` `Password` property is found in the `Areas/Identity/Pages/Account/Register.cshtml.cs` file after scaffolding Identity.

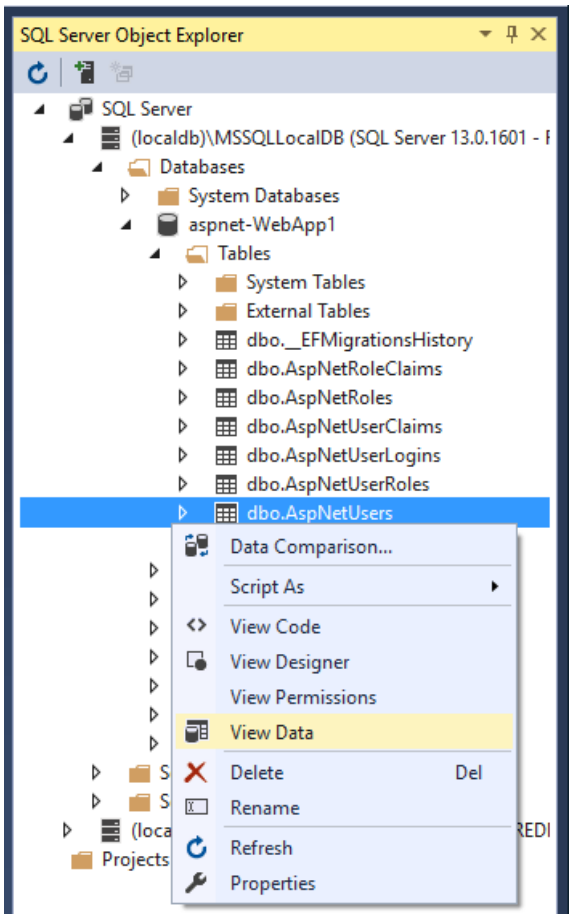
Test new user registration

Run the app, select the **Register** link, and register a user. At this point, the only validation on the email is with the `[EmailAddress]` attribute. After submitting the registration, you are logged into the app. Later in the tutorial, the code is updated so new users can't sign in until their email is validated.

View the Identity database

- Visual Studio
- .NET Core CLI

- From the **View** menu, select **SQL Server Object Explorer** (SSOX).
- Navigate to **(localdb)MSSQLLocalDB(SQL Server 13)**. Right-click on **dbo.AspNetUsers** > **View Data**:



Note the table's `EmailConfirmed` field is `False`.

You might want to use this email again in the next step when the app sends a confirmation email. Right-click on the row and select **Delete**. Deleting the email alias makes it easier in the following steps.

Require email confirmation

It's a best practice to confirm the email of a new user registration. Email confirmation helps to verify they're not impersonating someone else (that is, they haven't registered with someone else's email). Suppose you had a discussion forum, and you wanted to prevent "yli@example.com" from registering as "nolivetto@contoso.com". Without email confirmation, "nolivetto@contoso.com" could receive unwanted email from your app. Suppose the user accidentally registered as "ylo@example.com" and hadn't noticed the misspelling of "yli". They wouldn't be able to use password recovery because the app doesn't have their correct email. Email confirmation provides limited protection from bots. Email confirmation doesn't provide protection from malicious users with many email accounts.

You generally want to prevent new users from posting any data to your web site before they have a confirmed email.

Update `Startup.ConfigureServices` to require a confirmed email:

```
public void ConfigureServices(IServiceCollection services)
{

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));

    services.AddDefaultIdentity<IdentityUser>(config =>
    {
        config.SignIn.RequireConfirmedEmail = true;
    })
        .AddDefaultUI(UIFramework.Bootstrap4)
        .AddEntityFrameworkStores<ApplicationDbContext>();

    // requires
    // using Microsoft.AspNetCore.Identity.UI.Services;
    // using WebPWrecover.Services;
    services.AddTransient<IEmailSender, EmailSender>();
    services.Configure<AuthMessageSenderOptions>(Configuration);

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

`config.SignIn.RequireConfirmedEmail = true;` prevents registered users from logging in until their email is confirmed.

Configure email provider

In this tutorial, SendGrid is used to send email. You need a SendGrid account and key to send email. You can use other email providers. ASP.NET Core 2.x includes `System.Net.Mail`, which allows you to send email from your app. We recommend you use SendGrid or another email service to send email. SMTP is difficult to secure and set up correctly.

Create a class to fetch the secure email key. For this sample, create *Services/AuthMessageSenderOptions.cs*:

```
public class AuthMessageSenderOptions
{
    public string SendGridUser { get; set; }
    public string SendGridKey { get; set; }
}
```

Configure SendGrid user secrets

Set the `SendGridUser` and `SendGridKey` with the secret-manager tool. For example:

```
C:/WebAppl>dotnet user-secrets set SendGridUser RickAndMSFT
info: Successfully saved SendGridUser = RickAndMSFT to the secret store.
```

On Windows, Secret Manager stores keys/value pairs in a *secrets.json* file in the `%APPDATA%/Microsoft/UserSecrets/<WebAppName-userSecretsId>` directory.

The contents of the *secrets.json* file aren't encrypted. The following markup shows the *secrets.json* file. The `SendGridKey` value has been removed.

```
{
  "SendGridUser": "RickAndMSFT",
  "SendGridKey": "<key removed>"
}
```

For more information, see the Options pattern and configuration.

Install SendGrid

This tutorial shows how to add email notifications through SendGrid, but you can send email using SMTP and other mechanisms.

Install the `SendGrid` NuGet package:

- Visual Studio
- .NET Core CLI

From the Package Manager Console, enter the following command:

```
Install-Package SendGrid
```

See Get Started with SendGrid for Free to register for a free SendGrid account.

Implement IEmailSender

To Implement `IEmailSender`, create *Services/EmailSender.cs* with code similar to the following:

```
using Microsoft.AspNetCore.Identity.UI.Services;
using Microsoft.Extensions.Options;
using SendGrid;
using SendGrid.Helpers.Mail;
using System.Threading.Tasks;

namespace WebPWrecover.Services
{
    public class EmailSender : IEmailSender
    {
        public EmailSender(IOptions<AuthMessageSenderOptions> optionsAccessor)
        {
            Options = optionsAccessor.Value;
        }

        public AuthMessageSenderOptions Options { get; } //set only via Secret Manager

        public Task SendEmailAsync(string email, string subject, string message)
        {
            return Execute(Options.SendGridKey, subject, message, email);
        }

        public Task Execute(string apiKey, string subject, string message, string email)
        {
            var client = new SendGridClient(apiKey);
            var msg = new SendGridMessage()
            {
                From = new EmailAddress("Joe@contoso.com", "Joe Smith"),
                Subject = subject,
                PlainTextContent = message,
                HtmlContent = message
            };
            msg.AddTo(new EmailAddress(email));

            // Disable click tracking.
            // See https://sendgrid.com/docs/User_Guide/Settings/tracking.html
            msg.SetClickTracking(false, false);

            return client.SendEmailAsync(msg);
        }
    }
}
```

Configure startup to support email

Add the following code to the `ConfigureServices` method in the *Startup.cs* file:

- Add `EmailSender` as a transient service.
- Register the `AuthMessageSenderOptions` configuration instance.

```
public void ConfigureServices(IServiceCollection services)
{

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));

    services.AddDefaultIdentity<IdentityUser>(config =>
    {
        config.SignIn.RequireConfirmedEmail = true;
    })
        .AddDefaultUI(UIFramework.Bootstrap4)
        .AddEntityFrameworkStores<ApplicationDbContext>();

    // requires
    // using Microsoft.AspNetCore.Identity.UI.Services;
    // using WebPWrecover.Services;
    services.AddTransient<IEmailSender, EmailSender>();
    services.Configure<AuthMessageSenderOptions>(Configuration);

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

Enable account confirmation and password recovery

The template has the code for account confirmation and password recovery. Find the `OnPostAsync` method in *Areas/Identity/Pages/Account/Register.cshtml.cs*.

Prevent newly registered users from being automatically signed in by commenting out the following line:

```
await _signInManager.SignInAsync(user, isPersistent: false);
```

The complete method is shown with the changed line highlighted:

```
public async Task<IActionResult> OnPostAsync(string returnUrl = null)
{
    returnUrl = returnUrl ?? Url.Content("~/");
    if (ModelState.IsValid)
    {
        var user = new IdentityUser { UserName = Input.Email, Email = Input.Email };
        var result = await _userManager.CreateAsync(user, Input.Password);
        if (result.Succeeded)
        {
            _logger.LogInformation("User created a new account with password.");

            var code = await _userManager.GenerateEmailConfirmationTokenAsync(user);
            var callbackUrl = Url.Page(
                "/Account/ConfirmEmail",
                pageHandler: null,
                values: new { userId = user.Id, code = code },
                protocol: Request.Scheme);

            await _emailSender.SendEmailAsync(Input.Email, "Confirm your email",
                $"Please confirm your account by <a href='{HtmlEncoder.Default.Encode(callbackUrl)}'>clicking
here</a>.");

            //await _signInManager.SignInAsync(user, isPersistent: false);
            return LocalRedirect(returnUrl);
        }
        foreach (var error in result.Errors)
        {
            ModelState.AddModelError(string.Empty, error.Description);
        }
    }

    // If we got this far, something failed, redisplay form
    return Page();
}
```

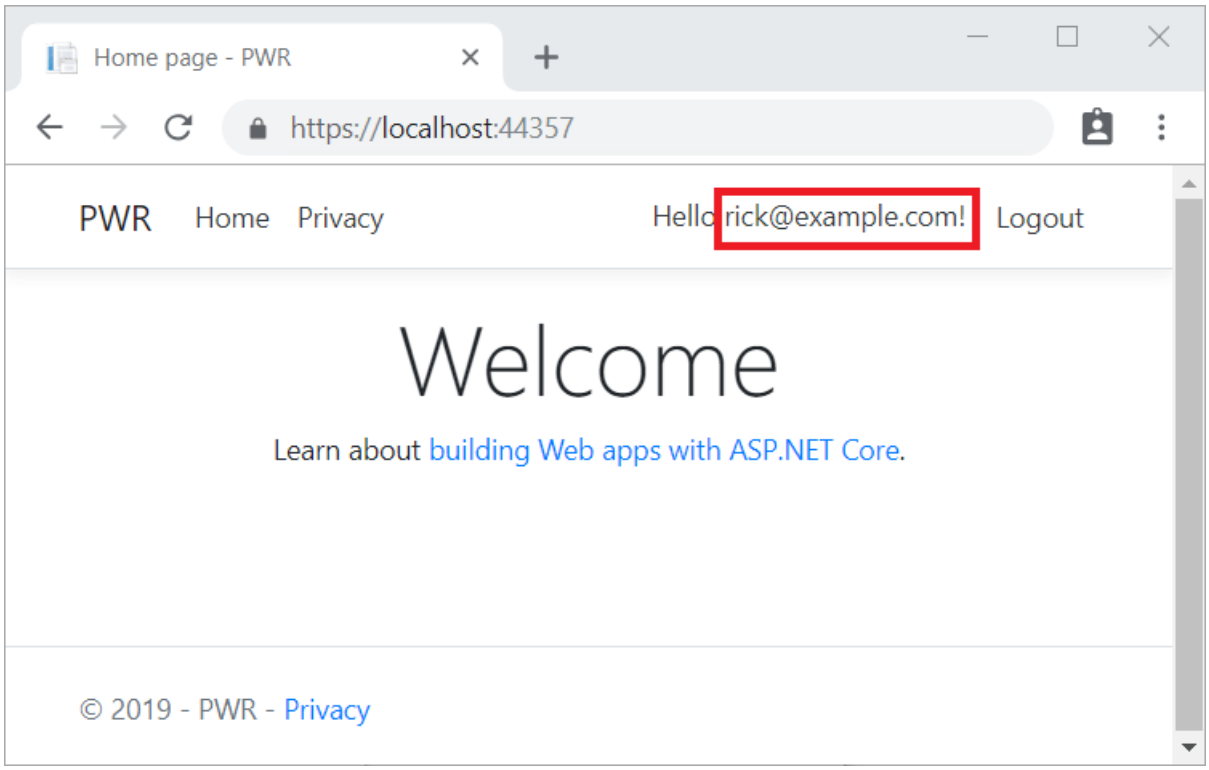
Register, confirm email, and reset password

Run the web app, and test the account confirmation and password recovery flow.

- Run the app and register a new user
- Check your email for the account confirmation link. See Debug email if you don't get the email.
- Click the link to confirm your email.
- Sign in with your email and password.
- Sign out.

View the manage page

Select your user name in the browser:



The manage page is displayed with the **Profile** tab selected. The **Email** shows a check box indicating the email has been confirmed.

Test password reset

- If you're signed in, select **Logout**.
- Select the **Log in** link and select the **Forgot your password?** link.
- Enter the email you used to register the account.
- An email with a link to reset your password is sent. Check your email and click the link to reset your password. After your password has been successfully reset, you can sign in with your email and new password.

Change email and activity timeout

The default inactivity timeout is 14 days. The following code sets the inactivity timeout to 5 days:

```
services.ConfigureApplicationCookie(o => {
    o.ExpireTimeSpan = TimeSpan.FromDays(5);
    o.SlidingExpiration = true;
});
```

Change all data protection token lifespans

The following code changes all data protection tokens timeout period to 3 hours:

```
public void ConfigureServices(IServiceCollection services)
{

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));

    services.AddDefaultIdentity<IdentityUser>(config =>
    {
        config.SignIn.RequireConfirmedEmail = true;
    })
        .AddDefaultUI(UIFramework.Bootstrap4)
        .AddEntityFrameworkStores<ApplicationDbContext>();

    services.Configure<DataProtectionTokenProviderOptions>(o =>
                o.TokenLifespan = TimeSpan.FromHours(3));

    services.AddTransient<IEmailSender, EmailSender>();
    services.Configure<AuthMessageSenderOptions>(Configuration);

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

The built in Identity user tokens (see AspNetCore/src/Identity/Extensions.Core/src/TokenOptions.cs)have a one day timeout.

Change the email token lifespan

The default token lifespan of the Identity user tokens is one day. This section shows how to change the email token lifespan.

Add a custom DataProtectorTokenProvider<TUser> and DataProtectionTokenProviderOptions:

```
public class CustomEmailConfirmationTokenProvider<TUser>
                                      : DataProtectorTokenProvider<TUser> where TUser : class
{
    public CustomEmailConfirmationTokenProvider(IDataProtectionProvider dataProtectionProvider,
        IOptions<EmailConfirmationTokenProviderOptions> options)
                                                          : base(dataProtectionProvider, options)
    {

    }
}
public class EmailConfirmationTokenProviderOptions : DataProtectionTokenProviderOptions
{
    public EmailConfirmationTokenProviderOptions()
    {
        Name = "EmailDataProtectorTokenProvider";
        TokenLifespan = TimeSpan.FromHours(4);
    }
}
```

Add the custom provider to the service container:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));

    services.AddDefaultIdentity<IdentityUser>(config =>
    {
        config.SignIn.RequireConfirmedEmail = true;
        config.Tokens.ProviderMap.Add("CustomEmailConfirmation",
            new TokenProviderDescriptor(
                typeof(CustomEmailConfirmationTokenProvider<IdentityUser>)));
        config.Tokens.EmailConfirmationTokenProvider = "CustomEmailConfirmation";
    })
        .AddDefaultUI(UIFramework.Bootstrap4)
        .AddEntityFrameworkStores<ApplicationDbContext>();

    services.AddTransient<CustomEmailConfirmationTokenProvider<IdentityUser>>();
    services.AddTransient<IEmailSender, EmailSender>();
    services.Configure<AuthMessageSenderOptions>(Configuration); // For SendGrid key.

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

Resend email confirmation

See this GitHub issue.

Debug email

If you can't get email working:

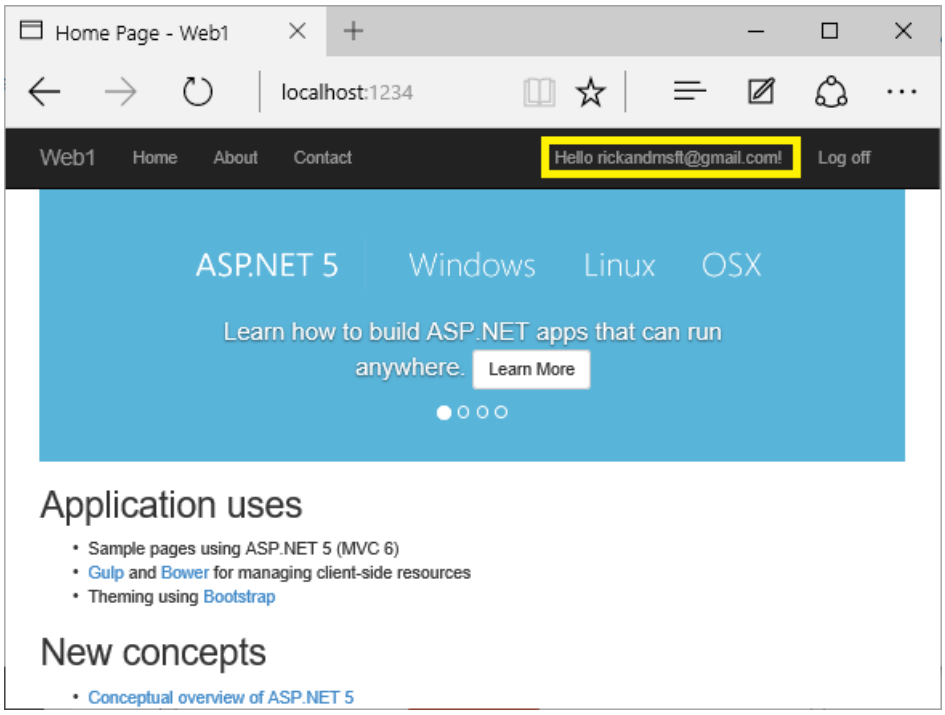
- Set a breakpoint in `EmailSender.Execute` to verify `SendGridClient.SendEmailAsync` is called.
- Create a console app to send email using similar code to `EmailSender.Execute`.
- Review the Email Activity page.
- Check your spam folder.
- Try another email alias on a different email provider (Microsoft, Yahoo, Gmail, etc.)
- Try sending to different email accounts.

A security best practice is to **not** use production secrets in test and development. If you publish the app to Azure, you can set the SendGrid secrets as application settings in the Azure Web App portal. The configuration system is set up to read keys from environment variables.

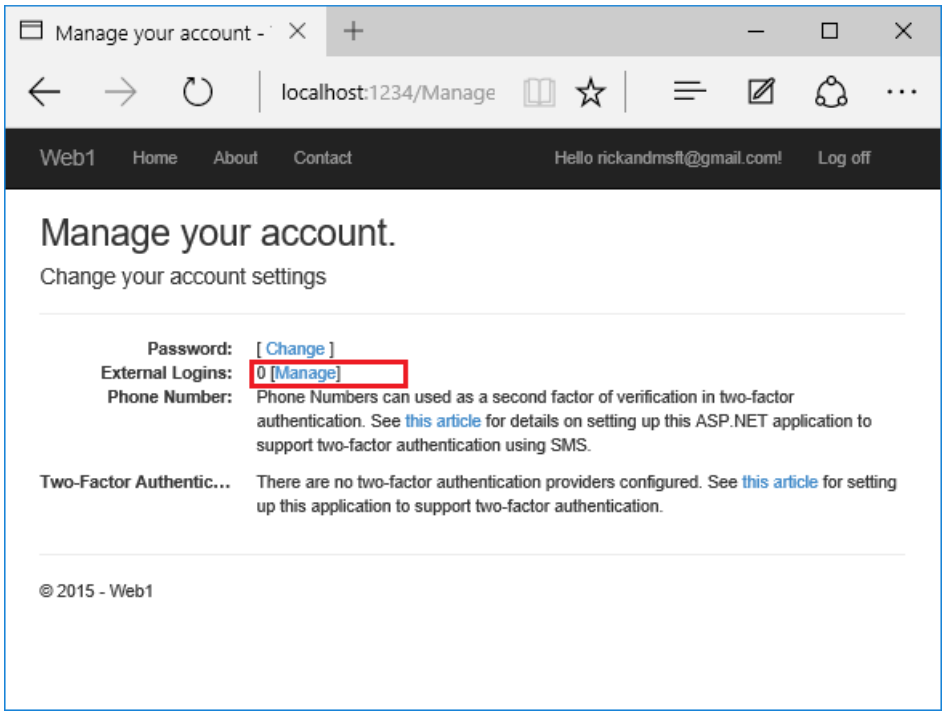
Combine social and local login accounts

To complete this section, you must first enable an external authentication provider. See Facebook, Google, and external provider authentication.

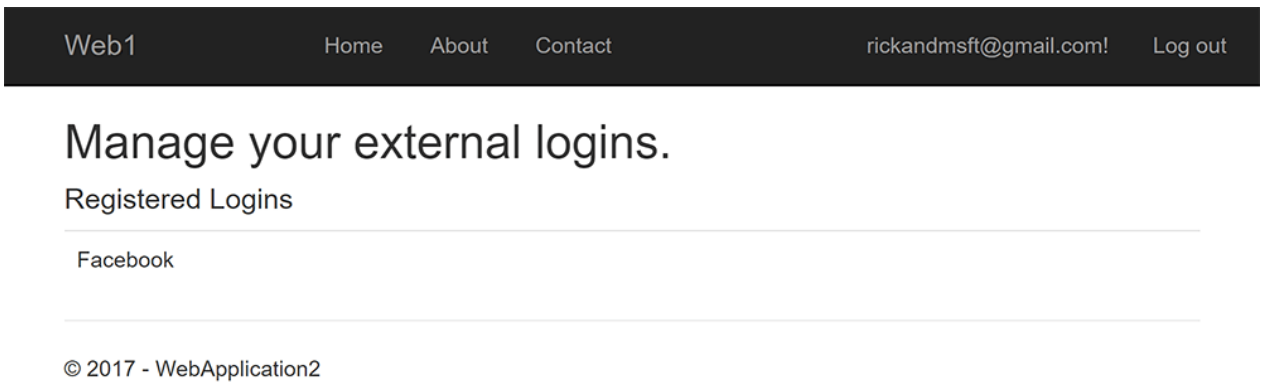
You can combine local and social accounts by clicking on your email link. In the following sequence, "RickAndMSFT@gmail.com" is first created as a local login; however, you can create the account as a social login first, then add a local login.



Click on the **Manage** link. Note the 0 external (social logins) associated with this account.



Click the link to another login service and accept the app requests. In the following image, Facebook is the external authentication provider:



The two accounts have been combined. You are able to sign in with either account. You might want your users to add local accounts in case their social login authentication service is down, or more likely they've lost access to their social account.

Enable account confirmation after a site has users

Enabling account confirmation on a site with users locks out all the existing users. Existing users are locked out because their accounts aren't confirmed. To work around existing user lockout, use one of the following approaches:

- Update the database to mark all existing users as being confirmed.
- Confirm existing users. For example, batch-send emails with confirmation links.

Enable QR Code generation for TOTP authenticator apps in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

QR Codes requires ASP.NET Core 2.0 or later.

ASP.NET Core ships with support for authenticator applications for individual authentication. Two factor authentication (2FA) authenticator apps, using a Time-based One-time Password Algorithm (TOTP), are the industry recommended approach for 2FA. 2FA using TOTP is preferred to SMS 2FA. An authenticator app provides a 6 to 8 digit code which users must enter after confirming their username and password. Typically an authenticator app is installed on a smart phone.

The ASP.NET Core web app templates support authenticators, but don't provide support for QRCode generation. QRCode generators ease the setup of 2FA. This document will guide you through adding QR Code generation to the 2FA configuration page.

Two factor authentication does not happen using an external authentication provider, such as Google or Facebook. External logins are protected by whatever mechanism the external login provider provides. Consider, for example, the Microsoft authentication provider requires a hardware key or another 2FA approach. If the default templates enforced "local" 2FA then users would be required to satisfy two 2FA approaches, which is not a commonly used scenario.

Adding QR Codes to the 2FA configuration page

These instructions use *qrcode.js* from the https://davidshimjs.github.io/qrcodejs/ repo.

- Download the qrcode.js javascript library to the `wwwroot\lib` folder in your project.
- Follow the instructions in Scaffold Identity to generate */Areas/Identity/Pages/Account/Manage/EnableAuthenticator.cshtml*.
- In */Areas/Identity/Pages/Account/Manage/EnableAuthenticator.cshtml*, locate the `Scripts` section at the end of the file:
- In *Pages/Account/Manage/EnableAuthenticator.cshtml* (Razor Pages) or *Views/Manage/EnableAuthenticator.cshtml* (MVC), locate the `Scripts` section at the end of the file:

```
@section Scripts {
    @await Html.PartialAsync("_ValidationScriptsPartial")
}
```

- Update the `Scripts` section to add a reference to the `qrcodejs` library you added and a call to generate the QR Code. It should look as follows:

```
@section Scripts {
    @await Html.PartialAsync("_ValidationScriptsPartial")

    <script type="text/javascript" src="~/lib/qrcode.js"></script>
    <script type="text/javascript">
        new QRCode(document.getElementById("qrCode"),
            {
                text: "@Html.Raw(Model.AuthenticatorUri)",
                width: 150,
                height: 150
            });
    </script>
}
```

- Delete the paragraph which links you to these instructions.

Run your app and ensure that you can scan the QR code and validate the code the authenticator proves.

Change the site name in the QR Code

The site name in the QR Code is taken from the project name you choose when initially creating your project. You can change it by looking for the `GenerateQrCodeUri(string email, string unformattedKey)` method in the */Areas/Identity/Pages/Account/Manage/EnableAuthenticator.cshtml.cs*.

The site name in the QR Code is taken from the project name you choose when initially creating your project. You can change it by looking for the `GenerateQrCodeUri(string email, string unformattedKey)` method in the *Pages/Account/Manage/EnableAuthenticator.cshtml.cs* (Razor Pages) file or the *Controllers/ManageController.cs* (MVC) file.

The default code from the template looks as follows:

```
private string GenerateQrCodeUri(string email, string unformattedKey)
{
    return string.Format(
        AuthenticatorUriFormat,
        _urlEncoder.Encode("Razor Pages"),
        _urlEncoder.Encode(email),
        unformattedKey);
}
```

The second parameter in the call to `string.Format` is your site name, taken from your solution name. It can be changed to any value, but it must always be URL encoded.

Using a different QR Code library

You can replace the QR Code library with your preferred library. The HTML contains a `qrCode` element into which you can place a QR Code by whatever mechanism your library provides.

The correctly formatted URL for the QR Code is available in the:

- `AuthenticatorUri` property of the model.
- `data-url` property in the `qrCodeData` element.

TOTP client and server time skew

TOTP (Time-based One-Time Password) authentication depends on both the server and authenticator device having an accurate time. Tokens only last for 30 seconds. If TOTP 2FA logins are failing, check that the server time is accurate, and preferably synchronized to an accurate NTP service.

Two-factor authentication with SMS in ASP.NET Core

9/22/2020 • 5 minutes to read • Edit Online

By Rick Anderson and Swiss-Devs

WARNING

Two factor authentication (2FA) authenticator apps, using a Time-based One-time Password Algorithm (TOTP), are the industry recommended approach for 2FA. 2FA using TOTP is preferred to SMS 2FA. For more information, see Enable QR Code generation for TOTP authenticator apps in ASP.NET Core for ASP.NET Core 2.0 and later.

This tutorial shows how to set up two-factor authentication (2FA) using SMS. Instructions are given for twilio and ASPSMS, but you can use any other SMS provider. We recommend you complete Account Confirmation and Password Recovery before starting this tutorial.

View or download sample code. How to download.

Create a new ASP.NET Core project

Create a new ASP.NET Core web app named `Web2FA` with individual user accounts. Follow the instructions in Enforce HTTPS in ASP.NET Core to set up and require HTTPS.

Create an SMS account

Create an SMS account, for example, from twilio or ASPSMS. Record the authentication credentials (for twilio: accountSid and authToken, for ASPSMS: Userkey and Password).

Figuring out SMS Provider credentials

Twilio:

From the Dashboard tab of your Twilio account, copy the **Account SID** and **Auth token**.

ASPSMS:

From your account settings, navigate to **Userkey** and copy it together with your **Password**.

We will later store these values in with the secret-manager tool within the keys `SMSAccountIdentification` and `SMSAccountPassword`.

Specifying SenderID / Originator

Twilio: From the Numbers tab, copy your Twilio **phone number**.

ASPSMS: Within the Unlock Originators Menu, unlock one or more Originators or choose an alphanumeric Originator (Not supported by all networks).

We will later store this value with the secret-manager tool within the key `SMSAccountFrom`.

Provide credentials for the SMS service

We'll use the Options pattern to access the user account and key settings.

- Create a class to fetch the secure SMS key. For this sample, the `SMSoptions` class is created in the *Services/SMSoptions.cs* file.

```
namespace Web2FA.Services
{
    public class SMSoptions
    {
        public string SMSAccountIdentification { get; set; }
        public string SMSAccountPassword { get; set; }
        public string SMSAccountFrom { get; set; }
    }
}
```

Set the `SMSAccountIdentification`, `SMSAccountPassword` and `SMSAccountFrom` with the secret-manager tool. For example:

```
C:/Web2FA/src/WebApp1>dotnet user-secrets set SMSAccountIdentification 12345
info: Successfully saved SMSAccountIdentification = 12345 to the secret store.
```

- Add the NuGet package for the SMS provider. From the Package Manager Console (PMC) run:

Twilio:

```
Install-Package Twilio
```

ASPSMS:

```
Install-Package ASPSMS
```

- Add code in the *Services/MessageServices.cs* file to enable SMS. Use either the Twilio or the ASPSMS section:

Twilio:

```
using Microsoft.Extensions.Options;
using System.Threading.Tasks;
using Twilio;
using Twilio.Rest.Api.V2010.Account;
using Twilio.Types;

namespace Web2FA.Services
{
    // This class is used by the application to send Email and SMS
    // when you turn on two-factor authentication in ASP.NET Identity.
    // For more details see this link https://go.microsoft.com/fwlink/?LinkID=532713
    public class AuthMessageSender : IEmailSender, ISmsSender
    {
        public AuthMessageSender(IOptions<SMSoptions> optionsAccessor)
        {
            Options = optionsAccessor.Value;
        }

        public SMSoptions Options { get; }  // set only via Secret Manager

        public Task SendEmailAsync(string email, string subject, string message)
        {
            // Plug in your email service here to send an email.
            return Task.FromResult(0);
        }

        public Task SendSmsAsync(string number, string message)
        {
            // Plug in your SMS service here to send a text message.
            // Your Account SID from twilio.com/console
            var accountSid = Options.SMSAccountIdentification;
            // Your Auth Token from twilio.com/console
            var authToken = Options.SMSAccountPassword;

            TwilioClient.Init(accountSid, authToken);

            return MessageResource.CreateAsync(
              to: new PhoneNumber(number),
              from: new PhoneNumber(Options.SMSAccountFrom),
              body: message);
        }
    }
}
```

ASPSMS:

```
using Microsoft.Extensions.Options;
using System.Threading.Tasks;

namespace Web2FA.Services
{
    // This class is used by the application to send Email and SMS
    // when you turn on two-factor authentication in ASP.NET Identity.
    // For more details see this link https://go.microsoft.com/fwlink/?LinkID=532713
    public class AuthMessageSender : IEmailSender, ISmsSender
    {
        public AuthMessageSender(IOptions<SMSoptions> optionsAccessor)
        {
            Options = optionsAccessor.Value;
        }

        public SMSoptions Options { get; }  // set only via Secret Manager

        public Task SendEmailAsync(string email, string subject, string message)
        {
            // Plug in your email service here to send an email.
            return Task.FromResult(0);
        }

        public Task SendSmsAsync(string number, string message)
        {
            ASPSMS.SMS SMSSender = new ASPSMS.SMS();

            SMSSender.Userkey = Options.SMSAccountIdentification;
            SMSSender.Password = Options.SMSAccountPassword;
            SMSSender.Originator = Options.SMSAccountFrom;

            SMSSender.AddRecipient(number);
            SMSSender.MessageData = message;

            SMSSender.SendTextSMS();

            return Task.FromResult(0);
        }
    }
}
```

Configure startup to use `SMSoptions`

Add `SMSoptions` to the service container in the `ConfigureServices` method in the *Startup.cs*:

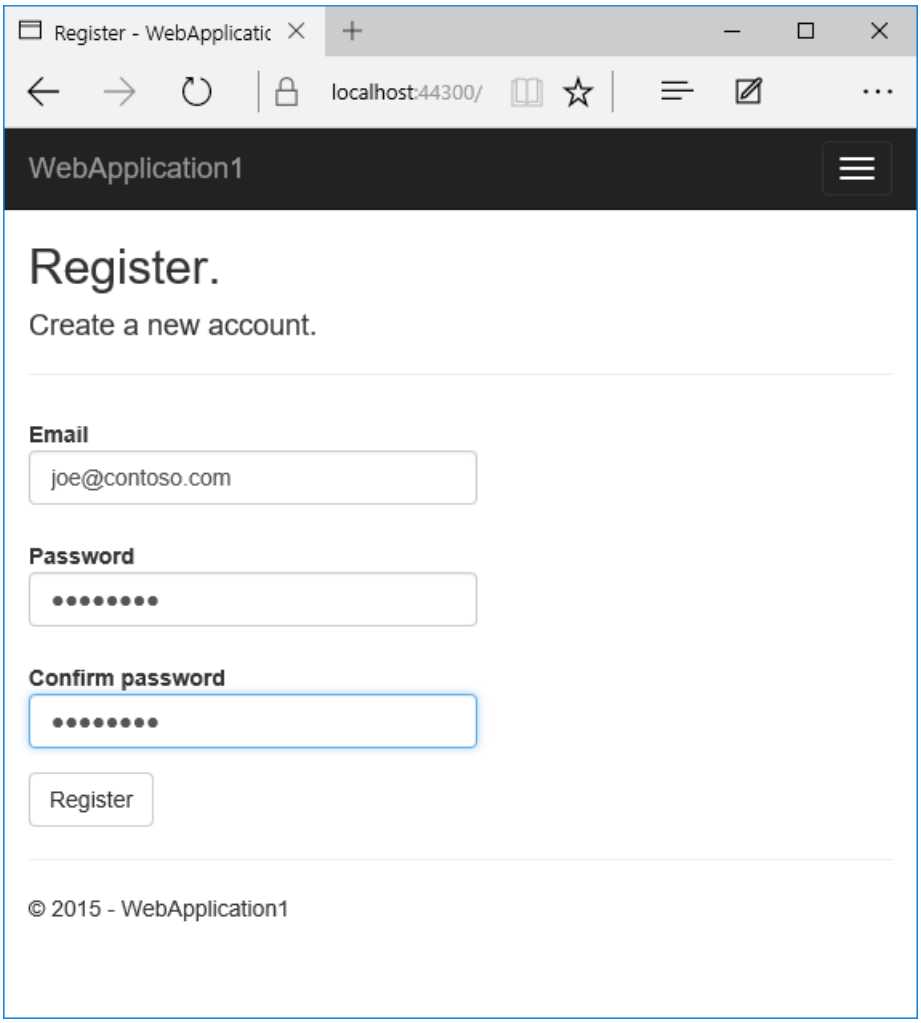
```
    // Add application services.
    services.AddTransient<IEmailSender, AuthMessageSender>();
    services.AddTransient<ISmsSender, AuthMessageSender>();
    services.Configure<SMSoptions>(Configuration);
}
```

Enable two-factor authentication

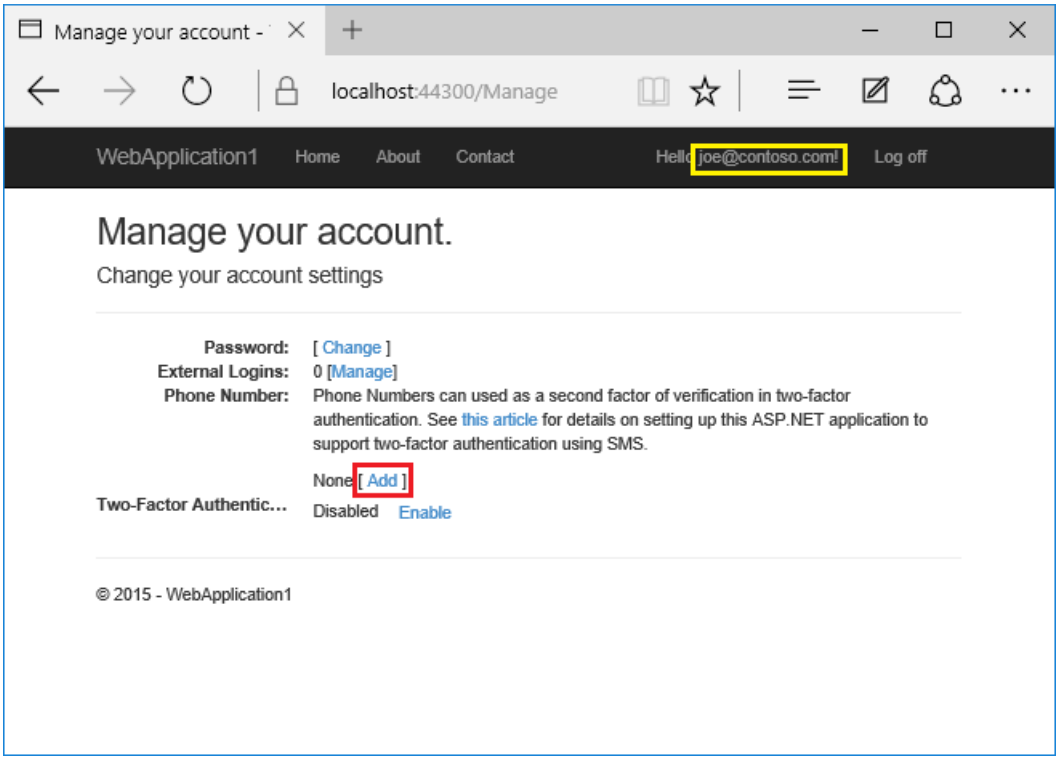
Open the *Views/Manage/Index.cshtml* Razor view file and remove the comment characters (so no markup is commented out).

Log in with two-factor authentication

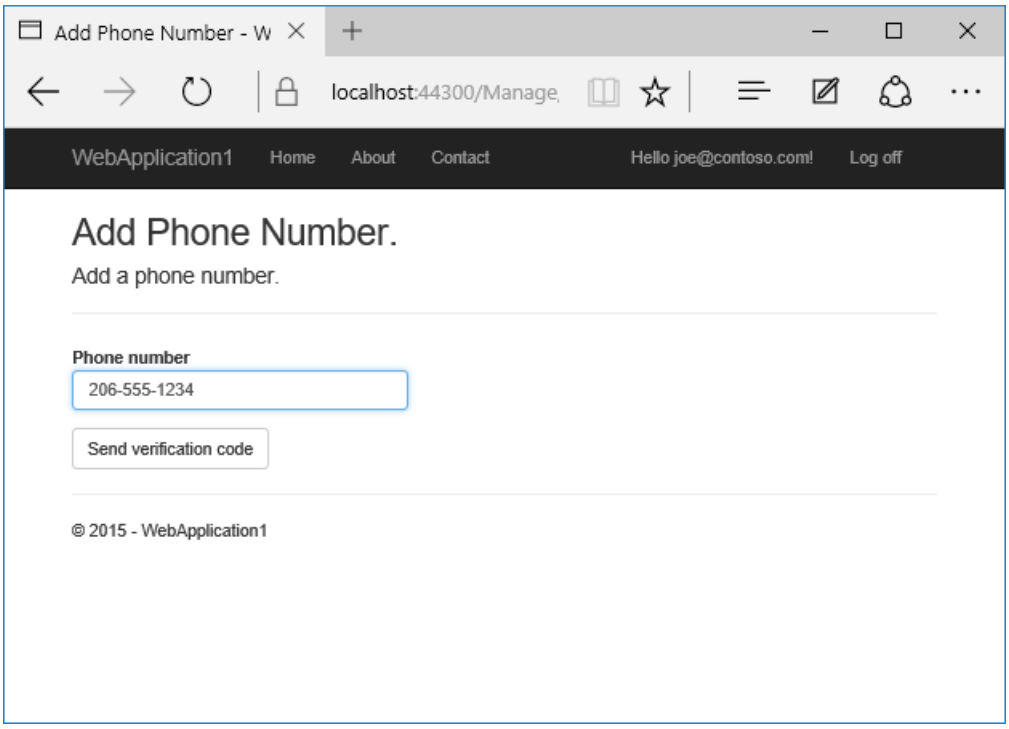
- Run the app and register a new user



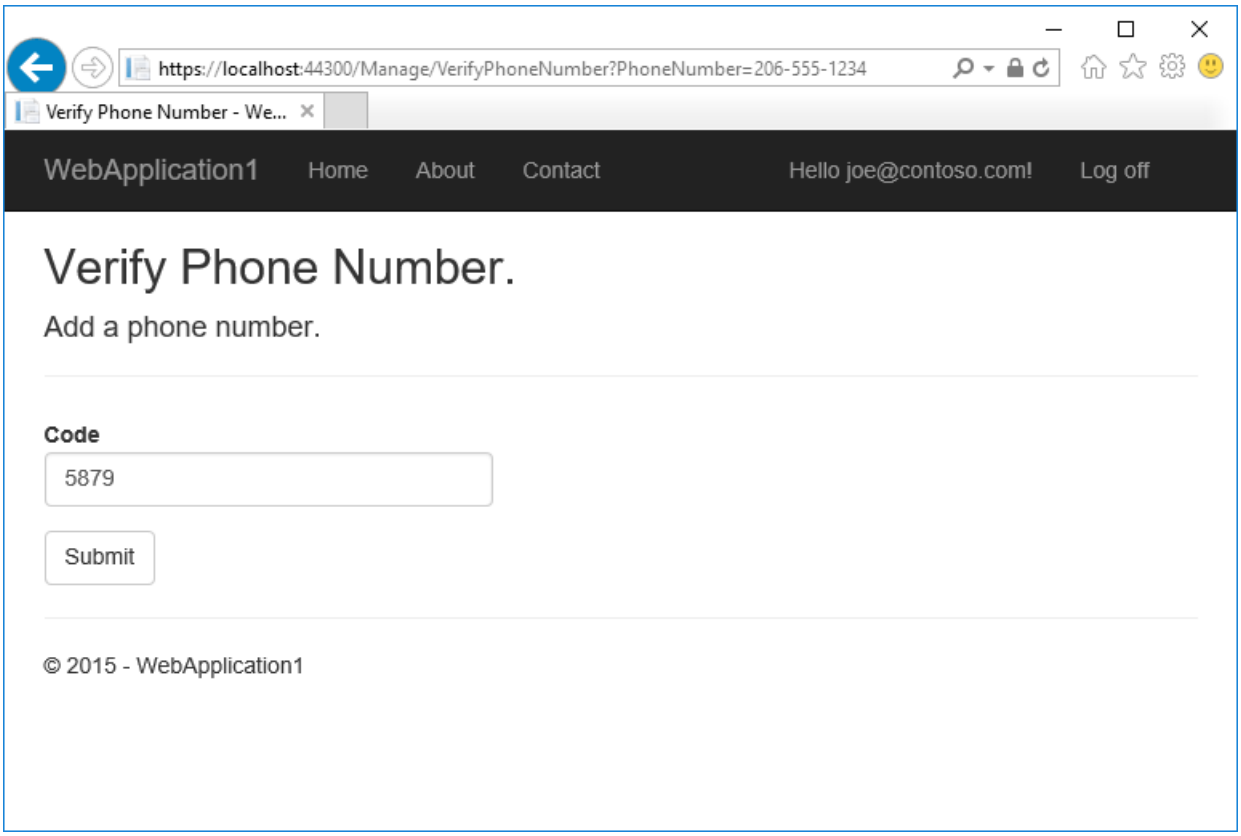
- Tap on your user name, which activates the `Index` action method in Manage controller. Then tap the phone number **Add** link.



- Add a phone number that will receive the verification code, and tap **Send verification code**.

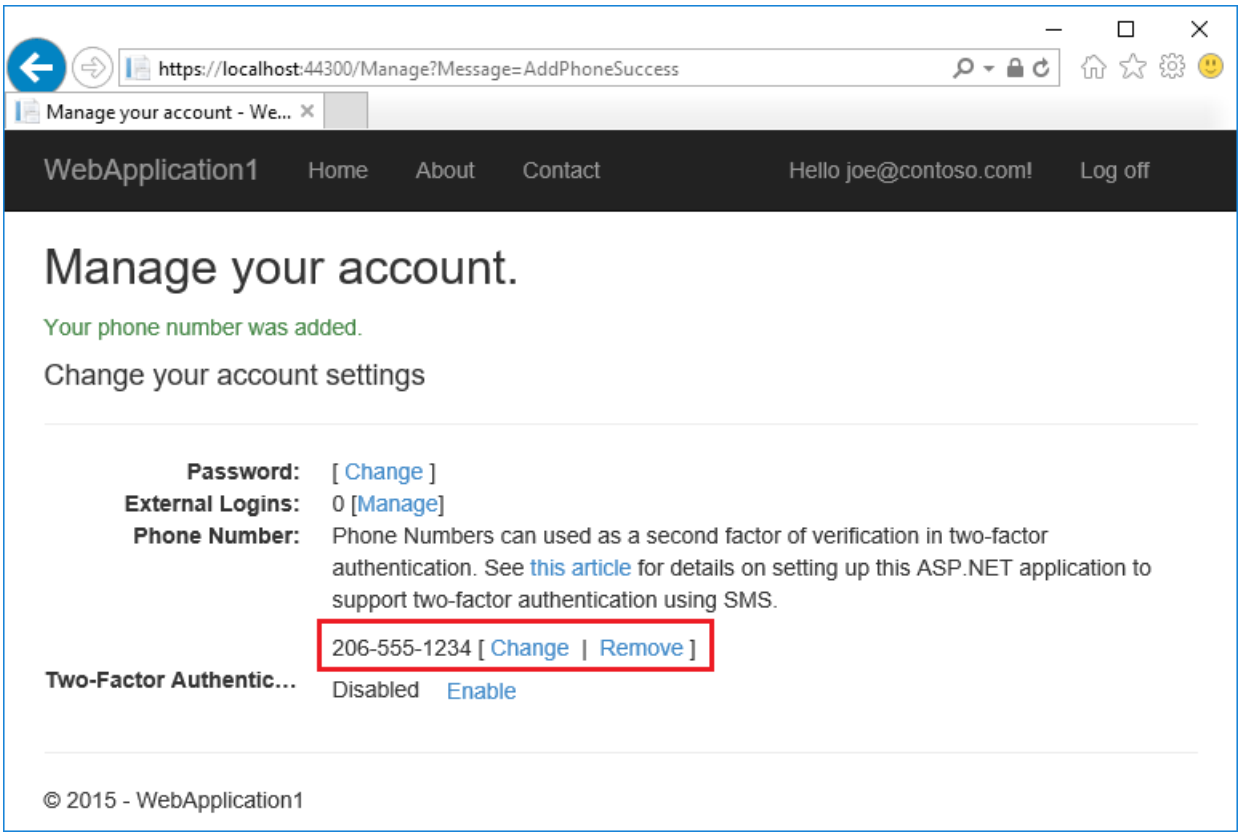


- You will get a text message with the verification code. Enter it and tap **Submit**

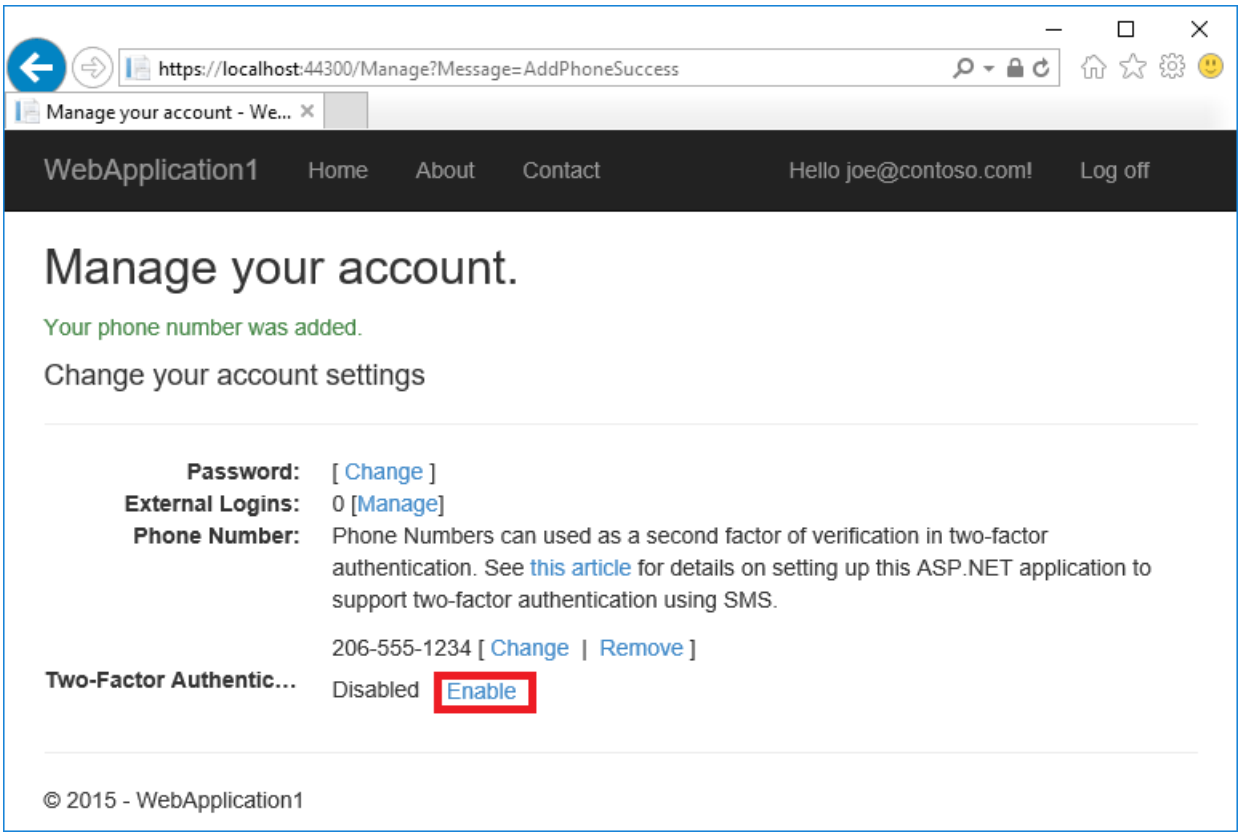


If you don't get a text message, see twilio log page.

- The Manage view shows your phone number was added successfully.



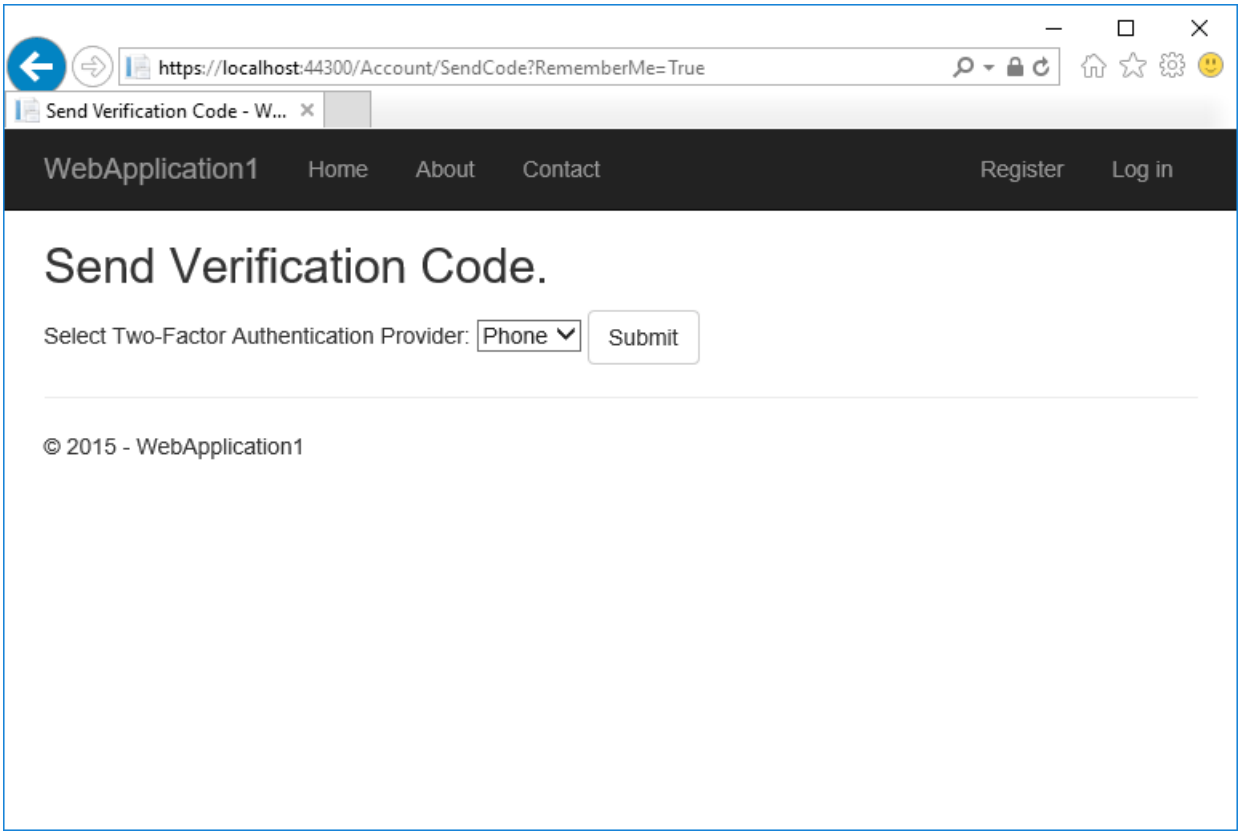
- Tap **Enable** to enable two-factor authentication.



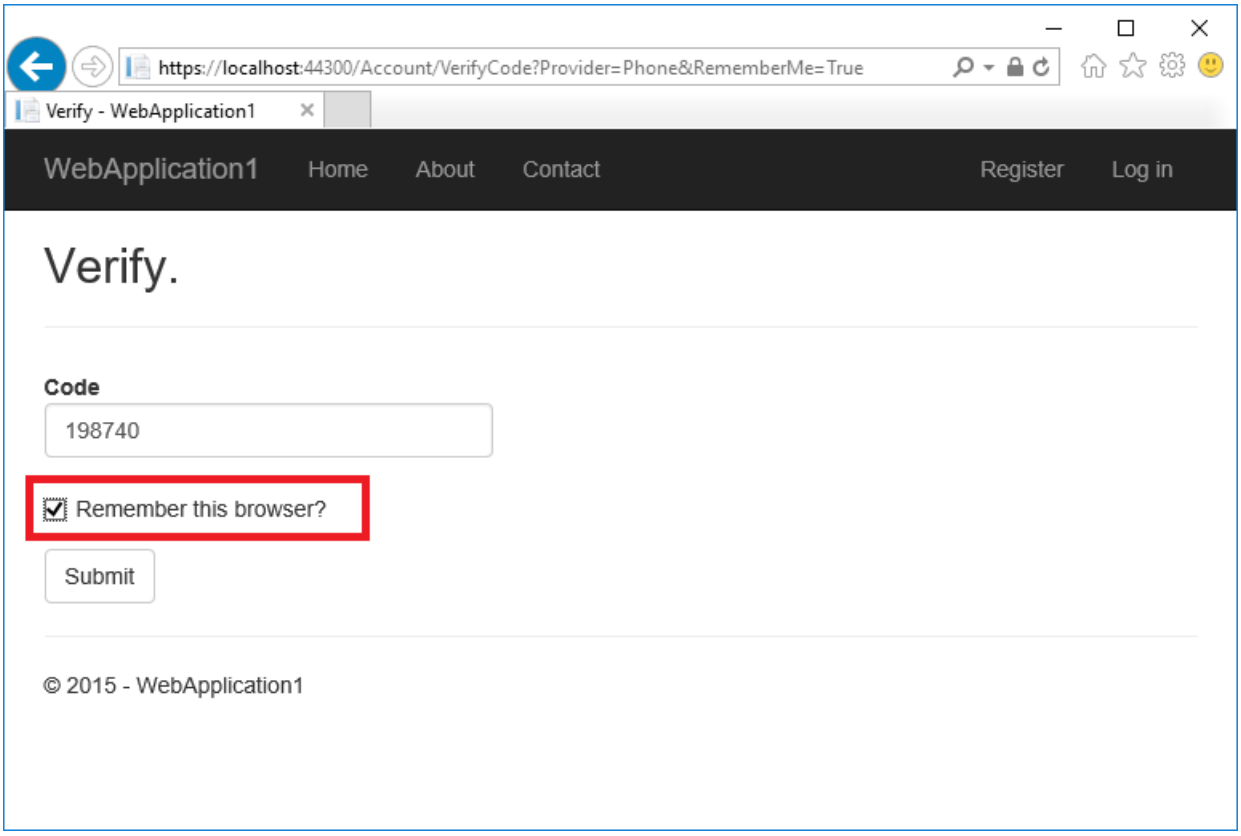
Test two-factor authentication

- Log off.
- Log in.
- The user account has enabled two-factor authentication, so you have to provide the second factor of authentication . In this tutorial you have enabled phone verification. The built in templates also allow you to set up email as the second factor. You can set up additional second factors for authentication such as QR

codes. Tap **Submit**.



- Enter the code you get in the SMS message.
- Clicking on the **Remember this browser** check box will exempt you from needing to use 2FA to log on when using the same device and browser. Enabling 2FA and clicking on **Remember this browser** will provide you with strong 2FA protection from malicious users trying to access your account, as long as they don't have access to your device. You can do this on any private device you regularly use. By setting **Remember this browser**, you get the added security of 2FA from devices you don't regularly use, and you get the convenience on not having to go through 2FA on your own devices.



Account lockout for protecting against brute force attacks

Account lockout is recommended with 2FA. Once a user signs in through a local account or social account, each failed attempt at 2FA is stored. If the maximum failed access attempts is reached, the user is locked out (default: 5 minute lockout after 5 failed access attempts). A successful authentication resets the failed access attempts count and resets the clock. The maximum failed access attempts and lockout time can be set with MaxFailedAccessAttempts and DefaultLockoutTimeSpan. The following configures account lockout for 10 minutes after 10 failed access attempts:

```
public void ConfigureServices(IServiceCollection services)
{
    // Add framework services.
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(Configuration.GetConnectionString("DefaultConnection")));

    services.AddIdentity<ApplicationUser, IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultTokenProviders();

    services.AddMvc();

    services.Configure<IdentityOptions>(options =>
    {
        options.Lockout.MaxFailedAccessAttempts = 10;
        options.Lockout.DefaultLockoutTimeSpan = TimeSpan.FromMinutes(10);
    });

    // Add application services.
    services.AddTransient<IEmailSender, AuthMessageSender>();
    services.AddTransient<ISmsSender, AuthMessageSender>();
    services.Configure<SMSoptions>(Configuration);
}
```

Confirm that PasswordSignInAsync sets `lockoutOnFailure` to `true`:

```
var result = await _signInManager.PasswordSignInAsync(
                Input.Email, Input.Password, Input.RememberMe, lockoutOnFailure: true);
```

Use cookie authentication without ASP.NET Core Identity

9/22/2020 • 14 minutes to read • Edit Online

By Rick Anderson

ASP.NET Core Identity is a complete, full-featured authentication provider for creating and maintaining logins. However, a cookie-based authentication provider without ASP.NET Core Identity can be used. For more information, see Introduction to Identity on ASP.NET Core.

View or download sample code (how to download)

For demonstration purposes in the sample app, the user account for the hypothetical user, Maria Rodriguez, is hardcoded into the app. Use the **Email** address `maria.rodriguez@contoso.com` and any password to sign in the user. The user is authenticated in the `AuthenticateUser` method in the *Pages/Account/Login.cshtml.cs* file. In a real-world example, the user would be authenticated against a database.

Configuration

If the app doesn't use the Microsoft.AspNetCore.App metapackage, create a package reference in the project file for the Microsoft.AspNetCore.Authentication.Cookies package.

In the `Startup.ConfigureServices` method, create the Authentication Middleware services with the AddAuthentication and AddCookie methods:

```
services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
    .AddCookie();
```

AuthenticationScheme passed to `AddAuthentication` sets the default authentication scheme for the app. `AuthenticationScheme` is useful when there are multiple instances of cookie authentication and you want to authorize with a specific scheme. Setting the `AuthenticationScheme` to CookieAuthenticationDefaults.AuthenticationScheme provides a value of "Cookies" for the scheme. You can supply any string value that distinguishes the scheme.

The app's authentication scheme is different from the app's cookie authentication scheme. When a cookie authentication scheme isn't provided to AddCookie, it uses `CookieAuthenticationDefaults.AuthenticationScheme` ("Cookies").

The authentication cookie's IsEssential property is set to `true` by default. Authentication cookies are allowed when a site visitor hasn't consented to data collection. For more information, see General Data Protection Regulation (GDPR) support in ASP.NET Core.

In `Startup.Configure`, call `UseAuthentication` and `UseAuthorization` to set the `HttpContext.User` property and run Authorization Middleware for requests. Call the `UseAuthentication` and `UseAuthorization` methods before calling `UseEndpoints`:

```
app.UseAuthentication();
app.UseAuthorization();

app.UseEndpoints(endpoints =>
{
    endpoints.MapControllers();
    endpoints.MapRazorPages();
});
```

The CookieAuthenticationOptions class is used to configure the authentication provider options.

Set `CookieAuthenticationOptions` in the service configuration for authentication in the `Startup.ConfigureServices` method:

```
services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
    .AddCookie(options =>
    {
        ...
    });
```

Cookie Policy Middleware

Cookie Policy Middleware enables cookie policy capabilities. Adding the middleware to the app processing pipeline is order sensitive—it only affects downstream components registered in the pipeline.

```
app.UseCookiePolicy(cookiePolicyOptions);
```

Use CookiePolicyOptions provided to the Cookie Policy Middleware to control global characteristics of cookie processing and hook into cookie processing handlers when cookies are appended or deleted.

The default MinimumSameSitePolicy value is `SameSiteMode.Lax` to permit OAuth2 authentication. To strictly enforce a same-site policy of `SameSiteMode.Strict`, set the `MinimumSameSitePolicy`. Although this setting breaks OAuth2 and other cross-origin authentication schemes, it elevates the level of cookie security for other types of apps that don't rely on cross-origin request processing.

```
var cookiePolicyOptions = new CookiePolicyOptions
{
    MinimumSameSitePolicy = SameSiteMode.Strict,
};
```

The Cookie Policy Middleware setting for `MinimumSameSitePolicy` can affect the setting of `Cookie.SameSite` in `CookieAuthenticationOptions` settings according to the matrix below.

MINIMUMSAMESITEPOLICY	COOKIE.SAMESITE	RESULTANT COOKIE.SAMESITE SETTING
SameSiteMode.None	SameSiteMode.None SameSiteMode.Lax SameSiteMode.Strict	SameSiteMode.None SameSiteMode.Lax SameSiteMode.Strict
SameSiteMode.Lax	SameSiteMode.None SameSiteMode.Lax SameSiteMode.Strict	SameSiteMode.Lax SameSiteMode.Lax SameSiteMode.Strict

MINIMUMSAMESITEPOLICY	COOKIE.SAMESITE	RESULTANT COOKIE.SAMESITE SETTING
SameSiteMode.Strict	SameSiteMode.None SameSiteMode.Lax SameSiteMode.Strict	SameSiteMode.Strict SameSiteMode.Strict SameSiteMode.Strict

Create an authentication cookie

To create a cookie holding user information, construct a ClaimsPrincipal. The user information is serialized and stored in the cookie.

Create a ClaimsIdentity with any required Claims and call SignInAsync to sign in the user:

```
var claims = new List<Claim>
{
    new Claim(ClaimTypes.Name, user.Email),
    new Claim("FullName", user.FullName),
    new Claim(ClaimTypes.Role, "Administrator"),
};

var claimsIdentity = new ClaimsIdentity(
    claims, CookieAuthenticationDefaults.AuthenticationScheme);

var authProperties = new AuthenticationProperties
{
    //AllowRefresh = <bool>,
    // Refreshing the authentication session should be allowed.

    //ExpiresUtc = DateTimeOffset.UtcNow.AddMinutes(10),
    // The time at which the authentication ticket expires. A
    // value set here overrides the ExpireTimeSpan option of
    // CookieAuthenticationOptions set with AddCookie.

    //IsPersistent = true,
    // Whether the authentication session is persisted across
    // multiple requests. When used with cookies, controls
    // whether the cookie's lifetime is absolute (matching the
    // lifetime of the authentication ticket) or session-based.

    //IssuedUtc = <DateTimeOffset>,
    // The time at which the authentication ticket was issued.

    //RedirectUri = <string>
    // The full path or absolute URI to be used as an http
    // redirect response value.
};

await HttpContext.SignInAsync(
    CookieAuthenticationDefaults.AuthenticationScheme,
    new ClaimsPrincipal(claimsIdentity),
    authProperties);
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

`SignInAsync` creates an encrypted cookie and adds it to the current response. If `AuthenticationScheme` isn't specified, the default scheme is used.

RedirectUri is only used on a few specific paths by default, for example, the login path and logout paths. For more information see the CookieAuthenticationHandler source.

ASP.NET Core's Data Protection system is used for encryption. For an app hosted on multiple machines, load balancing across apps, or using a web farm, configure data protection to use the same key ring and app identifier.

Sign out

To sign out the current user and delete their cookie, call SignOutAsync:

```
await HttpContext.SignOutAsync(
    CookieAuthenticationDefaults.AuthenticationScheme);
```

If `CookieAuthenticationDefaults.AuthenticationScheme` (or "Cookies") isn't used as the scheme (for example, "ContosoCookie"), supply the scheme used when configuring the authentication provider. Otherwise, the default scheme is used.

When the browser closes it automatically deletes session based cookies (non-persistent cookies), but no cookies are cleared when an individual tab is closed. The server is not notified of tab or browser close events.

React to back-end changes

Once a cookie is created, the cookie is the single source of identity. If a user account is disabled in back-end systems:

- The app's cookie authentication system continues to process requests based on the authentication cookie.
- The user remains signed into the app as long as the authentication cookie is valid.

The ValidatePrincipal event can be used to intercept and override validation of the cookie identity. Validating the cookie on every request mitigates the risk of revoked users accessing the app.

One approach to cookie validation is based on keeping track of when the user database changes. If the database hasn't been changed since the user's cookie was issued, there's no need to re-authenticate the user if their cookie is still valid. In the sample app, the database is implemented in `IUserRepository` and stores a `LastChanged` value. When a user is updated in the database, the `LastChanged` value is set to the current time.

In order to invalidate a cookie when the database changes based on the `LastChanged` value, create the cookie with a `LastChanged` claim containing the current `LastChanged` value from the database:

```
var claims = new List<Claim>
{
    new Claim(ClaimTypes.Name, user.Email),
    new Claim("LastChanged", {Database Value})
};

var claimsIdentity = new ClaimsIdentity(
    claims,
    CookieAuthenticationDefaults.AuthenticationScheme);

await HttpContext.SignInAsync(
    CookieAuthenticationDefaults.AuthenticationScheme,
    new ClaimsPrincipal(claimsIdentity));
```

To implement an override for the `ValidatePrincipal` event, write a method with the following signature in a class that derives from CookieAuthenticationEvents:

```
ValidatePrincipal(CookieValidatePrincipalContext)
```

The following is an example implementation of `CookieAuthenticationEvents`:

```
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Authentication.Cookies;

public class CustomCookieAuthenticationEvents : CookieAuthenticationEvents
{
    private readonly IUserRepository _userRepository;

    public CustomCookieAuthenticationEvents(IUserRepository userRepository)
    {
        // Get the database from registered DI services.
        _userRepository = userRepository;
    }

    public override async Task ValidatePrincipal(CookieValidatePrincipalContext context)
    {
        var userPrincipal = context.Principal;

        // Look for the LastChanged claim.
        var lastChanged = (from c in userPrincipal.Claims
                           where c.Type == "LastChanged"
                           select c.Value).FirstOrDefault();

        if (string.IsNullOrEmpty(lastChanged) ||
            !_userRepository.ValidateLastChanged(lastChanged))
        {
            context.RejectPrincipal();

            await context.HttpContext.SignOutAsync(
                CookieAuthenticationDefaults.AuthenticationScheme);
        }
    }
}
```

Register the events instance during cookie service registration in the `Startup.ConfigureServices` method. Provide a scoped service registration for your `CustomCookieAuthenticationEvents` class:

```
services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
    .AddCookie(options =>
    {
        options.EventsType = typeof(CustomCookieAuthenticationEvents);
    });

services.AddScoped<CustomCookieAuthenticationEvents>();
```

Consider a situation in which the user's name is updated—a decision that doesn't affect security in any way. If you want to non-destructively update the user principal, call `context.ReplacePrincipal` and set the `context.ShouldRenew` property to `true`.

> **WARNING**
>
> The approach described here is triggered on every request. Validating authentication cookies for all users on every request can result in a large performance penalty for the app.

Persistent cookies

You may want the cookie to persist across browser sessions. This persistence should only be enabled with explicit user consent with a "Remember Me" check box on sign in or a similar mechanism.

The following code snippet creates an identity and corresponding cookie that survives through browser closures. Any sliding expiration settings previously configured are honored. If the cookie expires while the browser is closed, the browser clears the cookie once it's restarted.

Set IsPersistent to `true` in AuthenticationProperties:

```
// using Microsoft.AspNetCore.Authentication;

await HttpContext.SignInAsync(
    CookieAuthenticationDefaults.AuthenticationScheme,
    new ClaimsPrincipal(claimsIdentity),
    new AuthenticationProperties
    {
        IsPersistent = true
    });
```

Absolute cookie expiration

An absolute expiration time can be set with ExpiresUtc. To create a persistent cookie, `IsPersistent` must also be set. Otherwise, the cookie is created with a session-based lifetime and could expire either before or after the authentication ticket that it holds. When `ExpiresUtc` is set, it overrides the value of the ExpireTimeSpan option of CookieAuthenticationOptions, if set.

The following code snippet creates an identity and corresponding cookie that lasts for 20 minutes. This ignores any sliding expiration settings previously configured.

```
// using Microsoft.AspNetCore.Authentication;

await HttpContext.SignInAsync(
    CookieAuthenticationDefaults.AuthenticationScheme,
    new ClaimsPrincipal(claimsIdentity),
    new AuthenticationProperties
    {
        IsPersistent = true,
        ExpiresUtc = DateTime.UtcNow.AddMinutes(20)
    });
```

ASP.NET Core Identity is a complete, full-featured authentication provider for creating and maintaining logins. However, a cookie-based authentication provider without ASP.NET Core Identity can be used. For more information, see Introduction to Identity on ASP.NET Core.

View or download sample code (how to download)

For demonstration purposes in the sample app, the user account for the hypothetical user, Maria Rodriguez, is hardcoded into the app. Use the **Email** address `maria.rodriguez@contoso.com` and any password to sign in the user. The user is authenticated in the `AuthenticateUser` method in the *Pages/Account/Login.cshtml.cs* file. In a real-world example, the user would be authenticated against a database.

Configuration

If the app doesn't use the Microsoft.AspNetCore.App metapackage, create a package reference in the project file for the Microsoft.AspNetCore.Authentication.Cookies package.

In the `Startup.ConfigureServices` method, create the Authentication Middleware service with the AddAuthentication and AddCookie methods:

```
services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
    .AddCookie();
```

AuthenticationScheme passed to `AddAuthentication` sets the default authentication scheme for the app. `AuthenticationScheme` is useful when there are multiple instances of cookie authentication and you want to authorize with a specific scheme. Setting the `AuthenticationScheme` to CookieAuthenticationDefaults.AuthenticationScheme provides a value of "Cookies" for the scheme. You can supply any string value that distinguishes the scheme.

The app's authentication scheme is different from the app's cookie authentication scheme. When a cookie authentication scheme isn't provided to AddCookie, it uses `CookieAuthenticationDefaults.AuthenticationScheme` ("Cookies").

The authentication cookie's IsEssential property is set to `true` by default. Authentication cookies are allowed when a site visitor hasn't consented to data collection. For more information, see General Data Protection Regulation (GDPR) support in ASP.NET Core.

In the `Startup.Configure` method, call the `UseAuthentication` method to invoke the Authentication Middleware that sets the `HttpContext.User` property. Call the `UseAuthentication` method before calling `UseMvcWithDefaultRoute` or `UseMvc`:

```
app.UseAuthentication();
```

The CookieAuthenticationOptions class is used to configure the authentication provider options.

Set `CookieAuthenticationOptions` in the service configuration for authentication in the `Startup.ConfigureServices` method:

```
services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
    .AddCookie(options =>
    {
        ...
    });
```

Cookie Policy Middleware

Cookie Policy Middleware enables cookie policy capabilities. Adding the middleware to the app processing pipeline is order sensitive—it only affects downstream components registered in the pipeline.

```
app.UseCookiePolicy(cookiePolicyOptions);
```

Use CookiePolicyOptions provided to the Cookie Policy Middleware to control global characteristics of cookie processing and hook into cookie processing handlers when cookies are appended or deleted.

The default MinimumSameSitePolicy value is `SameSiteMode.Lax` to permit OAuth2 authentication. To strictly enforce a same-site policy of `SameSiteMode.Strict`, set the `MinimumSameSitePolicy`. Although this setting breaks OAuth2 and other cross-origin authentication schemes, it elevates the level of cookie security for other types of apps that don't rely on cross-origin request processing.

```
var cookiePolicyOptions = new CookiePolicyOptions
{
    MinimumSameSitePolicy = SameSiteMode.Strict,
};
```

The Cookie Policy Middleware setting for `MinimumSameSitePolicy` can affect the setting of `Cookie.SameSite` in `CookieAuthenticationOptions` settings according to the matrix below.

MINIMUMSAMESITEPOLICY	COOKIE.SAMESITE	RESULTANT COOKIE.SAMESITE SETTING
SameSiteMode.None	SameSiteMode.None SameSiteMode.Lax SameSiteMode.Strict	SameSiteMode.None SameSiteMode.Lax SameSiteMode.Strict
SameSiteMode.Lax	SameSiteMode.None SameSiteMode.Lax SameSiteMode.Strict	SameSiteMode.Lax SameSiteMode.Lax SameSiteMode.Strict
SameSiteMode.Strict	SameSiteMode.None SameSiteMode.Lax SameSiteMode.Strict	SameSiteMode.Strict SameSiteMode.Strict SameSiteMode.Strict

Create an authentication cookie

To create a cookie holding user information, construct a ClaimsPrincipal. The user information is serialized and stored in the cookie.

Create a ClaimsIdentity with any required Claims and call SignInAsync to sign in the user:

```
var claims = new List<Claim>
{
    new Claim(ClaimTypes.Name, user.Email),
    new Claim("FullName", user.FullName),
    new Claim(ClaimTypes.Role, "Administrator"),
};

var claimsIdentity = new ClaimsIdentity(
    claims, CookieAuthenticationDefaults.AuthenticationScheme);

var authProperties = new AuthenticationProperties
{
    //AllowRefresh = <bool>,
    // Refreshing the authentication session should be allowed.

    //ExpiresUtc = DateTimeOffset.UtcNow.AddMinutes(10),
    // The time at which the authentication ticket expires. A
    // value set here overrides the ExpireTimeSpan option of
    // CookieAuthenticationOptions set with AddCookie.

    //IsPersistent = true,
    // Whether the authentication session is persisted across
    // multiple requests. When used with cookies, controls
    // whether the cookie's lifetime is absolute (matching the
    // lifetime of the authentication ticket) or session-based.

    //IssuedUtc = <DateTimeOffset>,
    // The time at which the authentication ticket was issued.

    //RedirectUri = <string>
    // The full path or absolute URI to be used as an http
    // redirect response value.
};

await HttpContext.SignInAsync(
    CookieAuthenticationDefaults.AuthenticationScheme,
    new ClaimsPrincipal(claimsIdentity),
    authProperties);
```

`SignInAsync` creates an encrypted cookie and adds it to the current response. If `AuthenticationScheme` isn't specified, the default scheme is used.

ASP.NET Core's Data Protection system is used for encryption. For an app hosted on multiple machines, load balancing across apps, or using a web farm, configure data protection to use the same key ring and app identifier.

Sign out

To sign out the current user and delete their cookie, call SignOutAsync:

```
await HttpContext.SignOutAsync(
    CookieAuthenticationDefaults.AuthenticationScheme);
```

If `CookieAuthenticationDefaults.AuthenticationScheme` (or "Cookies") isn't used as the scheme (for example, "ContosoCookie"), supply the scheme used when configuring the authentication provider. Otherwise, the default scheme is used.

React to back-end changes

Once a cookie is created, the cookie is the single source of identity. If a user account is disabled in back-end systems:

- The app's cookie authentication system continues to process requests based on the authentication cookie.
- The user remains signed into the app as long as the authentication cookie is valid.

The ValidatePrincipal event can be used to intercept and override validation of the cookie identity. Validating the cookie on every request mitigates the risk of revoked users accessing the app.

One approach to cookie validation is based on keeping track of when the user database changes. If the database hasn't been changed since the user's cookie was issued, there's no need to re-authenticate the user if their cookie is still valid. In the sample app, the database is implemented in `IUserRepository` and stores a `LastChanged` value. When a user is updated in the database, the `LastChanged` value is set to the current time.

In order to invalidate a cookie when the database changes based on the `LastChanged` value, create the cookie with a `LastChanged` claim containing the current `LastChanged` value from the database:

```
var claims = new List<Claim>
{
    new Claim(ClaimTypes.Name, user.Email),
    new Claim("LastChanged", {Database Value})
};

var claimsIdentity = new ClaimsIdentity(
    claims,
    CookieAuthenticationDefaults.AuthenticationScheme);

await HttpContext.SignInAsync(
    CookieAuthenticationDefaults.AuthenticationScheme,
    new ClaimsPrincipal(claimsIdentity));
```

To implement an override for the `ValidatePrincipal` event, write a method with the following signature in a class that derives from CookieAuthenticationEvents:

```
ValidatePrincipal(CookieValidatePrincipalContext)
```

The following is an example implementation of `CookieAuthenticationEvents`:

```
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Authentication.Cookies;

public class CustomCookieAuthenticationEvents : CookieAuthenticationEvents
{
    private readonly IUserRepository _userRepository;

    public CustomCookieAuthenticationEvents(IUserRepository userRepository)
    {
        // Get the database from registered DI services.
        _userRepository = userRepository;
    }

    public override async Task ValidatePrincipal(CookieValidatePrincipalContext context)
    {
        var userPrincipal = context.Principal;

        // Look for the LastChanged claim.
        var lastChanged = (from c in userPrincipal.Claims
                           where c.Type == "LastChanged"
                           select c.Value).FirstOrDefault();

        if (string.IsNullOrEmpty(lastChanged) ||
            !_userRepository.ValidateLastChanged(lastChanged))
        {
            context.RejectPrincipal();

            await context.HttpContext.SignOutAsync(
                CookieAuthenticationDefaults.AuthenticationScheme);
        }
    }
}
```

Register the events instance during cookie service registration in the `Startup.ConfigureServices` method. Provide a scoped service registration for your `CustomCookieAuthenticationEvents` class:

```
services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
    .AddCookie(options =>
    {
        options.EventsType = typeof(CustomCookieAuthenticationEvents);
    });

services.AddScoped<CustomCookieAuthenticationEvents>();
```

Consider a situation in which the user's name is updated—a decision that doesn't affect security in any way. If you want to non-destructively update the user principal, call `context.ReplacePrincipal` and set the `context.ShouldRenew` property to `true`.

> **WARNING**
>
> The approach described here is triggered on every request. Validating authentication cookies for all users on every request can result in a large performance penalty for the app.

Persistent cookies

You may want the cookie to persist across browser sessions. This persistence should only be enabled with explicit user consent with a "Remember Me" check box on sign in or a similar mechanism.

The following code snippet creates an identity and corresponding cookie that survives through browser closures. Any sliding expiration settings previously configured are honored. If the cookie expires while the browser is closed, the browser clears the cookie once it's restarted.

Set IsPersistent to `true` in AuthenticationProperties:

```
// using Microsoft.AspNetCore.Authentication;

await HttpContext.SignInAsync(
    CookieAuthenticationDefaults.AuthenticationScheme,
    new ClaimsPrincipal(claimsIdentity),
    new AuthenticationProperties
    {
        IsPersistent = true
    });
```

Absolute cookie expiration

An absolute expiration time can be set with ExpiresUtc. To create a persistent cookie, `IsPersistent` must also be set. Otherwise, the cookie is created with a session-based lifetime and could expire either before or after the authentication ticket that it holds. When `ExpiresUtc` is set, it overrides the value of the ExpireTimeSpan option of CookieAuthenticationOptions, if set.

The following code snippet creates an identity and corresponding cookie that lasts for 20 minutes. This ignores any sliding expiration settings previously configured.

```
// using Microsoft.AspNetCore.Authentication;

await HttpContext.SignInAsync(
    CookieAuthenticationDefaults.AuthenticationScheme,
    new ClaimsPrincipal(claimsIdentity),
    new AuthenticationProperties
    {
        IsPersistent = true,
        ExpiresUtc = DateTime.UtcNow.AddMinutes(20)
    });
```

Use social sign-in provider authentication without ASP.NET Core Identity

9/22/2020 • 4 minutes to read • Edit Online

By Kirk Larkin and Rick Anderson

Facebook, Google, and external provider authentication in ASP.NET Core describes how to enable users to sign in using OAuth 2.0 with credentials from external authentication providers. The approach described in that topic includes ASP.NET Core Identity as an authentication provider.

This sample demonstrates how to use an external authentication provider **without** ASP.NET Core Identity. This is useful for apps that don't require all of the features of ASP.NET Core Identity, but still require integration with a trusted external authentication provider.

This sample uses Google authentication for authenticating users. Using Google authentication shifts many of the complexities of managing the sign-in process to Google. To integrate with a different external authentication provider, see the following topics:

- Facebook authentication
- Microsoft authentication
- Twitter authentication
- Other providers

Configuration

In the `ConfigureServices` method, configure the app's authentication schemes with the AddAuthentication, AddCookie, and AddGoogle methods:

```
public void ConfigureServices(IServiceCollection services)
{
    // requires
    // using Microsoft.AspNetCore.Authentication.Cookies;
    // using Microsoft.AspNetCore.Authentication.Google;
    // NuGet package Microsoft.AspNetCore.Authentication.Google
    services
        .AddAuthentication(options =>
        {
            options.DefaultScheme = CookieAuthenticationDefaults.AuthenticationScheme;
            options.DefaultChallengeScheme = GoogleDefaults.AuthenticationScheme;
        })
        .AddCookie()
        .AddGoogle(options =>
        {
            options.ClientId = Configuration["Authentication:Google:ClientId"];
            options.ClientSecret = Configuration["Authentication:Google:ClientSecret"];
        });

    services.AddRazorPages();
}
```

The call to AddAuthentication sets the app's DefaultScheme. The `DefaultScheme` is the default scheme used by the following `HttpContext` authentication extension methods:

- AuthenticateAsync

- ChallengeAsync
- ForbidAsync
- SignInAsync
- SignOutAsync

Setting the app's `DefaultScheme` to CookieAuthenticationDefaults.AuthenticationScheme ("Cookies") configures the app to use Cookies as the default scheme for these extension methods. Setting the app's DefaultChallengeScheme to GoogleDefaults.AuthenticationScheme ("Google") configures the app to use Google as the default scheme for calls to `ChallengeAsync`. `DefaultChallengeScheme` overrides `DefaultScheme`. See AuthenticationOptions for additional properties that override `DefaultScheme` when set.

In `Startup.Configure`, call `UseAuthentication` and `UseAuthorization` between calling `UseRouting` and `UseEndpoints`. This sets the `HttpContext.User` property and runs the Authorization Middleware for requests:

```
app.UseRouting();

app.UseAuthentication();
app.UseAuthorization();

app.UseEndpoints(endpoints =>
{
    endpoints.MapRazorPages();
});
```

To learn more about authentication schemes, see Authentication Concepts. To learn more about cookie authentication, see Use cookie authentication without ASP.NET Core Identity.

Apply authorization

Test the app's authentication configuration by applying the `AuthorizeAttribute` attribute to a controller, action, or page. The following code limits access to the *Privacy* page to users that have been authenticated:

```
[Authorize]
public class PrivacyModel : PageModel
{

}
```

Sign out

To sign out the current user and delete their cookie, call SignOutAsync. The following code adds a `Logout` page handler to the *Index* page:

```
public class IndexModel : PageModel
{
    public async Task<IActionResult> OnPostLogoutAsync()
    {
        await HttpContext.SignOutAsync();
        return RedirectToPage();
    }
}
```

Notice that the call to `SignOutAsync` does not specify an authentication scheme. The app's `DefaultScheme` of `CookieAuthenticationDefaults.AuthenticationScheme` is used as a fall back.

Additional resources

- Simple authorization in ASP.NET Core
- Persist additional claims and tokens from external providers in ASP.NET Core

Facebook, Google, and external provider authentication in ASP.NET Core describes how to enable users to sign in using OAuth 2.0 with credentials from external authentication providers. The approach described in that topic includes ASP.NET Core Identity as an authentication provider.

This sample demonstrates how to use an external authentication provider **without** ASP.NET Core Identity. This is useful for apps that don't require all of the features of ASP.NET Core Identity, but still require integration with a trusted external authentication provider.

This sample uses Google authentication for authenticating users. Using Google authentication shifts many of the complexities of managing the sign-in process to Google. To integrate with a different external authentication provider, see the following topics:

- Facebook authentication
- Microsoft authentication
- Twitter authentication
- Other providers

Configuration

In the `ConfigureServices` method, configure the app's authentication schemes with the `AddAuthentication`, `AddCookie`, and `AddGoogle` methods:

```
services
    .AddAuthentication(options =>
    {
        options.DefaultScheme = CookieAuthenticationDefaults.AuthenticationScheme;
        options.DefaultChallengeScheme = GoogleDefaults.AuthenticationScheme;
    })
    .AddCookie()
    .AddGoogle(options =>
    {
        options.ClientId = Configuration["Authentication:Google:ClientId"];
        options.ClientSecret = Configuration["Authentication:Google:ClientSecret"];
    });
```

The call to AddAuthentication sets the app's DefaultScheme. The `DefaultScheme` is the default scheme used by the following `HttpContext` authentication extension methods:

- AuthenticateAsync
- ChallengeAsync
- ForbidAsync
- SignInAsync
- SignOutAsync

Setting the app's `DefaultScheme` to CookieAuthenticationDefaults.AuthenticationScheme ("Cookies") configures the app to use Cookies as the default scheme for these extension methods. Setting the app's DefaultChallengeScheme to GoogleDefaults.AuthenticationScheme ("Google") configures the app to use Google as the default scheme for calls to `ChallengeAsync`. `DefaultChallengeScheme` overrides `DefaultScheme`. See AuthenticationOptions for additional properties that override `DefaultScheme` when set.

In the `Configure` method, call the `UseAuthentication` method to invoke the Authentication Middleware that sets

the `HttpContext.User` property. Call the `UseAuthentication` method before calling `UseMvcWithDefaultRoute` or `UseMvc`:

```
app.UseAuthentication();
```

To learn more about authentication schemes, see Authentication Concepts. To learn more about cookie authentication, see Use cookie authentication without ASP.NET Core Identity.

Apply authorization

Test the app's authentication configuration by applying the `AuthorizeAttribute` attribute to a controller, action, or page. The following code limits access to the *Privacy* page to users that have been authenticated:

```
[Authorize]
public class PrivacyModel : PageModel
{

}
```

Sign out

To sign out the current user and delete their cookie, call SignOutAsync. The following code adds a `Logout` page handler to the *Index* page:

```
public class IndexModel : PageModel
{
    public async Task<IActionResult> OnPostLogoutAsync()
    {
        await HttpContext.SignOutAsync();
        return RedirectToPage();
    }
}
```

Notice that the call to `SignOutAsync` does not specify an authentication scheme. The app's `DefaultScheme` of `CookieAuthenticationDefaults.AuthenticationScheme` is used as a fall back.

Azure Active Directory with ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

These tutorials and samples demonstrate authentication in ASP.NET Core using Microsoft identity platform and Azure Active Directory. For additional tutorials and samples using ASP.NET Core with Azure AD, see Microsoft identity platform.

Application Scenarios

- Quickstart: Add sign-in with Microsoft to an ASP.NET Core web app
- Web app that signs in users
- Web app that calls web APIs
- Protected web API
- Web API that calls other web APIs
- Web app that signs in users with Azure AD B2C

Samples

- Enable your ASP.NET Core app to sign-in users and call web APIs using Azure AD V2:
  - See this associated video
- Calling an ASP.NET Core 2.0 Web API from a WPF application using Azure AD V2:
  - See this associated video
- An ASP.NET Core web API with Azure AD B2C

Cloud authentication with Azure Active Directory B2C in ASP.NET Core

9/22/2020 • 5 minutes to read • Edit Online

By Cam Soper

Azure Active Directory B2C (Azure AD B2C) is a cloud identity management solution for web and mobile apps. The service provides authentication for apps hosted in the cloud and on-premises. Authentication types include individual accounts, social network accounts, and federated enterprise accounts. Additionally, Azure AD B2C can provide multi-factor authentication with minimal configuration.

> **TIP**
> Azure Active Directory (Azure AD) and Azure AD B2C are separate product offerings. An Azure AD tenant represents an organization, while an Azure AD B2C tenant represents a collection of identities to be used with relying party applications. To learn more, see Azure AD B2C: Frequently asked questions (FAQ).

In this tutorial, learn how to:

- Create an Azure Active Directory B2C tenant
- Register an app in Azure AD B2C
- Use Visual Studio to create an ASP.NET Core web app configured to use the Azure AD B2C tenant for authentication
- Configure policies controlling the behavior of the Azure AD B2C tenant

Prerequisites

The following are required for this walkthrough:

- Microsoft Azure subscription
- Visual Studio 2019

Create the Azure Active Directory B2C tenant

Create an Azure Active Directory B2C tenant as described in the documentation. When prompted, associating the tenant with an Azure subscription is optional for this tutorial.

Register the app in Azure AD B2C

In the newly created Azure AD B2C tenant, register your app using the steps in the documentation under the **Register a web app** section. Stop at the **Create a web app client secret** section. A client secret isn't required for this tutorial.

Use the following values:

SETTING	VALUE	NOTES
Name	*<app name>*	Enter a **Name** for the app that describes your app to consumers.

SETTING	VALUE	NOTES
Include web app / web API	Yes	
Allow implicit flow	Yes	
Reply URL	`https://localhost:44300/signin-oidc`	Reply URLs are endpoints where Azure AD B2C returns any tokens that your app requests. Visual Studio provides the Reply URL to use. For now, enter `https://localhost:44300/signin-oidc` to complete the form.
App ID URI	Leave blank	Not required for this tutorial.
Include native client	No	

WARNING

If setting up a non-localhost Reply URL, be aware of the constraints on what is allowed in the Reply URL list.

After the app is registered, the list of apps in the tenant is displayed. Select the app that was just registered. Select the **Copy** icon to the right of the **Application ID** field to copy it to the clipboard.

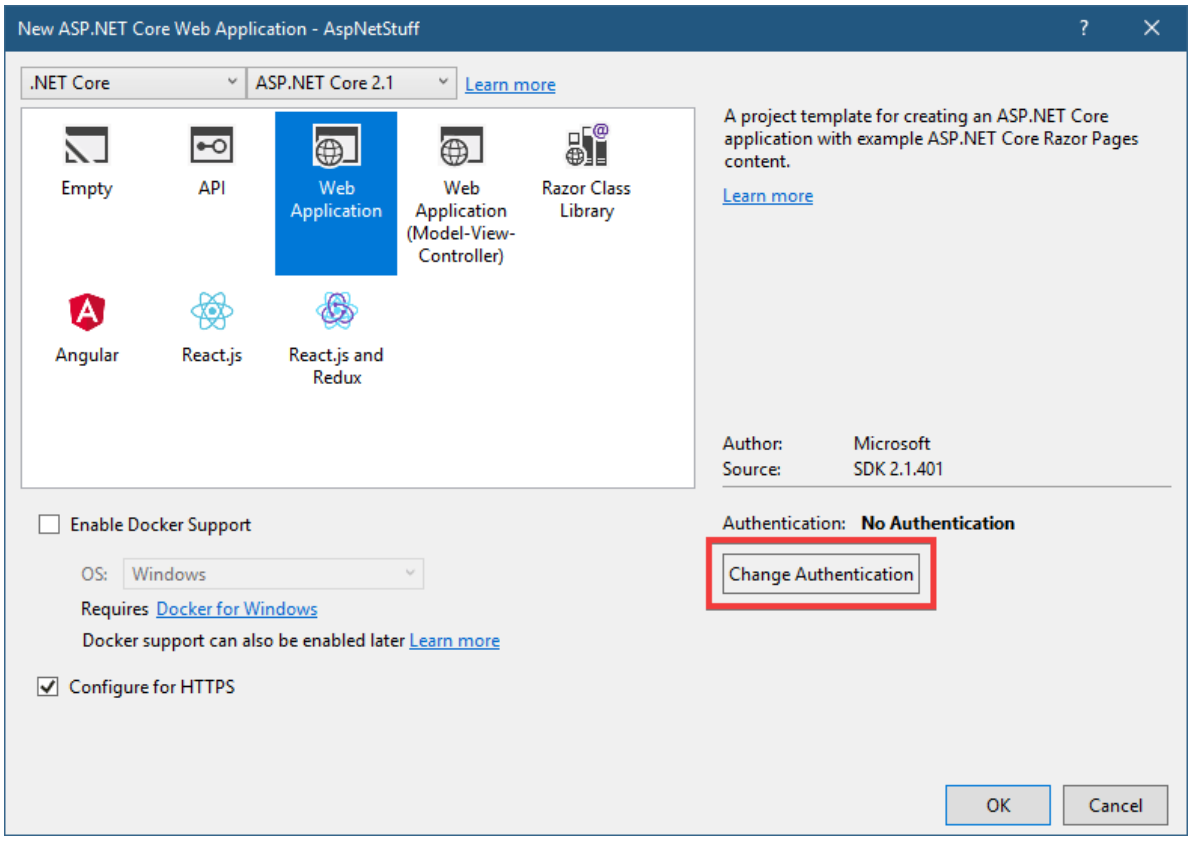
Nothing more can be configured in the Azure AD B2C tenant at this time, but leave the browser window open. There is more configuration after the ASP.NET Core app is created.

Create an ASP.NET Core app in Visual Studio

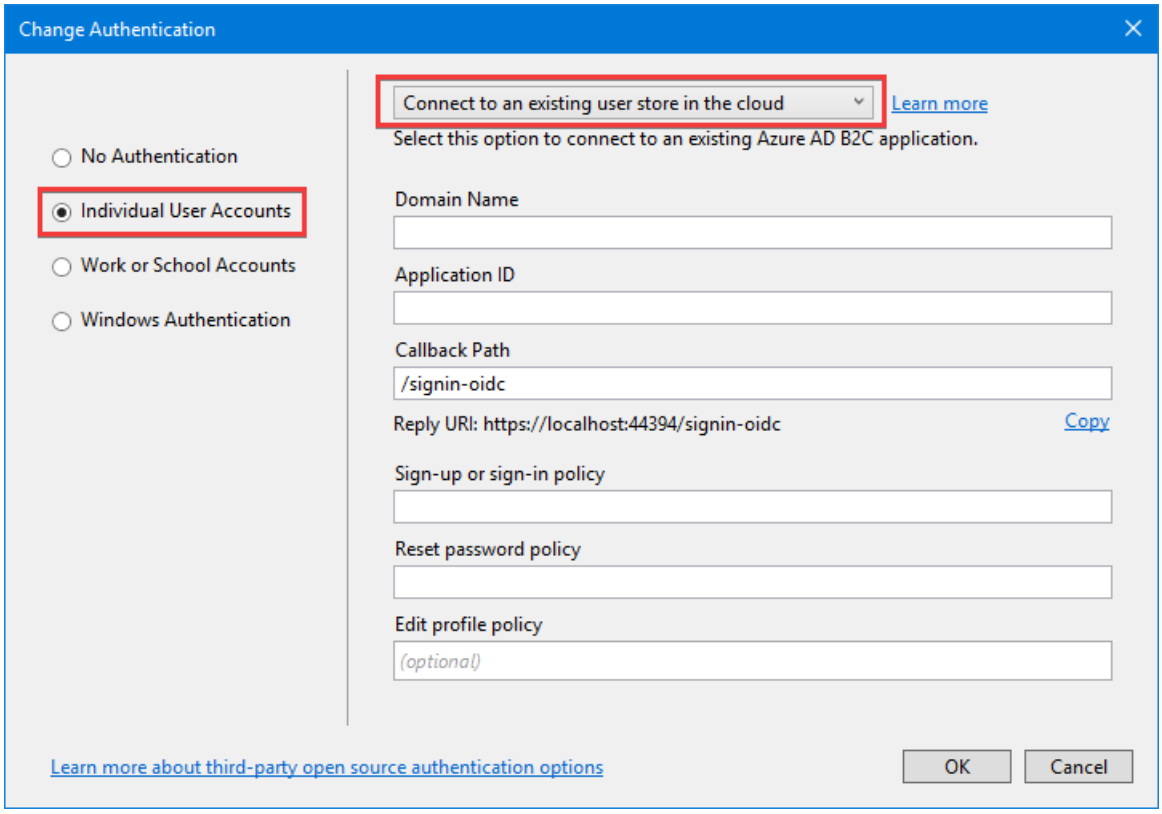
The Visual Studio Web Application template can be configured to use the Azure AD B2C tenant for authentication.

In Visual Studio:

1. Create a new ASP.NET Core Web Application.
2. Select **Web Application** from the list of templates.
3. Select the **Change Authentication** button.



4. In the **Change Authentication** dialog, select **Individual User Accounts**, and then select **Connect to an existing user store in the cloud** in the dropdown.



5. Complete the form with the following values:

SETTING	VALUE
Domain Name	*<the domain name of your B2C tenant>*
Application ID	*<paste the Application ID from the clipboard>*

SETTING	VALUE
Callback Path	*<use the default value>*
Sign-up or sign-in policy	`B2C_1_SiUpIn`
Reset password policy	`B2C_1_SSPR`
Edit profile policy	*<leave blank>*

Select the **Copy** link next to **Reply URI** to copy the Reply URI to the clipboard. Select **OK** to close the **Change Authentication** dialog. Select **OK** to create the web app.

Finish the B2C app registration

Return to the browser window with the B2C app properties still open. Change the temporary **Reply URL** specified earlier to the value copied from Visual Studio. Select **Save** at the top of the window.

> **TIP**
> If you didn't copy the Reply URL, use the HTTPS address from the Debug tab in the web project properties, and append the **CallbackPath** value from *appsettings.json*.

Configure policies

Use the steps in the Azure AD B2C documentation to create a sign-up or sign-in policy, and then create a password reset policy. Use the example values provided in the documentation for **Identity providers**, **Sign-up attributes**, and **Application claims**. Using the **Run now** button to test the policies as described in the documentation is optional.

> **WARNING**
> Ensure the policy names are exactly as described in the documentation, as those policies were used in the **Change Authentication** dialog in Visual Studio. The policy names can be verified in *appsettings.json*.

Configure the underlying OpenIdConnectOptions/JwtBearer/Cookie options

To configure the underlying options directly, use the appropriate scheme constant in `Startup.ConfigureServices`:

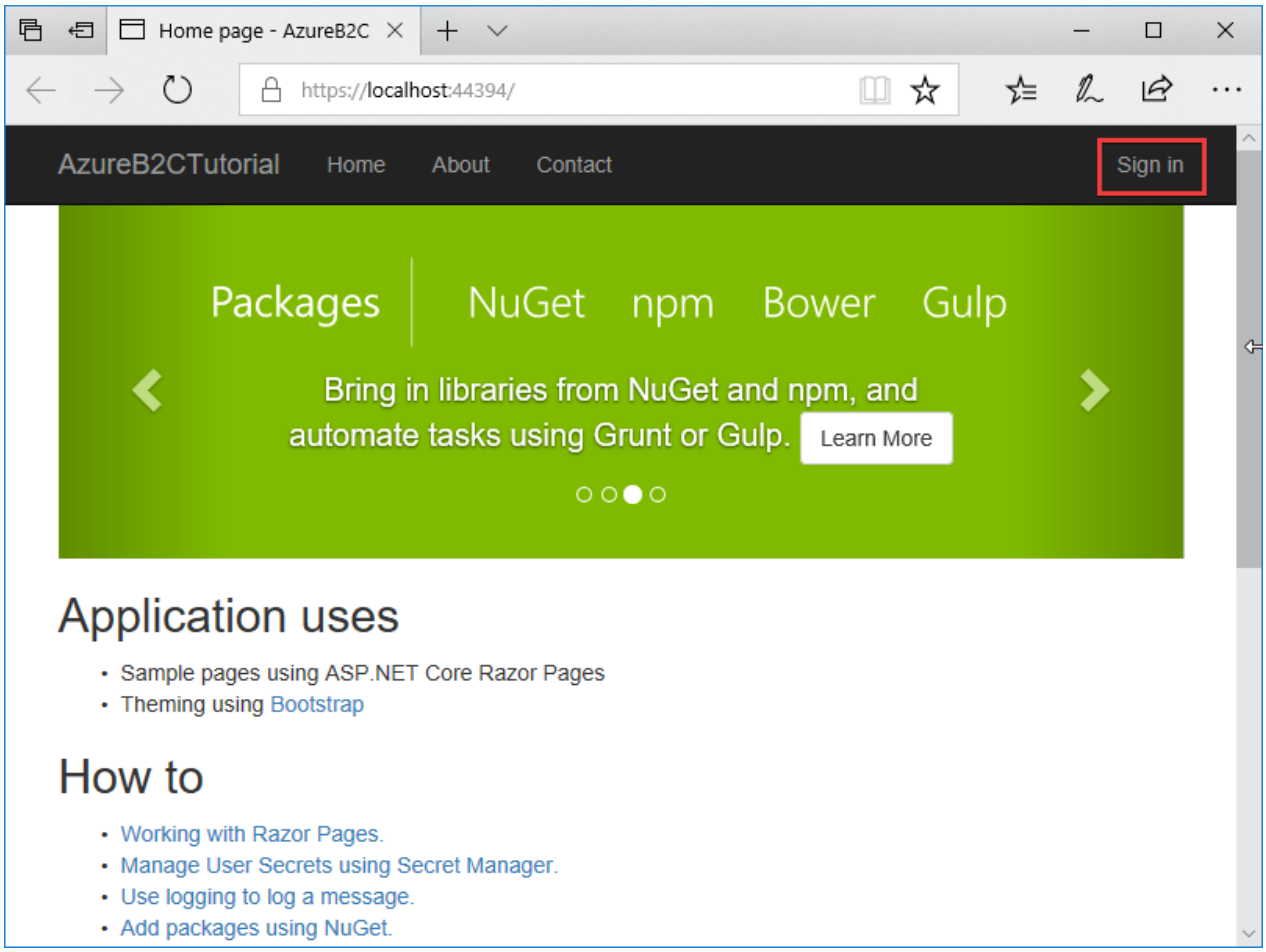
```
services.Configure<OpenIdConnectOptions>(
    AzureAD[B2C]Defaults.OpenIdScheme, options =>
    {
        // Omitted for brevity
    });

services.Configure<CookieAuthenticationOptions>(
    AzureAD[B2C]Defaults.CookieScheme, options =>
    {
        // Omitted for brevity
    });

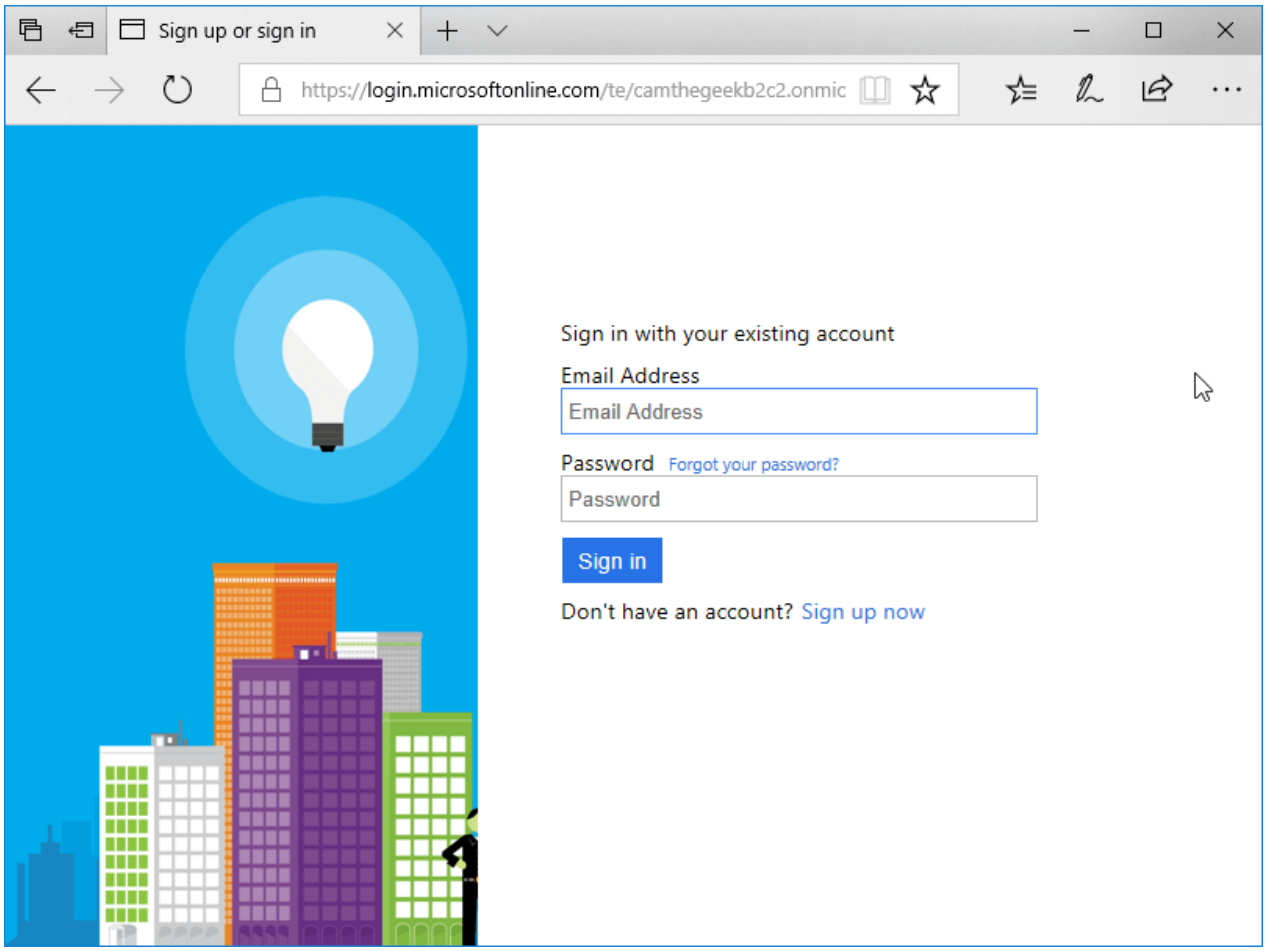
services.Configure<JwtBearerOptions>(
    AzureAD[B2C]Defaults.JwtBearerAuthenticationScheme, options =>
    {
        // Omitted for brevity
    });
```

Run the app

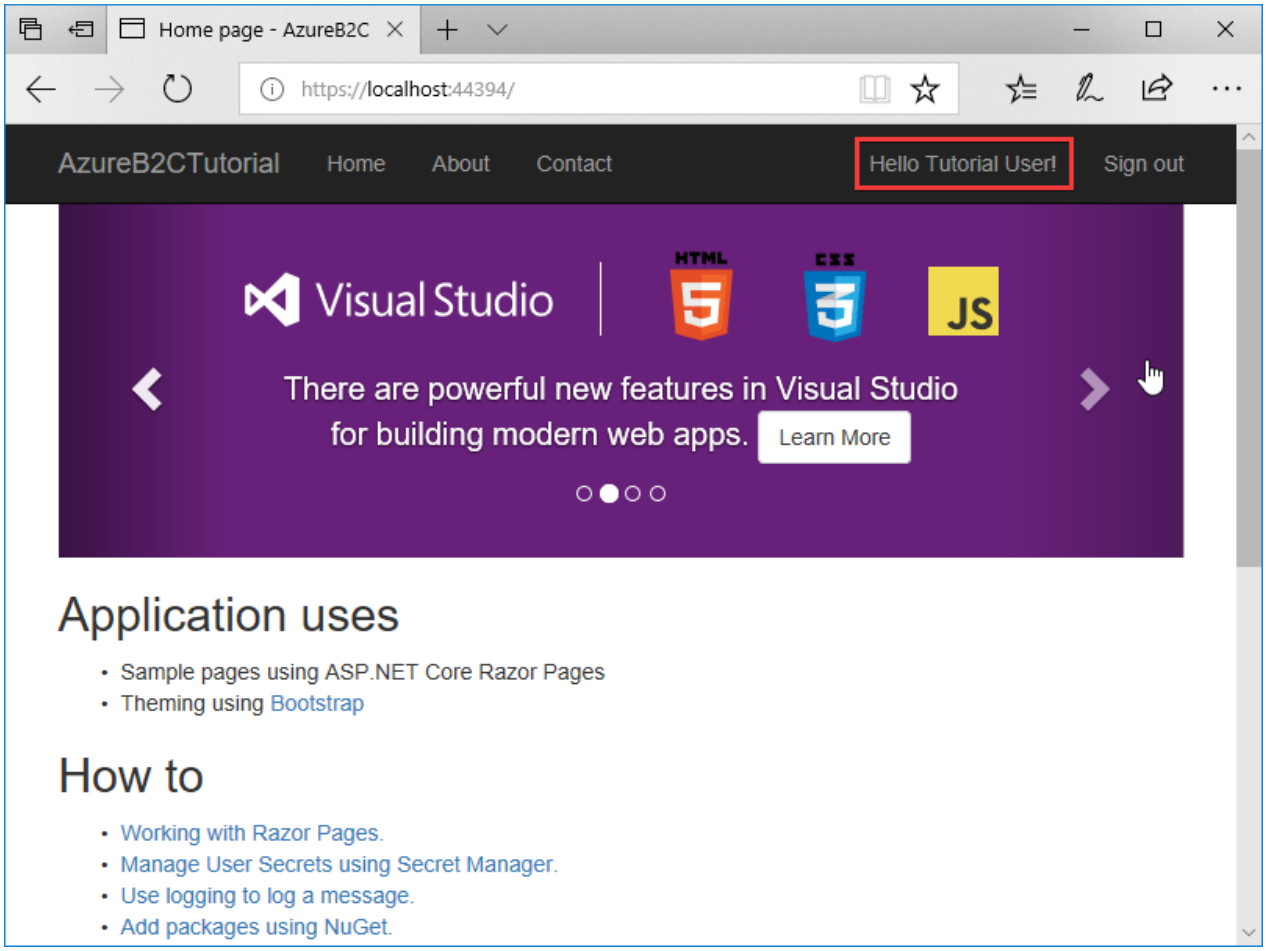
In Visual Studio, press **F5** to build and run the app. After the web app launches, select **Accept** to accept the use of cookies (if prompted), and then select **Sign in**.



The browser redirects to the Azure AD B2C tenant. Sign in with an existing account (if one was created testing the policies) or select **Sign up now** to create a new account. The **Forgot your password?** link is used to reset a forgotten password.



After successfully signing in, the browser redirects to the web app.



Next steps

In this tutorial, you learned how to:

- Create an Azure Active Directory B2C tenant
- Register an app in Azure AD B2C
- Use Visual Studio to create an ASP.NET Core Web Application configured to use the Azure AD B2C tenant for authentication
- Configure policies controlling the behavior of the Azure AD B2C tenant

Now that the ASP.NET Core app is configured to use Azure AD B2C for authentication, the Authorize attribute can be used to secure your app. Continue developing your app by learning to:

- Customize the Azure AD B2C user interface.
- Configure password complexity requirements.
- Enable multi-factor authentication.
- Configure additional identity providers, such as Microsoft, Facebook, Google, Amazon, Twitter, and others.
- Use the Azure AD Graph API to retrieve additional user information, such as group membership, from the Azure AD B2C tenant.
- How to secure a Web API built with ASP.NET Core using the Azure AD B2C.
- Tutorial: Grant access to an ASP.NET web API using Azure Active Directory B2C.

Articles based on ASP.NET Core projects created with individual user accounts

9/22/2020 • 2 minutes to read • Edit Online

ASP.NET Core Identity is included in project templates in Visual Studio with the "Individual User Accounts" option.

The authentication templates are available in .NET Core CLI with `-au Individual`:

```
dotnet new mvc -au Individual
dotnet new webapp -au Individual
```

```
dotnet new mvc -au Individual
dotnet new razor -au Individual
```

See this GitHub issue for web API authentication.

No Authentication

Authentication is specified in the .NET Core CLI with the `-au` option. In Visual Studio, the **Change Authentication** dialog is available for new web applications. The default for new web apps in Visual Studio is **No Authentication**.

Projects created with no authentication:

- Don't contain web pages and UI to sign in and sign out.
- Don't contain authentication code.

Windows Authentication

Windows Authentication is specified for new web apps in the .NET Core CLI with the `-au Windows` option. In Visual Studio, the **Change Authentication** dialog provides the **Windows Authentication** options.

If Windows Authentication is selected, the app is configured to use the Windows Authentication IIS module. Windows Authentication is intended for Intranet web sites.

dotnet new webapp authentication options

The following table shows the authentication options available for new web apps:

OPTION	TYPE OF AUTHENTICATION	LINK FOR MORE INFORMATION
None	No authentication	
Individual	Individual authentication	Introduction to Identity on ASP.NET Core
IndividualB2C	Cloud-hosted individual authentication with Azure AD B2C	Azure AD B2C

OPTION	TYPE OF AUTHENTICATION	LINK FOR MORE INFORMATION
SingleOrg	Organizational authentication for a single tenant	Azure AD
MultiOrg	Organizational authentication for multiple tenants	Azure AD
Windows	Windows authentication	Windows Authentication

Visual Studio new webapp authentication options

The following table shows the authentication options available when creating a new web app with Visual Studio:

OPTION	TYPE OF AUTHENTICATION	LINK FOR MORE INFORMATION
None	No authentication	
Individual User Accounts / Store user accounts in-app	Individual authentication	Introduction to Identity on ASP.NET Core
Individual User Accounts / Connect to an existing user store in the cloud	Cloud-hosted individual authentication with Azure AD B2C	Azure AD B2C
Work or School Cloud / Single Org	Organizational authentication for a single tenant	Azure AD
Work or School Cloud / Multiple Org	Organizational authentication for multiple tenants	Azure AD
Windows	Windows authentication	Windows Authentication

Additional resources

The following articles show how to use the code generated in ASP.NET Core templates that use individual user accounts:

- Account confirmation and password recovery in ASP.NET Core
- Create an ASP.NET Core app with user data protected by authorization

Configure certificate authentication in ASP.NET Core

9/22/2020 • 13 minutes to read • Edit Online

`Microsoft.AspNetCore.Authentication.Certificate` contains an implementation similar to Certificate Authentication for ASP.NET Core. Certificate authentication happens at the TLS level, long before it ever gets to ASP.NET Core. More accurately, this is an authentication handler that validates the certificate and then gives you an event where you can resolve that certificate to a `ClaimsPrincipal`.

Configure your server for certificate authentication, be it IIS, Kestrel, Azure Web Apps, or whatever else you're using.

Proxy and load balancer scenarios

Certificate authentication is a stateful scenario primarily used where a proxy or load balancer doesn't handle traffic between clients and servers. If a proxy or load balancer is used, certificate authentication only works if the proxy or load balancer:

- Handles the authentication.
- Passes the user authentication information to the app (for example, in a request header), which acts on the authentication information.

An alternative to certificate authentication in environments where proxies and load balancers are used is Active Directory Federated Services (ADFS) with OpenID Connect (OIDC).

Get started

Acquire an HTTPS certificate, apply it, and configure your server to require certificates.

In your web app, add a reference to the Microsoft.AspNetCore.Authentication.Certificate package. Then in the `Startup.ConfigureServices` method, call `services.AddAuthentication(CertificateAuthenticationDefaults.AuthenticationScheme).AddCertificate(...);` with your options, providing a delegate for `OnCertificateValidated` to do any supplementary validation on the client certificate sent with requests. Turn that information into a `ClaimsPrincipal` and set it on the `context.Principal` property.

If authentication fails, this handler returns a `403 (Forbidden)` response rather a `401 (Unauthorized)`, as you might expect. The reasoning is that the authentication should happen during the initial TLS connection. By the time it reaches the handler, it's too late. There's no way to upgrade the connection from an anonymous connection to one with a certificate.

Also add `app.UseAuthentication();` in the `Startup.Configure` method. Otherwise, the `HttpContext.User` will not be set to `ClaimsPrincipal` created from the certificate. For example:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddAuthentication(
        CertificateAuthenticationDefaults.AuthenticationScheme)
        .AddCertificate()
        // Adding an ICertificateValidationCache results in certificate auth caching the results.
        // The default implementation uses a memory cache.
        .AddCertificateCache();

    // All other service configuration
}

public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    app.UseAuthentication();

    // All other app configuration
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddAuthentication(
        CertificateAuthenticationDefaults.AuthenticationScheme)
        .AddCertificate();

    // All other service configuration
}

public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    app.UseAuthentication();

    // All other app configuration
}
```

The preceding example demonstrates the default way to add certificate authentication. The handler constructs a user principal using the common certificate properties.

Configure certificate validation

The `CertificateAuthenticationOptions` handler has some built-in validations that are the minimum validations you should perform on a certificate. Each of these settings is enabled by default.

AllowedCertificateTypes = Chained, SelfSigned, or All (Chained | SelfSigned)

Default value: `CertificateTypes.Chained`

This check validates that only the appropriate certificate type is allowed. If the app is using self-signed certificates, this option needs to be set to `CertificateTypes.All` or `CertificateTypes.SelfSigned`.

ValidateCertificateUse

Default value: `true`

This check validates that the certificate presented by the client has the Client Authentication extended key use (EKU), or no EKUs at all. As the specifications say, if no EKU is specified, then all EKUs are deemed valid.

ValidateValidityPeriod

Default value: `true`

This check validates that the certificate is within its validity period. On each request, the handler ensures that a certificate that was valid when it was presented hasn't expired during its current session.

RevocationFlag

Default value: `X509RevocationFlag.ExcludeRoot`

A flag that specifies which certificates in the chain are checked for revocation.

Revocation checks are only performed when the certificate is chained to a root certificate.

RevocationMode

Default value: `X509RevocationMode.Online`

A flag that specifies how revocation checks are performed.

Specifying an online check can result in a long delay while the certificate authority is contacted.

Revocation checks are only performed when the certificate is chained to a root certificate.

Can I configure my app to require a certificate only on certain paths?

This isn't possible. Remember the certificate exchange is done that the start of the HTTPS conversation, it's done by the server before the first request is received on that connection so it's not possible to scope based on any request fields.

Handler events

The handler has two events:

- `OnAuthenticationFailed`: Called if an exception happens during authentication and allows you to react.
- `OnCertificateValidated`: Called after the certificate has been validated, passed validation and a default principal has been created. This event allows you to perform your own validation and augment or replace the principal. For examples include:
  - Determining if the certificate is known to your services.
  - Constructing your own principal. Consider the following example in `Startup.ConfigureServices`:

```
services.AddAuthentication(
    CertificateAuthenticationDefaults.AuthenticationScheme)
    .AddCertificate(options =>
    {
        options.Events = new CertificateAuthenticationEvents
        {
            OnCertificateValidated = context =>
            {
                var claims = new[]
                {
                    new Claim(
                        ClaimTypes.NameIdentifier,
                        context.ClientCertificate.Subject,
                        ClaimValueTypes.String,
                        context.Options.ClaimsIssuer),
                    new Claim(ClaimTypes.Name,
                        context.ClientCertificate.Subject,
                        ClaimValueTypes.String,
                        context.Options.ClaimsIssuer)
                };

                context.Principal = new ClaimsPrincipal(
                    new ClaimsIdentity(claims, context.Scheme.Name));
                context.Success();

                return Task.CompletedTask;
            }
        };
    });
```

If you find the inbound certificate doesn't meet your extra validation, call `context.Fail("failure reason")` with a failure reason.

For real functionality, you'll probably want to call a service registered in dependency injection that connects to a database or other type of user store. Access your service by using the context passed into your delegate. Consider the following example in `Startup.ConfigureServices`:

```
services.AddAuthentication(
    CertificateAuthenticationDefaults.AuthenticationScheme)
    .AddCertificate(options =>
    {
        options.Events = new CertificateAuthenticationEvents
        {
            OnCertificateValidated = context =>
            {
                var validationService =
                    context.HttpContext.RequestServices
                        .GetService<ICertificateValidationService>();

                if (validationService.ValidateCertificate(
                    context.ClientCertificate))
                {
                    var claims = new[]
                    {
                        new Claim(
                            ClaimTypes.NameIdentifier,
                            context.ClientCertificate.Subject,
                            ClaimValueTypes.String,
                            context.Options.ClaimsIssuer),
                        new Claim(
                            ClaimTypes.Name,
                            context.ClientCertificate.Subject,
                            ClaimValueTypes.String,
                            context.Options.ClaimsIssuer)
                    };

                    context.Principal = new ClaimsPrincipal(
                        new ClaimsIdentity(claims, context.Scheme.Name));
                    context.Success();
                }

                return Task.CompletedTask;
            }
        };
    });
```

Conceptually, the validation of the certificate is an authorization concern. Adding a check on, for example, an issuer or thumbprint in an authorization policy, rather than inside `OnCertificateValidated`, is perfectly acceptable.

Configure your server to require certificates

Kestrel

In *Program.cs*, configure Kestrel as follows:

```
public static void Main(string[] args)
{
    CreateHostBuilder(args).Build().Run();
}

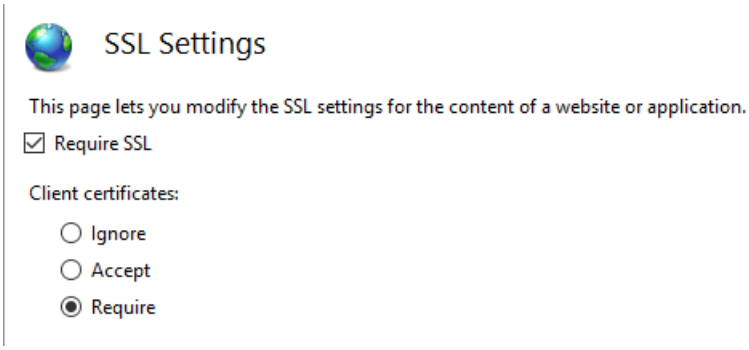
public static IHostBuilder CreateHostBuilder(string[] args)
{
    return Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
            webBuilder.ConfigureKestrel(o =>
            {
                o.ConfigureHttpsDefaults(o =>
      o.ClientCertificateMode =
          ClientCertificateMode.RequireCertificate);
            });
        });
}
```

> **NOTE**
>
> Endpoints created by calling Listen **before** calling ConfigureHttpsDefaults won't have the defaults applied.

IIS

Complete the following steps in IIS Manager:

1. Select your site from the **Connections** tab.
2. Double-click the **SSL Settings** option in the **Features View** window.
3. Check the **Require SSL** checkbox, and select the **Require** radio button in the **Client certificates** section.



Azure and custom web proxies

See the host and deploy documentation for how to configure the certificate forwarding middleware.

Use certificate authentication in Azure Web Apps

No forwarding configuration is required for Azure. This is already setup in the certificate forwarding middleware.

> **NOTE**
>
> This requires that the CertificateForwardingMiddleware is present.

Use certificate authentication in custom web proxies

The `AddCertificateForwarding` method is used to specify:

- The client header name.
- How the certificate is to be loaded (using the `HeaderConverter` property).

In custom web proxies, the certificate is passed as a custom request header, for example `X-SSL-CERT`. To use it, configure certificate forwarding in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddCertificateForwarding(options =>
    {
        options.CertificateHeader = "X-SSL-CERT";
        options.HeaderConverter = (headerValue) =>
        {
            X509Certificate2 clientCertificate = null;

            if(!string.IsNullOrWhiteSpace(headerValue))
            {
                byte[] bytes = StringToByteArray(headerValue);
                clientCertificate = new X509Certificate2(bytes);
            }

            return clientCertificate;
        };
    });
}

private static byte[] StringToByteArray(string hex)
{
    int NumberChars = hex.Length;
    byte[] bytes = new byte[NumberChars / 2];

    for (int i = 0; i < NumberChars; i += 2)
    {
        bytes[i / 2] = Convert.ToByte(hex.Substring(i, 2), 16);
    }

    return bytes;
}
```

The `Startup.Configure` method then adds the middleware. `UseCertificateForwarding` is called before the calls to `UseAuthentication` and `UseAuthorization`:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    ...

    app.UseRouting();

    app.UseCertificateForwarding();
    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
    });
}
```

A separate class can be used to implement validation logic. Because the same self-signed certificate is used in this example, ensure that only your certificate can be used. Validate that the thumbprints of both the client certificate and the server certificate match, otherwise any certificate can be used and will be enough to authenticate. This would be used inside the `AddCertificate` method. You could also validate the subject or the issuer here if you're using intermediate or child certificates.

```
using System.IO;
using System.Security.Cryptography.X509Certificates;

namespace AspNetCoreCertificateAuthApi
{
    public class MyCertificateValidationService
    {
        public bool ValidateCertificate(X509Certificate2 clientCertificate)
        {
            // Do not hardcode passwords in production code
            // Use thumbprint or key vault
            var cert = new X509Certificate2(
                Path.Combine("sts_dev_cert.pfx"), "1234");

            if (clientCertificate.Thumbprint == cert.Thumbprint)
            {
                return true;
            }

            return false;
        }
    }
}
```

Implement an HttpClient using a certificate and the HttpClientHandler

The `HttpClientHandler` could be added directly in the constructor of the `HttpClient` class. Care should be taken when creating instances of the `HttpClient`. The `HttpClient` will then send the certificate with each request.

```
private async Task<JsonDocument> GetApiDataUsingHttpClientHandler()
{
    var cert = new X509Certificate2(Path.Combine(_environment.ContentRootPath, "sts_dev_cert.pfx"), "1234");
    var handler = new HttpClientHandler();
    handler.ClientCertificates.Add(cert);
    var client = new HttpClient(handler);

    var request = new HttpRequestMessage()
    {
        RequestUri = new Uri("https://localhost:44379/api/values"),
        Method = HttpMethod.Get,
    };
    var response = await client.SendAsync(request);
    if (response.IsSuccessStatusCode)
    {
        var responseContent = await response.Content.ReadAsStringAsync();
        var data = JsonDocument.Parse(responseContent);
        return data;
    }

    throw new ApplicationException($"Status code: {response.StatusCode}, Error: {response.ReasonPhrase}");
}
```

Implement an HttpClient using a certificate and a named HttpClient from IHttpClientFactory

In the following example, a client certificate is added to a `HttpClientHandler` using the `ClientCertificates` property from the handler. This handler can then be used in a named instance of an `HttpClient` using the `ConfigurePrimaryHttpMessageHandler` method. This is setup in `Startup.ConfigureServices`:

```
var clientCertificate =
    new X509Certificate2(
      Path.Combine(_environment.ContentRootPath, "sts_dev_cert.pfx"), "1234");

var handler = new HttpClientHandler();
handler.ClientCertificates.Add(clientCertificate);

services.AddHttpClient("namedClient", c =>
{
}).ConfigurePrimaryHttpMessageHandler(() => handler);
```

The `IHttpClientFactory` can then be used to get the named instance with the handler and the certificate. The `CreateClient` method with the name of the client defined in the `Startup` class is used to get the instance. The HTTP request can be sent using the client as required.

```
private readonly IHttpClientFactory _clientFactory;

public ApiService(IHttpClientFactory clientFactory)
{
    _clientFactory = clientFactory;
}

private async Task<JsonDocument> GetApiDataWithNamedClient()
{
    var client = _clientFactory.CreateClient("namedClient");

    var request = new HttpRequestMessage()
    {
        RequestUri = new Uri("https://localhost:44379/api/values"),
        Method = HttpMethod.Get,
    };
    var response = await client.SendAsync(request);
    if (response.IsSuccessStatusCode)
    {
        var responseContent = await response.Content.ReadAsStringAsync();
        var data = JsonDocument.Parse(responseContent);
        return data;
    }

    throw new ApplicationException($"Status code: {response.StatusCode}, Error: {response.ReasonPhrase}");
}
```

If the correct certificate is sent to the server, the data is returned. If no certificate or the wrong certificate is sent, an HTTP 403 status code is returned.

Create certificates in PowerShell

Creating the certificates is the hardest part in setting up this flow. A root certificate can be created using the `New-SelfSignedCertificate` PowerShell cmdlet. When creating the certificate, use a strong password. It's important to add the `KeyUsageProperty` parameter and the `KeyUsage` parameter as shown.

Create root CA

```
New-SelfSignedCertificate -DnsName "root_ca_dev_damienbod.com", "root_ca_dev_damienbod.com" -CertStoreLocation
"cert:\LocalMachine\My" -NotAfter (Get-Date).AddYears(20) -FriendlyName "root_ca_dev_damienbod.com" -
KeyUsageProperty All -KeyUsage CertSign, CRLSign, DigitalSignature

$mypwd = ConvertTo-SecureString -String "1234" -Force -AsPlainText

Get-ChildItem -Path cert:\localMachine\my\"The thumbprint..." | Export-PfxCertificate -FilePath
C:\git\root_ca_dev_damienbod.pfx -Password $mypwd

Export-Certificate -Cert cert:\localMachine\my\"The thumbprint..." -FilePath root_ca_dev_damienbod.crt
```

NOTE

The `-DnsName` parameter value must match the deployment target of the app. For example, "localhost" for development.

Install in the trusted root

The root certificate needs to be trusted on your host system. A root certificate which was not created by a certificate authority won't be trusted by default. The following link explains how this can be accomplished on Windows:

https://social.msdn.microsoft.com/Forums/SqlServer/5ed119ef-1704-4be4-8a4f-ef11de7c8f34/a-certificate-chain-processed-but-terminated-in-a-root-certificate-which-is-not-trusted-by-the

Intermediate certificate

An intermediate certificate can now be created from the root certificate. This isn't required for all use cases, but you might need to create many certificates or need to activate or disable groups of certificates. The `TextExtension` parameter is required to set the path length in the basic constraints of the certificate.

The intermediate certificate can then be added to the trusted intermediate certificate in the Windows host system.

```
$mypwd = ConvertTo-SecureString -String "1234" -Force -AsPlainText

$parentcert = ( Get-ChildItem -Path cert:\LocalMachine\My\"The thumbprint of the root..." )

New-SelfSignedCertificate -certstorelocation cert:\localmachine\my -dnsname "intermediate_dev_damienbod.com" -
Signer $parentcert -NotAfter (Get-Date).AddYears(20) -FriendlyName "intermediate_dev_damienbod.com" -
KeyUsageProperty All -KeyUsage CertSign, CRLSign, DigitalSignature -TextExtension @("2.5.29.19=
{text}CA=1&pathlength=1")

Get-ChildItem -Path cert:\localMachine\my\"The thumbprint..." | Export-PfxCertificate -FilePath
C:\git\AspNetCoreCertificateAuth\Certs\intermediate_dev_damienbod.pfx -Password $mypwd

Export-Certificate -Cert cert:\localMachine\my\"The thumbprint..." -FilePath intermediate_dev_damienbod.crt
```

Create child certificate from intermediate certificate

A child certificate can be created from the intermediate certificate. This is the end entity and doesn't need to create more child certificates.

```
$parentcert = ( Get-ChildItem -Path cert:\LocalMachine\My\"The thumbprint from the Intermediate
certificate..." )

New-SelfSignedCertificate -certstorelocation cert:\localmachine\my -dnsname "child_a_dev_damienbod.com" -
Signer $parentcert -NotAfter (Get-Date).AddYears(20) -FriendlyName "child_a_dev_damienbod.com"

$mypwd = ConvertTo-SecureString -String "1234" -Force -AsPlainText

Get-ChildItem -Path cert:\localMachine\my\"The thumbprint..." | Export-PfxCertificate -FilePath
C:\git\AspNetCoreCertificateAuth\Certs\child_a_dev_damienbod.pfx -Password $mypwd

Export-Certificate -Cert cert:\localMachine\my\"The thumbprint..." -FilePath child_a_dev_damienbod.crt
```

Create child certificate from root certificate

A child certificate can also be created from the root certificate directly.

```
$rootcert = ( Get-ChildItem -Path cert:\LocalMachine\My\"The thumbprint from the root cert..." )

New-SelfSignedCertificate -certstorelocation cert:\localmachine\my -dnsname "child_a_dev_damienbod.com" -
Signer $rootcert -NotAfter (Get-Date).AddYears(20) -FriendlyName "child_a_dev_damienbod.com"

$mypwd = ConvertTo-SecureString -String "1234" -Force -AsPlainText

Get-ChildItem -Path cert:\localMachine\my\"The thumbprint..." | Export-PfxCertificate -FilePath
C:\git\AspNetCoreCertificateAuth\Certs\child_a_dev_damienbod.pfx -Password $mypwd

Export-Certificate -Cert cert:\localMachine\my\"The thumbprint..." -FilePath child_a_dev_damienbod.crt
```

Example root - intermediate certificate - certificate

```
$mypwdroot = ConvertTo-SecureString -String "1234" -Force -AsPlainText
$mypwd = ConvertTo-SecureString -String "1234" -Force -AsPlainText

New-SelfSignedCertificate -DnsName "root_ca_dev_damienbod.com", "root_ca_dev_damienbod.com" -CertStoreLocation
"cert:\LocalMachine\My" -NotAfter (Get-Date).AddYears(20) -FriendlyName "root_ca_dev_damienbod.com" -
KeyUsageProperty All -KeyUsage CertSign, CRLSign, DigitalSignature

Get-ChildItem -Path cert:\localMachine\my\0C89639E4E2998A93E423F919B36D4009A0F9991 | Export-PfxCertificate -
FilePath C:\git\root_ca_dev_damienbod.pfx -Password $mypwdroot

Export-Certificate -Cert cert:\localMachine\my\0C89639E4E2998A93E423F919B36D4009A0F9991 -FilePath
root_ca_dev_damienbod.crt

$rootcert = ( Get-ChildItem -Path cert:\LocalMachine\My\0C89639E4E2998A93E423F919B36D4009A0F9991 )

New-SelfSignedCertificate -certstorelocation cert:\localmachine\my -dnsname "child_a_dev_damienbod.com" -
Signer $rootcert -NotAfter (Get-Date).AddYears(20) -FriendlyName "child_a_dev_damienbod.com" -KeyUsageProperty
All -KeyUsage CertSign, CRLSign, DigitalSignature -TextExtension @("2.5.29.19={text}CA=1&pathlength=1")

Get-ChildItem -Path cert:\localMachine\my\BA9BF91ED35538A01375EFC212A2F46104B33A44 | Export-PfxCertificate -
FilePath C:\git\AspNetCoreCertificateAuth\Certs\child_a_dev_damienbod.pfx -Password $mypwd

Export-Certificate -Cert cert:\localMachine\my\BA9BF91ED35538A01375EFC212A2F46104B33A44 -FilePath
child_a_dev_damienbod.crt

$parentcert = ( Get-ChildItem -Path cert:\LocalMachine\My\BA9BF91ED35538A01375EFC212A2F46104B33A44 )

New-SelfSignedCertificate -certstorelocation cert:\localmachine\my -dnsname "child_b_from_a_dev_damienbod.com"
-Signer $parentcert -NotAfter (Get-Date).AddYears(20) -FriendlyName "child_b_from_a_dev_damienbod.com"

Get-ChildItem -Path cert:\localMachine\my\141594A0AE38CBBECED7AF680F7945CD51D8F28A | Export-PfxCertificate -
FilePath C:\git\AspNetCoreCertificateAuth\Certs\child_b_from_a_dev_damienbod.pfx -Password $mypwd

Export-Certificate -Cert cert:\localMachine\my\141594A0AE38CBBECED7AF680F7945CD51D8F28A -FilePath
child_b_from_a_dev_damienbod.crt
```

When using the root, intermediate, or child certificates, the certificates can be validated using the Thumbprint or PublicKey as required.

```
using System.Collections.Generic;
using System.IO;
using System.Security.Cryptography.X509Certificates;

namespace AspNetCoreCertificateAuthApi
{
    public class MyCertificateValidationService
    {
        public bool ValidateCertificate(X509Certificate2 clientCertificate)
        {
            return CheckIfThumbprintIsValid(clientCertificate);
        }

        private bool CheckIfThumbprintIsValid(X509Certificate2 clientCertificate)
        {
            var listOfValidThumbprints = new List<string>
            {
                "141594A0AE38CBBECED7AF680F7945CD51D8F28A",
                "0C89639E4E2998A93E423F919B36D4009A0F9991",
                "BA9BF91ED35538A01375EFC212A2F46104B33A44"
            };

            if (listOfValidThumbprints.Contains(clientCertificate.Thumbprint))
            {
                return true;
            }

            return false;
        }
    }
}
```

Certificate validation caching

ASP.NET Core 5.0 and later versions support the ability to enable caching of validation results. The caching dramatically improves performance of certificate authentication, as validation is an expensive operation.

By default, certificate authentication disables caching. To enable caching, call `AddCertificateCache` in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddAuthentication(
        CertificateAuthenticationDefaults.AuthenticationScheme)
            .AddCertificate()
            .AddCertificateCache(options =>
            {
                options.CacheSize = 1024;
                options.CacheEntryExpiration = TimeSpan.FromMinutes(2);
            });
}
```

The default caching implementation stores results in memory. You can provide your own cache by implementing `ICertificateValidationCache` and registering it with dependency injection. For example, `services.AddSingleton<ICertificateValidationCache, YourCache>()`.

Optional client certificates

This section provides information for apps that must protect a subset of the app with a certificate. For example, a Razor Page or controller in the app might require client certificates. This presents challenges as client certificates:

- Are a TLS feature, not an HTTP feature.
- Are negotiated per-connection and must be be negotiated at the start of the connection before any HTTP data is available. At the start of the connection, only the Server Name Indication (SNI)† is known. The client and server certificates are negotiated prior to the first request on a connection and requests generally aren't able to renegotiate.

TLS renegotiation was an old way to implement optional client certificates. This is no longer recommended because:

- In HTTP/1.1, renegotiating during a POST request could cause a deadlock where the request body filled up the TCP window and the renegotiation packets can't be received.
- HTTP/2 explicitly prohibits renegotiation.
- TLS 1.3 has removed support for renegotiation.

ASP.NET Core 5 preview 7 and later adds more convenient support for optional client certificates. For more information, see the Optional certificates sample.

The following approach supports optional client certificates:

- Set up binding for the domain and subdomain:
  - For example, set up bindings on `contoso.com` and `myClient.contoso.com`. The `contoso.com` host doesn't require a client certificate but `myClient.contoso.com` does.
  - For more information, see:
    - Kestrel:
      - ListenOptions.UseHttps
      - ClientCertificateMode
      - Note Kestrel does not currently support multiple TLS configurations on one binding, you'll need two bindings with unique IPs or ports. See https://github.com/dotnet/runtime/issues/31097
    - IIS
      - Hosting IIS
      - Configure security on IIS
    - Http.Sys: Configure Windows Server
- For requests to the web app that require a client certificate and don't have one:
  - Redirect to the same page using the client certificate protected subdomain.
  - For example, redirect to `myClient.contoso.com/requestedPage`. Because the request to `myClient.contoso.com/requestedPage` is a different hostname than `contoso.com/requestedPage`, the client establishes a different connection and the client certificate is provided.
  - For more information, see Introduction to authorization in ASP.NET Core.

Leave questions, comments, and other feedback on optional client certificates in this GitHub discussion issue.

† Server Name Indication (SNI) is a TLS extension to include a virtual domain as a part of SSL negotiation. This effectively means the virtual domain name, or a hostname, can be used to identify the network end point.

Multi-factor authentication in ASP.NET Core

9/22/2020 • 11 minutes to read • Edit Online

By Damien Bowden

Multi-factor authentication (MFA) is a process in which a user is requested during a sign-in event for additional forms of identification. This prompt could be to enter a code from a cellphone, use a FIDO2 key, or to provide a fingerprint scan. When you require a second form of authentication, security is enhanced. The additional factor isn't easily obtained or duplicated by an attacker.

This article covers the following areas:

- What is MFA and what MFA flows are recommended
- Configure MFA for administration pages using ASP.NET Core Identity
- Send MFA sign-in requirement to OpenID Connect server
- Force ASP.NET Core OpenID Connect client to require MFA

MFA, 2FA

MFA requires at least two or more types of proof for an identity like something you know, something you possess, or biometric validation for the user to authenticate.

Two-factor authentication (2FA) is like a subset of MFA, but the difference being that MFA can require two or more factors to prove the identity.

MFA TOTP (Time-based One-time Password Algorithm)

MFA using TOTP is a supported implementation using ASP.NET Core Identity. This can be used together with any compliant authenticator app, including:

- Microsoft Authenticator App
- Google Authenticator App

See the following link for implementation details:

Enable QR Code generation for TOTP authenticator apps in ASP.NET Core

MFA FIDO2 or passwordless

FIDO2 is currently:

- The most secure way of achieving MFA.
- The only MFA flow that protects against phishing attacks.

At present, ASP.NET Core doesn't support FIDO2 directly. FIDO2 can be used for MFA or passwordless flows.

Azure Active Directory provides support for FIDO2 and passwordless flows. For more information, see Passwordless authentication options for Azure Active Directory.

MFA SMS

MFA with SMS increases security massively compared with password authentication (single factor). However, using SMS as a second factor is no longer recommended. Too many known attack vectors exist for this type of implementation.

NIST guidelines

Configure MFA for administration pages using ASP.NET Core Identity

MFA could be forced on users to access sensitive pages within an ASP.NET Core Identity app. This could be useful for apps where different levels of access exist for the different identities. For example, users might be able to view the profile data using a password login, but an administrator would be required to use MFA to access the administrative pages.

Extend the login with an MFA claim

The demo code is setup using ASP.NET Core with Identity and Razor Pages. The `AddIdentity` method is used instead of `AddDefaultIdentity` one, so an `IUserClaimsPrincipalFactory` implementation can be used to add claims to the identity after a successful login.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlite(
            Configuration.GetConnectionString("DefaultConnection")));

    services.AddIdentity<IdentityUser, IdentityRole>(
            options => options.SignIn.RequireConfirmedAccount = false)
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultTokenProviders();

    services.AddSingleton<IEmailSender, EmailSender>();
    services.AddScoped<IUserClaimsPrincipalFactory<IdentityUser>,
        AdditionalUserClaimsPrincipalFactory>();

    services.AddAuthorization(options =>
        options.AddPolicy("TwoFactorEnabled",
            x => x.RequireClaim("amr", "mfa")));

    services.AddRazorPages();
}
```

The `AdditionalUserClaimsPrincipalFactory` class adds the `amr` claim to the user claims only after a successful login. The claim's value is read from the database. The claim is added here because the user should only access the higher protected view if the identity has logged in with MFA. If the database view is read from the database directly instead of using the claim, it's possible to access the view without MFA directly after activating the MFA.

```
using Microsoft.AspNetCore.Identity;
using Microsoft.Extensions.Options;
using System.Collections.Generic;
using System.Security.Claims;
using System.Threading.Tasks;

namespace IdentityStandaloneMfa
{
    public class AdditionalUserClaimsPrincipalFactory :
        UserClaimsPrincipalFactory<IdentityUser, IdentityRole>
    {
        public AdditionalUserClaimsPrincipalFactory(
            UserManager<IdentityUser> userManager,
            RoleManager<IdentityRole> roleManager,
            IOptions<IdentityOptions> optionsAccessor)
            : base(userManager, roleManager, optionsAccessor)
        {
        }

        public async override Task<ClaimsPrincipal> CreateAsync(IdentityUser user)
        {
            var principal = await base.CreateAsync(user);
            var identity = (ClaimsIdentity)principal.Identity;

            var claims = new List<Claim>();

            if (user.TwoFactorEnabled)
            {
                claims.Add(new Claim("amr", "mfa"));
            }
            else
            {
                claims.Add(new Claim("amr", "pwd"));
            }

            identity.AddClaims(claims);
            return principal;
        }
    }
}
```

Because the Identity service setup changed in the `Startup` class, the layouts of the Identity need to be updated. Scaffold the Identity pages into the app. Define the layout in the *Identity/Account/Manage/_Layout.cshtml* file.

```
@{
    Layout = "/Pages/Shared/_Layout.cshtml";
}
```

Also assign the layout for all the manage pages from the Identity pages:

```
@{
    Layout = "_Layout.cshtml";
}
```

Validate the MFA requirement in the administration page

The administration Razor Page validates that the user has logged in using MFA. In the `OnGet` method, the identity is used to access the user claims. The `amr` claim is checked for the value `mfa`. If the identity is missing this claim or is `false`, the page redirects to the Enable MFA page. This is possible because the user has logged in already, but without MFA.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace IdentityStandaloneMfa
{
    public class AdminModel : PageModel
    {
        public IActionResult OnGet()
        {
            var claimTwoFactorEnabled =
                User.Claims.FirstOrDefault(t => t.Type == "amr");

            if (claimTwoFactorEnabled != null &&
                "mfa".Equals(claimTwoFactorEnabled.Value))
            {
                // You logged in with MFA, do the administrative stuff
            }
            else
            {
                return Redirect(
                    "/Identity/Account/Manage/TwoFactorAuthentication");
            }

            return Page();
        }
    }
}
```

UI logic to toggle user login information

An authorization policy was added at startup. The policy requires the `amr` claim with the value `mfa`.

```
services.AddAuthorization(options =>
    options.AddPolicy("TwoFactorEnabled",
        x => x.RequireClaim("amr", "mfa")));
```

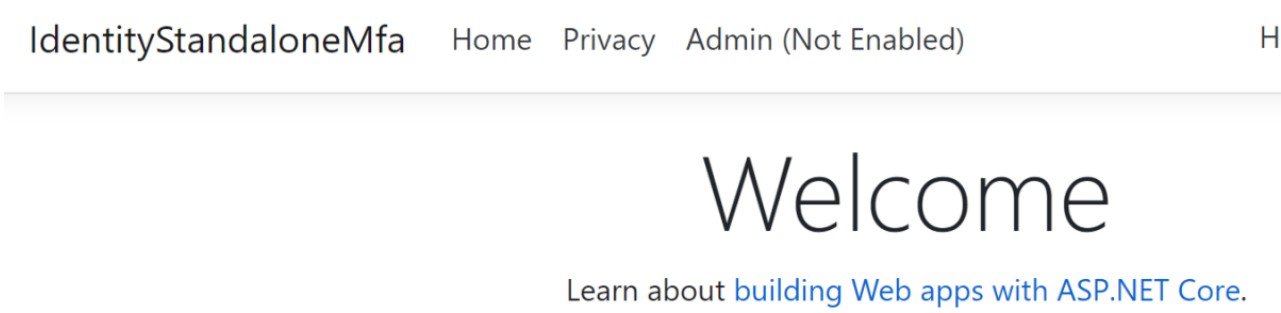
This policy can then be used in the `_Layout` view to show or hide the **Admin** menu with the warning:

```
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Identity
@inject SignInManager<IdentityUser> SignInManager
@inject UserManager<IdentityUser> UserManager
@inject IAuthorizationService AuthorizationService
```

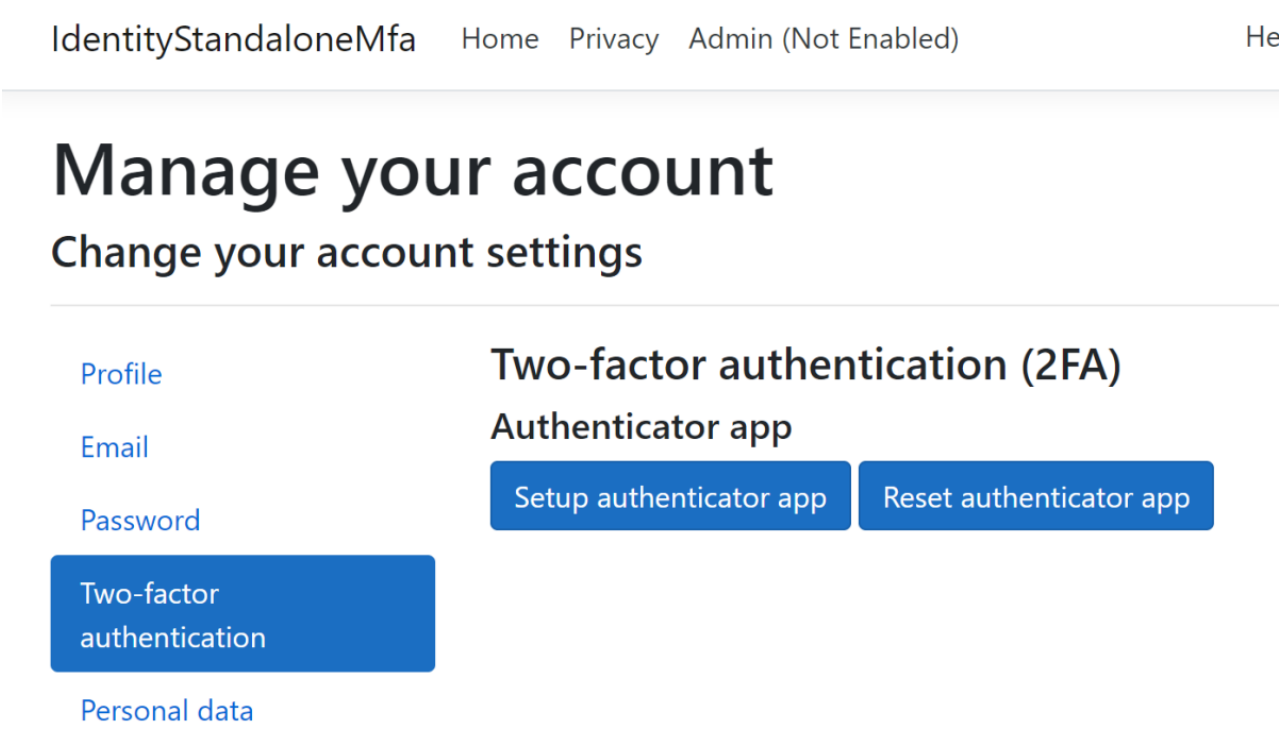
If the identity has logged in using MFA, the **Admin** menu is displayed without the tooltip warning. When the user has logged in without MFA, the **Admin (Not Enabled)** menu is displayed along with the tooltip that informs the user (explaining the warning).

```
@if (SignInManager.IsSignedIn(User))
{
    @if ((AuthorizationService.AuthorizeAsync(User, "TwoFactorEnabled")).Result.Succeeded)
    {
        <li class="nav-item">
            <a class="nav-link text-dark" asp-area="" asp-page="/Admin">Admin</a>
        </li>
    }
    else
    {
        <li class="nav-item">
            <a class="nav-link text-dark" asp-area="" asp-page="/Admin"
               id="tooltip-demo"
               data-toggle="tooltip"
               data-placement="bottom"
               title="MFA is NOT enabled. This is required for the Admin Page. If you have activated MFA, then
logout, login again.">
                Admin (Not Enabled)
            </a>
        </li>
    }
}
```

If the user logs in without MFA, the warning is displayed:



The user is redirected to the MFA enable view when clicking the **Admin** link:



Send MFA sign-in requirement to OpenID Connect server

The `acr_values` parameter can be used to pass the `mfa` required value from the client to the server in an authentication request.

> **NOTE**
> The `acr_values` parameter needs to be handled on the OpenID Connect server for this to work.

OpenID Connect ASP.NET Core client

The ASP.NET Core Razor Pages OpenID Connect client app uses the `AddOpenIdConnect` method to login to the OpenID Connect server. The `acr_values` parameter is set with the `mfa` value and sent with the authentication request. The `OpenIdConnectEvents` is used to add this.

For recommended `acr_values` parameter values, see Authentication Method Reference Values.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddAuthentication(options =>
    {
        options.DefaultScheme =
            CookieAuthenticationDefaults.AuthenticationScheme;
        options.DefaultChallengeScheme =
            OpenIdConnectDefaults.AuthenticationScheme;
    })
    .AddCookie()
    .AddOpenIdConnect(options =>
    {
        options.SignInScheme =
            CookieAuthenticationDefaults.AuthenticationScheme;
        options.Authority = "<OpenID Connect server URL>";
        options.RequireHttpsMetadata = true;
        options.ClientId = "<OpenID Connect client ID>";
        options.ClientSecret = "<>";
        // Code with PKCE can also be used here
        options.ResponseType = "code id_token";
        options.Scope.Add("profile");
        options.Scope.Add("offline_access");
        options.SaveTokens = true;
        options.Events = new OpenIdConnectEvents
        {
            OnRedirectToIdentityProvider = context =>
            {
                context.ProtocolMessage.SetParameter("acr_values", "mfa");
                return Task.FromResult(0);
            }
        };
    });
```

Example OpenID Connect IdentityServer 4 server with ASP.NET Core Identity

On the OpenID Connect server, which is implemented using ASP.NET Core Identity with MVC views, a new view named *ErrorEnable2FA.cshtml* is created. The view:

- Displays if the Identity comes from an app that requires MFA but the user hasn't activated this in Identity.
- Informs the user and adds a link to activate this.

```
@{
    ViewData["Title"] = "ErrorEnable2FA";
}

<h1>The client application requires you to have MFA enabled. Enable this, try login again.</h1>

<br />

You can enable MFA to login here:

<br />

<a asp-controller="Manage" asp-action="TwoFactorAuthentication">Enable MFA</a>
```

In the `Login` method, the `IIdentityServerInteractionService` interface implementation `_interaction` is used to access the OpenID Connect request parameters. The `acr_values` parameter is accessed using the `AcrValues` property. As the client sent this with `mfa` set, this can then be checked.

If MFA is required, and the user in ASP.NET Core Identity has MFA enabled, then the login continues. When the user has no MFA enabled, the user is redirected to the custom view *ErrorEnable2FA.cshtml*. Then ASP.NET Core Identity signs the user in.

```
//
// POST: /Account/Login
[HttpPost]
[AllowAnonymous]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Login(LoginInputModel model)
{
    var returnUrl = model.ReturnUrl;
    var context =
        await _interaction.GetAuthorizationContextAsync(returnUrl);
    var requires2Fa =
        context?.AcrValues.Count(t => t.Contains("mfa")) >= 1;

    var user = await _userManager.FindByNameAsync(model.Email);
    if (user != null && !user.TwoFactorEnabled && requires2Fa)
    {
        return RedirectToAction(nameof(ErrorEnable2FA));
    }

    // code omitted for brevity
```

The `ExternalLoginCallback` method works like the local Identity login. The `AcrValues` property is checked for the `mfa` value. If the `mfa` value is present, MFA is forced before the login completes (for example, redirected to the `ErrorEnable2FA` view).

```
//
// GET: /Account/ExternalLoginCallback
[HttpGet]
[AllowAnonymous]
public async Task<IActionResult> ExternalLoginCallback(
    string returnUrl = null,
    string remoteError = null)
{
    var context =
        await _interaction.GetAuthorizationContextAsync(returnUrl);
    var requires2Fa =
        context?.AcrValues.Count(t => t.Contains("mfa")) >= 1;

    if (remoteError != null)
    {
        ModelState.AddModelError(
            string.Empty,
            _sharedLocalizer["EXTERNAL_PROVIDER_ERROR",
            remoteError]);
        return View(nameof(Login));
    }
    var info = await _signInManager.GetExternalLoginInfoAsync();

    if (info == null)
    {
        return RedirectToAction(nameof(Login));
    }

    var email = info.Principal.FindFirstValue(ClaimTypes.Email);

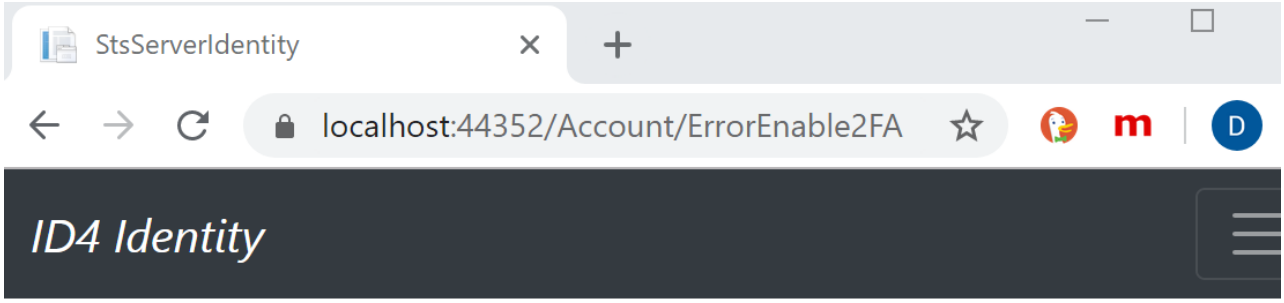
    if (!string.IsNullOrEmpty(email))
    {
        var user = await _userManager.FindByNameAsync(email);
        if (user != null && !user.TwoFactorEnabled && requires2Fa)
        {
            return RedirectToAction(nameof(ErrorEnable2FA));
        }
    }

    // Sign in the user with this external login provider if the user already has a login.
    var result = await _signInManager
        .ExternalLoginSignInAsync(
            info.LoginProvider,
            info.ProviderKey,
            isPersistent:
            false);

    // code omitted for brevity
```

If the user is already logged in, the client app:

- Still validates the `amr` claim.
- Can set up the MFA with a link to the ASP.NET Core Identity view.



Force ASP.NET Core OpenID Connect client to require MFA

This example shows how an ASP.NET Core Razor Page app, which uses OpenID Connect to sign in, can require that users have authenticated using MFA.

To validate the MFA requirement, an `IAuthorizationRequirement` requirement is created. This will be added to the pages using a policy that requires MFA.

```
using Microsoft.AspNetCore.Authorization;

namespace AspNetCoreRequireMfaOidc
{
    public class RequireMfa : IAuthorizationRequirement{}
}
```

An `AuthorizationHandler` is implemented that will use the `amr` claim and check for the value `mfa`. The `amr` is returned in the `id_token` of a successful authentication and can have many different values as defined in the Authentication Method Reference Values specification.

The returned value depends on how the identity authenticated and on the OpenID Connect server implementation.

The `AuthorizationHandler` uses the `RequireMfa` requirement and validates the `amr` claim. The OpenID Connect server can be implemented using IdentityServer4 with ASP.NET Core Identity. When a user logs in using TOTP, the `amr` claim is returned with an MFA value. If using a different OpenID Connect server implementation or a different MFA type, the `amr` claim will, or can, have a different value. The code must be extended to accept this as well.

```
using Microsoft.AspNetCore.Authorization;
using System;
using System.Linq;
using System.Threading.Tasks;

namespace AspNetCoreRequireMfaOidc
{
    public class RequireMfaHandler : AuthorizationHandler<RequireMfa>
    {
        protected override Task HandleRequirementAsync(
            AuthorizationHandlerContext context,
            RequireMfa requirement)
        {
            if (context == null)
                throw new ArgumentNullException(nameof(context));
            if (requirement == null)
                throw new ArgumentNullException(nameof(requirement));

            var amrClaim =
                context.User.Claims.FirstOrDefault(t => t.Type == "amr");

            if (amrClaim != null && amrClaim.Value == Amr.Mfa)
            {
                context.Succeed(requirement);
            }

            return Task.CompletedTask;
        }
    }
}
```

In the `Startup.ConfigureServices` method, the `AddOpenIdConnect` method is used as the default challenge scheme. The authorization handler, which is used to check the `amr` claim, is added to the Inversion of Control container. A policy is then created which adds the `RequireMfa` requirement.

```
public void ConfigureServices(IServiceCollection services)
{
    services.ConfigureApplicationCookie(options =>
        options.Cookie.SecurePolicy =
            CookieSecurePolicy.Always);

    services.AddSingleton<IAuthorizationHandler, RequireMfaHandler>();

    services.AddAuthentication(options =>
    {
        options.DefaultScheme =
            CookieAuthenticationDefaults.AuthenticationScheme;
        options.DefaultChallengeScheme =
            OpenIdConnectDefaults.AuthenticationScheme;
    })
    .AddCookie()
    .AddOpenIdConnect(options =>
    {
        options.SignInScheme =
            CookieAuthenticationDefaults.AuthenticationScheme;
        options.Authority = "https://localhost:44352";
        options.RequireHttpsMetadata = true;
        options.ClientId = "AspNetCoreRequireMfaOidc";
        options.ClientSecret = "AspNetCoreRequireMfaOidcSecret";
        options.ResponseType = "code id_token";
        options.Scope.Add("profile");
        options.Scope.Add("offline_access");
        options.SaveTokens = true;
    });

    services.AddAuthorization(options =>
    {
        options.AddPolicy("RequireMfa", policyIsAdminRequirement =>
        {
            policyIsAdminRequirement.Requirements.Add(new RequireMfa());
        });
    });

    services.AddRazorPages();
}
```

This policy is then used in the Razor page as required. The policy could be added globally for the entire app as well.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.Extensions.Logging;

namespace AspNetCoreRequireMfaOidc.Pages
{
    [Authorize(Policy= "RequireMfa")]
    public class IndexModel : PageModel
    {
        private readonly ILogger<IndexModel> _logger;

        public IndexModel(ILogger<IndexModel> logger)
        {
            _logger = logger;
        }

        public void OnGet()
        {
        }
    }
}
```

If the user authenticates without MFA, the `amr` claim will probably have a `pwd` value. The request won't be authorized to access the page. Using the default values, the user will be redirected to the *Account/AccessDenied* page. This behavior can be changed or you can implement your own custom logic here. In this example, a link is added so that the valid user can set up MFA for their account.

```
@page
@model AspNetCoreRequireMfaOidc.AccessDeniedModel
@{
    ViewData["Title"] = "AccessDenied";
    Layout = "~/Pages/Shared/_Layout.cshtml";
}

<h1>AccessDenied</h1>

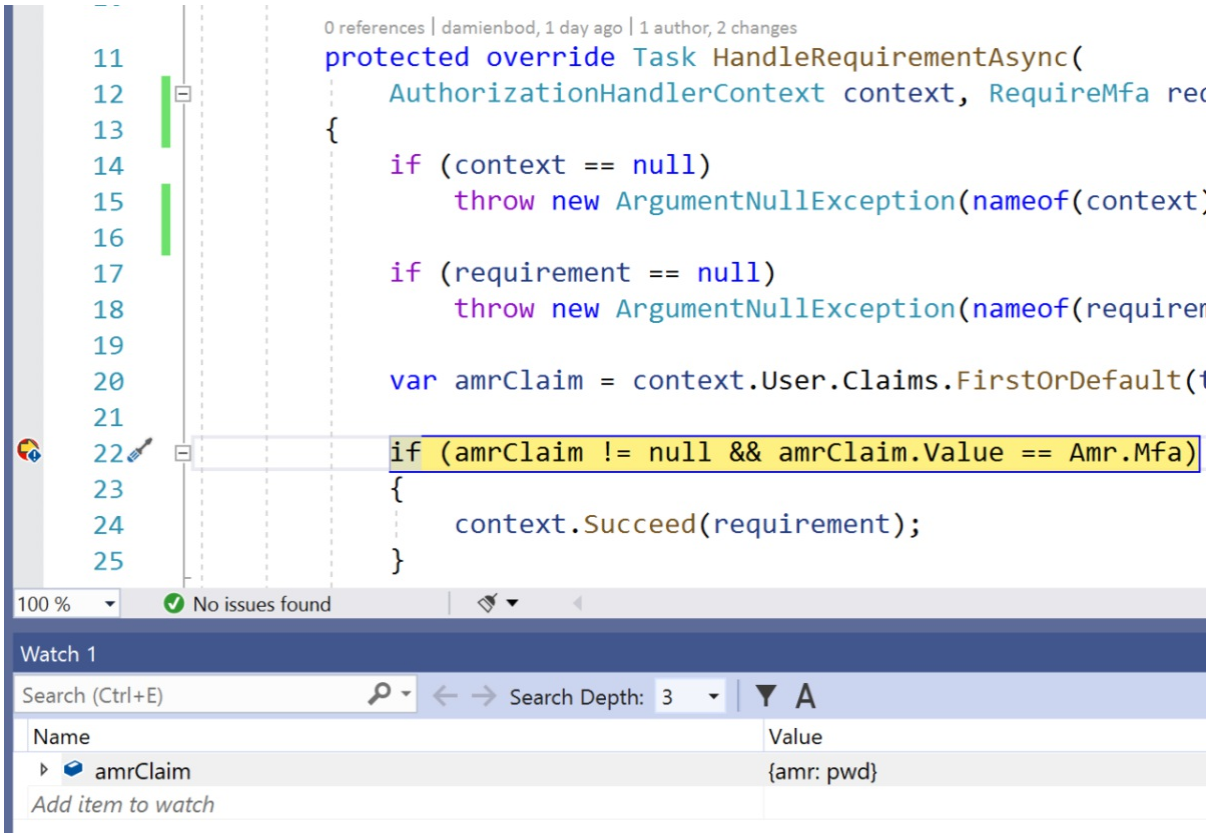
You require MFA to login here

<a href="https://localhost:44352/Manage/TwoFactorAuthentication">Enable MFA</a>
```

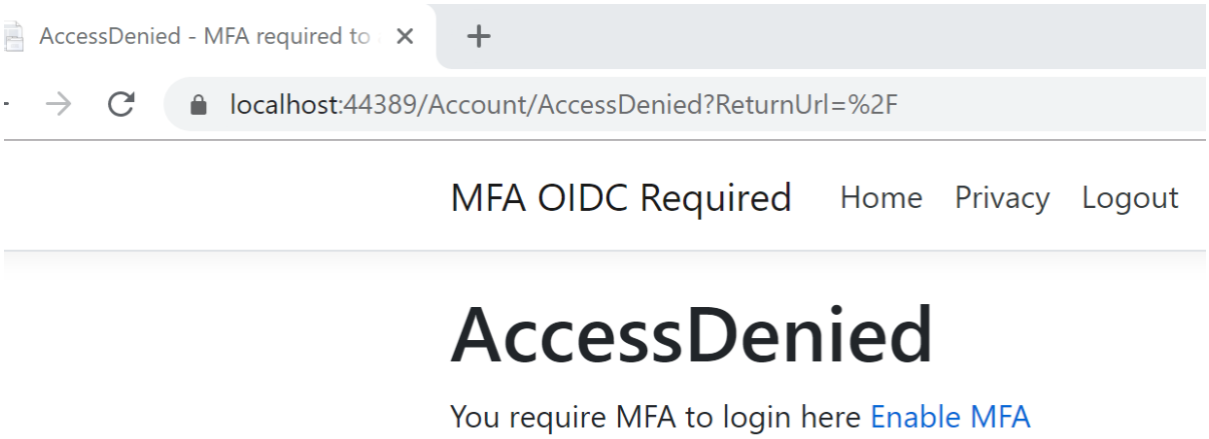
Now only users that authenticate with MFA can access the page or website. If different MFA types are used or if 2FA is okay, the `amr` claim will have different values and needs to be processed correctly. Different OpenID Connect servers also return different values for this claim and might not follow the Authentication Method Reference Values specification.

When logging in without MFA (for example, using just a password):

- The `amr` has the `pwd` value:



- Access is denied:



Alternatively, logging in using OTP with Identity:

Introduction to authorization in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

Authorization refers to the process that determines what a user is able to do. For example, an administrative user is allowed to create a document library, add documents, edit documents, and delete them. A non-administrative user working with the library is only authorized to read the documents.

Authorization is orthogonal and independent from authentication. However, authorization requires an authentication mechanism. Authentication is the process of ascertaining who a user is. Authentication may create one or more identities for the current user.

For more information about authentication in ASP.NET Core, see Overview of ASP.NET Core Authentication.

Authorization types

ASP.NET Core authorization provides a simple, declarative role and a rich policy-based model. Authorization is expressed in requirements, and handlers evaluate a user's claims against requirements. Imperative checks can be based on simple policies or policies which evaluate both the user identity and properties of the resource that the user is attempting to access.

Namespaces

Authorization components, including the `AuthorizeAttribute` and `AllowAnonymousAttribute` attributes, are found in the `Microsoft.AspNetCore.Authorization` namespace.

Consult the documentation on simple authorization.

Create an ASP.NET Core web app with user data protected by authorization

9/22/2020 • 39 minutes to read • Edit Online

By Rick Anderson and Joe Audette

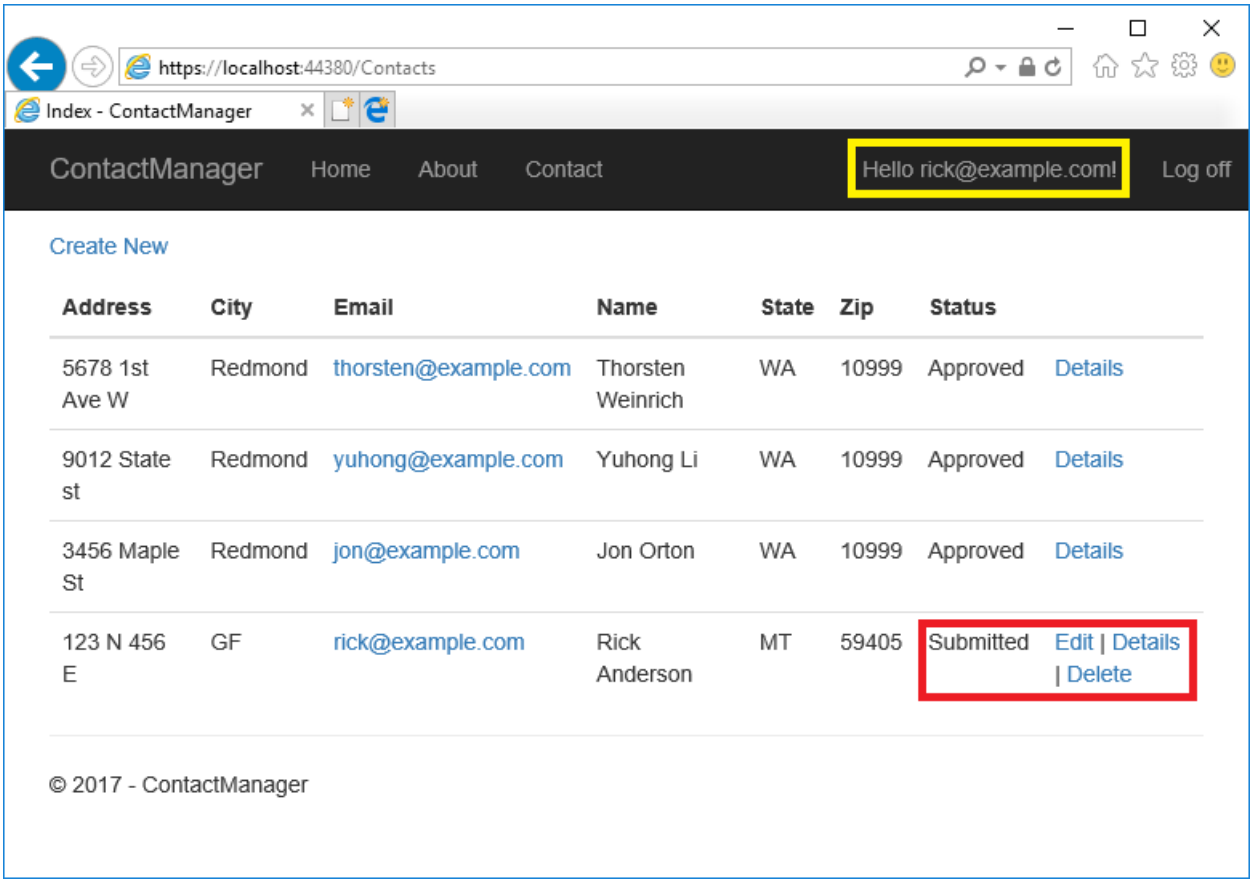
See this pdf

This tutorial shows how to create an ASP.NET Core web app with user data protected by authorization. It displays a list of contacts that authenticated (registered) users have created. There are three security groups:

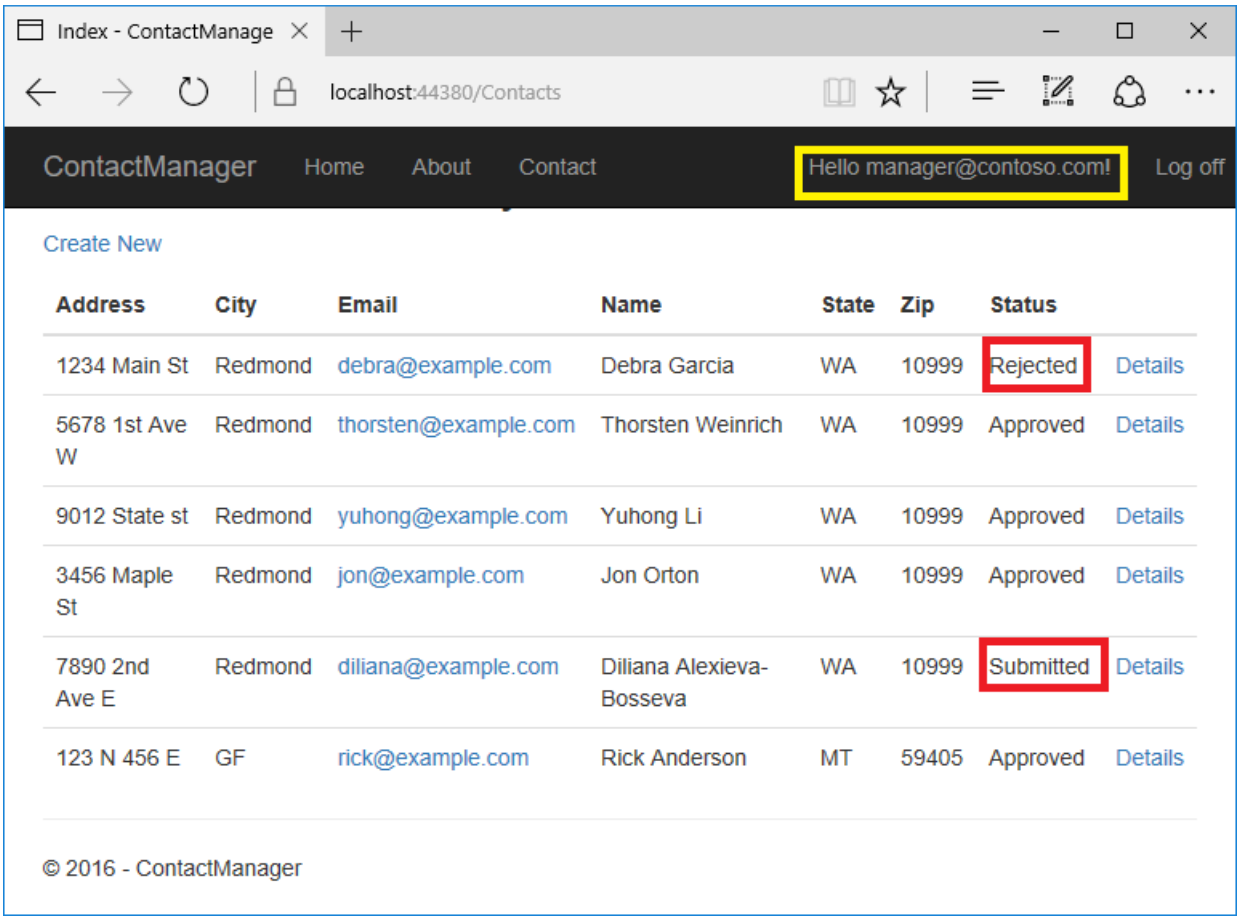
- **Registered users** can view all the approved data and can edit/delete their own data.
- **Managers** can approve or reject contact data. Only approved contacts are visible to users.
- **Administrators** can approve/reject and edit/delete any data.

The images in this document don't exactly match the latest templates.

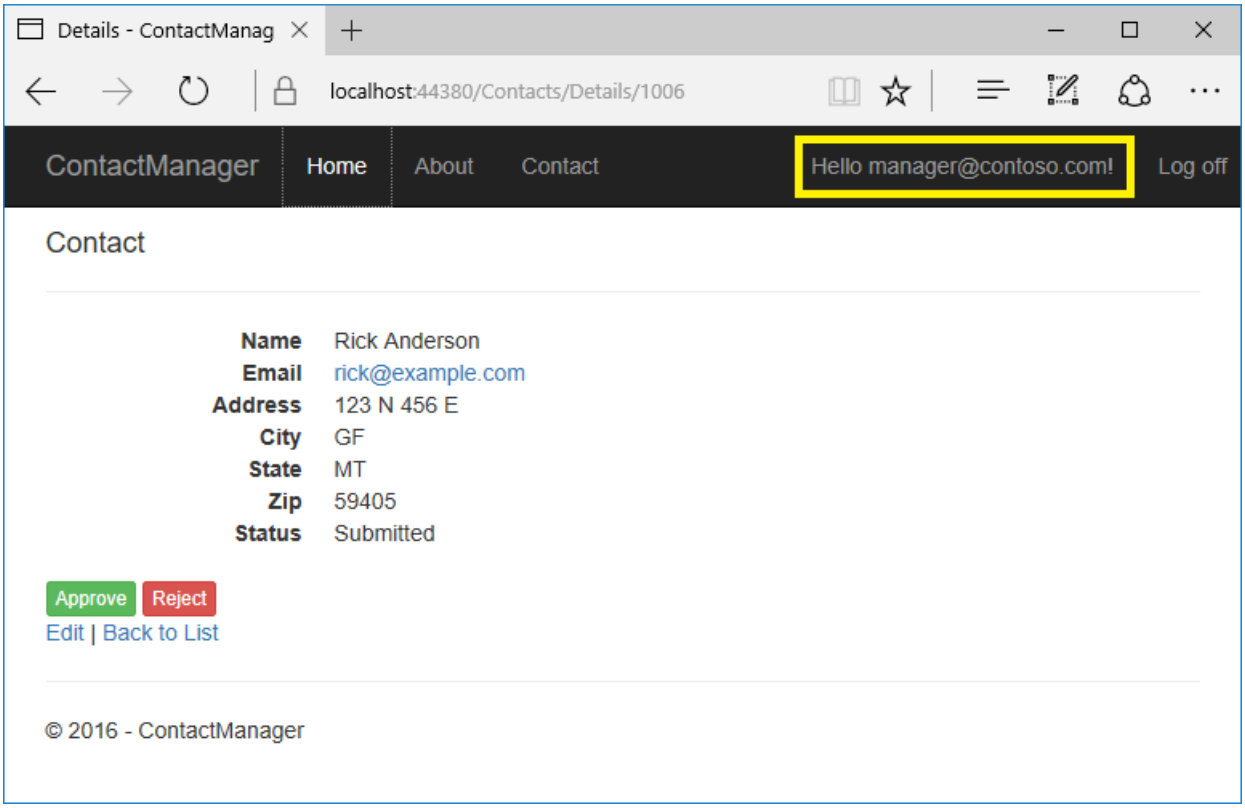
In the following image, user Rick (`rick@example.com`) is signed in. Rick can only view approved contacts and **Edit/Delete/Create New** links for his contacts. Only the last record, created by Rick, displays **Edit** and **Delete** links. Other users won't see the last record until a manager or administrator changes the status to "Approved".



In the following image, `manager@contoso.com` is signed in and in the manager's role:

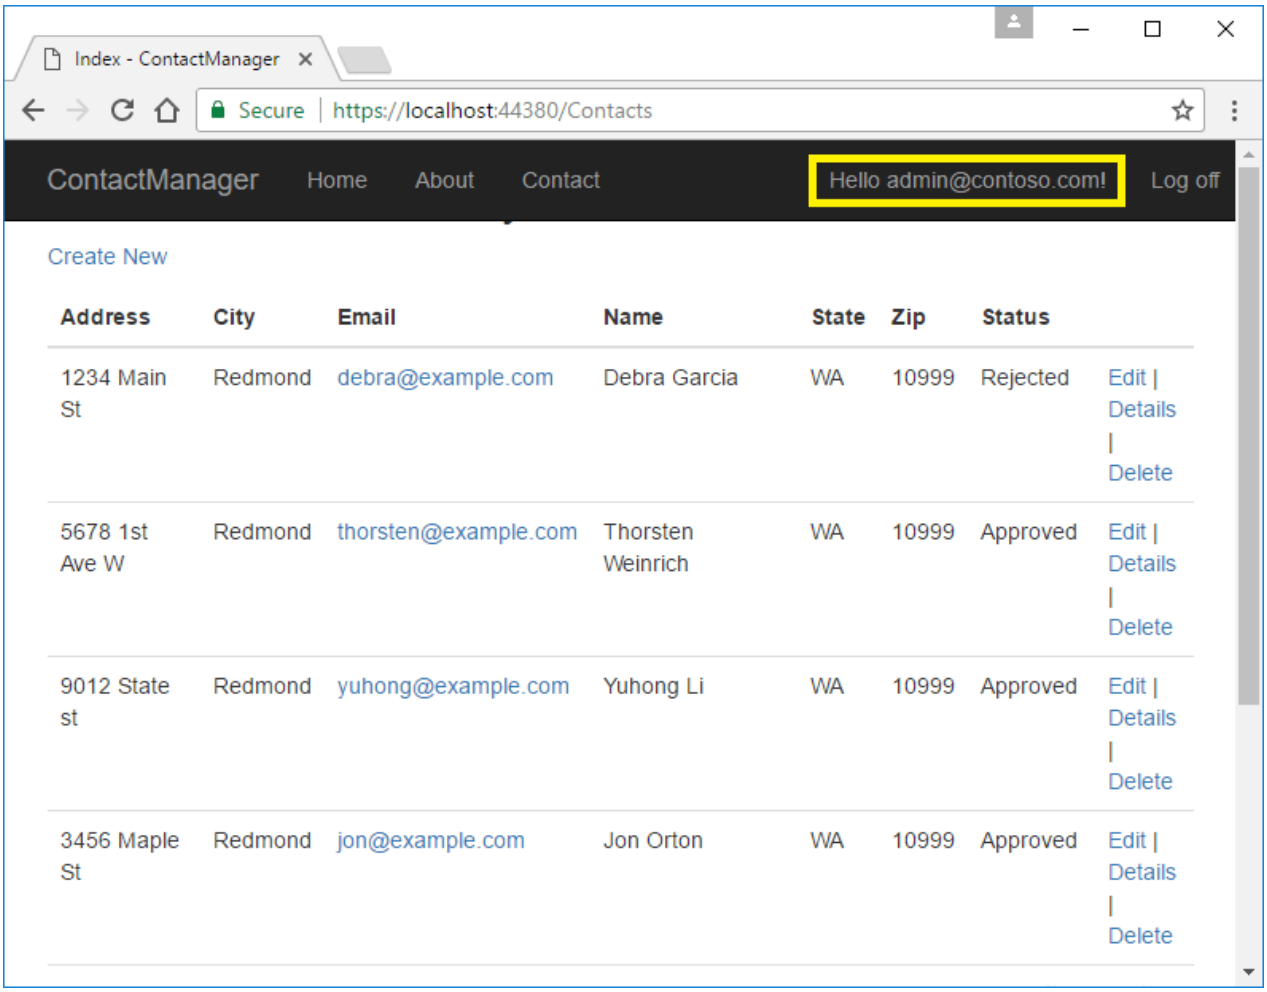


The following image shows the managers details view of a contact:



The **Approve** and **Reject** buttons are only displayed for managers and administrators.

In the following image, `admin@contoso.com` is signed in and in the administrator's role:



The administrator has all privileges. She can read/edit/delete any contact and change the status of contacts.

The app was created by scaffolding the following `Contact` model:

```
public class Contact
{
    public int ContactId { get; set; }
    public string Name { get; set; }
    public string Address { get; set; }
    public string City { get; set; }
    public string State { get; set; }
    public string Zip { get; set; }
    [DataType(DataType.EmailAddress)]
    public string Email { get; set; }
}
```

The sample contains the following authorization handlers:

- `ContactIsOwnerAuthorizationHandler`: Ensures that a user can only edit their data.
- `ContactManagerAuthorizationHandler`: Allows managers to approve or reject contacts.
- `ContactAdministratorsAuthorizationHandler`: Allows administrators to approve or reject contacts and to edit/delete contacts.

Prerequisites

This tutorial is advanced. You should be familiar with:

- ASP.NET Core
- Authentication

- Account Confirmation and Password Recovery
- Authorization
- Entity Framework Core

The starter and completed app

Download the completed app. Test the completed app so you become familiar with its security features.

The starter app

Download the starter app.

Run the app, tap the **ContactManager** link, and verify you can create, edit, and delete a contact.

Secure user data

The following sections have all the major steps to create the secure user data app. You may find it helpful to refer to the completed project.

Tie the contact data to the user

Use the ASP.NET Identity user ID to ensure users can edit their data, but not other users data. Add `OwnerID` and `ContactStatus` to the `Contact` model:

```
public class Contact
{
    public int ContactId { get; set; }

    // user ID from AspNetUser table.
    public string OwnerID { get; set; }

    public string Name { get; set; }
    public string Address { get; set; }
    public string City { get; set; }
    public string State { get; set; }
    public string Zip { get; set; }
    [DataType(DataType.EmailAddress)]
    public string Email { get; set; }

    public ContactStatus Status { get; set; }
}

public enum ContactStatus
{
    Submitted,
    Approved,
    Rejected
}
```

`OwnerID` is the user's ID from the `AspNetUser` table in the Identity database. The `Status` field determines if a contact is viewable by general users.

Create a new migration and update the database:

```
dotnet ef migrations add userID_Status
dotnet ef database update
```

Add Role services to Identity

Append AddRoles to add Role services:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>(
        options => options.SignIn.RequireConfirmedAccount = true)
        .AddRoles<IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext>();
```

Require authenticated users

Set the fallback authentication policy to require users to be authenticated:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>(
        options => options.SignIn.RequireConfirmedAccount = true)
        .AddRoles<IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext>();

    services.AddRazorPages();

    services.AddAuthorization(options =>
    {
        options.FallbackPolicy = new AuthorizationPolicyBuilder()
            .RequireAuthenticatedUser()
            .Build();
    });
```

The preceding highlighted code sets the fallback authentication policy. The fallback authentication policy requires ***all*** users to be authenticated, except for Razor Pages, controllers, or action methods with an authentication attribute. For example, Razor Pages, controllers, or action methods with `[AllowAnonymous]` or `[Authorize(PolicyName="MyPolicy")]` use the applied authentication attribute rather than the fallback authentication policy.

The fallback authentication policy:

- Is applied to all requests that do not explicitly specify an authentication policy. For requests served by endpoint routing, this would include any endpoint that does not specify an authorization attribute. For requests served by other middleware after the authorization middleware, such as static files, this would apply the policy to all requests.

Setting the fallback authentication policy to require users to be authenticated protects newly added Razor Pages and controllers. Having authentication required by default is more secure than relying on new controllers and Razor Pages to include the `[Authorize]` attribute.

The AuthorizationOptions class also contains AuthorizationOptions.DefaultPolicy. The `DefaultPolicy` is the policy used with the `[Authorize]` attribute when no policy is specified. `[Authorize]` doesn't contain a named policy, unlike `[Authorize(PolicyName="MyPolicy")]`.

For more information on policies, see Policy-based authorization in ASP.NET Core.

An alternative way for MVC controllers and Razor Pages to require all users be authenticated is adding an authorization filter:

```
public void ConfigureServices(IServiceCollection services)
{

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>(
        options => options.SignIn.RequireConfirmedAccount = true)
        .AddRoles<IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext>();

    services.AddRazorPages();

    services.AddControllers(config =>
    {
        // using Microsoft.AspNetCore.Mvc.Authorization;
        // using Microsoft.AspNetCore.Authorization;
        var policy = new AuthorizationPolicyBuilder()
                         .RequireAuthenticatedUser()
                         .Build();
        config.Filters.Add(new AuthorizeFilter(policy));
    });
```

The preceding code uses an authorization filter, setting the fallback policy uses endpoint routing. Setting the fallback policy is the preferred way to require all users be authenticated.

Add AllowAnonymous to the `Index` and `Privacy` pages so anonymous users can get information about the site before they register:

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.Extensions.Logging;

namespace ContactManager.Pages
{
    [AllowAnonymous]
    public class IndexModel : PageModel
    {
        private readonly ILogger<IndexModel> _logger;

        public IndexModel(ILogger<IndexModel> logger)
        {
            _logger = logger;
        }

        public void OnGet()
        {

        }
    }
}
```

Configure the test account

The `SeedData` class creates two accounts: administrator and manager. Use the Secret Manager tool to set a password for these accounts. Set the password from the project directory (the directory containing *Program.cs*):

```
dotnet user-secrets set SeedUserPW <PW>
```

If a strong password is not specified, an exception is thrown when `SeedData.Initialize` is called.

Update `Main` to use the test password:

```
public class Program
{
    public static void Main(string[] args)
    {
        var host = CreateHostBuilder(args).Build();

        using (var scope = host.Services.CreateScope())
        {
            var services = scope.ServiceProvider;

            try
            {
                var context = services.GetRequiredService<ApplicationDbContext>();
                context.Database.Migrate();

                // requires using Microsoft.Extensions.Configuration;
                var config = host.Services.GetRequiredService<IConfiguration>();
                // Set password with the Secret Manager tool.
                // dotnet user-secrets set SeedUserPW <pw>

                var testUserPw = config["SeedUserPW"];

                SeedData.Initialize(services, testUserPw).Wait();
            }
            catch (Exception ex)
            {
                var logger = services.GetRequiredService<ILogger<Program>>();
                logger.LogError(ex, "An error occurred seeding the DB.");
            }
        }

        host.Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

Create the test accounts and update the contacts

Update the `Initialize` method in the `SeedData` class to create the test accounts:

```
public static async Task Initialize(IServiceProvider serviceProvider, string testUserPw)
{
    using (var context = new ApplicationDbContext(
        serviceProvider.GetRequiredService<DbContextOptions<ApplicationDbContext>>()))
    {
        // For sample purposes seed both with the same password.
        // Password is set with the following:
        // dotnet user-secrets set SeedUserPW <pw>
        // The admin user can do anything

        var adminID = await EnsureUser(serviceProvider, testUserPw, "admin@contoso.com");
        await EnsureRole(serviceProvider, adminID, Constants.ContactAdministratorsRole);

        // allowed user can create and edit contacts that they create
        var managerID = await EnsureUser(serviceProvider, testUserPw, "manager@contoso.com");
        await EnsureRole(serviceProvider, managerID, Constants.ContactManagersRole);

        SeedDB(context, adminID);
    }
}
```

```
private static async Task<string> EnsureUser(IServiceProvider serviceProvider,
                                             string testUserPw, string UserName)
{
    var userManager = serviceProvider.GetService<UserManager<IdentityUser>>();

    var user = await userManager.FindByNameAsync(UserName);
    if (user == null)
    {
        user = new IdentityUser {
            UserName = UserName,
            EmailConfirmed = true
        };
        await userManager.CreateAsync(user, testUserPw);
    }

    if (user == null)
    {
        throw new Exception("The password is probably not strong enough!");
    }

    return user.Id;
}

private static async Task<IdentityResult> EnsureRole(IServiceProvider serviceProvider,
                                                     string uid, string role)
{
    IdentityResult IR = null;
    var roleManager = serviceProvider.GetService<RoleManager<IdentityRole>>();

    if (roleManager == null)
    {
        throw new Exception("roleManager null");
    }

    if (!await roleManager.RoleExistsAsync(role))
    {
        IR = await roleManager.CreateAsync(new IdentityRole(role));
    }

    var userManager = serviceProvider.GetService<UserManager<IdentityUser>>();

    var user = await userManager.FindByIdAsync(uid);

    if(user == null)
    {
        throw new Exception("The testUserPw password was probably not strong enough!");
    }

    IR = await userManager.AddToRoleAsync(user, role);

    return IR;
}
```

Add the administrator user ID and `ContactStatus` to the contacts. Make one of the contacts "Submitted" and one "Rejected". Add the user ID and status to all the contacts. Only one contact is shown:

```
public static void SeedDB(ApplicationDbContext context, string adminID)
{
    if (context.Contact.Any())
    {
        return;   // DB has been seeded
    }

    context.Contact.AddRange(
        new Contact
        {
            Name = "Debra Garcia",
            Address = "1234 Main St",
            City = "Redmond",
            State = "WA",
            Zip = "10999",
            Email = "debra@example.com",
            Status = ContactStatus.Approved,
            OwnerID = adminID
        },
```

Create owner, manager, and administrator authorization handlers

Create a `ContactIsOwnerAuthorizationHandler` class in the *Authorization* folder. The `ContactIsOwnerAuthorizationHandler` verifies that the user acting on a resource owns the resource.

```
using ContactManager.Models;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Authorization.Infrastructure;
using Microsoft.AspNetCore.Identity;
using System.Threading.Tasks;

namespace ContactManager.Authorization
{
    public class ContactIsOwnerAuthorizationHandler
                : AuthorizationHandler<OperationAuthorizationRequirement, Contact>
    {
        UserManager<IdentityUser> _userManager;

        public ContactIsOwnerAuthorizationHandler(UserManager<IdentityUser>
            userManager)
        {
            _userManager = userManager;
        }

        protected override Task
            HandleRequirementAsync(AuthorizationHandlerContext context,
                                   OperationAuthorizationRequirement requirement,
                                   Contact resource)
        {
            if (context.User == null || resource == null)
            {
                return Task.CompletedTask;
            }

            // If not asking for CRUD permission, return.

            if (requirement.Name != Constants.CreateOperationName &&
                requirement.Name != Constants.ReadOperationName   &&
                requirement.Name != Constants.UpdateOperationName &&
                requirement.Name != Constants.DeleteOperationName )
            {
                return Task.CompletedTask;
            }

            if (resource.OwnerID == _userManager.GetUserId(context.User))
            {
                context.Succeed(requirement);
            }

            return Task.CompletedTask;
        }
    }
}
```

The `ContactIsOwnerAuthorizationHandler` calls context.Succeed if the current authenticated user is the contact owner. Authorization handlers generally:

- Return `context.Succeed` when the requirements are met.
- Return `Task.CompletedTask` when requirements aren't met. `Task.CompletedTask` is not success or failure—it allows other authorization handlers to run.

If you need to explicitly fail, return context.Fail.

The app allows contact owners to edit/delete/create their own data. `ContactIsOwnerAuthorizationHandler` doesn't need to check the operation passed in the requirement parameter.

Create a manager authorization handler

Create a `ContactManagerAuthorizationHandler` class in the *Authorization* folder. The

`ContactManagerAuthorizationHandler` verifies the user acting on the resource is a manager. Only managers can approve or reject content changes (new or changed).

```
using System.Threading.Tasks;
using ContactManager.Models;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Authorization.Infrastructure;
using Microsoft.AspNetCore.Identity;

namespace ContactManager.Authorization
{
    public class ContactManagerAuthorizationHandler :
        AuthorizationHandler<OperationAuthorizationRequirement, Contact>
    {
        protected override Task
            HandleRequirementAsync(AuthorizationHandlerContext context,
                                   OperationAuthorizationRequirement requirement,
                                   Contact resource)
        {
            if (context.User == null || resource == null)
            {
                return Task.CompletedTask;
            }

            // If not asking for approval/reject, return.
            if (requirement.Name != Constants.ApproveOperationName &&
                requirement.Name != Constants.RejectOperationName)
            {
                return Task.CompletedTask;
            }

            // Managers can approve or reject.
            if (context.User.IsInRole(Constants.ContactManagersRole))
            {
                context.Succeed(requirement);
            }

            return Task.CompletedTask;
        }
    }
}
```

Create an administrator authorization handler

Create a `ContactAdministratorsAuthorizationHandler` class in the *Authorization* folder. The `ContactAdministratorsAuthorizationHandler` verifies the user acting on the resource is an administrator. Administrator can do all operations.

```
using System.Threading.Tasks;
using ContactManager.Models;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Authorization.Infrastructure;

namespace ContactManager.Authorization
{
    public class ContactAdministratorsAuthorizationHandler
                    : AuthorizationHandler<OperationAuthorizationRequirement, Contact>
    {
        protected override Task HandleRequirementAsync(
                                            AuthorizationHandlerContext context,
                                    OperationAuthorizationRequirement requirement,
                                     Contact resource)
        {
            if (context.User == null)
            {
                return Task.CompletedTask;
            }

            // Administrators can do anything.
            if (context.User.IsInRole(Constants.ContactAdministratorsRole))
            {
                context.Succeed(requirement);
            }

            return Task.CompletedTask;
        }
    }
}
```

Register the authorization handlers

Services using Entity Framework Core must be registered for dependency injection using AddScoped. The `ContactIsOwnerAuthorizationHandler` uses ASP.NET Core Identity, which is built on Entity Framework Core. Register the handlers with the service collection so they're available to the `ContactsController` through dependency injection. Add the following code to the end of `ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>(
        options => options.SignIn.RequireConfirmedAccount = true)
        .AddRoles<IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext>();

    services.AddRazorPages();

    services.AddAuthorization(options =>
    {
        options.FallbackPolicy = new AuthorizationPolicyBuilder()
            .RequireAuthenticatedUser()
            .Build();
    });

    // Authorization handlers.
    services.AddScoped<IAuthorizationHandler,
                          ContactIsOwnerAuthorizationHandler>();

    services.AddSingleton<IAuthorizationHandler,
                          ContactAdministratorsAuthorizationHandler>();

    services.AddSingleton<IAuthorizationHandler,
                          ContactManagerAuthorizationHandler>();
}
```

`ContactAdministratorsAuthorizationHandler` and `ContactManagerAuthorizationHandler` are added as singletons. They're singletons because they don't use EF and all the information needed is in the `Context` parameter of the `HandleRequirementAsync` method.

Support authorization

In this section, you update the Razor Pages and add an operations requirements class.

Review the contact operations requirements class

Review the `ContactOperations` class. This class contains the requirements the app supports:

```
using Microsoft.AspNetCore.Authorization.Infrastructure;

namespace ContactManager.Authorization
{
    public static class ContactOperations
    {
        public static OperationAuthorizationRequirement Create =
          new OperationAuthorizationRequirement {Name=Constants.CreateOperationName};
        public static OperationAuthorizationRequirement Read =
          new OperationAuthorizationRequirement {Name=Constants.ReadOperationName};
        public static OperationAuthorizationRequirement Update =
          new OperationAuthorizationRequirement {Name=Constants.UpdateOperationName};
        public static OperationAuthorizationRequirement Delete =
          new OperationAuthorizationRequirement {Name=Constants.DeleteOperationName};
        public static OperationAuthorizationRequirement Approve =
          new OperationAuthorizationRequirement {Name=Constants.ApproveOperationName};
        public static OperationAuthorizationRequirement Reject =
          new OperationAuthorizationRequirement {Name=Constants.RejectOperationName};
    }

    public class Constants
    {
        public static readonly string CreateOperationName = "Create";
        public static readonly string ReadOperationName = "Read";
        public static readonly string UpdateOperationName = "Update";
        public static readonly string DeleteOperationName = "Delete";
        public static readonly string ApproveOperationName = "Approve";
        public static readonly string RejectOperationName = "Reject";

        public static readonly string ContactAdministratorsRole =
                                                          "ContactAdministrators";
        public static readonly string ContactManagersRole = "ContactManagers";
    }
}
```

Create a base class for the Contacts Razor Pages

Create a base class that contains the services used in the contacts Razor Pages. The base class puts the initialization code in one location:

```
using ContactManager.Data;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace ContactManager.Pages.Contacts
{
    public class DI_BasePageModel : PageModel
    {
        protected ApplicationDbContext Context { get; }
        protected IAuthorizationService AuthorizationService { get; }
        protected UserManager<IdentityUser> UserManager { get; }

        public DI_BasePageModel(
            ApplicationDbContext context,
            IAuthorizationService authorizationService,
            UserManager<IdentityUser> userManager) : base()
        {
            Context = context;
            UserManager = userManager;
            AuthorizationService = authorizationService;
        }
    }
}
```

The preceding code:

- Adds the `IAuthorizationService` service to access to the authorization handlers.
- Adds the Identity `UserManager` service.
- Add the `ApplicationDbContext`.

Update the CreateModel

Update the create page model constructor to use the `DI_BasePageModel` base class:

```
public class CreateModel : DI_BasePageModel
{
    public CreateModel(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }
```

Update the `CreateModel.OnPostAsync` method to:

- Add the user ID to the `Contact` model.
- Call the authorization handler to verify the user has permission to create contacts.

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    Contact.OwnerID = UserManager.GetUserId(User);

    // requires using ContactManager.Authorization;
    var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                            User, Contact,
                                            ContactOperations.Create);
    if (!isAuthorized.Succeeded)
    {
        return Forbid();
    }

    Context.Contact.Add(Contact);
    await Context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

Update the IndexModel

Update the `OnGetAsync` method so only approved contacts are shown to general users:

```
public class IndexModel : DI_BasePageModel
{
    public IndexModel(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }

    public IList<Contact> Contact { get; set; }

    public async Task OnGetAsync()
    {
        var contacts = from c in Context.Contact
                       select c;

        var isAuthorized = User.IsInRole(Constants.ContactManagersRole) ||
                           User.IsInRole(Constants.ContactAdministratorsRole);

        var currentUserId = UserManager.GetUserId(User);

        // Only approved contacts are shown UNLESS you're authorized to see them
        // or you are the owner.
        if (!isAuthorized)
        {
            contacts = contacts.Where(c => c.Status == ContactStatus.Approved
                                      || c.OwnerID == currentUserId);
        }

        Contact = await contacts.ToListAsync();
    }
}
```

Update the EditModel

Add an authorization handler to verify the user owns the contact. Because resource authorization is being validated, the `[Authorize]` attribute is not enough. The app doesn't have access to the resource when attributes are evaluated. Resource-based authorization must be imperative. Checks must be performed once the app has access to the resource, either by loading it in the page model or by loading it within the handler itself. You frequently access the resource by passing in the resource key.

```
public class EditModel : DI_BasePageModel
{
    public EditModel(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }

    [BindProperty]
    public Contact Contact { get; set; }

    public async Task<IActionResult> OnGetAsync(int id)
    {
        Contact = await Context.Contact.FirstOrDefaultAsync(
                                            m => m.ContactId == id);

        if (Contact == null)
        {
            return NotFound();
        }
```

```
        var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                                 User, Contact,
                                                 ContactOperations.Update);
        if (!isAuthorized.Succeeded)
        {
            return Forbid();
        }

        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int id)
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        // Fetch Contact from DB to get OwnerID.
        var contact = await Context
            .Contact.AsNoTracking()
            .FirstOrDefaultAsync(m => m.ContactId == id);

        if (contact == null)
        {
            return NotFound();
        }

        var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                                User, contact,
                                                ContactOperations.Update);
        if (!isAuthorized.Succeeded)
        {
            return Forbid();
        }

        Contact.OwnerID = contact.OwnerID;

        Context.Attach(Contact).State = EntityState.Modified;

        if (Contact.Status == ContactStatus.Approved)
        {
            // If the contact is updated after approval,
            // and the user cannot approve,
            // set the status back to submitted so the update can be
            // checked and approved.
            var canApprove = await AuthorizationService.AuthorizeAsync(User,
                                    Contact,
                                    ContactOperations.Approve);

            if (!canApprove.Succeeded)
            {
                Contact.Status = ContactStatus.Submitted;
            }
        }

        await Context.SaveChangesAsync();

        return RedirectToPage("./Index");
    }
}
```

Update the DeleteModel

Update the delete page model to use the authorization handler to verify the user has delete permission on the contact.

```
public class DeleteModel : DI_BasePageModel
{
    public DeleteModel(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }

    [BindProperty]
    public Contact Contact { get; set; }

    public async Task<IActionResult> OnGetAsync(int id)
    {
        Contact = await Context.Contact.FirstOrDefaultAsync(
                                          m => m.ContactId == id);

        if (Contact == null)
        {
            return NotFound();
        }

        var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                               User, Contact,
                                               ContactOperations.Delete);
        if (!isAuthorized.Succeeded)
        {
            return Forbid();
        }

        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int id)
    {
        var contact = await Context
            .Contact.AsNoTracking()
            .FirstOrDefaultAsync(m => m.ContactId == id);

        if (contact == null)
        {
            return NotFound();
        }

        var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                               User, contact,
                                               ContactOperations.Delete);
        if (!isAuthorized.Succeeded)
        {
            return Forbid();
        }

        Context.Contact.Remove(contact);
        await Context.SaveChangesAsync();

        return RedirectToPage("./Index");
    }
}
```

Inject the authorization service into the views

Currently, the UI shows edit and delete links for contacts the user can't modify.

Inject the authorization service in the *Pages/_ViewImports.cshtml* file so it's available to all views:

```
@using Microsoft.AspNetCore.Identity
@using ContactManager
@using ContactManager.Data
@namespace ContactManager.Pages
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@using ContactManager.Authorization;
@using Microsoft.AspNetCore.Authorization
@using ContactManager.Models
@inject IAuthorizationService AuthorizationService
```

The preceding markup adds several `using` statements.

Update the **Edit** and **Delete** links in *Pages/Contacts/Index.cshtml* so they're only rendered for users with the appropriate permissions:

```
@page
@model ContactManager.Pages.Contacts.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].Name)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].Address)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].City)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].State)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].Zip)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].Email)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].Status)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Contact)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Name)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Address)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.City)
```

```
                @Html.DisplayFor(modelItem => item.City)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.State)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Zip)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Email)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Status)
            </td>
            <td>
                @if ((await AuthorizationService.AuthorizeAsync(
                 User, item,
                 ContactOperations.Update)).Succeeded)
                {
                    <a asp-page="./Edit" asp-route-id="@item.ContactId">Edit</a>
                    <text> | </text>
                }

                <a asp-page="./Details" asp-route-id="@item.ContactId">Details</a>

                @if ((await AuthorizationService.AuthorizeAsync(
                 User, item,
                 ContactOperations.Delete)).Succeeded)
                {
                    <text> | </text>
                    <a asp-page="./Delete" asp-route-id="@item.ContactId">Delete</a>
                }
            </td>
        </tr>
    }
</tbody>
</table>
```

> **WARNING**
>
> Hiding links from users that don't have permission to change data doesn't secure the app. Hiding links makes the app more user-friendly by displaying only valid links. Users can hack the generated URLs to invoke edit and delete operations on data they don't own. The Razor Page or controller must enforce access checks to secure the data.

Update Details

Update the details view so managers can approve or reject contacts:

```
        @*Precedng markup omitted for brevity.*@
        <dt>
            @Html.DisplayNameFor(model => model.Contact.Email)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Contact.Email)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Contact.Status)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Contact.Status)
        </dd>
    </dl>
</div>

@if (Model.Contact.Status != ContactStatus.Approved)
{
    @if ((await AuthorizationService.AuthorizeAsync(
     User, Model.Contact, ContactOperations.Approve)).Succeeded)
    {
        <form style="display:inline;" method="post">
            <input type="hidden" name="id" value="@Model.Contact.ContactId" />
            <input type="hidden" name="status" value="@ContactStatus.Approved" />
            <button type="submit" class="btn btn-xs btn-success">Approve</button>
        </form>
    }
}

@if (Model.Contact.Status != ContactStatus.Rejected)
{
    @if ((await AuthorizationService.AuthorizeAsync(
     User, Model.Contact, ContactOperations.Reject)).Succeeded)
    {
        <form style="display:inline;" method="post">
            <input type="hidden" name="id" value="@Model.Contact.ContactId" />
            <input type="hidden" name="status" value="@ContactStatus.Rejected" />
            <button type="submit" class="btn btn-xs btn-danger">Reject</button>
        </form>
    }
}

<div>
    @if ((await AuthorizationService.AuthorizeAsync(
         User, Model.Contact,
         ContactOperations.Update)).Succeeded)
    {
        <a asp-page="./Edit" asp-route-id="@Model.Contact.ContactId">Edit</a>
        <text> | </text>
    }
    <a asp-page="./Index">Back to List</a>
</div>
```

Update the details page model:

```
public class DetailsModel : DI_BasePageModel
{
    public DetailsModel(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }

    public Contact Contact { get; set; }

    public async Task<IActionResult> OnGetAsync(int id)
    {
        Contact = await Context.Contact.FirstOrDefaultAsync(m => m.ContactId == id);

        if (Contact == null)
        {
            return NotFound();
        }

        var isAuthorized = User.IsInRole(Constants.ContactManagersRole) ||
                           User.IsInRole(Constants.ContactAdministratorsRole);

        var currentUserId = UserManager.GetUserId(User);

        if (!isAuthorized
            && currentUserId != Contact.OwnerID
            && Contact.Status != ContactStatus.Approved)
        {
            return Forbid();
        }

        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int id, ContactStatus status)
    {
        var contact = await Context.Contact.FirstOrDefaultAsync(
                                                m => m.ContactId == id);

        if (contact == null)
        {
            return NotFound();
        }

        var contactOperation = (status == ContactStatus.Approved)
                                                   ? ContactOperations.Approve
                                                   : ContactOperations.Reject;

        var isAuthorized = await AuthorizationService.AuthorizeAsync(User, contact,
                                   contactOperation);
        if (!isAuthorized.Succeeded)
        {
            return Forbid();
        }
        contact.Status = status;
        Context.Contact.Update(contact);
        await Context.SaveChangesAsync();

        return RedirectToPage("./Index");
    }
}
```

Add or remove a user to a role

See this issue for information on:

- Removing privileges from a user. For example, muting a user in a chat app.
- Adding privileges to a user.

Differences between Challenge and Forbid

This app sets the default policy to require authenticated users. The following code allows anonymous users. Anonymous users are allowed to show the differences between Challenge vs Forbid.

```
[AllowAnonymous]
public class Details2Model : DI_BasePageModel
{
    public Details2Model(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }

    public Contact Contact { get; set; }

    public async Task<IActionResult> OnGetAsync(int id)
    {
        Contact = await Context.Contact.FirstOrDefaultAsync(m => m.ContactId == id);

        if (Contact == null)
        {
            return NotFound();
        }

        if (!User.Identity.IsAuthenticated)
        {
            return Challenge();
        }

        var isAuthorized = User.IsInRole(Constants.ContactManagersRole) ||
                           User.IsInRole(Constants.ContactAdministratorsRole);

        var currentUserId = UserManager.GetUserId(User);

        if (!isAuthorized
            && currentUserId != Contact.OwnerID
            && Contact.Status != ContactStatus.Approved)
        {
            return Forbid();
        }

        return Page();
    }
}
```

In the preceding code:

- When the user is **not** authenticated, a `ChallengeResult` is returned. When a `ChallengeResult` is returned, the user is redirected to the sign-in page.
- When the user is authenticated, but not authorized, a `ForbidResult` is returned. When a `ForbidResult` is returned, the user is redirected to the access denied page.

Test the completed app

If you haven't already set a password for seeded user accounts, use the Secret Manager tool to set a password:

- Choose a strong password: Use eight or more characters and at least one upper-case character, number, and symbol. For example, `Passw0rd!` meets the strong password requirements.
- Execute the following command from the project's folder, where `<PW>` is the password:

```
dotnet user-secrets set SeedUserPW <PW>
```

If the app has contacts:

- Delete all of the records in the `Contact` table.
- Restart the app to seed the database.

An easy way to test the completed app is to launch three different browsers (or incognito/InPrivate sessions). In one browser, register a new user (for example, `test@example.com`). Sign in to each browser with a different user. Verify the following operations:

- Registered users can view all of the approved contact data.
- Registered users can edit/delete their own data.
- Managers can approve/reject contact data. The `Details` view shows **Approve** and **Reject** buttons.
- Administrators can approve/reject and edit/delete all data.

USER	SEEDED BY THE APP	OPTIONS
test@example.com	No	Edit/delete the own data.
manager@contoso.com	Yes	Approve/reject and edit/delete own data.
admin@contoso.com	Yes	Approve/reject and edit/delete all data.

Create a contact in the administrator's browser. Copy the URL for delete and edit from the administrator contact. Paste these links into the test user's browser to verify the test user can't perform these operations.

Create the starter app

- Create a Razor Pages app named "ContactManager"
  - Create the app with **Individual User Accounts**.
  - Name it "ContactManager" so the namespace matches the namespace used in the sample.
  - `-uld` specifies LocalDB instead of SQLite

```
dotnet new webapp -o ContactManager -au Individual -uld
```

- Add *Models/Contact.cs*:

```
public class Contact
{
    public int ContactId { get; set; }
    public string Name { get; set; }
    public string Address { get; set; }
    public string City { get; set; }
    public string State { get; set; }
    public string Zip { get; set; }
    [DataType(DataType.EmailAddress)]
    public string Email { get; set; }
}
```

- Scaffold the `Contact` model.
- Create initial migration and update the database:

```
dotnet add package Microsoft.VisualStudio.Web.CodeGeneration.Design
dotnet tool install -g dotnet-aspnet-codegenerator
dotnet aspnet-codegenerator razorpage -m Contact -udl -dc ApplicationDbContext -outDir Pages\Contacts --
referenceScriptLibraries
dotnet ef database drop -f
dotnet ef migrations add initial
dotnet ef database update
```

If you experience a bug with the `dotnet aspnet-codegenerator razorpage` command, see this GitHub issue.

- Update the **ContactManager** anchor in the *Pages/Shared/_Layout.cshtml* file:

```
<a class="navbar-brand" asp-area="" asp-page="/Contacts/Index">ContactManager</a>
```

- Test the app by creating, editing, and deleting a contact

Seed the database

Add the SeedData class to the *Data* folder:

```
using ContactManager.Models;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using System;
using System.Linq;
using System.Threading.Tasks;

// dotnet aspnet-codegenerator razorpage -m Contact -dc ApplicationDbContext -udl -outDir Pages\Contacts --
referenceScriptLibraries

namespace ContactManager.Data
{
    public static class SeedData
    {
        public static async Task Initialize(IServiceProvider serviceProvider, string testUserPw)
        {
            using (var context = new ApplicationDbContext(
                serviceProvider.GetRequiredService<DbContextOptions<ApplicationDbContext>>()))
            {
                SeedDB(context, "0");
            }
        }

        public static void SeedDB(ApplicationDbContext context, string adminID)
        {
            if (context.Contact.Any())
```

```
            {
                return;   // DB has been seeded
            }

            context.Contact.AddRange(
                new Contact
                {
                    Name = "Debra Garcia",
                    Address = "1234 Main St",
                    City = "Redmond",
                    State = "WA",
                    Zip = "10999",
                    Email = "debra@example.com"
                },
                new Contact
                {
                    Name = "Thorsten Weinrich",
                    Address = "5678 1st Ave W",
                    City = "Redmond",
                    State = "WA",
                    Zip = "10999",
                    Email = "thorsten@example.com"
                },
             new Contact
             {
                 Name = "Yuhong Li",
                 Address = "9012 State st",
                 City = "Redmond",
                 State = "WA",
                 Zip = "10999",
                 Email = "yuhong@example.com"
             },
             new Contact
             {
                 Name = "Jon Orton",
                 Address = "3456 Maple St",
                 City = "Redmond",
                 State = "WA",
                 Zip = "10999",
                 Email = "jon@example.com"
             },
             new Contact
             {
                 Name = "Diliana Alexieva-Bosseva",
                 Address = "7890 2nd Ave E",
                 City = "Redmond",
                 State = "WA",
                 Zip = "10999",
                 Email = "diliana@example.com"
             }
             );
            context.SaveChanges();
        }

    }
}
```

Call `SeedData.Initialize` from `Main`:

```
using ContactManager.Data;
using Microsoft.AspNetCore.Hosting;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
using System;

namespace ContactManager
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateHostBuilder(args).Build();

            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    var context = services.GetRequiredService<ApplicationDbContext>();
                    context.Database.Migrate();
                    SeedData.Initialize(services, "not used");
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred seeding the DB.");
                }
            }

            host.Run();
        }

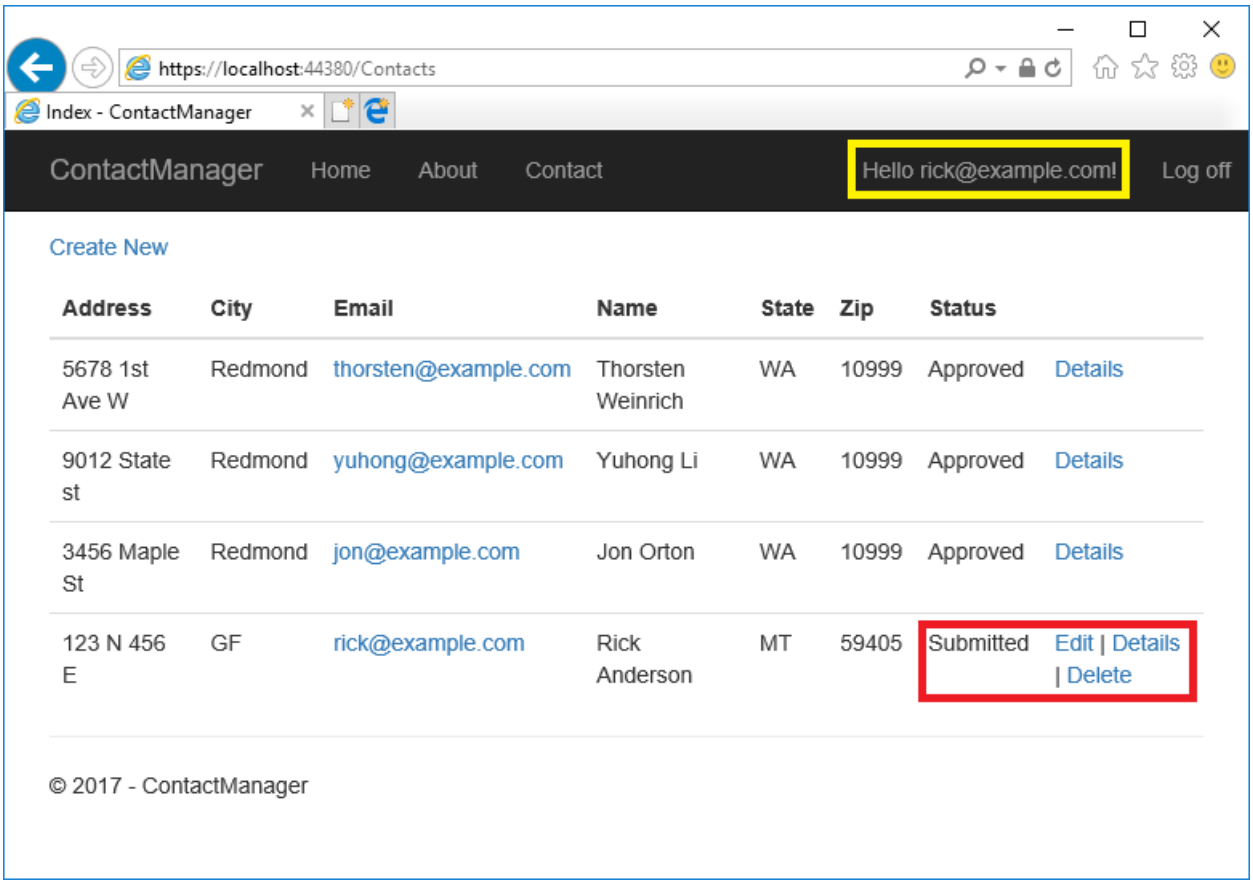
        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureWebHostDefaults(webBuilder =>
                {
                    webBuilder.UseStartup<Startup>();
                });
    }
}
```

Test that the app seeded the database. If there are any rows in the contact DB, the seed method doesn't run.

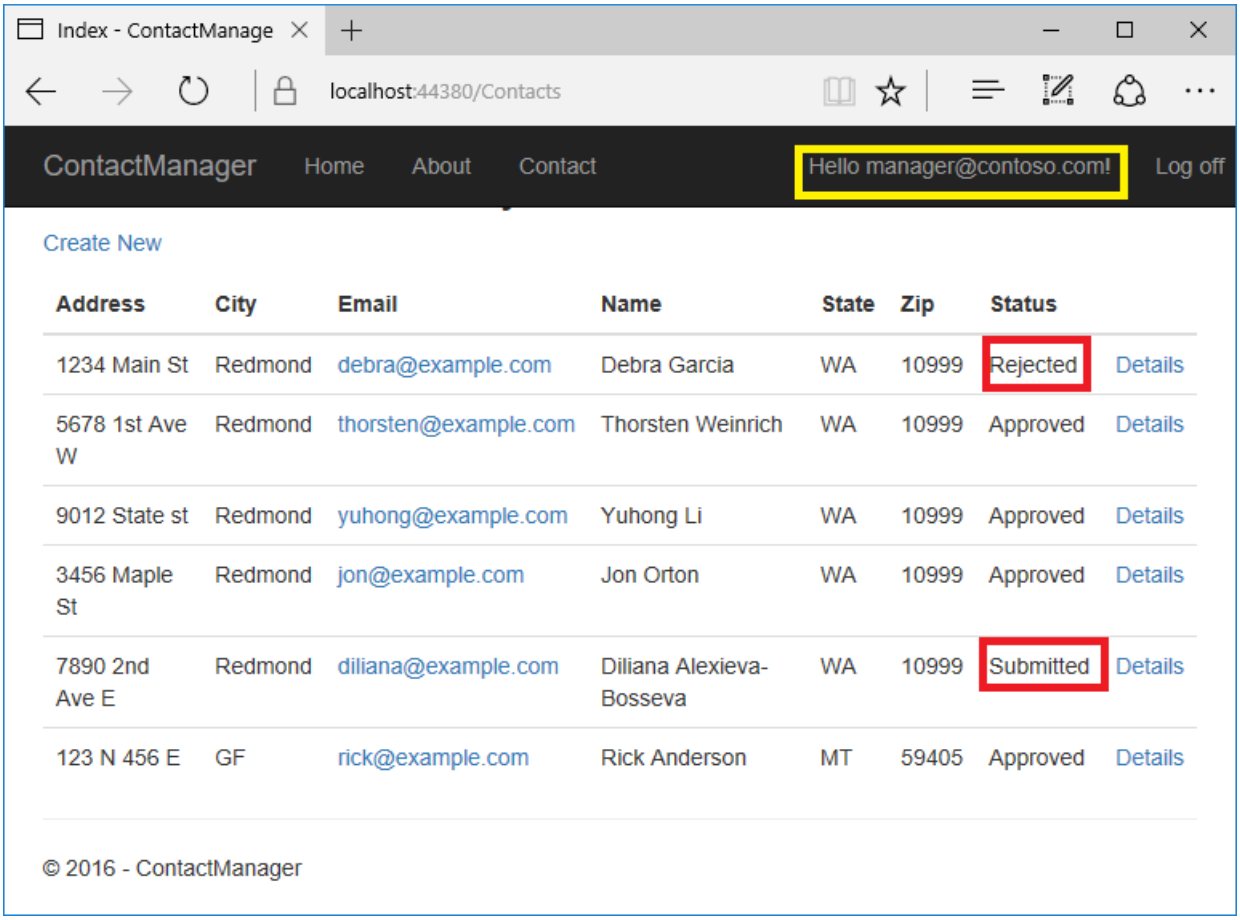
This tutorial shows how to create an ASP.NET Core web app with user data protected by authorization. It displays a list of contacts that authenticated (registered) users have created. There are three security groups:

- **Registered users** can view all the approved data and can edit/delete their own data.
- **Managers** can approve or reject contact data. Only approved contacts are visible to users.
- **Administrators** can approve/reject and edit/delete any data.

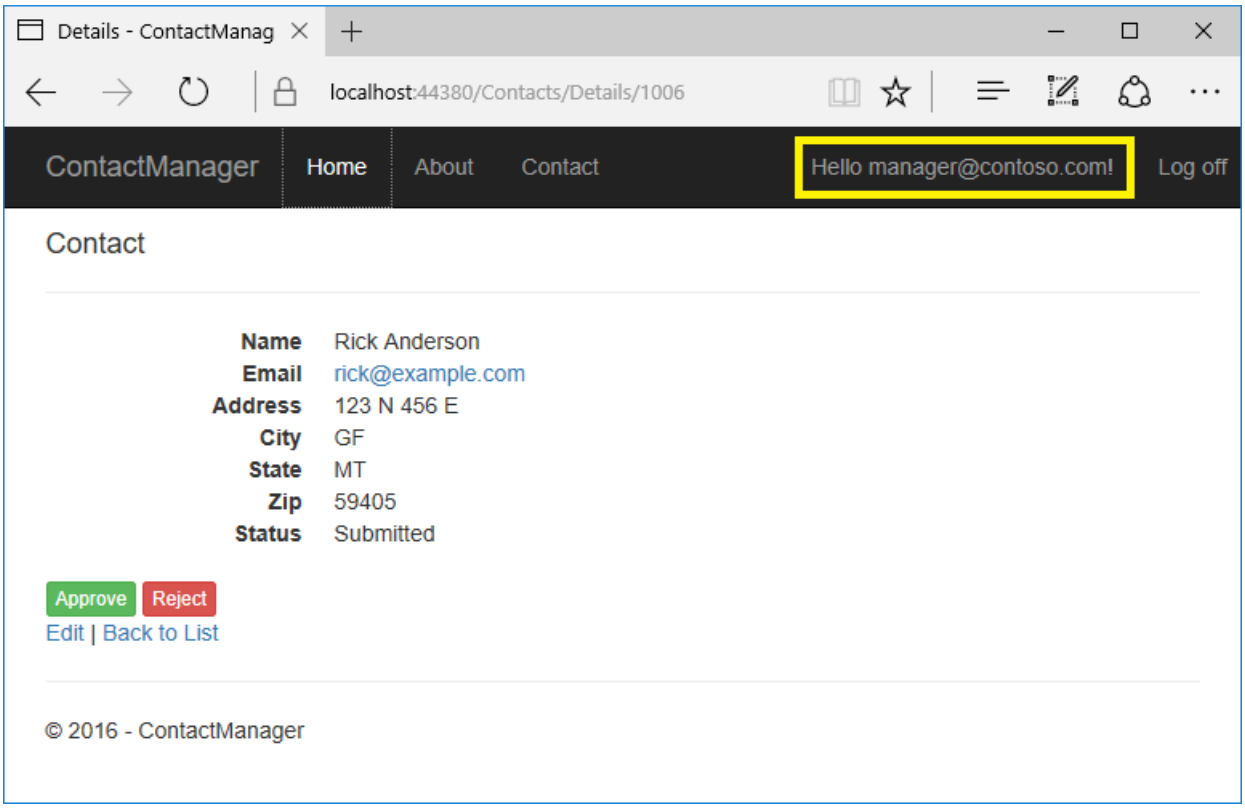
In the following image, user Rick (`rick@example.com`) is signed in. Rick can only view approved contacts and **Edit**/**Delete**/**Create New** links for his contacts. Only the last record, created by Rick, displays **Edit** and **Delete** links. Other users won't see the last record until a manager or administrator changes the status to "Approved".



In the following image, `manager@contoso.com` is signed in and in the manager's role:

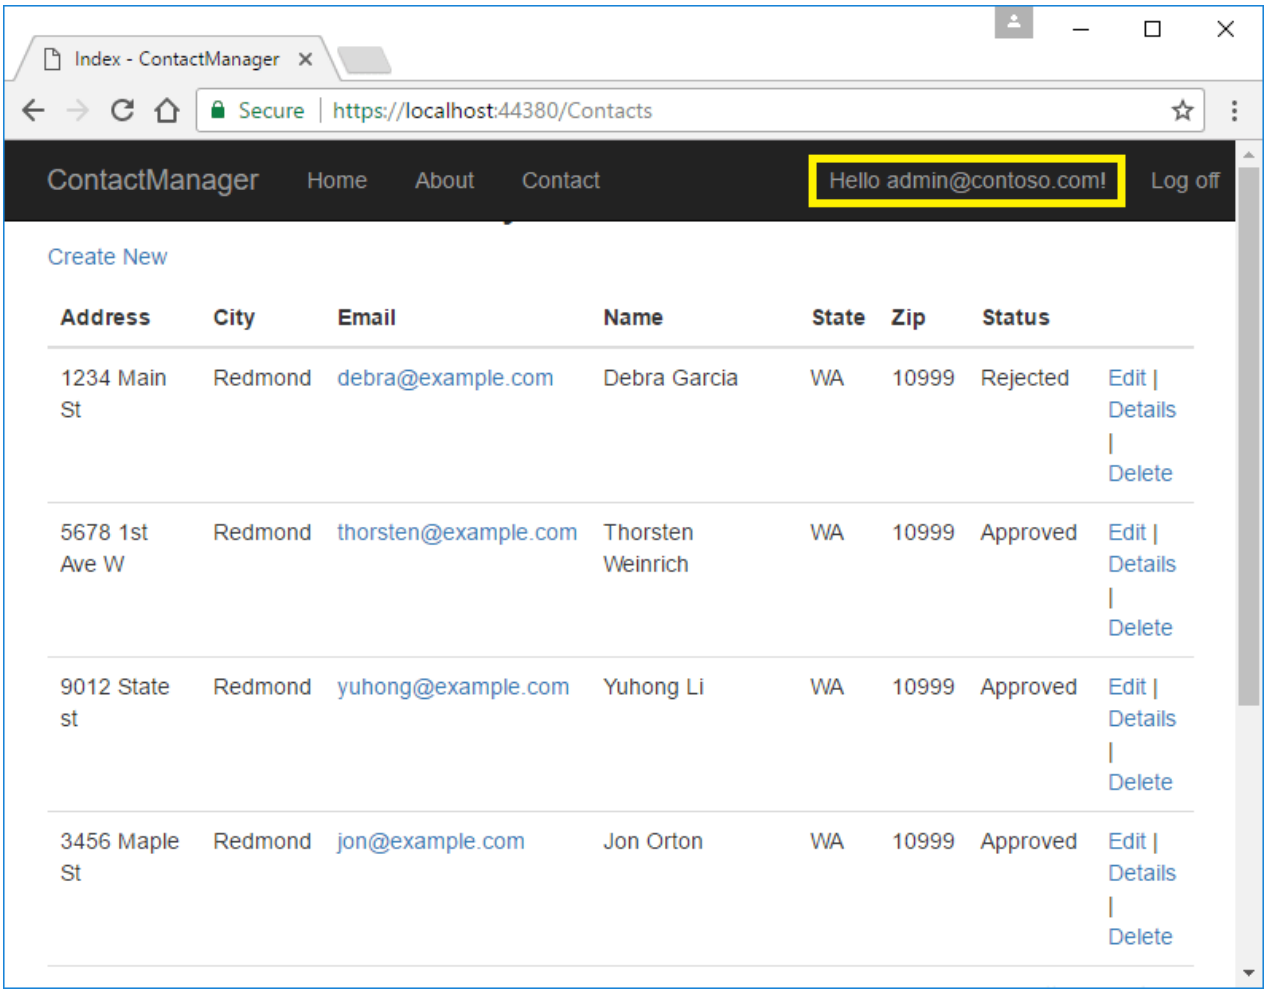


The following image shows the managers details view of a contact:



The **Approve** and **Reject** buttons are only displayed for managers and administrators.

In the following image, `admin@contoso.com` is signed in and in the administrator's role:



The administrator has all privileges. She can read/edit/delete any contact and change the status of contacts.

The app was created by scaffolding the following `Contact` model:

```
public class Contact
{
    public int ContactId { get; set; }
    public string Name { get; set; }
    public string Address { get; set; }
    public string City { get; set; }
    public string State { get; set; }
    public string Zip { get; set; }
    [DataType(DataType.EmailAddress)]
    public string Email { get; set; }
}
```

The sample contains the following authorization handlers:

- `ContactIsOwnerAuthorizationHandler`: Ensures that a user can only edit their data.
- `ContactManagerAuthorizationHandler`: Allows managers to approve or reject contacts.
- `ContactAdministratorsAuthorizationHandler`: Allows administrators to approve or reject contacts and to edit/delete contacts.

Prerequisites

This tutorial is advanced. You should be familiar with:

- ASP.NET Core
- Authentication
- Account Confirmation and Password Recovery
- Authorization
- Entity Framework Core

The starter and completed app

Download the completed app. Test the completed app so you become familiar with its security features.

The starter app

Download the starter app.

Run the app, tap the **ContactManager** link, and verify you can create, edit, and delete a contact.

Secure user data

The following sections have all the major steps to create the secure user data app. You may find it helpful to refer to the completed project.

Tie the contact data to the user

Use the ASP.NET Identity user ID to ensure users can edit their data, but not other users data. Add `OwnerID` and `ContactStatus` to the `Contact` model:

```
public class Contact
{
    public int ContactId { get; set; }

    // user ID from AspNetUser table.
    public string OwnerID { get; set; }

    public string Name { get; set; }
    public string Address { get; set; }
    public string City { get; set; }
    public string State { get; set; }
    public string Zip { get; set; }
    [DataType(DataType.EmailAddress)]
    public string Email { get; set; }

    public ContactStatus Status { get; set; }
}

public enum ContactStatus
{
    Submitted,
    Approved,
    Rejected
}
```

`OwnerID` is the user's ID from the `AspNetUser` table in the Identity database. The `Status` field determines if a contact is viewable by general users.

Create a new migration and update the database:

```
dotnet ef migrations add userID_Status
dotnet ef database update
```

Add Role services to Identity

Append AddRoles to add Role services:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>().AddRoles<IdentityRole>()
         .AddEntityFrameworkStores<ApplicationDbContext>();
```

Require authenticated users

Set the default authentication policy to require users to be authenticated:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>().AddRoles<IdentityRole>()
         .AddEntityFrameworkStores<ApplicationDbContext>();

    services.AddMvc(config =>
    {
        // using Microsoft.AspNetCore.Mvc.Authorization;
        // using Microsoft.AspNetCore.Authorization;
        var policy = new AuthorizationPolicyBuilder()
                         .RequireAuthenticatedUser()
                         .Build();
        config.Filters.Add(new AuthorizeFilter(policy));
    })
       .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
```

You can opt out of authentication at the Razor Page, controller, or action method level with the `[AllowAnonymous]` attribute. Setting the default authentication policy to require users to be authenticated protects newly added Razor Pages and controllers. Having authentication required by default is more secure than relying on new controllers and Razor Pages to include the `[Authorize]` attribute.

Add AllowAnonymous to the Index, About, and Contact pages so anonymous users can get information about the site before they register.

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace ContactManager.Pages
{
    [AllowAnonymous]
    public class IndexModel : PageModel
    {
        public void OnGet()
        {

        }
    }
}
```

Configure the test account

The `SeedData` class creates two accounts: administrator and manager. Use the Secret Manager tool to set a password for these accounts. Set the password from the project directory (the directory containing *Program.cs*):

```
dotnet user-secrets set SeedUserPW <PW>
```

If a strong password is not specified, an exception is thrown when `SeedData.Initialize` is called.

Update `Main` to use the test password:

```
public class Program
{
    public static void Main(string[] args)
    {
        var host = CreateWebHostBuilder(args).Build();

        using (var scope = host.Services.CreateScope())
        {
            var services = scope.ServiceProvider;
            var context = services.GetRequiredService<ApplicationDbContext>();
            context.Database.Migrate();

            // requires using Microsoft.Extensions.Configuration;
            var config = host.Services.GetRequiredService<IConfiguration>();
            // Set password with the Secret Manager tool.
            // dotnet user-secrets set SeedUserPW <pw>

            var testUserPw = config["SeedUserPW"];
            try
            {
                SeedData.Initialize(services, testUserPw).Wait();
            }
            catch (Exception ex)
            {
                var logger = services.GetRequiredService<ILogger<Program>>();
                logger.LogError(ex.Message, "An error occurred seeding the DB.");
            }
        }

        host.Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

Create the test accounts and update the contacts

Update the `Initialize` method in the `SeedData` class to create the test accounts:

```
public static async Task Initialize(IServiceProvider serviceProvider, string testUserPw)
{
    using (var context = new ApplicationDbContext(
        serviceProvider.GetRequiredService<DbContextOptions<ApplicationDbContext>>()))
    {
        // For sample purposes seed both with the same password.
        // Password is set with the following:
        // dotnet user-secrets set SeedUserPW <pw>
        // The admin user can do anything

        var adminID = await EnsureUser(serviceProvider, testUserPw, "admin@contoso.com");
        await EnsureRole(serviceProvider, adminID, Constants.ContactAdministratorsRole);

        // allowed user can create and edit contacts that they create
        var managerID = await EnsureUser(serviceProvider, testUserPw, "manager@contoso.com");
        await EnsureRole(serviceProvider, managerID, Constants.ContactManagersRole);

        SeedDB(context, adminID);
    }
}

private static async Task<string> EnsureUser(IServiceProvider serviceProvider,
                                            string testUserPw, string UserName)
{
    var userManager = serviceProvider.GetService<UserManager<IdentityUser>>();

    var user = await userManager.FindByNameAsync(UserName);
    if (user == null)
    {
        user = new IdentityUser { UserName = UserName };
        await userManager.CreateAsync(user, testUserPw);
    }

    return user.Id;
}

private static async Task<IdentityResult> EnsureRole(IServiceProvider serviceProvider,
                                                      string uid, string role)
{
    IdentityResult IR = null;
    var roleManager = serviceProvider.GetService<RoleManager<IdentityRole>>();

    if (roleManager == null)
    {
        throw new Exception("roleManager null");
    }

    if (!await roleManager.RoleExistsAsync(role))
    {
        IR = await roleManager.CreateAsync(new IdentityRole(role));
    }

    var userManager = serviceProvider.GetService<UserManager<IdentityUser>>();

    var user = await userManager.FindByIdAsync(uid);

    if(user == null)
    {
        throw new Exception("The testUserPw password was probably not strong enough!");
    }

    IR = await userManager.AddToRoleAsync(user, role);

    return IR;
}
```

Add the administrator user ID and `ContactStatus` to the contacts. Make one of the contacts "Submitted" and one "Rejected". Add the user ID and status to all the contacts. Only one contact is shown:

```
public static void SeedDB(ApplicationDbContext context, string adminID)
{
    if (context.Contact.Any())
    {
        return;   // DB has been seeded
    }

    context.Contact.AddRange(
        new Contact
        {
            Name = "Debra Garcia",
            Address = "1234 Main St",
            City = "Redmond",
            State = "WA",
            Zip = "10999",
            Email = "debra@example.com",
            Status = ContactStatus.Approved,
            OwnerID = adminID
        },
```

Create owner, manager, and administrator authorization handlers

Create an *Authorization* folder and create a `ContactIsOwnerAuthorizationHandler` class in it. The `ContactIsOwnerAuthorizationHandler` verifies that the user acting on a resource owns the resource.

```
using System.Threading.Tasks;
using ContactManager.Data;
using ContactManager.Models;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Authorization.Infrastructure;
using Microsoft.AspNetCore.Identity;

namespace ContactManager.Authorization
{
    public class ContactIsOwnerAuthorizationHandler
                : AuthorizationHandler<OperationAuthorizationRequirement, Contact>
    {
        UserManager<IdentityUser> _userManager;

        public ContactIsOwnerAuthorizationHandler(UserManager<IdentityUser>
            userManager)
        {
            _userManager = userManager;
        }

        protected override Task
            HandleRequirementAsync(AuthorizationHandlerContext context,
                                   OperationAuthorizationRequirement requirement,
                                   Contact resource)
        {
            if (context.User == null || resource == null)
            {
                // Return Task.FromResult(0) if targeting a version of
                // .NET Framework older than 4.6:
                return Task.CompletedTask;
            }

            // If we're not asking for CRUD permission, return.

            if (requirement.Name != Constants.CreateOperationName &&
                requirement.Name != Constants.ReadOperationName   &&
                requirement.Name != Constants.UpdateOperationName &&
                requirement.Name != Constants.DeleteOperationName )
            {
                return Task.CompletedTask;
            }

            if (resource.OwnerID == _userManager.GetUserId(context.User))
            {
                context.Succeed(requirement);
            }

            return Task.CompletedTask;
        }
    }
}
```

The `ContactIsOwnerAuthorizationHandler` calls context.Succeed if the current authenticated user is the contact owner. Authorization handlers generally:

- Return `context.Succeed` when the requirements are met.
- Return `Task.CompletedTask` when requirements aren't met. `Task.CompletedTask` is not success or failure—it allows other authorization handlers to run.

If you need to explicitly fail, return context.Fail.

The app allows contact owners to edit/delete/create their own data. `ContactIsOwnerAuthorizationHandler` doesn't need to check the operation passed in the requirement parameter.

Create a manager authorization handler

Create a `ContactManagerAuthorizationHandler` class in the *Authorization* folder. The `ContactManagerAuthorizationHandler` verifies the user acting on the resource is a manager. Only managers can approve or reject content changes (new or changed).

```
using System.Threading.Tasks;
using ContactManager.Models;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Authorization.Infrastructure;
using Microsoft.AspNetCore.Identity;

namespace ContactManager.Authorization
{
    public class ContactManagerAuthorizationHandler :
        AuthorizationHandler<OperationAuthorizationRequirement, Contact>
    {
        protected override Task
            HandleRequirementAsync(AuthorizationHandlerContext context,
                                   OperationAuthorizationRequirement requirement,
                                   Contact resource)
        {
            if (context.User == null || resource == null)
            {
                return Task.CompletedTask;
            }

            // If not asking for approval/reject, return.
            if (requirement.Name != Constants.ApproveOperationName &&
                requirement.Name != Constants.RejectOperationName)
            {
                return Task.CompletedTask;
            }

            // Managers can approve or reject.
            if (context.User.IsInRole(Constants.ContactManagersRole))
            {
                context.Succeed(requirement);
            }

            return Task.CompletedTask;
        }
    }
}
```

Create an administrator authorization handler

Create a `ContactAdministratorsAuthorizationHandler` class in the *Authorization* folder. The `ContactAdministratorsAuthorizationHandler` verifies the user acting on the resource is an administrator. Administrator can do all operations.

```
using System.Threading.Tasks;
using ContactManager.Models;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Authorization.Infrastructure;

namespace ContactManager.Authorization
{
    public class ContactAdministratorsAuthorizationHandler
                    : AuthorizationHandler<OperationAuthorizationRequirement, Contact>
    {
        protected override Task HandleRequirementAsync(
                                            AuthorizationHandlerContext context,
                                    OperationAuthorizationRequirement requirement,
                                     Contact resource)
        {
            if (context.User == null)
            {
                return Task.CompletedTask;
            }

            // Administrators can do anything.
            if (context.User.IsInRole(Constants.ContactAdministratorsRole))
            {
                context.Succeed(requirement);
            }

            return Task.CompletedTask;
        }
    }
}
```

Register the authorization handlers

Services using Entity Framework Core must be registered for dependency injection using AddScoped. The `ContactIsOwnerAuthorizationHandler` uses ASP.NET Core Identity, which is built on Entity Framework Core. Register the handlers with the service collection so they're available to the `ContactsController` through dependency injection. Add the following code to the end of `ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>().AddRoles<IdentityRole>()
         .AddEntityFrameworkStores<ApplicationDbContext>();

    services.AddMvc(config =>
    {
        // using Microsoft.AspNetCore.Mvc.Authorization;
        // using Microsoft.AspNetCore.Authorization;
        var policy = new AuthorizationPolicyBuilder()
                         .RequireAuthenticatedUser()
                         .Build();
        config.Filters.Add(new AuthorizeFilter(policy));
    })
       .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);

    // Authorization handlers.
    services.AddScoped<IAuthorizationHandler,
                          ContactIsOwnerAuthorizationHandler>();

    services.AddSingleton<IAuthorizationHandler,
                          ContactAdministratorsAuthorizationHandler>();

    services.AddSingleton<IAuthorizationHandler,
                          ContactManagerAuthorizationHandler>();
}
```

`ContactAdministratorsAuthorizationHandler` and `ContactManagerAuthorizationHandler` are added as singletons. They're singletons because they don't use EF and all the information needed is in the `Context` parameter of the `HandleRequirementAsync` method.

Support authorization

In this section, you update the Razor Pages and add an operations requirements class.

Review the contact operations requirements class

Review the `ContactOperations` class. This class contains the requirements the app supports:

```
using Microsoft.AspNetCore.Authorization.Infrastructure;

namespace ContactManager.Authorization
{
    public static class ContactOperations
    {
        public static OperationAuthorizationRequirement Create =
          new OperationAuthorizationRequirement {Name=Constants.CreateOperationName};
        public static OperationAuthorizationRequirement Read =
          new OperationAuthorizationRequirement {Name=Constants.ReadOperationName};
        public static OperationAuthorizationRequirement Update =
          new OperationAuthorizationRequirement {Name=Constants.UpdateOperationName};
        public static OperationAuthorizationRequirement Delete =
          new OperationAuthorizationRequirement {Name=Constants.DeleteOperationName};
        public static OperationAuthorizationRequirement Approve =
          new OperationAuthorizationRequirement {Name=Constants.ApproveOperationName};
        public static OperationAuthorizationRequirement Reject =
          new OperationAuthorizationRequirement {Name=Constants.RejectOperationName};
    }

    public class Constants
    {
        public static readonly string CreateOperationName = "Create";
        public static readonly string ReadOperationName = "Read";
        public static readonly string UpdateOperationName = "Update";
        public static readonly string DeleteOperationName = "Delete";
        public static readonly string ApproveOperationName = "Approve";
        public static readonly string RejectOperationName = "Reject";

        public static readonly string ContactAdministratorsRole =
                                                          "ContactAdministrators";
        public static readonly string ContactManagersRole = "ContactManagers";
    }
}
```

Create a base class for the Contacts Razor Pages

Create a base class that contains the services used in the contacts Razor Pages. The base class puts the initialization code in one location:

```
using ContactManager.Data;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace ContactManager.Pages.Contacts
{
    public class DI_BasePageModel : PageModel
    {
        protected ApplicationDbContext Context { get; }
        protected IAuthorizationService AuthorizationService { get; }
        protected UserManager<IdentityUser> UserManager { get; }

        public DI_BasePageModel(
            ApplicationDbContext context,
            IAuthorizationService authorizationService,
            UserManager<IdentityUser> userManager) : base()
        {
            Context = context;
            UserManager = userManager;
            AuthorizationService = authorizationService;
        }
    }
}
```

The preceding code:

- Adds the `IAuthorizationService` service to access to the authorization handlers.
- Adds the Identity `UserManager` service.
- Add the `ApplicationDbContext`.

Update the CreateModel

Update the create page model constructor to use the `DI_BasePageModel` base class:

```
public class CreateModel : DI_BasePageModel
{
    public CreateModel(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }
```

Update the `CreateModel.OnPostAsync` method to:

- Add the user ID to the `Contact` model.
- Call the authorization handler to verify the user has permission to create contacts.

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    Contact.OwnerID = UserManager.GetUserId(User);

    // requires using ContactManager.Authorization;
    var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                            User, Contact,
                                            ContactOperations.Create);
    if (!isAuthorized.Succeeded)
    {
        return new ChallengeResult();
    }

    Context.Contact.Add(Contact);
    await Context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

Update the IndexModel

Update the `OnGetAsync` method so only approved contacts are shown to general users:

```
public class IndexModel : DI_BasePageModel
{
    public IndexModel(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }

    public IList<Contact> Contact { get; set; }

    public async Task OnGetAsync()
    {
        var contacts = from c in Context.Contact
                       select c;

        var isAuthorized = User.IsInRole(Constants.ContactManagersRole) ||
                           User.IsInRole(Constants.ContactAdministratorsRole);

        var currentUserId = UserManager.GetUserId(User);

        // Only approved contacts are shown UNLESS you're authorized to see them
        // or you are the owner.
        if (!isAuthorized)
        {
            contacts = contacts.Where(c => c.Status == ContactStatus.Approved
                                      || c.OwnerID == currentUserId);
        }

        Contact = await contacts.ToListAsync();
    }
}
```

Update the EditModel

Add an authorization handler to verify the user owns the contact. Because resource authorization is being validated, the `[Authorize]` attribute is not enough. The app doesn't have access to the resource when attributes are evaluated. Resource-based authorization must be imperative. Checks must be performed once the app has access to the resource, either by loading it in the page model or by loading it within the handler itself. You frequently access the resource by passing in the resource key.

```
public class EditModel : DI_BasePageModel
{
    public EditModel(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }

    [BindProperty]
    public Contact Contact { get; set; }

    public async Task<IActionResult> OnGetAsync(int id)
    {
        Contact = await Context.Contact.FirstOrDefaultAsync(
                                            m => m.ContactId == id);

        if (Contact == null)
        {
            return NotFound();
        }
```

```
        var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                                 User, Contact,
                                                 ContactOperations.Update);
        if (!isAuthorized.Succeeded)
        {
            return new ChallengeResult();
        }

        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int id)
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        // Fetch Contact from DB to get OwnerID.
        var contact = await Context
            .Contact.AsNoTracking()
            .FirstOrDefaultAsync(m => m.ContactId == id);

        if (contact == null)
        {
            return NotFound();
        }

        var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                                User, contact,
                                                ContactOperations.Update);
        if (!isAuthorized.Succeeded)
        {
            return new ChallengeResult();
        }

        Contact.OwnerID = contact.OwnerID;

        Context.Attach(Contact).State = EntityState.Modified;

        if (contact.Status == ContactStatus.Approved)
        {
            // If the contact is updated after approval,
            // and the user cannot approve,
            // set the status back to submitted so the update can be
            // checked and approved.
            var canApprove = await AuthorizationService.AuthorizeAsync(User,
                                    contact,
                                    ContactOperations.Approve);

            if (!canApprove.Succeeded)
            {
                contact.Status = ContactStatus.Submitted;
            }
        }

        await Context.SaveChangesAsync();

        return RedirectToPage("./Index");
    }

    private bool ContactExists(int id)
    {
        return Context.Contact.Any(e => e.ContactId == id);
    }
}
```

Update the DeleteModel

Update the delete page model to use the authorization handler to verify the user has delete permission on the contact.

```
public class DeleteModel : DI_BasePageModel
{
    public DeleteModel(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }

    [BindProperty]
    public Contact Contact { get; set; }

    public async Task<IActionResult> OnGetAsync(int id)
    {
        Contact = await Context.Contact.FirstOrDefaultAsync(
                                          m => m.ContactId == id);

        if (Contact == null)
        {
            return NotFound();
        }

        var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                                User, Contact,
                                                ContactOperations.Delete);
        if (!isAuthorized.Succeeded)
        {
            return new ChallengeResult();
        }

        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int id)
    {
        Contact = await Context.Contact.FindAsync(id);

        var contact = await Context
            .Contact.AsNoTracking()
            .FirstOrDefaultAsync(m => m.ContactId == id);

        if (contact == null)
        {
            return NotFound();
        }

        var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                                User, contact,
                                                ContactOperations.Delete);
        if (!isAuthorized.Succeeded)
        {
            return new ChallengeResult();
        }

        Context.Contact.Remove(Contact);
        await Context.SaveChangesAsync();

        return RedirectToPage("./Index");
    }
}
```

Inject the authorization service into the views

Currently, the UI shows edit and delete links for contacts the user can't modify.

Inject the authorization service in the *Views/_ViewImports.cshtml* file so it's available to all views:

```
@using Microsoft.AspNetCore.Identity
@using ContactManager
@using ContactManager.Data
@namespace ContactManager.Pages
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@using ContactManager.Authorization;
@using Microsoft.AspNetCore.Authorization
@using ContactManager.Models
@inject IAuthorizationService AuthorizationService
```

The preceding markup adds several `using` statements.

Update the **Edit** and **Delete** links in *Pages/Contacts/Index.cshtml* so they're only rendered for users with the appropriate permissions:

```
@page
@model ContactManager.Pages.Contacts.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].Name)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].Address)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].City)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].State)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].Zip)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].Email)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].Status)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Contact)
        {
            <tr>
                <td>
```

```
                    @Html.DisplayFor(modelItem => item.Name)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Address)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.City)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.State)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Zip)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Email)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Status)
                </td>
                <td>
                    @if ((await AuthorizationService.AuthorizeAsync(
                     User, item,
                     ContactOperations.Update)).Succeeded)
                    {
                        <a asp-page="./Edit" asp-route-id="@item.ContactId">Edit</a>
                        <text> | </text>
                    }

                    <a asp-page="./Details" asp-route-id="@item.ContactId">Details</a>

                    @if ((await AuthorizationService.AuthorizeAsync(
                     User, item,
                     ContactOperations.Delete)).Succeeded)
                    {
                        <text> | </text>
                        <a asp-page="./Delete" asp-route-id="@item.ContactId">Delete</a>
                    }
                </td>
            </tr>
        }
    </tbody>
</table>
```

WARNING

Hiding links from users that don't have permission to change data doesn't secure the app. Hiding links makes the app more user-friendly by displaying only valid links. Users can hack the generated URLs to invoke edit and delete operations on data they don't own. The Razor Page or controller must enforce access checks to secure the data.

Update Details

Update the details view so managers can approve or reject contacts:

```
        @*Precedng markup omitted for brevity.*@
        <dt>
            @Html.DisplayNameFor(model => model.Contact.Email)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Contact.Email)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Contact.Status)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Contact.Status)
        </dd>
    </dl>
</div>

@if (Model.Contact.Status != ContactStatus.Approved)
{
    @if ((await AuthorizationService.AuthorizeAsync(
     User, Model.Contact, ContactOperations.Approve)).Succeeded)
    {
        <form style="display:inline;" method="post">
            <input type="hidden" name="id" value="@Model.Contact.ContactId" />
            <input type="hidden" name="status" value="@ContactStatus.Approved" />
            <button type="submit" class="btn btn-xs btn-success">Approve</button>
        </form>
    }
}

@if (Model.Contact.Status != ContactStatus.Rejected)
{
    @if ((await AuthorizationService.AuthorizeAsync(
     User, Model.Contact, ContactOperations.Reject)).Succeeded)
    {
        <form style="display:inline;" method="post">
            <input type="hidden" name="id" value="@Model.Contact.ContactId" />
            <input type="hidden" name="status" value="@ContactStatus.Rejected" />
            <button type="submit" class="btn btn-xs btn-success">Reject</button>
        </form>
    }
}

<div>
    @if ((await AuthorizationService.AuthorizeAsync(
         User, Model.Contact,
         ContactOperations.Update)).Succeeded)
    {
        <a asp-page="./Edit" asp-route-id="@Model.Contact.ContactId">Edit</a>
        <text> | </text>
    }
    <a asp-page="./Index">Back to List</a>
</div>
```

Update the details page model:

```
public class DetailsModel : DI_BasePageModel
{
    public DetailsModel(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }

    public Contact Contact { get; set; }

    public async Task<IActionResult> OnGetAsync(int id)
    {
        Contact = await Context.Contact.FirstOrDefaultAsync(m => m.ContactId == id);

        if (Contact == null)
        {
            return NotFound();
        }

        var isAuthorized = User.IsInRole(Constants.ContactManagersRole) ||
                           User.IsInRole(Constants.ContactAdministratorsRole);

        var currentUserId = UserManager.GetUserId(User);

        if (!isAuthorized
            &&  currentUserId != Contact.OwnerID
            && Contact.Status != ContactStatus.Approved)
        {
            return new ChallengeResult();
        }

        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int id, ContactStatus status)
    {
        var contact = await Context.Contact.FirstOrDefaultAsync(
                                                m => m.ContactId == id);

        if (contact == null)
        {
            return NotFound();
        }

        var contactOperation = (status == ContactStatus.Approved)
                                                   ? ContactOperations.Approve
                                                   : ContactOperations.Reject;

        var isAuthorized = await AuthorizationService.AuthorizeAsync(User, contact,
                                   contactOperation);
        if (!isAuthorized.Succeeded)
        {
            return new ChallengeResult();
        }
        contact.Status = status;
        Context.Contact.Update(contact);
        await Context.SaveChangesAsync();

        return RedirectToPage("./Index");
    }
}
```

Add or remove a user to a role

See this issue for information on:

- Removing privileges from a user. For example, muting a user in a chat app.
- Adding privileges to a user.

Test the completed app

If you haven't already set a password for seeded user accounts, use the Secret Manager tool to set a password:

- Choose a strong password: Use eight or more characters and at least one upper-case character, number, and symbol. For example, `Passw0rd!` meets the strong password requirements.
- Execute the following command from the project's folder, where `<PW>` is the password:

```
dotnet user-secrets set SeedUserPW <PW>
```

- Drop and update the Database

```
dotnet ef database drop -f
dotnet ef database update
```

- Restart the app to seed the database.

An easy way to test the completed app is to launch three different browsers (or incognito/InPrivate sessions). In one browser, register a new user (for example, `test@example.com`). Sign in to each browser with a different user. Verify the following operations:

- Registered users can view all of the approved contact data.
- Registered users can edit/delete their own data.
- Managers can approve/reject contact data. The `Details` view shows **Approve** and **Reject** buttons.
- Administrators can approve/reject and edit/delete all data.

USER	SEEDED BY THE APP	OPTIONS
test@example.com	No	Edit/delete the own data.
manager@contoso.com	Yes	Approve/reject and edit/delete own data.
admin@contoso.com	Yes	Approve/reject and edit/delete all data.

Create a contact in the administrator's browser. Copy the URL for delete and edit from the administrator contact. Paste these links into the test user's browser to verify the test user can't perform these operations.

Create the starter app

- Create a Razor Pages app named "ContactManager"
  - Create the app with **Individual User Accounts**.
  - Name it "ContactManager" so the namespace matches the namespace used in the sample.
  - `-uld` specifies LocalDB instead of SQLite

```
dotnet new webapp -o ContactManager -au Individual -uld
```

- Add *Models/Contact.cs*:

```
public class Contact
{
    public int ContactId { get; set; }
    public string Name { get; set; }
    public string Address { get; set; }
    public string City { get; set; }
    public string State { get; set; }
    public string Zip { get; set; }
    [DataType(DataType.EmailAddress)]
    public string Email { get; set; }
}
```

- Scaffold the `Contact` model.
- Create initial migration and update the database:

```
dotnet aspnet-codegenerator razorpage -m Contact -udl -dc ApplicationDbContext -outDir Pages\Contacts -
-referenceScriptLibraries
dotnet ef database drop -f
dotnet ef migrations add initial
dotnet ef database update
```

- Update the **ContactManager** anchor in the *Pages/_Layout.cshtml* file:

```
<a asp-page="/Contacts/Index" class="navbar-brand">ContactManager</a>
```

- Test the app by creating, editing, and deleting a contact

Seed the database

Add the SeedData class to the *Data* folder.

Call `SeedData.Initialize` from `Main`:

```
public class Program
{
    public static void Main(string[] args)
    {
        var host = CreateWebHostBuilder(args).Build();

        using (var scope = host.Services.CreateScope())
        {
            var services = scope.ServiceProvider;

            try
            {
                var context = services.GetRequiredService<ApplicationDbContext>();
                context.Database.Migrate();
                SeedData.Initialize(services, "not used");
            }
            catch (Exception ex)
            {
                var logger = services.GetRequiredService<ILogger<Program>>();
                logger.LogError(ex, "An error occurred seeding the DB.");
            }
        }

        host.Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

Test that the app seeded the database. If there are any rows in the contact DB, the seed method doesn't run.

Razor Pages authorization conventions in ASP.NET Core

9/22/2020 • 6 minutes to read • Edit Online

One way to control access in your Razor Pages app is to use authorization conventions at startup. These conventions allow you to authorize users and allow anonymous users to access individual pages or folders of pages. The conventions described in this topic automatically apply authorization filters to control access.

View or download sample code (how to download)

The sample app uses cookie authentication without ASP.NET Core Identity. The concepts and examples shown in this topic apply equally to apps that use ASP.NET Core Identity. To use ASP.NET Core Identity, follow the guidance in Introduction to Identity on ASP.NET Core.

Require authorization to access a page

Use the AuthorizePage convention to add an AuthorizeFilter to the page at the specified path:

```
services.AddRazorPages(options =>
{
    options.Conventions.AuthorizePage("/Contact");
    options.Conventions.AuthorizeFolder("/Private");
    options.Conventions.AllowAnonymousToPage("/Private/PublicPage");
    options.Conventions.AllowAnonymousToFolder("/Private/PublicPages");
});
```

The specified path is the View Engine path, which is the Razor Pages root relative path without an extension and containing only forward slashes.

To specify an authorization policy, use an AuthorizePage overload:

```
options.Conventions.AuthorizePage("/Contact", "AtLeast21");
```

NOTE

An AuthorizeFilter can be applied to a page model class with the `[Authorize]` filter attribute. For more information, see Authorize filter attribute.

Require authorization to access a folder of pages

Use the AuthorizeFolder convention to add an AuthorizeFilter to all of the pages in a folder at the specified path:

```
services.AddRazorPages(options =>
{
    options.Conventions.AuthorizePage("/Contact");
    options.Conventions.AuthorizeFolder("/Private");
    options.Conventions.AllowAnonymousToPage("/Private/PublicPage");
    options.Conventions.AllowAnonymousToFolder("/Private/PublicPages");
});
```

The specified path is the View Engine path, which is the Razor Pages root relative path.

To specify an authorization policy, use an AuthorizeFolder overload:

```
options.Conventions.AuthorizeFolder("/Private", "AtLeast21");
```

Require authorization to access an area page

Use the AuthorizeAreaPage convention to add an AuthorizeFilter to the area page at the specified path:

```
options.Conventions.AuthorizeAreaPage("Identity", "/Manage/Accounts");
```

The page name is the path of the file without an extension relative to the pages root directory for the specified area. For example, the page name for the file *Areas/Identity/Pages/Manage/Accounts.cshtml* is */Manage/Accounts*.

To specify an authorization policy, use an AuthorizeAreaPage overload:

```
options.Conventions.AuthorizeAreaPage("Identity", "/Manage/Accounts", "AtLeast21");
```

Require authorization to access a folder of areas

Use the AuthorizeAreaFolder convention to add an AuthorizeFilter to all of the areas in a folder at the specified path:

```
options.Conventions.AuthorizeAreaFolder("Identity", "/Manage");
```

The folder path is the path of the folder relative to the pages root directory for the specified area. For example, the folder path for the files under *Areas/Identity/Pages/Manage/* is */Manage*.

To specify an authorization policy, use an AuthorizeAreaFolder overload:

```
options.Conventions.AuthorizeAreaFolder("Identity", "/Manage", "AtLeast21");
```

Allow anonymous access to a page

Use the AllowAnonymousToPage convention to add an AllowAnonymousFilter to a page at the specified path:

```
services.AddRazorPages(options =>
{
    options.Conventions.AuthorizePage("/Contact");
    options.Conventions.AuthorizeFolder("/Private");
    options.Conventions.AllowAnonymousToPage("/Private/PublicPage");
    options.Conventions.AllowAnonymousToFolder("/Private/PublicPages");
});
```

The specified path is the View Engine path, which is the Razor Pages root relative path without an extension and containing only forward slashes.

Allow anonymous access to a folder of pages

Use the AllowAnonymousToFolder convention to add an AllowAnonymousFilter to all of the pages in a folder at the specified path:

```
services.AddRazorPages(options =>
{
    options.Conventions.AuthorizePage("/Contact");
    options.Conventions.AuthorizeFolder("/Private");
    options.Conventions.AllowAnonymousToPage("/Private/PublicPage");
    options.Conventions.AllowAnonymousToFolder("/Private/PublicPages");
});
```

The specified path is the View Engine path, which is the Razor Pages root relative path.

Note on combining authorized and anonymous access

It's valid to specify that a folder of pages requires authorization and then specify that a page within that folder allows anonymous access:

```
// This works.
.AuthorizeFolder("/Private").AllowAnonymousToPage("/Private/Public")
```

The reverse, however, isn't valid. You can't declare a folder of pages for anonymous access and then specify a page within that folder that requires authorization:

```
// This doesn't work!
.AllowAnonymousToFolder("/Public").AuthorizePage("/Public/Private")
```

Requiring authorization on the Private page fails. When both the AllowAnonymousFilter and AuthorizeFilter are applied to the page, the AllowAnonymousFilter takes precedence and controls access.

Require authorization to access a page

Use the AuthorizePage convention via AddRazorPagesOptions to add an AuthorizeFilter to the page at the specified path:

```
services.AddMvc()
    .AddRazorPagesOptions(options =>
    {
        options.Conventions.AuthorizePage("/Contact");
        options.Conventions.AuthorizeFolder("/Private");
        options.Conventions.AllowAnonymousToPage("/Private/PublicPage");
        options.Conventions.AllowAnonymousToFolder("/Private/PublicPages");
    })
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

The specified path is the View Engine path, which is the Razor Pages root relative path without an extension and containing only forward slashes.

To specify an authorization policy, use an AuthorizePage overload:

```
options.Conventions.AuthorizePage("/Contact", "AtLeast21");
```

> **NOTE**
> An AuthorizeFilter can be applied to a page model class with the `[Authorize]` filter attribute. For more information, see Authorize filter attribute.

Require authorization to access a folder of pages

Use the AuthorizeFolder convention via AddRazorPagesOptions to add an AuthorizeFilter to all of the pages in a folder at the specified path:

```
services.AddMvc()
    .AddRazorPagesOptions(options =>
    {
        options.Conventions.AuthorizePage("/Contact");
        options.Conventions.AuthorizeFolder("/Private");
        options.Conventions.AllowAnonymousToPage("/Private/PublicPage");
        options.Conventions.AllowAnonymousToFolder("/Private/PublicPages");
    })
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

The specified path is the View Engine path, which is the Razor Pages root relative path.

To specify an authorization policy, use an AuthorizeFolder overload:

```
options.Conventions.AuthorizeFolder("/Private", "AtLeast21");
```

Require authorization to access an area page

Use the AuthorizeAreaPage convention via AddRazorPagesOptions to add an AuthorizeFilter to the area page at the specified path:

```
options.Conventions.AuthorizeAreaPage("Identity", "/Manage/Accounts");
```

The page name is the path of the file without an extension relative to the pages root directory for the specified area. For example, the page name for the file *Areas/Identity/Pages/Manage/Accounts.cshtml* is */Manage/Accounts*.

To specify an authorization policy, use an AuthorizeAreaPage overload:

```
options.Conventions.AuthorizeAreaPage("Identity", "/Manage/Accounts", "AtLeast21");
```

Require authorization to access a folder of areas

Use the AuthorizeAreaFolder convention via AddRazorPagesOptions to add an AuthorizeFilter to all of the areas in a folder at the specified path:

```
options.Conventions.AuthorizeAreaFolder("Identity", "/Manage");
```

The folder path is the path of the folder relative to the pages root directory for the specified area. For example, the folder path for the files under *Areas/Identity/Pages/Manage/* is */Manage*.

To specify an authorization policy, use an AuthorizeAreaFolder overload:

```
options.Conventions.AuthorizeAreaFolder("Identity", "/Manage", "AtLeast21");
```

Allow anonymous access to a page

Use the AllowAnonymousToPage convention via AddRazorPagesOptions to add an AllowAnonymousFilter to a page at the specified path:

```
services.AddMvc()
    .AddRazorPagesOptions(options =>
    {
        options.Conventions.AuthorizePage("/Contact");
        options.Conventions.AuthorizeFolder("/Private");
        options.Conventions.AllowAnonymousToPage("/Private/PublicPage");
        options.Conventions.AllowAnonymousToFolder("/Private/PublicPages");
    })
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

The specified path is the View Engine path, which is the Razor Pages root relative path without an extension and containing only forward slashes.

Allow anonymous access to a folder of pages

Use the AllowAnonymousToFolder convention via AddRazorPagesOptions to add an AllowAnonymousFilter to all of the pages in a folder at the specified path:

```
services.AddMvc()
    .AddRazorPagesOptions(options =>
    {
        options.Conventions.AuthorizePage("/Contact");
        options.Conventions.AuthorizeFolder("/Private");
        options.Conventions.AllowAnonymousToPage("/Private/PublicPage");
        options.Conventions.AllowAnonymousToFolder("/Private/PublicPages");
    })
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

The specified path is the View Engine path, which is the Razor Pages root relative path.

Note on combining authorized and anonymous access

It's valid to specify that a folder of pages that require authorization and than specify that a page within that folder allows anonymous access:

```
// This works.
.AuthorizeFolder("/Private").AllowAnonymousToPage("/Private/Public")
```

The reverse, however, isn't valid. You can't declare a folder of pages for anonymous access and then specify a page within that folder that requires authorization:

```
// This doesn't work!
.AllowAnonymousToFolder("/Public").AuthorizePage("/Public/Private")
```

Requiring authorization on the Private page fails. When both the AllowAnonymousFilter and AuthorizeFilter are applied to the page, the AllowAnonymousFilter takes precedence and controls access.

Simple authorization in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

Authorization in ASP.NET Core is controlled with AuthorizeAttribute and its various parameters. In its simplest form, applying the `[Authorize]` attribute to a controller, action, or Razor Page, limits access to that component to any authenticated user.

For example, the following code limits access to the `AccountController` to any authenticated user.

```
[Authorize]
public class AccountController : Controller
{
    public ActionResult Login()
    {
    }

    public ActionResult Logout()
    {
    }
}
```

If you want to apply authorization to an action rather than the controller, apply the `AuthorizeAttribute` attribute to the action itself:

```
public class AccountController : Controller
{
   public ActionResult Login()
   {
   }

   [Authorize]
   public ActionResult Logout()
   {
   }
}
```

Now only authenticated users can access the `Logout` function.

You can also use the `AllowAnonymous` attribute to allow access by non-authenticated users to individual actions. For example:

```
[Authorize]
public class AccountController : Controller
{
    [AllowAnonymous]
    public ActionResult Login()
    {
    }

    public ActionResult Logout()
    {
    }
}
```

This would allow only authenticated users to the `AccountController`, except for the `Login` action, which is

accessible by everyone, regardless of their authenticated or unauthenticated / anonymous status.

> **WARNING**
> `[AllowAnonymous]` bypasses all authorization statements. If you combine `[AllowAnonymous]` and any `[Authorize]` attribute, the `[Authorize]` attributes are ignored. For example if you apply `[AllowAnonymous]` at the controller level, any `[Authorize]` attributes on the same controller (or on any action within it) is ignored.

For information on how to globally require all users to be authenticated, see Require authenticated users.

Authorize attribute and Razor Pages

The AuthorizeAttribute can ***not*** be applied to Razor Page handlers. For example, `[Authorize]` can't be applied to `OnGet`, `OnPost`, or any other page handler. Consider using an ASP.NET Core MVC controller for pages with different authorization requirements for different handlers.

The following two approaches can be used to apply authorization to Razor Page handler methods:

- Use separate pages for page handlers requiring different authorization. Moved shared content into one or more partial views. When possible, this is the recommended approach.
- For content that must share a common page, write a filter that performs authorization as part of IAsyncPageFilter.OnPageHandlerSelectionAsync. The PageHandlerAuth GitHub project demonstrates this approach:
  - The AuthorizeIndexPageHandlerFilter implements the authorization filter:

```
[TypeFilter(typeof(AuthorizeIndexPageHandlerFilter))]
public class IndexModel : PageModel
{
    private readonly ILogger<IndexModel> _logger;

    public IndexModel(ILogger<IndexModel> logger)
    {
        _logger = logger;
    }

    public void OnGet()
    {

    }

    public void OnPost()
    {

    }

    [AuthorizePageHandler]
    public void OnPostAuthorized()
    {

    }
}
```

  - The [AuthorizePageHandler] attribute is applied to the `OnGet` page handler:

```
public class AuthorizeIndexPageHandlerFilter : IAsyncPageFilter, IOrderedFilter
{
    private readonly IAuthorizationPolicyProvider policyProvider;
    private readonly IPolicyEvaluator policyEvaluator;
```

```
    public AuthorizeIndexPageHandlerFilter(
        IAuthorizationPolicyProvider policyProvider,
        IPolicyEvaluator policyEvaluator)
    {
        this.policyProvider = policyProvider;
        this.policyEvaluator = policyEvaluator;
    }

    // Run late in the selection pipeline
    public int Order => 10000;

    public Task OnPageHandlerExecutionAsync(PageHandlerExecutingContext context,
PageHandlerExecutionDelegate next) => next();

    public async Task OnPageHandlerSelectionAsync(PageHandlerSelectedContext context)
    {
        var attribute =
context.HandlerMethod?.MethodInfo?.GetCustomAttribute<AuthorizePageHandlerAttribute>();
        if (attribute is null)
        {
            return;
        }

        var policy = await AuthorizationPolicy.CombineAsync(policyProvider, new[] { attribute });
        if (policy is null)
        {
            return;
        }

        await AuthorizeAsync(context, policy);
    }

    #region AuthZ - do not change
    private async Task AuthorizeAsync(ActionContext actionContext, AuthorizationPolicy policy)
    {
        var httpContext = actionContext.HttpContext;
        var authenticateResult = await policyEvaluator.AuthenticateAsync(policy, httpContext);
        var authorizeResult = await policyEvaluator.AuthorizeAsync(policy, authenticateResult,
httpContext, actionContext.ActionDescriptor);
        if (authorizeResult.Challenged)
        {
            if (policy.AuthenticationSchemes.Count > 0)
            {
                foreach (var scheme in policy.AuthenticationSchemes)
                {
                    await httpContext.ChallengeAsync(scheme);
                }
            }
            else
            {
                await httpContext.ChallengeAsync();
            }

            return;
        }
        else if (authorizeResult.Forbidden)
        {
            if (policy.AuthenticationSchemes.Count > 0)
            {
                foreach (var scheme in policy.AuthenticationSchemes)
                {
                    await httpContext.ForbidAsync(scheme);
                }
            }
            else
            {
                await httpContext.ForbidAsync();
            }
```

```
            return;
        }
    }
```

WARNING

The PageHandlerAuth sample approach does ***not***:

- Compose with authorization attributes applied to the page, page model, or globally. Composing authorization attributes results in authentication and authorization executing multiple times when you have one more `AuthorizeAttribute` or `AuthorizeFilter` instances also applied to the page.
- Work in conjunction with the rest of ASP.NET Core authentication and authorization system. You must verify using this approach works correctly for your application.

There are no plans to support the `AuthorizeAttribute` on Razor Page handlers.

Role-based authorization in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

When an identity is created it may belong to one or more roles. For example, Tracy may belong to the Administrator and User roles whilst Scott may only belong to the User role. How these roles are created and managed depends on the backing store of the authorization process. Roles are exposed to the developer through the IsInRole method on the ClaimsPrincipal class.

Adding role checks

Role-based authorization checks are declarative—the developer embeds them within their code, against a controller or an action within a controller, specifying roles which the current user must be a member of to access the requested resource.

For example, the following code limits access to any actions on the `AdministrationController` to users who are a member of the `Administrator` role:

```
[Authorize(Roles = "Administrator")]
public class AdministrationController : Controller
{
}
```

You can specify multiple roles as a comma separated list:

```
[Authorize(Roles = "HRManager,Finance")]
public class SalaryController : Controller
{
}
```

This controller would be only accessible by users who are members of the `HRManager` role or the `Finance` role.

If you apply multiple attributes then an accessing user must be a member of all the roles specified; the following sample requires that a user must be a member of both the `PowerUser` and `ControlPanelUser` role.

```
[Authorize(Roles = "PowerUser")]
[Authorize(Roles = "ControlPanelUser")]
public class ControlPanelController : Controller
{
}
```

You can further limit access by applying additional role authorization attributes at the action level:

```
[Authorize(Roles = "Administrator, PowerUser")]
public class ControlPanelController : Controller
{
    public ActionResult SetTime()
    {
    }

    [Authorize(Roles = "Administrator")]
    public ActionResult ShutDown()
    {
    }
}
```

In the previous code snippet members of the `Administrator` role or the `PowerUser` role can access the controller and the `SetTime` action, but only members of the `Administrator` role can access the `ShutDown` action.

You can also lock down a controller but allow anonymous, unauthenticated access to individual actions.

```
[Authorize]
public class ControlPanelController : Controller
{
    public ActionResult SetTime()
    {
    }

    [AllowAnonymous]
    public ActionResult Login()
    {
    }
}
```

For Razor Pages, the `AuthorizeAttribute` can be applied by either:

- Using a convention, or
- Applying the `AuthorizeAttribute` to the `PageModel` instance:

```
[Authorize(Policy = "RequireAdministratorRole")]
public class UpdateModel : PageModel
{
    public ActionResult OnPost()
    {
    }
}
```

IMPORTANT

Filter attributes, including `AuthorizeAttribute`, can only be applied to PageModel and cannot be applied to specific page handler methods.

Policy based role checks

Role requirements can also be expressed using the new Policy syntax, where a developer registers a policy at startup as part of the Authorization service configuration. This normally occurs in `ConfigureServices()` in your *Startup.cs* file.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();
    services.AddRazorPages();

    services.AddAuthorization(options =>
    {
        options.AddPolicy("RequireAdministratorRole",
             policy => policy.RequireRole("Administrator"));
    });
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc();

    services.AddAuthorization(options =>
    {
        options.AddPolicy("RequireAdministratorRole",
             policy => policy.RequireRole("Administrator"));
    });
}
```

Policies are applied using the `Policy` property on the `AuthorizeAttribute` attribute:

```
[Authorize(Policy = "RequireAdministratorRole")]
public IActionResult Shutdown()
{
    return View();
}
```

If you want to specify multiple allowed roles in a requirement then you can specify them as parameters to the `RequireRole` method:

```
options.AddPolicy("ElevatedRights", policy =>
                  policy.RequireRole("Administrator", "PowerUser", "BackupAdministrator"));
```

This example authorizes users who belong to the `Administrator`, `PowerUser` or `BackupAdministrator` roles.

Add Role services to Identity

Append AddRoles to add Role services:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>()
        .AddRoles<IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext>();

    services.AddControllersWithViews();
    services.AddRazorPages();
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>()
        .AddRoles<IdentityRole>()
        .AddDefaultUI(UIFramework.Bootstrap4)
        .AddEntityFrameworkStores<ApplicationDbContext>();

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

Claims-based authorization in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

When an identity is created it may be assigned one or more claims issued by a trusted party. A claim is a name value pair that represents what the subject is, not what the subject can do. For example, you may have a driver's license, issued by a local driving license authority. Your driver's license has your date of birth on it. In this case the claim name would be `DateOfBirth`, the claim value would be your date of birth, for example `8th June 1970` and the issuer would be the driving license authority. Claims based authorization, at its simplest, checks the value of a claim and allows access to a resource based upon that value. For example if you want access to a night club the authorization process might be:

The door security officer would evaluate the value of your date of birth claim and whether they trust the issuer (the driving license authority) before granting you access.

An identity can contain multiple claims with multiple values and can contain multiple claims of the same type.

Adding claims checks

Claim based authorization checks are declarative - the developer embeds them within their code, against a controller or an action within a controller, specifying claims which the current user must possess, and optionally the value the claim must hold to access the requested resource. Claims requirements are policy based, the developer must build and register a policy expressing the claims requirements.

The simplest type of claim policy looks for the presence of a claim and doesn't check the value.

First you need to build and register the policy. This takes place as part of the Authorization service configuration, which normally takes part in `ConfigureServices()` in your *Startup.cs* file.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();
    services.AddRazorPages();

    services.AddAuthorization(options =>
    {
        options.AddPolicy("EmployeeOnly", policy => policy.RequireClaim("EmployeeNumber"));
    });
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc();

    services.AddAuthorization(options =>
    {
        options.AddPolicy("EmployeeOnly", policy => policy.RequireClaim("EmployeeNumber"));
    });
}
```

In this case the `EmployeeOnly` policy checks for the presence of an `EmployeeNumber` claim on the current identity.

You then apply the policy using the `Policy` property on the `AuthorizeAttribute` attribute to specify the policy name;

```
[Authorize(Policy = "EmployeeOnly")]
public IActionResult VacationBalance()
{
    return View();
}
```

The `AuthorizeAttribute` attribute can be applied to an entire controller, in this instance only identities matching the policy will be allowed access to any Action on the controller.

```
[Authorize(Policy = "EmployeeOnly")]
public class VacationController : Controller
{
    public ActionResult VacationBalance()
    {
    }
}
```

If you have a controller that's protected by the `AuthorizeAttribute` attribute, but want to allow anonymous access to particular actions you apply the `AllowAnonymousAttribute` attribute.

```
[Authorize(Policy = "EmployeeOnly")]
public class VacationController : Controller
{
    public ActionResult VacationBalance()
    {
    }

    [AllowAnonymous]
    public ActionResult VacationPolicy()
    {
    }
}
```

Most claims come with a value. You can specify a list of allowed values when creating the policy. The following example would only succeed for employees whose employee number was 1, 2, 3, 4 or 5.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();
    services.AddRazorPages();

    services.AddAuthorization(options =>
    {
        options.AddPolicy("Founders", policy =>
                          policy.RequireClaim("EmployeeNumber", "1", "2", "3", "4", "5"));
    });
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc();

    services.AddAuthorization(options =>
    {
        options.AddPolicy("Founders", policy =>
                          policy.RequireClaim("EmployeeNumber", "1", "2", "3", "4", "5"));
    });
}
```

Add a generic claim check

If the claim value isn't a single value or a transformation is required, use RequireAssertion. For more information, see Use a func to fulfill a policy.

Multiple Policy Evaluation

If you apply multiple policies to a controller or action, then all policies must pass before access is granted. For example:

```
[Authorize(Policy = "EmployeeOnly")]
public class SalaryController : Controller
{
    public ActionResult Payslip()
    {
    }

    [Authorize(Policy = "HumanResources")]
    public ActionResult UpdateSalary()
    {
    }
}
```

In the above example any identity which fulfills the `EmployeeOnly` policy can access the `Payslip` action as that policy is enforced on the controller. However in order to call the `UpdateSalary` action the identity must fulfill *both* the `EmployeeOnly` policy and the `HumanResources` policy.

If you want more complicated policies, such as taking a date of birth claim, calculating an age from it then checking the age is 21 or older then you need to write custom policy handlers.

Policy-based authorization in ASP.NET Core

9/22/2020 • 20 minutes to read • Edit Online

Underneath the covers, role-based authorization and claims-based authorization use a requirement, a requirement handler, and a pre-configured policy. These building blocks support the expression of authorization evaluations in code. The result is a richer, reusable, testable authorization structure.

An authorization policy consists of one or more requirements. It's registered as part of the authorization service configuration, in the `Startup.ConfigureServices` method:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();
    services.AddRazorPages();
    services.AddAuthorization(options =>
    {
        options.AddPolicy("AtLeast21", policy =>
            policy.Requirements.Add(new MinimumAgeRequirement(21)));
    });
}
```

In the preceding example, an "AtLeast21" policy is created. It has a single requirement—that of a minimum age, which is supplied as a parameter to the requirement.

IAuthorizationService

The primary service that determines if authorization is successful is IAuthorizationService:

```
/// <summary>
/// Checks policy based permissions for a user
/// </summary>
public interface IAuthorizationService
{
    /// <summary>
    /// Checks if a user meets a specific set of requirements for the specified resource
    /// </summary>
    /// <param name="user">The user to evaluate the requirements against.</param>
    /// <param name="resource">
    /// An optional resource the policy should be checked with.
    /// If a resource is not required for policy evaluation you may pass null as the value
    /// </param>
    /// <param name="requirements">The requirements to evaluate.</param>
    /// <returns>
    /// A flag indicating whether authorization has succeeded.
    /// This value is <value>true</value> when the user fulfills the policy;
    /// otherwise <value>false</value>.
    /// </returns>
    /// <remarks>
    /// Resource is an optional parameter and may be null. Please ensure that you check
    /// it is not null before acting upon it.
    /// </remarks>
    Task<AuthorizationResult> AuthorizeAsync(ClaimsPrincipal user, object resource,
                                     IEnumerable<IAuthorizationRequirement> requirements);

    /// <summary>
    /// Checks if a user meets a specific authorization policy
    /// </summary>
    /// <param name="user">The user to check the policy against.</param>
    /// <param name="resource">
    /// An optional resource the policy should be checked with.
    /// If a resource is not required for policy evaluation you may pass null as the value
    /// </param>
    /// <param name="policyName">The name of the policy to check against a specific
    /// context.</param>
    /// <returns>
    /// A flag indicating whether authorization has succeeded.
    /// Returns a flag indicating whether the user, and optional resource has fulfilled
    /// the policy.
    /// <value>true</value> when the policy has been fulfilled;
    /// otherwise <value>false</value>.
    /// </returns>
    /// <remarks>
    /// Resource is an optional parameter and may be null. Please ensure that you check
    /// it is not null before acting upon it.
    /// </remarks>
    Task<AuthorizationResult> AuthorizeAsync(
                                ClaimsPrincipal user, object resource, string policyName);
}
```

The preceding code highlights the two methods of the IAuthorizationService.

IAuthorizationRequirement is a marker service with no methods, and the mechanism for tracking whether authorization is successful.

Each IAuthorizationHandler is responsible for checking if requirements are met:

```
/// <summary>
/// Classes implementing this interface are able to make a decision if authorization
/// is allowed.
/// </summary>
public interface IAuthorizationHandler
{
    /// <summary>
    /// Makes a decision if authorization is allowed.
    /// </summary>
    /// <param name="context">The authorization information.</param>
    Task HandleAsync(AuthorizationHandlerContext context);
}
```

The AuthorizationHandlerContext class is what the handler uses to mark whether requirements have been met:

```
 context.Succeed(requirement)
```

The following code shows the simplified (and annotated with comments) default implementation of the authorization service:

```
public async Task<AuthorizationResult> AuthorizeAsync(ClaimsPrincipal user,
             object resource, IEnumerable<IAuthorizationRequirement> requirements)
{
    // Create a tracking context from the authorization inputs.
    var authContext = _contextFactory.CreateContext(requirements, user, resource);

    // By default this returns an IEnumerable<IAuthorizationHandlers> from DI.
    var handlers = await _handlers.GetHandlersAsync(authContext);

    // Invoke all handlers.
    foreach (var handler in handlers)
    {
        await handler.HandleAsync(authContext);
    }

    // Check the context, by default success is when all requirements have been met.
    return _evaluator.Evaluate(authContext);
}
```

The following code shows a typical `ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    // Add all of your handlers to DI.
    services.AddSingleton<IAuthorizationHandler, MyHandler1>();
    // MyHandler2, ...

    services.AddSingleton<IAuthorizationHandler, MyHandlerN>();

    // Configure your policies
    services.AddAuthorization(options =>
          options.AddPolicy("Something",
          policy => policy.RequireClaim("Permission", "CanViewPage", "CanViewAnything")));

    services.AddControllersWithViews();
    services.AddRazorPages();
}
```

Use IAuthorizationService or `[Authorize(Policy = "Something")]` for authorization.

Apply policies to MVC controllers

If you're using Razor Pages, see Apply policies to Razor Pages in this document.

Policies are applied to controllers by using the `[Authorize]` attribute with the policy name. For example:

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;

[Authorize(Policy = "AtLeast21")]
public class AlcoholPurchaseController : Controller
{
    public IActionResult Index() => View();
}
```

Apply policies to Razor Pages

Policies are applied to Razor Pages by using the `[Authorize]` attribute with the policy name. For example:

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc.RazorPages;

[Authorize(Policy = "AtLeast21")]
public class AlcoholPurchaseModel : PageModel
{
}
```

Policies can ***not*** be applied at the Razor Page handler level, they must be applied to the Page.

Policies can be applied to Razor Pages by using an authorization convention.

Requirements

An authorization requirement is a collection of data parameters that a policy can use to evaluate the current user principal. In our "AtLeast21" policy, the requirement is a single parameter—the minimum age. A requirement implements IAuthorizationRequirement, which is an empty marker interface. A parameterized minimum age requirement could be implemented as follows:

```
using Microsoft.AspNetCore.Authorization;

public class MinimumAgeRequirement : IAuthorizationRequirement
{
    public int MinimumAge { get; }

    public MinimumAgeRequirement(int minimumAge)
    {
        MinimumAge = minimumAge;
    }
}
```

If an authorization policy contains multiple authorization requirements, all requirements must pass in order for the policy evaluation to succeed. In other words, multiple authorization requirements added to a single authorization policy are treated on an **AND** basis.

> **NOTE**
>
> A requirement doesn't need to have data or properties.

Authorization handlers

An authorization handler is responsible for the evaluation of a requirement's properties. The authorization handler evaluates the requirements against a provided AuthorizationHandlerContext to determine if access is allowed.

A requirement can have multiple handlers. A handler may inherit AuthorizationHandler<TRequirement>, where `TRequirement` is the requirement to be handled. Alternatively, a handler may implement IAuthorizationHandler to handle more than one type of requirement.

Use a handler for one requirement

The following is an example of a one-to-one relationship in which a minimum age handler utilizes a single requirement:

```
using System;
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using PoliciesAuthApp1.Services.Requirements;

public class MinimumAgeHandler : AuthorizationHandler<MinimumAgeRequirement>
{
    protected override Task HandleRequirementAsync(AuthorizationHandlerContext context,
                                                   MinimumAgeRequirement requirement)
    {
        if (!context.User.HasClaim(c => c.Type == ClaimTypes.DateOfBirth &&
                                        c.Issuer == "http://contoso.com"))
        {
            //TODO: Use the following if targeting a version of
            //.NET Framework older than 4.6:
            //      return Task.FromResult(0);
            return Task.CompletedTask;
        }

        var dateOfBirth = Convert.ToDateTime(
            context.User.FindFirst(c => c.Type == ClaimTypes.DateOfBirth &&
                                        c.Issuer == "http://contoso.com").Value);

        int calculatedAge = DateTime.Today.Year - dateOfBirth.Year;
        if (dateOfBirth > DateTime.Today.AddYears(-calculatedAge))
        {
            calculatedAge--;
        }

        if (calculatedAge >= requirement.MinimumAge)
        {
            context.Succeed(requirement);
        }

        //TODO: Use the following if targeting a version of
        //.NET Framework older than 4.6:
        //      return Task.FromResult(0);
        return Task.CompletedTask;
    }
}
```

The preceding code determines if the current user principal has a date of birth claim which has been issued

by a known and trusted Issuer. Authorization can't occur when the claim is missing, in which case a completed task is returned. When a claim is present, the user's age is calculated. If the user meets the minimum age defined by the requirement, authorization is deemed successful. When authorization is successful, `context.Succeed` is invoked with the satisfied requirement as its sole parameter.

Use a handler for multiple requirements

The following is an example of a one-to-many relationship in which a permission handler can handle three different types of requirements:

```
using System.Linq;
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using PoliciesAuthApp1.Services.Requirements;

public class PermissionHandler : IAuthorizationHandler
{
    public Task HandleAsync(AuthorizationHandlerContext context)
    {
        var pendingRequirements = context.PendingRequirements.ToList();

        foreach (var requirement in pendingRequirements)
        {
            if (requirement is ReadPermission)
            {
                if (IsOwner(context.User, context.Resource) ||
                    IsSponsor(context.User, context.Resource))
                {
                    context.Succeed(requirement);
                }
            }
            else if (requirement is EditPermission ||
                     requirement is DeletePermission)
            {
                if (IsOwner(context.User, context.Resource))
                {
                    context.Succeed(requirement);
                }
            }
        }

        //TODO: Use the following if targeting a version of
        //.NET Framework older than 4.6:
        //      return Task.FromResult(0);
        return Task.CompletedTask;
    }

    private bool IsOwner(ClaimsPrincipal user, object resource)
    {
        // Code omitted for brevity

        return true;
    }

    private bool IsSponsor(ClaimsPrincipal user, object resource)
    {
        // Code omitted for brevity

        return true;
    }
}
```

The preceding code traverses PendingRequirements—a property containing requirements not marked as successful. For a `ReadPermission` requirement, the user must be either an owner or a sponsor to access the

requested resource. In the case of an `EditPermission` or `DeletePermission` requirement, he or she must be an owner to access the requested resource.

Handler registration

Handlers are registered in the services collection during configuration. For example:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();
    services.AddRazorPages();
    services.AddAuthorization(options =>
    {
        options.AddPolicy("AtLeast21", policy =>
            policy.Requirements.Add(new MinimumAgeRequirement(21)));
    });

    services.AddSingleton<IAuthorizationHandler, MinimumAgeHandler>();
}
```

The preceding code registers `MinimumAgeHandler` as a singleton by invoking `services.AddSingleton<IAuthorizationHandler, MinimumAgeHandler>();`. Handlers can be registered using any of the built-in service lifetimes.

What should a handler return?

Note that the `Handle` method in the handler example returns no value. How is a status of either success or failure indicated?

- A handler indicates success by calling `context.Succeed(IAuthorizationRequirement requirement)`, passing the requirement that has been successfully validated.
- A handler doesn't need to handle failures generally, as other handlers for the same requirement may succeed.
- To guarantee failure, even if other requirement handlers succeed, call `context.Fail`.

If a handler calls `context.Succeed` or `context.Fail`, all other handlers are still called. This allows requirements to produce side effects, such as logging, which takes place even if another handler has successfully validated or failed a requirement. When set to `false`, the InvokeHandlersAfterFailure property (available in ASP.NET Core 1.1 and later) short-circuits the execution of handlers when `context.Fail` is called. `InvokeHandlersAfterFailure` defaults to `true`, in which case all handlers are called.

> **NOTE**
> Authorization handlers are called even if authentication fails.

Why would I want multiple handlers for a requirement?

In cases where you want evaluation to be on an **OR** basis, implement multiple handlers for a single requirement. For example, Microsoft has doors which only open with key cards. If you leave your key card at home, the receptionist prints a temporary sticker and opens the door for you. In this scenario, you'd have a single requirement, *BuildingEntry*, but multiple handlers, each one examining a single requirement.

BuildingEntryRequirement.cs

```
using Microsoft.AspNetCore.Authorization;

public class BuildingEntryRequirement : IAuthorizationRequirement
{
}
```

BadgeEntryHandler.cs

```
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using PoliciesAuthApp1.Services.Requirements;

public class BadgeEntryHandler : AuthorizationHandler<BuildingEntryRequirement>
{
    protected override Task HandleRequirementAsync(AuthorizationHandlerContext context,
                                                   BuildingEntryRequirement requirement)
    {
        if (context.User.HasClaim(c => c.Type == "BadgeId" &&
                                       c.Issuer == "http://microsoftsecurity"))
        {
            context.Succeed(requirement);
        }

        //TODO: Use the following if targeting a version of
        //.NET Framework older than 4.6:
        //      return Task.FromResult(0);
        return Task.CompletedTask;
    }
}
```

TemporaryStickerHandler.cs

```
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using PoliciesAuthApp1.Services.Requirements;

public class TemporaryStickerHandler : AuthorizationHandler<BuildingEntryRequirement>
{
    protected override Task HandleRequirementAsync(AuthorizationHandlerContext context,
                                                   BuildingEntryRequirement requirement)
    {
        if (context.User.HasClaim(c => c.Type == "TemporaryBadgeId" &&
                                       c.Issuer == "https://microsoftsecurity"))
        {
            // We'd also check the expiration date on the sticker.
            context.Succeed(requirement);
        }

        //TODO: Use the following if targeting a version of
        //.NET Framework older than 4.6:
        //      return Task.FromResult(0);
        return Task.CompletedTask;
    }
}
```

Ensure that both handlers are registered. If either handler succeeds when a policy evaluates the `BuildingEntryRequirement`, the policy evaluation succeeds.

Use a func to fulfill a policy

There may be situations in which fulfilling a policy is simple to express in code. It's possible to supply a `Func<AuthorizationHandlerContext, bool>` when configuring your policy with the `RequireAssertion` policy builder.

For example, the previous `BadgeEntryHandler` could be rewritten as follows:

```
services.AddAuthorization(options =>
{
     options.AddPolicy("BadgeEntry", policy =>
        policy.RequireAssertion(context =>
            context.User.HasClaim(c =>
                (c.Type == "BadgeId" ||
                 c.Type == "TemporaryBadgeId") &&
                 c.Issuer == "https://microsoftsecurity")));
});
```

Access MVC request context in handlers

The `HandleRequirementAsync` method you implement in an authorization handler has two parameters: an `AuthorizationHandlerContext` and the `TRequirement` you are handling. Frameworks such as MVC or SignalR are free to add any object to the `Resource` property on the `AuthorizationHandlerContext` to pass extra information.

When using endpoint routing, authorization is typically handled by the Authorization Middleware. In this case, the `Resource` property is an instance of Endpoint. The endpoint can be used to probe the underlying resource to which you're routing. For example:

```
if (context.Resource is Endpoint endpoint)
{
   var actionDescriptor = endpoint.Metadata.GetMetadata<ControllerActionDescriptor>();
   ...
}
```

The endpoint doesn't provide access to the current `HttpContext`. When using endpoint routing, use `IHttpContextAcessor` to access `HttpContext` inside of an authorization handler. For more information, see Use HttpContext from custom components.

With traditional routing, or when authorization happens as part of MVC's authorization filter, the value of `Resource` is an AuthorizationFilterContext instance. This property provides access to `HttpContext`, `RouteData`, and everything else provided by MVC and Razor Pages.

The use of the `Resource` property is framework specific. Using information in the `Resource` property limits your authorization policies to particular frameworks. You should cast the `Resource` property using the `is` keyword, and then confirm the cast has succeeded to ensure your code doesn't crash with an `InvalidCastException` when run on other frameworks:

```
// Requires the following import:
//     using Microsoft.AspNetCore.Mvc.Filters;
if (context.Resource is AuthorizationFilterContext mvcContext)
{
    // Examine MVC-specific things like routing data.
}
```

Globally require all users to be authenticated

For information on how to globally require all users to be authenticated, see Require authenticated users.

Underneath the covers, role-based authorization and claims-based authorization use a requirement, a requirement handler, and a pre-configured policy. These building blocks support the expression of authorization evaluations in code. The result is a richer, reusable, testable authorization structure.

An authorization policy consists of one or more requirements. It's registered as part of the authorization service configuration, in the `Startup.ConfigureServices` method:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    services.AddAuthorization(options =>
    {
        options.AddPolicy("AtLeast21", policy =>
            policy.Requirements.Add(new MinimumAgeRequirement(21)));
    });
}
```

In the preceding example, an "AtLeast21" policy is created. It has a single requirement—that of a minimum age, which is supplied as a parameter to the requirement.

IAuthorizationService

The primary service that determines if authorization is successful is IAuthorizationService:

```
/// <summary>
/// Checks policy based permissions for a user
/// </summary>
public interface IAuthorizationService
{
    /// <summary>
    /// Checks if a user meets a specific set of requirements for the specified resource
    /// </summary>
    /// <param name="user">The user to evaluate the requirements against.</param>
    /// <param name="resource">
    /// An optional resource the policy should be checked with.
    /// If a resource is not required for policy evaluation you may pass null as the value
    /// </param>
    /// <param name="requirements">The requirements to evaluate.</param>
    /// <returns>
    /// A flag indicating whether authorization has succeeded.
    /// This value is <value>true</value> when the user fulfills the policy;
    /// otherwise <value>false</value>.
    /// </returns>
    /// <remarks>
    /// Resource is an optional parameter and may be null. Please ensure that you check
    /// it is not null before acting upon it.
    /// </remarks>
    Task<AuthorizationResult> AuthorizeAsync(ClaimsPrincipal user, object resource,
                                    IEnumerable<IAuthorizationRequirement> requirements);

    /// <summary>
    /// Checks if a user meets a specific authorization policy
    /// </summary>
    /// <param name="user">The user to check the policy against.</param>
    /// <param name="resource">
    /// An optional resource the policy should be checked with.
    /// If a resource is not required for policy evaluation you may pass null as the value
    /// </param>
    /// <param name="policyName">The name of the policy to check against a specific
    /// context.</param>
    /// <returns>
    /// A flag indicating whether authorization has succeeded.
    /// Returns a flag indicating whether the user, and optional resource has fulfilled
    /// the policy.
    /// <value>true</value> when the policy has been fulfilled;
    /// otherwise <value>false</value>.
    /// </returns>
    /// <remarks>
    /// Resource is an optional parameter and may be null. Please ensure that you check
    /// it is not null before acting upon it.
    /// </remarks>
    Task<AuthorizationResult> AuthorizeAsync(
                                ClaimsPrincipal user, object resource, string policyName);
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

The preceding code highlights the two methods of the IAuthorizationService.

IAuthorizationRequirement is a marker service with no methods, and the mechanism for tracking whether authorization is successful.

Each IAuthorizationHandler is responsible for checking if requirements are met:

```
/// <summary>
/// Classes implementing this interface are able to make a decision if authorization
/// is allowed.
/// </summary>
public interface IAuthorizationHandler
{
    /// <summary>
    /// Makes a decision if authorization is allowed.
    /// </summary>
    /// <param name="context">The authorization information.</param>
    Task HandleAsync(AuthorizationHandlerContext context);
}
```

The AuthorizationHandlerContext class is what the handler uses to mark whether requirements have been met:

```
 context.Succeed(requirement)
```

The following code shows the simplified (and annotated with comments) default implementation of the authorization service:

```
public async Task<AuthorizationResult> AuthorizeAsync(ClaimsPrincipal user,
             object resource, IEnumerable<IAuthorizationRequirement> requirements)
{
    // Create a tracking context from the authorization inputs.
    var authContext = _contextFactory.CreateContext(requirements, user, resource);

    // By default this returns an IEnumerable<IAuthorizationHandlers> from DI.
    var handlers = await _handlers.GetHandlersAsync(authContext);

    // Invoke all handlers.
    foreach (var handler in handlers)
    {
        await handler.HandleAsync(authContext);
    }

    // Check the context, by default success is when all requirements have been met.
    return _evaluator.Evaluate(authContext);
}
```

The following code shows a typical `ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    // Add all of your handlers to DI.
    services.AddSingleton<IAuthorizationHandler, MyHandler1>();
    // MyHandler2, ...

    services.AddSingleton<IAuthorizationHandler, MyHandlerN>();

    // Configure your policies
    services.AddAuthorization(options =>
          options.AddPolicy("Something",
          policy => policy.RequireClaim("Permission", "CanViewPage", "CanViewAnything")));

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

Use IAuthorizationService or `[Authorize(Policy = "Something")]` for authorization.

Apply policies to MVC controllers

If you're using Razor Pages, see Apply policies to Razor Pages in this document.

Policies are applied to controllers by using the `[Authorize]` attribute with the policy name. For example:

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;

[Authorize(Policy = "AtLeast21")]
public class AlcoholPurchaseController : Controller
{
    public IActionResult Index() => View();
}
```

Apply policies to Razor Pages

Policies are applied to Razor Pages by using the `[Authorize]` attribute with the policy name. For example:

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc.RazorPages;

[Authorize(Policy = "AtLeast21")]
public class AlcoholPurchaseModel : PageModel
{
}
```

Policies can also be applied to Razor Pages by using an authorization convention.

Requirements

An authorization requirement is a collection of data parameters that a policy can use to evaluate the current user principal. In our "AtLeast21" policy, the requirement is a single parameter—the minimum age. A requirement implements IAuthorizationRequirement, which is an empty marker interface. A parameterized minimum age requirement could be implemented as follows:

```
using Microsoft.AspNetCore.Authorization;

public class MinimumAgeRequirement : IAuthorizationRequirement
{
    public int MinimumAge { get; }

    public MinimumAgeRequirement(int minimumAge)
    {
        MinimumAge = minimumAge;
    }
}
```

If an authorization policy contains multiple authorization requirements, all requirements must pass in order for the policy evaluation to succeed. In other words, multiple authorization requirements added to a single authorization policy are treated on an **AND** basis.

> **NOTE**
>
> A requirement doesn't need to have data or properties.

Authorization handlers

An authorization handler is responsible for the evaluation of a requirement's properties. The authorization handler evaluates the requirements against a provided AuthorizationHandlerContext to determine if access is allowed.

A requirement can have multiple handlers. A handler may inherit AuthorizationHandler<TRequirement>, where `TRequirement` is the requirement to be handled. Alternatively, a handler may implement IAuthorizationHandler to handle more than one type of requirement.

Use a handler for one requirement

The following is an example of a one-to-one relationship in which a minimum age handler utilizes a single requirement:

```
using System;
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using PoliciesAuthApp1.Services.Requirements;

public class MinimumAgeHandler : AuthorizationHandler<MinimumAgeRequirement>
{
    protected override Task HandleRequirementAsync(AuthorizationHandlerContext context,
                                                   MinimumAgeRequirement requirement)
    {
        if (!context.User.HasClaim(c => c.Type == ClaimTypes.DateOfBirth &&
                                        c.Issuer == "http://contoso.com"))
        {
            //TODO: Use the following if targeting a version of
            //.NET Framework older than 4.6:
            //      return Task.FromResult(0);
            return Task.CompletedTask;
        }

        var dateOfBirth = Convert.ToDateTime(
            context.User.FindFirst(c => c.Type == ClaimTypes.DateOfBirth &&
                                        c.Issuer == "http://contoso.com").Value);

        int calculatedAge = DateTime.Today.Year - dateOfBirth.Year;
        if (dateOfBirth > DateTime.Today.AddYears(-calculatedAge))
        {
            calculatedAge--;
        }

        if (calculatedAge >= requirement.MinimumAge)
        {
            context.Succeed(requirement);
        }

        //TODO: Use the following if targeting a version of
        //.NET Framework older than 4.6:
        //      return Task.FromResult(0);
        return Task.CompletedTask;
    }
}
```

The preceding code determines if the current user principal has a date of birth claim which has been issued by a known and trusted Issuer. Authorization can't occur when the claim is missing, in which case a completed task is returned. When a claim is present, the user's age is calculated. If the user meets the minimum age defined by the requirement, authorization is deemed successful. When authorization is successful, `context.Succeed` is invoked with the satisfied requirement as its sole parameter.

Use a handler for multiple requirements

The following is an example of a one-to-many relationship in which a permission handler can handle three different types of requirements:

```
using System.Linq;
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using PoliciesAuthApp1.Services.Requirements;

public class PermissionHandler : IAuthorizationHandler
{
    public Task HandleAsync(AuthorizationHandlerContext context)
    {
        var pendingRequirements = context.PendingRequirements.ToList();

        foreach (var requirement in pendingRequirements)
        {
            if (requirement is ReadPermission)
            {
                if (IsOwner(context.User, context.Resource) ||
                    IsSponsor(context.User, context.Resource))
                {
                    context.Succeed(requirement);
                }
            }
            else if (requirement is EditPermission ||
                     requirement is DeletePermission)
            {
                if (IsOwner(context.User, context.Resource))
                {
                    context.Succeed(requirement);
                }
            }
        }

        //TODO: Use the following if targeting a version of
        //.NET Framework older than 4.6:
        //      return Task.FromResult(0);
        return Task.CompletedTask;
    }

    private bool IsOwner(ClaimsPrincipal user, object resource)
    {
        // Code omitted for brevity

        return true;
    }

    private bool IsSponsor(ClaimsPrincipal user, object resource)
    {
        // Code omitted for brevity

        return true;
    }
}
```

The preceding code traverses PendingRequirements—a property containing requirements not marked as successful. For a `ReadPermission` requirement, the user must be either an owner or a sponsor to access the requested resource. In the case of an `EditPermission` or `DeletePermission` requirement, he or she must be an owner to access the requested resource.

Handler registration

Handlers are registered in the services collection during configuration. For example:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    services.AddAuthorization(options =>
    {
        options.AddPolicy("AtLeast21", policy =>
            policy.Requirements.Add(new MinimumAgeRequirement(21)));
    });

    services.AddSingleton<IAuthorizationHandler, MinimumAgeHandler>();
}
```

The preceding code registers `MinimumAgeHandler` as a singleton by invoking `services.AddSingleton<IAuthorizationHandler, MinimumAgeHandler>();`. Handlers can be registered using any of the built-in service lifetimes.

What should a handler return?

Note that the `Handle` method in the handler example returns no value. How is a status of either success or failure indicated?

- A handler indicates success by calling `context.Succeed(IAuthorizationRequirement requirement)`, passing the requirement that has been successfully validated.
- A handler doesn't need to handle failures generally, as other handlers for the same requirement may succeed.
- To guarantee failure, even if other requirement handlers succeed, call `context.Fail`.

If a handler calls `context.Succeed` or `context.Fail`, all other handlers are still called. This allows requirements to produce side effects, such as logging, which takes place even if another handler has successfully validated or failed a requirement. When set to `false`, the InvokeHandlersAfterFailure property (available in ASP.NET Core 1.1 and later) short-circuits the execution of handlers when `context.Fail` is called. `InvokeHandlersAfterFailure` defaults to `true`, in which case all handlers are called.

> **NOTE**
> Authorization handlers are called even if authentication fails.

Why would I want multiple handlers for a requirement?

In cases where you want evaluation to be on an **OR** basis, implement multiple handlers for a single requirement. For example, Microsoft has doors which only open with key cards. If you leave your key card at home, the receptionist prints a temporary sticker and opens the door for you. In this scenario, you'd have a single requirement, *BuildingEntry*, but multiple handlers, each one examining a single requirement.

BuildingEntryRequirement.cs

```
using Microsoft.AspNetCore.Authorization;

public class BuildingEntryRequirement : IAuthorizationRequirement
{
}
```

BadgeEntryHandler.cs

```
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using PoliciesAuthApp1.Services.Requirements;

public class BadgeEntryHandler : AuthorizationHandler<BuildingEntryRequirement>
{
    protected override Task HandleRequirementAsync(AuthorizationHandlerContext context,
                                                   BuildingEntryRequirement requirement)
    {
        if (context.User.HasClaim(c => c.Type == "BadgeId" &&
                                       c.Issuer == "http://microsoftsecurity"))
        {
            context.Succeed(requirement);
        }

        //TODO: Use the following if targeting a version of
        //.NET Framework older than 4.6:
        //      return Task.FromResult(0);
        return Task.CompletedTask;
    }
}
```

TemporaryStickerHandler.cs

```
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using PoliciesAuthApp1.Services.Requirements;

public class TemporaryStickerHandler : AuthorizationHandler<BuildingEntryRequirement>
{
    protected override Task HandleRequirementAsync(AuthorizationHandlerContext context,
                                                   BuildingEntryRequirement requirement)
    {
        if (context.User.HasClaim(c => c.Type == "TemporaryBadgeId" &&
                                       c.Issuer == "https://microsoftsecurity"))
        {
            // We'd also check the expiration date on the sticker.
            context.Succeed(requirement);
        }

        //TODO: Use the following if targeting a version of
        //.NET Framework older than 4.6:
        //      return Task.FromResult(0);
        return Task.CompletedTask;
    }
}
```

Ensure that both handlers are registered. If either handler succeeds when a policy evaluates the `BuildingEntryRequirement`, the policy evaluation succeeds.

Use a func to fulfill a policy

There may be situations in which fulfilling a policy is simple to express in code. It's possible to supply a `Func<AuthorizationHandlerContext, bool>` when configuring your policy with the `RequireAssertion` policy builder.

For example, the previous `BadgeEntryHandler` could be rewritten as follows:

```
services.AddAuthorization(options =>
{
     options.AddPolicy("BadgeEntry", policy =>
        policy.RequireAssertion(context =>
            context.User.HasClaim(c =>
                (c.Type == "BadgeId" ||
                 c.Type == "TemporaryBadgeId") &&
                 c.Issuer == "https://microsoftsecurity")));
});
```

Access MVC request context in handlers

The `HandleRequirementAsync` method you implement in an authorization handler has two parameters: an `AuthorizationHandlerContext` and the `TRequirement` you are handling. Frameworks such as MVC or SignalR are free to add any object to the `Resource` property on the `AuthorizationHandlerContext` to pass extra information.

For example, MVC passes an instance of AuthorizationFilterContext in the `Resource` property. This property provides access to `HttpContext`, `RouteData`, and everything else provided by MVC and Razor Pages.

The use of the `Resource` property is framework specific. Using information in the `Resource` property limits your authorization policies to particular frameworks. You should cast the `Resource` property using the `is` keyword, and then confirm the cast has succeeded to ensure your code doesn't crash with an `InvalidCastException` when run on other frameworks:

```
// Requires the following import:
//     using Microsoft.AspNetCore.Mvc.Filters;
if (context.Resource is AuthorizationFilterContext mvcContext)
{
    // Examine MVC-specific things like routing data.
}
```

Custom Authorization Policy Providers using IAuthorizationPolicyProvider in ASP.NET Core

9/22/2020 • 5 minutes to read • Edit Online

By Mike Rousos

Typically when using policy-based authorization, policies are registered by calling `AuthorizationOptions.AddPolicy` as part of authorization service configuration. In some scenarios, it may not be possible (or desirable) to register all authorization policies in this way. In those cases, you can use a custom `IAuthorizationPolicyProvider` to control how authorization policies are supplied.

Examples of scenarios where a custom IAuthorizationPolicyProvider may be useful include:

- Using an external service to provide policy evaluation.
- Using a large range of policies (for different room numbers or ages, for example), so it doesn't make sense to add each individual authorization policy with an `AuthorizationOptions.AddPolicy` call.
- Creating policies at runtime based on information in an external data source (like a database) or determining authorization requirements dynamically through another mechanism.

View or download sample code from the AspNetCore GitHub repository. Download the dotnet/AspNetCore repository ZIP file. Unzip the file. Navigate to the *src/Security/samples/CustomPolicyProvider* project folder.

Customize policy retrieval

ASP.NET Core apps use an implementation of the `IAuthorizationPolicyProvider` interface to retrieve authorization policies. By default, DefaultAuthorizationPolicyProvider is registered and used. `DefaultAuthorizationPolicyProvider` returns policies from the `AuthorizationOptions` provided in an `IServiceCollection.AddAuthorization` call.

Customize this behavior by registering a different `IAuthorizationPolicyProvider` implementation in the app's dependency injection container.

The `IAuthorizationPolicyProvider` interface contains three APIs:

- GetPolicyAsync returns an authorization policy for a given name.
- GetDefaultPolicyAsync returns the default authorization policy (the policy used for `[Authorize]` attributes without a policy specified).
- GetFallbackPolicyAsync returns the fallback authorization policy (the policy used by the Authorization Middleware when no policy is specified).

By implementing these APIs, you can customize how authorization policies are provided.

Parameterized authorize attribute example

One scenario where `IAuthorizationPolicyProvider` is useful is enabling custom `[Authorize]` attributes whose requirements depend on a parameter. For example, in policy-based authorization documentation, an age-based ("AtLeast21") policy was used as a sample. If different controller actions in an app should be made available to users of *different* ages, it might be useful to have many different age-based policies. Instead of registering all the different age-based policies that the application will need in `AuthorizationOptions`, you can generate the policies dynamically with a custom `IAuthorizationPolicyProvider`. To make using the policies easier, you can annotate actions with custom authorization attribute like `[MinimumAgeAuthorize(20)]`.

Custom Authorization attributes

Authorization policies are identified by their names. The custom `MinimumAgeAuthorizeAttribute` described previously needs to map arguments into a string that can be used to retrieve the corresponding authorization policy. You can do this by deriving from `AuthorizeAttribute` and making the `Age` property wrap the `AuthorizeAttribute.Policy` property.

```
internal class MinimumAgeAuthorizeAttribute : AuthorizeAttribute
{
    const string POLICY_PREFIX = "MinimumAge";

    public MinimumAgeAuthorizeAttribute(int age) => Age = age;

    // Get or set the Age property by manipulating the underlying Policy property
    public int Age
    {
        get
        {
            if (int.TryParse(Policy.Substring(POLICY_PREFIX.Length), out var age))
            {
                return age;
            }
            return default(int);
        }
        set
        {
            Policy = $"{POLICY_PREFIX}{value.ToString()}";
        }
    }
}
```

This attribute type has a `Policy` string based on the hard-coded prefix (`"MinimumAge"`) and an integer passed in via the constructor.

You can apply it to actions in the same way as other `Authorize` attributes except that it takes an integer as a parameter.

```
[MinimumAgeAuthorize(10)]
public IActionResult RequiresMinimumAge10()
```

Custom IAuthorizationPolicyProvider

The custom `MinimumAgeAuthorizeAttribute` makes it easy to request authorization policies for any minimum age desired. The next problem to solve is making sure that authorization policies are available for all of those different ages. This is where an `IAuthorizationPolicyProvider` is useful.

When using `MinimumAgeAuthorizationAttribute` , the authorization policy names will follow the pattern `"MinimumAge" + Age` , so the custom `IAuthorizationPolicyProvider` should generate authorization policies by:

- Parsing the age from the policy name.
- Using `AuthorizationPolicyBuilder` to create a new `AuthorizationPolicy`
- In this and following examples it will be assumed that the user is authenticated via a cookie. The `AuthorizationPolicyBuilder` should either be constructed with at least one authorization scheme name or always succeed. Otherwise there is no information on how to provide a challenge to the user and an exception will be thrown.
- Adding requirements to the policy based on the age with `AuthorizationPolicyBuilder.AddRequirements` . In other scenarios, you might use `RequireClaim` , `RequireRole` , or `RequireUserName` instead.

```
internal class MinimumAgePolicyProvider : IAuthorizationPolicyProvider
{
    const string POLICY_PREFIX = "MinimumAge";

    // Policies are looked up by string name, so expect 'parameters' (like age)
    // to be embedded in the policy names. This is abstracted away from developers
    // by the more strongly-typed attributes derived from AuthorizeAttribute
    // (like [MinimumAgeAuthorize()] in this sample)
    public Task<AuthorizationPolicy> GetPolicyAsync(string policyName)
    {
        if (policyName.StartsWith(POLICY_PREFIX, StringComparison.OrdinalIgnoreCase) &&
            int.TryParse(policyName.Substring(POLICY_PREFIX.Length), out var age))
        {
            var policy = new AuthorizationPolicyBuilder(CookieAuthenticationDefaults.AuthenticationScheme);
            policy.AddRequirements(new MinimumAgeRequirement(age));
            return Task.FromResult(policy.Build());
        }

        return Task.FromResult<AuthorizationPolicy>(null);
    }
}
```

Multiple authorization policy providers

When using custom `IAuthorizationPolicyProvider` implementations, keep in mind that ASP.NET Core only uses one instance of `IAuthorizationPolicyProvider`. If a custom provider isn't able to provide authorization policies for all policy names that will be used, it should defer to a backup provider.

For example, consider an application that needs both custom age policies and more traditional role-based policy retrieval. Such an app could use a custom authorization policy provider that:

- Attempts to parse policy names.
- Calls into a different policy provider (like `DefaultAuthorizationPolicyProvider`) if the policy name doesn't contain an age.

The example `IAuthorizationPolicyProvider` implementation shown above can be updated to use the `DefaultAuthorizationPolicyProvider` by creating a backup policy provider in its constructor (to be used in case the policy name doesn't match its expected pattern of 'MinimumAge' + age).

```
private DefaultAuthorizationPolicyProvider BackupPolicyProvider { get; }

public MinimumAgePolicyProvider(IOptions<AuthorizationOptions> options)
{
    // ASP.NET Core only uses one authorization policy provider, so if the custom implementation
    // doesn't handle all policies it should fall back to an alternate provider.
    BackupPolicyProvider = new DefaultAuthorizationPolicyProvider(options);
}
```

Then, the `GetPolicyAsync` method can be updated to use the `BackupPolicyProvider` instead of returning null:

```
...
return BackupPolicyProvider.GetPolicyAsync(policyName);
```

Default policy

In addition to providing named authorization policies, a custom `IAuthorizationPolicyProvider` needs to implement `GetDefaultPolicyAsync` to provide an authorization policy for `[Authorize]` attributes without a policy name

specified.

In many cases, this authorization attribute only requires an authenticated user, so you can make the necessary policy with a call to `RequireAuthenticatedUser`:

```
public Task<AuthorizationPolicy> GetDefaultPolicyAsync() =>
    Task.FromResult(new
AuthorizationPolicyBuilder(CookieAuthenticationDefaults.AuthenticationScheme).RequireAuthenticatedUser().Build(
));
```

As with all aspects of a custom `IAuthorizationPolicyProvider`, you can customize this, as needed. In some cases, it may be desirable to retrieve the default policy from a fallback `IAuthorizationPolicyProvider`.

Fallback policy

A custom `IAuthorizationPolicyProvider` can optionally implement `GetFallbackPolicyAsync` to provide a policy that's used when combining policies and when no policies are specified. If `GetFallbackPolicyAsync` returns a non-null policy, the returned policy is used by the Authorization Middleware when no policies are specified for the request.

If no fallback policy is required, the provider can return `null` or defer to the fallback provider:

```
public Task<AuthorizationPolicy> GetFallbackPolicyAsync() =>
    Task.FromResult<AuthorizationPolicy>(null);
```

Use a custom IAuthorizationPolicyProvider

To use custom policies from an `IAuthorizationPolicyProvider`, you ***must***:

- Register the appropriate `AuthorizationHandler` types with dependency injection (described in policy-based authorization), as with all policy-based authorization scenarios.
- Register the custom `IAuthorizationPolicyProvider` type in the app's dependency injection service collection in `Startup.ConfigureServices` to replace the default policy provider.

  ```
  services.AddSingleton<IAuthorizationPolicyProvider, MinimumAgePolicyProvider>();
  ```

A complete custom `IAuthorizationPolicyProvider` sample is available in the dotnet/aspnetcore GitHub repository.

Dependency injection in requirement handlers in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

Authorization handlers must be registered in the service collection during configuration (using dependency injection).

Suppose you had a repository of rules you wanted to evaluate inside an authorization handler and that repository was registered in the service collection. Authorization will resolve and inject that into your constructor.

For example, if you wanted to use ASP.NET's logging infrastructure you would want to inject `ILoggerFactory` into your handler. Such a handler might look like:

```
public class LoggingAuthorizationHandler : AuthorizationHandler<MyRequirement>
   {
       ILogger _logger;

       public LoggingAuthorizationHandler(ILoggerFactory loggerFactory)
       {
           _logger = loggerFactory.CreateLogger(this.GetType().FullName);
       }

       protected override Task HandleRequirementAsync(AuthorizationHandlerContext context, MyRequirement
requirement)
       {
           _logger.LogInformation("Inside my handler");
           // Check if the requirement is fulfilled.
           return Task.CompletedTask;
       }
   }
```

You would register the handler with `services.AddSingleton()`:

```
services.AddSingleton<IAuthorizationHandler, LoggingAuthorizationHandler>();
```

An instance of the handler will be created when your application starts, and DI will inject the registered `ILoggerFactory` into your constructor.

> **NOTE**
> Handlers that use Entity Framework shouldn't be registered as singletons.

Resource-based authorization in ASP.NET Core

9/22/2020 • 5 minutes to read • Edit Online

Authorization strategy depends upon the resource being accessed. Consider a document that has an author property. Only the author is allowed to update the document. Consequently, the document must be retrieved from the data store before authorization evaluation can occur.

Attribute evaluation occurs before data binding and before execution of the page handler or action that loads the document. For these reasons, declarative authorization with an `[Authorize]` attribute doesn't suffice. Instead, you can invoke a custom authorization method—a style known as *imperative authorization*.

View or download sample code (how to download).

View or download sample code (how to download).

View or download sample code (how to download).

Create an ASP.NET Core app with user data protected by authorization contains a sample app that uses resource-based authorization.

Use imperative authorization

Authorization is implemented as an IAuthorizationService service and is registered in the service collection within the `Startup` class. The service is made available via dependency injection to page handlers or actions.

```
public class DocumentController : Controller
{
    private readonly IAuthorizationService _authorizationService;
    private readonly IDocumentRepository _documentRepository;

    public DocumentController(IAuthorizationService authorizationService,
                              IDocumentRepository documentRepository)
    {
        _authorizationService = authorizationService;
        _documentRepository = documentRepository;
    }
```

`IAuthorizationService` has two `AuthorizeAsync` method overloads: one accepting the resource and the policy name and the other accepting the resource and a list of requirements to evaluate.

```
Task<AuthorizationResult> AuthorizeAsync(ClaimsPrincipal user,
                          object resource,
                          IEnumerable<IAuthorizationRequirement> requirements);
Task<AuthorizationResult> AuthorizeAsync(ClaimsPrincipal user,
                          object resource,
                          string policyName);
```

```
Task<bool> AuthorizeAsync(ClaimsPrincipal user,
                          object resource,
                          IEnumerable<IAuthorizationRequirement> requirements);
Task<bool> AuthorizeAsync(ClaimsPrincipal user,
                          object resource,
                          string policyName);
```

In the following example, the resource to be secured is loaded into a custom `Document` object. An `AuthorizeAsync` overload is invoked to determine whether the current user is allowed to edit the provided document. A custom "EditPolicy" authorization policy is factored into the decision. See Custom policy-based authorization for more on creating authorization policies.

> **NOTE**
> The following code samples assume authentication has run and set the `User` property.

```
public async Task<IActionResult> OnGetAsync(Guid documentId)
{
    Document = _documentRepository.Find(documentId);

    if (Document == null)
    {
        return new NotFoundResult();
    }

    var authorizationResult = await _authorizationService
            .AuthorizeAsync(User, Document, "EditPolicy");

    if (authorizationResult.Succeeded)
    {
        return Page();
    }
    else if (User.Identity.IsAuthenticated)
    {
        return new ForbidResult();
    }
    else
    {
        return new ChallengeResult();
    }
}
```

```
[HttpGet]
public async Task<IActionResult> Edit(Guid documentId)
{
    Document document = _documentRepository.Find(documentId);

    if (document == null)
    {
        return new NotFoundResult();
    }

    if (await _authorizationService
        .AuthorizeAsync(User, document, "EditPolicy"))
    {
        return View(document);
    }
    else
    {
        return new ChallengeResult();
    }
}
```

Write a resource-based handler

Writing a handler for resource-based authorization isn't much different than writing a plain requirements handler. Create a custom requirement class, and implement a requirement handler class. For more information on creating

a requirement class, see Requirements.

The handler class specifies both the requirement and resource type. For example, a handler utilizing a `SameAuthorRequirement` and a `Document` resource follows:

```
public class DocumentAuthorizationHandler :
    AuthorizationHandler<SameAuthorRequirement, Document>
{
    protected override Task HandleRequirementAsync(AuthorizationHandlerContext context,
                                                   SameAuthorRequirement requirement,
                                                   Document resource)
    {
        if (context.User.Identity?.Name == resource.Author)
        {
            context.Succeed(requirement);
        }

        return Task.CompletedTask;
    }
}

public class SameAuthorRequirement : IAuthorizationRequirement { }
```

```
public class DocumentAuthorizationHandler :
    AuthorizationHandler<SameAuthorRequirement, Document>
{
    protected override Task HandleRequirementAsync(AuthorizationHandlerContext context,
                                                   SameAuthorRequirement requirement,
                                                   Document resource)
    {
        if (context.User.Identity?.Name == resource.Author)
        {
            context.Succeed(requirement);
        }

        //TODO: Use the following if targeting a version of
        //.NET Framework older than 4.6:
        //      return Task.FromResult(0);
        return Task.CompletedTask;
    }
}

public class SameAuthorRequirement : IAuthorizationRequirement { }
```

In the preceding example, imagine that `SameAuthorRequirement` is a special case of a more generic `SpecificAuthorRequirement` class. The `SpecificAuthorRequirement` class (not shown) contains a `Name` property representing the name of the author. The `Name` property could be set to the current user.

Register the requirement and handler in `Startup.ConfigureServices`:

```
services.AddControllersWithViews();
services.AddRazorPages();

services.AddAuthorization(options =>
{
    options.AddPolicy("EditPolicy", policy =>
        policy.Requirements.Add(new SameAuthorRequirement()));
});

services.AddSingleton<IAuthorizationHandler, DocumentAuthorizationHandler>();
services.AddSingleton<IAuthorizationHandler, DocumentAuthorizationCrudHandler>();
services.AddScoped<IDocumentRepository, DocumentRepository>();
```

```
services.AddMvc();

services.AddAuthorization(options =>
{
    options.AddPolicy("EditPolicy", policy =>
        policy.Requirements.Add(new SameAuthorRequirement()));
});

services.AddSingleton<IAuthorizationHandler, DocumentAuthorizationHandler>();
services.AddSingleton<IAuthorizationHandler, DocumentAuthorizationCrudHandler>();
services.AddScoped<IDocumentRepository, DocumentRepository>();
```

```
services.AddAuthorization(options =>
{
    options.AddPolicy("EditPolicy", policy =>
        policy.Requirements.Add(new SameAuthorRequirement()));
});

services.AddSingleton<IAuthorizationHandler, DocumentAuthorizationHandler>();
services.AddSingleton<IAuthorizationHandler, DocumentAuthorizationCrudHandler>();
services.AddScoped<IDocumentRepository, DocumentRepository>();
```

Operational requirements

If you're making decisions based on the outcomes of CRUD (Create, Read, Update, Delete) operations, use the OperationAuthorizationRequirement helper class. This class enables you to write a single handler instead of an individual class for each operation type. To use it, provide some operation names:

```
public static class Operations
{
    public static OperationAuthorizationRequirement Create =
        new OperationAuthorizationRequirement { Name = nameof(Create) };
    public static OperationAuthorizationRequirement Read =
        new OperationAuthorizationRequirement { Name = nameof(Read) };
    public static OperationAuthorizationRequirement Update =
        new OperationAuthorizationRequirement { Name = nameof(Update) };
    public static OperationAuthorizationRequirement Delete =
        new OperationAuthorizationRequirement { Name = nameof(Delete) };
}
```

The handler is implemented as follows, using an `OperationAuthorizationRequirement` requirement and a `Document` resource:

```
public class DocumentAuthorizationCrudHandler :
    AuthorizationHandler<OperationAuthorizationRequirement, Document>
{
    protected override Task HandleRequirementAsync(AuthorizationHandlerContext context,
                                                   OperationAuthorizationRequirement requirement,
                                                   Document resource)
    {
        if (context.User.Identity?.Name == resource.Author &&
            requirement.Name == Operations.Read.Name)
        {
            context.Succeed(requirement);
        }

        return Task.CompletedTask;
    }
}
```

```
public class DocumentAuthorizationCrudHandler :
    AuthorizationHandler<OperationAuthorizationRequirement, Document>
{
    protected override Task HandleRequirementAsync(AuthorizationHandlerContext context,
                                                   OperationAuthorizationRequirement requirement,
                                                   Document resource)
    {
        if (context.User.Identity?.Name == resource.Author &&
            requirement.Name == Operations.Read.Name)
        {
            context.Succeed(requirement);
        }

        //TODO: Use the following if targeting a version of
        //.NET Framework older than 4.6:
        //      return Task.FromResult(0);
        return Task.CompletedTask;
    }
}
```

The preceding handler validates the operation using the resource, the user's identity, and the requirement's `Name` property.

Challenge and forbid with an operational resource handler

This section shows how the challenge and forbid action results are processed and how challenge and forbid differ.

To call an operational resource handler, specify the operation when invoking `AuthorizeAsync` in your page handler or action. The following example determines whether the authenticated user is permitted to view the provided document.

> **NOTE**
> The following code samples assume authentication has run and set the `User` property.

```
public async Task<IActionResult> OnGetAsync(Guid documentId)
{
    Document = _documentRepository.Find(documentId);

    if (Document == null)
    {
        return new NotFoundResult();
    }

    var authorizationResult = await _authorizationService
            .AuthorizeAsync(User, Document, Operations.Read);

    if (authorizationResult.Succeeded)
    {
        return Page();
    }
    else if (User.Identity.IsAuthenticated)
    {
        return new ForbidResult();
    }
    else
    {
        return new ChallengeResult();
    }
}
```

If authorization succeeds, the page for viewing the document is returned. If authorization fails but the user is authenticated, returning `ForbidResult` informs any authentication middleware that authorization failed. A `ChallengeResult` is returned when authentication must be performed. For interactive browser clients, it may be appropriate to redirect the user to a login page.

```
[HttpGet]
public async Task<IActionResult> View(Guid documentId)
{
    Document document = _documentRepository.Find(documentId);

    if (document == null)
    {
        return new NotFoundResult();
    }

    if (await _authorizationService
        .AuthorizeAsync(User, document, Operations.Read))
    {
        return View(document);
    }
    else
    {
        return new ChallengeResult();
    }
}
```

If authorization succeeds, the view for the document is returned. If authorization fails, returning `ChallengeResult` informs any authentication middleware that authorization failed, and the middleware can take the appropriate response. An appropriate response could be returning a 401 or 403 status code. For interactive browser clients, it could mean redirecting the user to a login page.

View-based authorization in ASP.NET Core MVC

9/22/2020 • 2 minutes to read • Edit Online

A developer often wants to show, hide, or otherwise modify a UI based on the current user identity. You can access the authorization service within MVC views via dependency injection. To inject the authorization service into a Razor view, use the `@inject` directive:

```
@using Microsoft.AspNetCore.Authorization
@inject IAuthorizationService AuthorizationService
```

If you want the authorization service in every view, place the `@inject` directive into the *_ViewImports.cshtml* file of the *Views* directory. For more information, see Dependency injection into views.

Use the injected authorization service to invoke `AuthorizeAsync` in exactly the same way you would check during resource-based authorization:

```
@if ((await AuthorizationService.AuthorizeAsync(User, "PolicyName")).Succeeded)
{
    <p>This paragraph is displayed because you fulfilled PolicyName.</p>
}
```

In some cases, the resource will be your view model. Invoke `AuthorizeAsync` in exactly the same way you would check during resource-based authorization:

```
@if ((await AuthorizationService.AuthorizeAsync(User, Model, Operations.Edit)).Succeeded)
{
    <p><a class="btn btn-default" role="button"
        href="@Url.Action("Edit", "Document", new { id = Model.Id })">Edit</a></p>
}
```

In the preceding code, the model is passed as a resource the policy evaluation should take into consideration.

WARNING

Don't rely on toggling visibility of your app's UI elements as the sole authorization check. Hiding a UI element may not completely prevent access to its associated controller action. For example, consider the button in the preceding code snippet. A user can invoke the `Edit` action method if he or she knows the relative resource URL is */Document/Edit/1*. For this reason, the `Edit` action method should perform its own authorization check.

Authorize with a specific scheme in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

In some scenarios, such as Single Page Applications (SPAs), it's common to use multiple authentication methods. For example, the app may use cookie-based authentication to log in and JWT bearer authentication for JavaScript requests. In some cases, the app may have multiple instances of an authentication handler. For example, two cookie handlers where one contains a basic identity and one is created when a multi-factor authentication (MFA) has been triggered. MFA may be triggered because the user requested an operation that requires extra security. For more information on enforcing MFA when a user requests a resource that requires MFA, see the GitHub issue Protect section with MFA.

An authentication scheme is named when the authentication service is configured during authentication. For example:

```
public void ConfigureServices(IServiceCollection services)
{
    // Code omitted for brevity

    services.AddAuthentication()
        .AddCookie(options => {
            options.LoginPath = "/Account/Unauthorized/";
            options.AccessDeniedPath = "/Account/Forbidden/";
        })
        .AddJwtBearer(options => {
            options.Audience = "http://localhost:5001/";
            options.Authority = "http://localhost:5000/";
        });
```

In the preceding code, two authentication handlers have been added: one for cookies and one for bearer.

> **NOTE**
> Specifying the default scheme results in the `HttpContext.User` property being set to that identity. If that behavior isn't desired, disable it by invoking the parameterless form of `AddAuthentication`.

Selecting the scheme with the Authorize attribute

At the point of authorization, the app indicates the handler to be used. Select the handler with which the app will authorize by passing a comma-delimited list of authentication schemes to `[Authorize]`. The `[Authorize]` attribute specifies the authentication scheme or schemes to use regardless of whether a default is configured. For example:

```
[Authorize(AuthenticationSchemes = AuthSchemes)]
public class MixedController : Controller
    // Requires the following imports:
    // using Microsoft.AspNetCore.Authentication.Cookies;
    // using Microsoft.AspNetCore.Authentication.JwtBearer;
    private const string AuthSchemes =
        CookieAuthenticationDefaults.AuthenticationScheme + "," +
        JwtBearerDefaults.AuthenticationScheme;
```

In the preceding example, both the cookie and bearer handlers run and have a chance to create and append an

identity for the current user. By specifying a single scheme only, the corresponding handler runs.

```
[Authorize(AuthenticationSchemes =
    JwtBearerDefaults.AuthenticationScheme)]
public class MixedController : Controller
```

In the preceding code, only the handler with the "Bearer" scheme runs. Any cookie-based identities are ignored.

Selecting the scheme with policies

If you prefer to specify the desired schemes in policy, you can set the `AuthenticationSchemes` collection when adding your policy:

```
services.AddAuthorization(options =>
{
    options.AddPolicy("Over18", policy =>
    {
        policy.AuthenticationSchemes.Add(JwtBearerDefaults.AuthenticationScheme);
        policy.RequireAuthenticatedUser();
        policy.Requirements.Add(new MinimumAgeRequirement());
    });
});
```

In the preceding example, the "Over18" policy only runs against the identity created by the "Bearer" handler. Use the policy by setting the `[Authorize]` attribute's `Policy` property:

```
[Authorize(Policy = "Over18")]
public class RegistrationController : Controller
```

Use multiple authentication schemes

Some apps may need to support multiple types of authentication. For example, your app might authenticate users from Azure Active Directory and from a users database. Another example is an app that authenticates users from both Active Directory Federation Services and Azure Active Directory B2C. In this case, the app should accept a JWT bearer token from several issuers.

Add all authentication schemes you'd like to accept. For example, the following code in `Startup.ConfigureServices` adds two JWT bearer authentication schemes with different issuers:

```
public void ConfigureServices(IServiceCollection services)
{
    // Code omitted for brevity

    services.AddAuthentication(JwtBearerDefaults.AuthenticationScheme)
        .AddJwtBearer(options =>
        {
            options.Audience = "https://localhost:5000/";
            options.Authority = "https://localhost:5000/identity/";
        })
        .AddJwtBearer("AzureAD", options =>
        {
            options.Audience = "https://localhost:5000/";
            options.Authority = "https://login.microsoftonline.com/eb971100-6f99-4bdc-8611-1bc8edd7f436/";
        });
}
```

NOTE

Only one JWT bearer authentication is registered with the default authentication scheme `JwtBearerDefaults.AuthenticationScheme`. Additional authentication has to be registered with a unique authentication scheme.

The next step is to update the default authorization policy to accept both authentication schemes. For example:

```
public void ConfigureServices(IServiceCollection services)
{
    // Code omitted for brevity

    services.AddAuthorization(options =>
    {
        var defaultAuthorizationPolicyBuilder = new AuthorizationPolicyBuilder(
            JwtBearerDefaults.AuthenticationScheme,
            "AzureAD");
        defaultAuthorizationPolicyBuilder =
            defaultAuthorizationPolicyBuilder.RequireAuthenticatedUser();
        options.DefaultPolicy = defaultAuthorizationPolicyBuilder.Build();
    });
}
```

As the default authorization policy is overridden, it's possible to use the `[Authorize]` attribute in controllers. The controller then accepts requests with JWT issued by the first or second issuer.

ASP.NET Core Data Protection

9/22/2020 • 5 minutes to read • Edit Online

Web applications often need to store security-sensitive data. Windows provides DPAPI for desktop applications but this is unsuitable for web applications. The ASP.NET Core data protection stack provide a simple, easy to use cryptographic API a developer can use to protect data, including key management and rotation.

The ASP.NET Core data protection stack is designed to serve as the long-term replacement for the <machineKey> element in ASP.NET 1.x - 4.x. It was designed to address many of the shortcomings of the old cryptographic stack while providing an out-of-the-box solution for the majority of use cases modern applications are likely to encounter.

Problem statement

The overall problem statement can be succinctly stated in a single sentence: I need to persist trusted information for later retrieval, but I don't trust the persistence mechanism. In web terms, this might be written as "I need to round-trip trusted state via an untrusted client."

The canonical example of this is an authentication cookie or bearer token. The server generates an "I am Groot and have xyz permissions" token and hands it to the client. At some future date the client will present that token back to the server, but the server needs some kind of assurance that the client hasn't forged the token. Thus the first requirement: authenticity (a.k.a. integrity, tamper-proofing).

Since the persisted state is trusted by the server, we anticipate that this state might contain information that's specific to the operating environment. This could be in the form of a file path, a permission, a handle or other indirect reference, or some other piece of server-specific data. Such information should generally not be disclosed to an untrusted client. Thus the second requirement: confidentiality.

Finally, since modern applications are componentized, what we've seen is that individual components will want to take advantage of this system without regard to other components in the system. For instance, if a bearer token component is using this stack, it should operate without interference from an anti-CSRF mechanism that might also be using the same stack. Thus the final requirement: isolation.

We can provide further constraints in order to narrow the scope of our requirements. We assume that all services operating within the cryptosystem are equally trusted and that the data doesn't need to be generated or consumed outside of the services under our direct control. Furthermore, we require that operations are as fast as possible since each request to the web service might go through the cryptosystem one or more times. This makes symmetric cryptography ideal for our scenario, and we can discount asymmetric cryptography until such a time that it's needed.

Design philosophy

We started by identifying problems with the existing stack. Once we had that, we surveyed the landscape of existing solutions and concluded that no existing solution quite had the capabilities we sought. We then engineered a solution based on several guiding principles.

- The system should offer simplicity of configuration. Ideally the system would be zero-configuration and developers could hit the ground running. In situations where developers need to configure a specific aspect (such as the key repository), consideration should be given to making those specific configurations simple.

- Offer a simple consumer-facing API. The APIs should be easy to use correctly and difficult to use incorrectly.
- Developers shouldn't learn key management principles. The system should handle algorithm selection and key lifetime on the developer's behalf. Ideally the developer should never even have access to the raw key material.
- Keys should be protected at rest when possible. The system should figure out an appropriate default protection mechanism and apply it automatically.

With these principles in mind we developed a simple, easy to use data protection stack.

The ASP.NET Core data protection APIs are not primarily intended for indefinite persistence of confidential payloads. Other technologies like Windows CNG DPAPI and Azure Rights Management are more suited to the scenario of indefinite storage, and they have correspondingly strong key management capabilities. That said, there's nothing prohibiting a developer from using the ASP.NET Core data protection APIs for long-term protection of confidential data.

Audience

The data protection system is divided into five main packages. Various aspects of these APIs target three main audiences;

1. The Consumer APIs Overview target application and framework developers.

   "I don't want to learn about how the stack operates or about how it's configured. I simply want to perform some operation in as simple a manner as possible with high probability of using the APIs successfully."

2. The configuration APIs target application developers and system administrators.

   "I need to tell the data protection system that my environment requires non-default paths or settings."

3. The extensibility APIs target developers in charge of implementing custom policy. Usage of these APIs would be limited to rare situations and experienced, security aware developers.

   "I need to replace an entire component within the system because I have truly unique behavioral requirements. I am willing to learn uncommonly-used parts of the API surface in order to build a plugin that fulfills my requirements."

Package layout

The data protection stack consists of five packages.

- Microsoft.AspNetCore.DataProtection.Abstractions contains the IDataProtectionProvider and IDataProtector interfaces to create data protection services. It also contains useful extension methods for working with these types (for example, IDataProtector.Protect). If the data protection system is instantiated elsewhere and you're consuming the API, reference `Microsoft.AspNetCore.DataProtection.Abstractions`.
- Microsoft.AspNetCore.DataProtection contains the core implementation of the data protection system, including core cryptographic operations, key management, configuration, and extensibility. To instantiate the data protection system (for example, adding it to an IServiceCollection) or modifying or extending its behavior, reference `Microsoft.AspNetCore.DataProtection`.
- Microsoft.AspNetCore.DataProtection.Extensions contains additional APIs which developers might find useful but which don't belong in the core package. For instance, this package contains factory methods to instantiate the data protection system to store keys at a location on the file system without

dependency injection (see DataProtectionProvider). It also contains extension methods for limiting the lifetime of protected payloads (see ITimeLimitedDataProtector).

- Microsoft.AspNetCore.DataProtection.SystemWeb can be installed into an existing ASP.NET 4.x app to redirect its `<machineKey>` operations to use the new ASP.NET Core data protection stack. For more information, see Replace the ASP.NET machineKey in ASP.NET Core.
- Microsoft.AspNetCore.Cryptography.KeyDerivation provides an implementation of the PBKDF2 password hashing routine and can be used by systems that must handle user passwords securely. For more information, see Hash passwords in ASP.NET Core.

Get started with the Data Protection APIs in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

At its simplest, protecting data consists of the following steps:

1. Create a data protector from a data protection provider.
2. Call the `Protect` method with the data you want to protect.
3. Call the `Unprotect` method with the data you want to turn back into plain text.

Most frameworks and app models, such as ASP.NET Core or SignalR, already configure the data protection system and add it to a service container you access via dependency injection. The following sample demonstrates configuring a service container for dependency injection and registering the data protection stack, receiving the data protection provider via DI, creating a protector and protecting then unprotecting data.

```
using System;
using Microsoft.AspNetCore.DataProtection;
using Microsoft.Extensions.DependencyInjection;

public class Program
{
    public static void Main(string[] args)
    {
        // add data protection services
        var serviceCollection = new ServiceCollection();
        serviceCollection.AddDataProtection();
        var services = serviceCollection.BuildServiceProvider();

        // create an instance of MyClass using the service provider
        var instance = ActivatorUtilities.CreateInstance<MyClass>(services);
        instance.RunSample();
    }

    public class MyClass
    {
        IDataProtector _protector;

        // the 'provider' parameter is provided by DI
        public MyClass(IDataProtectionProvider provider)
        {
            _protector = provider.CreateProtector("Contoso.MyClass.v1");
        }

        public void RunSample()
        {
            Console.Write("Enter input: ");
            string input = Console.ReadLine();

            // protect the payload
            string protectedPayload = _protector.Protect(input);
            Console.WriteLine($"Protect returned: {protectedPayload}");

            // unprotect the payload
            string unprotectedPayload = _protector.Unprotect(protectedPayload);
            Console.WriteLine($"Unprotect returned: {unprotectedPayload}");
        }
    }
}

/*
 * SAMPLE OUTPUT
 *
 * Enter input: Hello world!
 * Protect returned: CfDJ8ICcgQwZZhlAlTZT...OdfH66i1PnGmpCR5e441xQ
 * Unprotect returned: Hello world!
 */
```

When you create a protector you must provide one or more Purpose Strings. A purpose string provides isolation between consumers. For example, a protector created with a purpose string of "green" wouldn't be able to unprotect data provided by a protector with a purpose of "purple".

TIP

Instances of `IDataProtectionProvider` and `IDataProtector` are thread-safe for multiple callers. It's intended that once a component gets a reference to an `IDataProtector` via a call to `CreateProtector`, it will use that reference for multiple calls to `Protect` and `Unprotect`.

A call to `Unprotect` will throw CryptographicException if the protected payload cannot be verified or deciphered. Some components may wish to ignore errors during unprotect operations; a component which reads authentication cookies might handle this error and treat the request as if it had no cookie at all rather than fail the request outright. Components which want this behavior should specifically catch CryptographicException instead of swallowing all exceptions.

Consumer APIs overview for ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

The `IDataProtectionProvider` and `IDataProtector` interfaces are the basic interfaces through which consumers use the data protection system. They're located in the Microsoft.AspNetCore.DataProtection.Abstractions package.

IDataProtectionProvider

The provider interface represents the root of the data protection system. It cannot directly be used to protect or unprotect data. Instead, the consumer must get a reference to an `IDataProtector` by calling `IDataProtectionProvider.CreateProtector(purpose)`, where purpose is a string that describes the intended consumer use case. See Purpose Strings for much more information on the intent of this parameter and how to choose an appropriate value.

IDataProtector

The protector interface is returned by a call to `CreateProtector`, and it's this interface which consumers can use to perform protect and unprotect operations.

To protect a piece of data, pass the data to the `Protect` method. The basic interface defines a method which converts byte[] -> byte[], but there's also an overload (provided as an extension method) which converts string -> string. The security offered by the two methods is identical; the developer should choose whichever overload is most convenient for their use case. Irrespective of the overload chosen, the value returned by the Protect method is now protected (enciphered and tamper-proofed), and the application can send it to an untrusted client.

To unprotect a previously-protected piece of data, pass the protected data to the `Unprotect` method. (There are byte[]-based and string-based overloads for developer convenience.) If the protected payload was generated by an earlier call to `Protect` on this same `IDataProtector`, the `Unprotect` method will return the original unprotected payload. If the protected payload has been tampered with or was produced by a different `IDataProtector`, the `Unprotect` method will throw CryptographicException.

The concept of same vs. different `IDataProtector` ties back to the concept of purpose. If two `IDataProtector` instances were generated from the same root `IDataProtectionProvider` but via different purpose strings in the call to `IDataProtectionProvider.CreateProtector`, then they're considered different protectors, and one won't be able to unprotect payloads generated by the other.

Consuming these interfaces

For a DI-aware component, the intended usage is that the component takes an `IDataProtectionProvider` parameter in its constructor and that the DI system automatically provides this service when the component is instantiated.

> **NOTE**
>
> Some applications (such as console applications or ASP.NET 4.x applications) might not be DI-aware so cannot use the mechanism described here. For these scenarios consult the Non DI Aware Scenarios document for more information on getting an instance of an `IDataProtection` provider without going through DI.

The following sample demonstrates three concepts:

1. Add the data protection system to the service container,

2. Using DI to receive an instance of an `IDataProtectionProvider`, and
3. Creating an `IDataProtector` from an `IDataProtectionProvider` and using it to protect and unprotect data.

```
using System;
using Microsoft.AspNetCore.DataProtection;
using Microsoft.Extensions.DependencyInjection;

public class Program
{
    public static void Main(string[] args)
    {
        // add data protection services
        var serviceCollection = new ServiceCollection();
        serviceCollection.AddDataProtection();
        var services = serviceCollection.BuildServiceProvider();

        // create an instance of MyClass using the service provider
        var instance = ActivatorUtilities.CreateInstance<MyClass>(services);
        instance.RunSample();
    }

    public class MyClass
    {
        IDataProtector _protector;

        // the 'provider' parameter is provided by DI
        public MyClass(IDataProtectionProvider provider)
        {
            _protector = provider.CreateProtector("Contoso.MyClass.v1");
        }

        public void RunSample()
        {
            Console.Write("Enter input: ");
            string input = Console.ReadLine();

            // protect the payload
            string protectedPayload = _protector.Protect(input);
            Console.WriteLine($"Protect returned: {protectedPayload}");

            // unprotect the payload
            string unprotectedPayload = _protector.Unprotect(protectedPayload);
            Console.WriteLine($"Unprotect returned: {unprotectedPayload}");
        }
    }
}

/*
 * SAMPLE OUTPUT
 *
 * Enter input: Hello world!
 * Protect returned: CfDJ8ICcgQwZZhlAlTZT...OdfH66i1PnGmpCR5e441xQ
 * Unprotect returned: Hello world!
 */
```

The package Microsoft.AspNetCore.DataProtection.Abstractions contains an extension method `IServiceProvider.GetDataProtector` as a developer convenience. It encapsulates as a single operation both retrieving an `IDataProtectionProvider` from the service provider and calling `IDataProtectionProvider.CreateProtector`. The following sample demonstrates its usage.

```
using System;
using Microsoft.AspNetCore.DataProtection;
using Microsoft.Extensions.DependencyInjection;

public class Program
{
    public static void Main(string[] args)
    {
        // add data protection services
        var serviceCollection = new ServiceCollection();
        serviceCollection.AddDataProtection();
        var services = serviceCollection.BuildServiceProvider();

        // get an IDataProtector from the IServiceProvider
        var protector = services.GetDataProtector("Contoso.Example.v2");
        Console.Write("Enter input: ");
        string input = Console.ReadLine();

        // protect the payload
        string protectedPayload = protector.Protect(input);
        Console.WriteLine($"Protect returned: {protectedPayload}");

        // unprotect the payload
        string unprotectedPayload = protector.Unprotect(protectedPayload);
        Console.WriteLine($"Unprotect returned: {unprotectedPayload}");
    }
}
```

TIP

Instances of `IDataProtectionProvider` and `IDataProtector` are thread-safe for multiple callers. It's intended that once a component gets a reference to an `IDataProtector` via a call to `CreateProtector`, it will use that reference for multiple calls to `Protect` and `Unprotect`. A call to `Unprotect` will throw CryptographicException if the protected payload cannot be verified or deciphered. Some components may wish to ignore errors during unprotect operations; a component which reads authentication cookies might handle this error and treat the request as if it had no cookie at all rather than fail the request outright. Components which want this behavior should specifically catch CryptographicException instead of swallowing all exceptions.

Purpose strings in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

Components which consume `IDataProtectionProvider` must pass a unique *purposes* parameter to the `CreateProtector` method. The purposes *parameter* is inherent to the security of the data protection system, as it provides isolation between cryptographic consumers, even if the root cryptographic keys are the same.

When a consumer specifies a purpose, the purpose string is used along with the root cryptographic keys to derive cryptographic subkeys unique to that consumer. This isolates the consumer from all other cryptographic consumers in the application: no other component can read its payloads, and it cannot read any other component's payloads. This isolation also renders infeasible entire categories of attack against the component.

In the diagram above, `IDataProtector` instances A and B **cannot** read each other's payloads, only their own.

The purpose string doesn't have to be secret. It should simply be unique in the sense that no other well-behaved component will ever provide the same purpose string.

> **TIP**
>
> Using the namespace and type name of the component consuming the data protection APIs is a good rule of thumb, as in practice this information will never conflict.
>
> A Contoso-authored component which is responsible for minting bearer tokens might use Contoso.Security.BearerToken as its purpose string. Or - even better - it might use Contoso.Security.BearerToken.v1 as its purpose string. Appending the version number allows a future version to use Contoso.Security.BearerToken.v2 as its purpose, and the different versions would be completely isolated from one another as far as payloads go.

Since the purposes parameter to `CreateProtector` is a string array, the above could've been instead specified as `[ "Contoso.Security.BearerToken", "v1" ]`. This allows establishing a hierarchy of purposes and opens up the possibility of multi-tenancy scenarios with the data protection system.

WARNING

Components shouldn't allow untrusted user input to be the sole source of input for the purposes chain.

For example, consider a component Contoso.Messaging.SecureMessage which is responsible for storing secure messages. If the secure messaging component were to call `CreateProtector([ username ])`, then a malicious user might create an account with username "Contoso.Security.BearerToken" in an attempt to get the component to call `CreateProtector([ "Contoso.Security.BearerToken" ])`, thus inadvertently causing the secure messaging system to mint payloads that could be perceived as authentication tokens.

A better purposes chain for the messaging component would be `CreateProtector([ "Contoso.Messaging.SecureMessage", "User: username" ])`, which provides proper isolation.

The isolation provided by and behaviors of `IDataProtectionProvider`, `IDataProtector`, and purposes are as follows:

- For a given `IDataProtectionProvider` object, the `CreateProtector` method will create an `IDataProtector` object uniquely tied to both the `IDataProtectionProvider` object which created it and the purposes parameter which was passed into the method.
- The purpose parameter must not be null. (If purposes is specified as an array, this means that the array must not be of zero length and all elements of the array must be non-null.) An empty string purpose is technically allowed but is discouraged.
- Two purposes arguments are equivalent if and only if they contain the same strings (using an ordinal comparer) in the same order. A single purpose argument is equivalent to the corresponding single-element purposes array.
- Two `IDataProtector` objects are equivalent if and only if they're created from equivalent `IDataProtectionProvider` objects with equivalent purposes parameters.
- For a given `IDataProtector` object, a call to `Unprotect(protectedData)` will return the original `unprotectedData` if and only if `protectedData := Protect(unprotectedData)` for an equivalent `IDataProtector` object.

NOTE

We're not considering the case where some component intentionally chooses a purpose string which is known to conflict with another component. Such a component would essentially be considered malicious, and this system isn't intended to provide security guarantees in the event that malicious code is already running inside of the worker process.

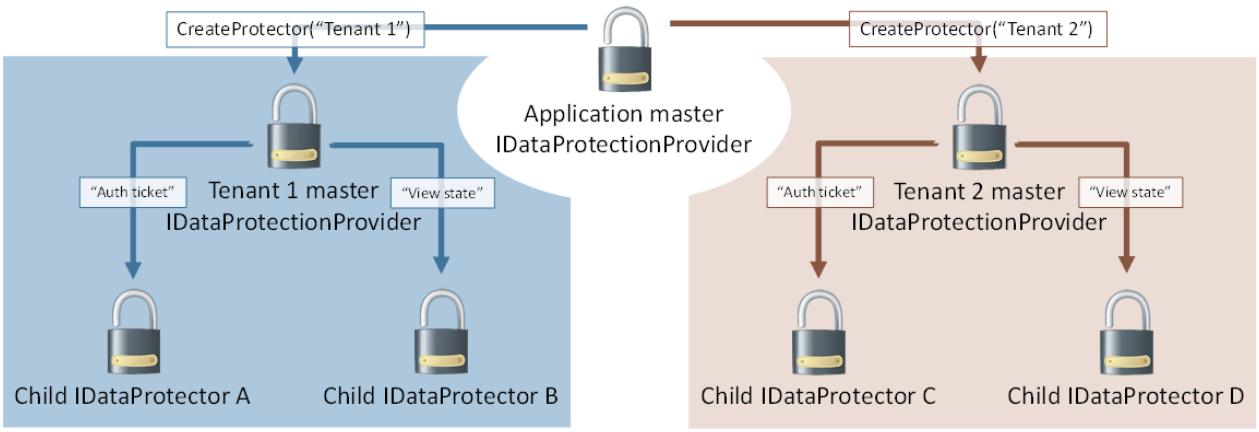
Purpose hierarchy and multi-tenancy in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

Since an `IDataProtector` is also implicitly an `IDataProtectionProvider`, purposes can be chained together. In this sense, `provider.CreateProtector([ "purpose1", "purpose2" ])` is equivalent to `provider.CreateProtector("purpose1").CreateProtector("purpose2")`.

This allows for some interesting hierarchical relationships through the data protection system. In the earlier example of Contoso.Messaging.SecureMessage, the SecureMessage component can call `provider.CreateProtector("Contoso.Messaging.SecureMessage")` once up-front and cache the result into a private `_myProvider` field. Future protectors can then be created via calls to `_myProvider.CreateProtector("User: username")`, and these protectors would be used for securing the individual messages.

This can also be flipped. Consider a single logical application which hosts multiple tenants (a CMS seems reasonable), and each tenant can be configured with its own authentication and state management system. The umbrella application has a single master provider, and it calls `provider.CreateProtector("Tenant 1")` and `provider.CreateProtector("Tenant 2")` to give each tenant its own isolated slice of the data protection system. The tenants could then derive their own individual protectors based on their own needs, but no matter how hard they try they cannot create protectors which collide with any other tenant in the system. Graphically, this is represented as below.



WARNING

This assumes the umbrella application controls which APIs are available to individual tenants and that tenants cannot execute arbitrary code on the server. If a tenant can execute arbitrary code, they could perform private reflection to break the isolation guarantees, or they could just read the master keying material directly and derive whatever subkeys they desire.

The data protection system actually uses a sort of multi-tenancy in its default out-of-the-box configuration. By default master keying material is stored in the worker process account's user profile folder (or the registry, for IIS application pool identities). But it's actually fairly common to use a single account to run multiple applications, and thus all these applications would end up sharing the master keying material. To solve this, the data protection system automatically inserts a unique-per-application identifier as the first element in the overall purpose chain. This implicit purpose serves to isolate individual applications from one another by effectively treating each application as a unique tenant within the system, and the protector creation process looks identical to the image above.

Hash passwords in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

The data protection code base includes a package *Microsoft.AspNetCore.Cryptography.KeyDerivation* which contains cryptographic key derivation functions. This package is a standalone component and has no dependencies on the rest of the data protection system. It can be used completely independently. The source exists alongside the data protection code base as a convenience.

The package currently offers a method `KeyDerivation.Pbkdf2` which allows hashing a password using the PBKDF2 algorithm. This API is very similar to the .NET Framework's existing Rfc2898DeriveBytes type, but there are three important distinctions:

1. The `KeyDerivation.Pbkdf2` method supports consuming multiple PRFs (currently `HMACSHA1`, `HMACSHA256`, and `HMACSHA512`), whereas the `Rfc2898DeriveBytes` type only supports `HMACSHA1`.
2. The `KeyDerivation.Pbkdf2` method detects the current operating system and attempts to choose the most optimized implementation of the routine, providing much better performance in certain cases. (On Windows 8, it offers around 10x the throughput of `Rfc2898DeriveBytes`.)
3. The `KeyDerivation.Pbkdf2` method requires the caller to specify all parameters (salt, PRF, and iteration count). The `Rfc2898DeriveBytes` type provides default values for these.

```
using System;
using System.Security.Cryptography;
using Microsoft.AspNetCore.Cryptography.KeyDerivation;

public class Program
{
    public static void Main(string[] args)
    {
        Console.Write("Enter a password: ");
        string password = Console.ReadLine();

        // generate a 128-bit salt using a secure PRNG
        byte[] salt = new byte[128 / 8];
        using (var rng = RandomNumberGenerator.Create())
        {
            rng.GetBytes(salt);
        }
        Console.WriteLine($"Salt: {Convert.ToBase64String(salt)}");

        // derive a 256-bit subkey (use HMACSHA1 with 10,000 iterations)
        string hashed = Convert.ToBase64String(KeyDerivation.Pbkdf2(
            password: password,
            salt: salt,
            prf: KeyDerivationPrf.HMACSHA1,
            iterationCount: 10000,
            numBytesRequested: 256 / 8));
        Console.WriteLine($"Hashed: {hashed}");
    }
}

/*
 * SAMPLE OUTPUT
 *
 * Enter a password: Xtw9NMgx
 * Salt: NZsP6NnmfBuYeJrrAKNuVQ==
 * Hashed: /OOoOer10+tGwTRDTrQSoeCxVTFr6dtYly7d0cPxIak=
 */
```

See the source code for ASP.NET Core Identity's `PasswordHasher` type for a real-world use case.

Limit the lifetime of protected payloads in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

There are scenarios where the application developer wants to create a protected payload that expires after a set period of time. For instance, the protected payload might represent a password reset token that should only be valid for one hour. It's certainly possible for the developer to create their own payload format that contains an embedded expiration date, and advanced developers may wish to do this anyway, but for the majority of developers managing these expirations can grow tedious.

To make this easier for our developer audience, the package Microsoft.AspNetCore.DataProtection.Extensions contains utility APIs for creating payloads that automatically expire after a set period of time. These APIs hang off of the `ITimeLimitedDataProtector` type.

API usage

The `ITimeLimitedDataProtector` interface is the core interface for protecting and unprotecting time-limited / self-expiring payloads. To create an instance of an `ITimeLimitedDataProtector`, you'll first need an instance of a regular IDataProtector constructed with a specific purpose. Once the `IDataProtector` instance is available, call the `IDataProtector.ToTimeLimitedDataProtector` extension method to get back a protector with built-in expiration capabilities.

`ITimeLimitedDataProtector` exposes the following API surface and extension methods:

- CreateProtector(string purpose) : ITimeLimitedDataProtector - This API is similar to the existing `IDataProtectionProvider.CreateProtector` in that it can be used to create purpose chains from a root time-limited protector.
- Protect(byte[] plaintext, DateTimeOffset expiration) : byte[]
- Protect(byte[] plaintext, TimeSpan lifetime) : byte[]
- Protect(byte[] plaintext) : byte[]
- Protect(string plaintext, DateTimeOffset expiration) : string
- Protect(string plaintext, TimeSpan lifetime) : string
- Protect(string plaintext) : string

In addition to the core `Protect` methods which take only the plaintext, there are new overloads which allow specifying the payload's expiration date. The expiration date can be specified as an absolute date (via a `DateTimeOffset`) or as a relative time (from the current system time, via a `TimeSpan`). If an overload which doesn't take an expiration is called, the payload is assumed never to expire.

- Unprotect(byte[] protectedData, out DateTimeOffset expiration) : byte[]
- Unprotect(byte[] protectedData) : byte[]
- Unprotect(string protectedData, out DateTimeOffset expiration) : string
- Unprotect(string protectedData) : string

The `Unprotect` methods return the original unprotected data. If the payload hasn't yet expired, the absolute

expiration is returned as an optional out parameter along with the original unprotected data. If the payload is expired, all overloads of the Unprotect method will throw CryptographicException.

> **WARNING**
> It's not advised to use these APIs to protect payloads which require long-term or indefinite persistence. "Can I afford for the protected payloads to be permanently unrecoverable after a month?" can serve as a good rule of thumb; if the answer is no then developers should consider alternative APIs.

The sample below uses the non-DI code paths for instantiating the data protection system. To run this sample, ensure that you have first added a reference to the Microsoft.AspNetCore.DataProtection.Extensions package.

```
using System;
using System.IO;
using System.Threading;
using Microsoft.AspNetCore.DataProtection;

public class Program
{
    public static void Main(string[] args)
    {
        // create a protector for my application

        var provider = DataProtectionProvider.Create(new DirectoryInfo(@"c:\myapp-keys\"));
        var baseProtector = provider.CreateProtector("Contoso.TimeLimitedSample");

        // convert the normal protector into a time-limited protector
        var timeLimitedProtector = baseProtector.ToTimeLimitedDataProtector();

        // get some input and protect it for five seconds
        Console.Write("Enter input: ");
        string input = Console.ReadLine();
        string protectedData = timeLimitedProtector.Protect(input, lifetime: TimeSpan.FromSeconds(5));
        Console.WriteLine($"Protected data: {protectedData}");

        // unprotect it to demonstrate that round-tripping works properly
        string roundtripped = timeLimitedProtector.Unprotect(protectedData);
        Console.WriteLine($"Round-tripped data: {roundtripped}");

        // wait 6 seconds and perform another unprotect, demonstrating that the payload self-expires
        Console.WriteLine("Waiting 6 seconds...");
        Thread.Sleep(6000);
        timeLimitedProtector.Unprotect(protectedData);
    }
}

/*
 * SAMPLE OUTPUT

Unprotect payloads whose keys have been revoked in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

The ASP.NET Core data protection APIs are not primarily intended for indefinite persistence of confidential payloads. Other technologies like Windows CNG DPAPI and Azure Rights Management are more suited to the scenario of indefinite storage, and they have correspondingly strong key management capabilities. That said, there's nothing prohibiting a developer from using the ASP.NET Core data protection APIs for long-term protection of confidential data. Keys are never removed from the key ring, so `IDataProtector.Unprotect` can always recover existing payloads as long as the keys are available and valid.

However, an issue arises when the developer tries to unprotect data that has been protected with a revoked key, as `IDataProtector.Unprotect` will throw an exception in this case. This might be fine for short-lived or transient payloads (like authentication tokens), as these kinds of payloads can easily be recreated by the system, and at worst the site visitor might be required to log in again. But for persisted payloads, having `Unprotect` throw could lead to unacceptable data loss.

IPersistedDataProtector

To support the scenario of allowing payloads to be unprotected even in the face of revoked keys, the data protection system contains an `IPersistedDataProtector` type. To get an instance of `IPersistedDataProtector`, simply get an instance of `IDataProtector` in the normal fashion and try casting the `IDataProtector` to `IPersistedDataProtector`.

> **NOTE**
> Not all `IDataProtector` instances can be cast to `IPersistedDataProtector`. Developers should use the C# as operator or similar to avoid runtime exceptions caused by invalid casts, and they should be prepared to handle the failure case appropriately.

`IPersistedDataProtector` exposes the following API surface:

```
DangerousUnprotect(byte[] protectedData, bool ignoreRevocationErrors,
     out bool requiresMigration, out bool wasRevoked) : byte[]
```

This API takes the protected payload (as a byte array) and returns the unprotected payload. There's no string-based overload. The two out parameters are as follows.

- `requiresMigration`: will be set to true if the key used to protect this payload is no longer the active default key, e.g., the key used to protect this payload is old and a key rolling operation has since taken place. The caller may wish to consider reprotecting the payload depending on their business needs.
- `wasRevoked`: will be set to true if the key used to protect this payload was revoked.

WARNING

Exercise extreme caution when passing `ignoreRevocationErrors: true` to the `DangerousUnprotect` method. If after calling this method the `wasRevoked` value is true, then the key used to protect this payload was revoked, and the payload's authenticity should be treated as suspect. In this case, only continue operating on the unprotected payload if you have some separate assurance that it's authentic, e.g. that it's coming from a secure database rather than being sent by an untrusted web client.

```
using System;
using System.IO;
using System.Text;
using Microsoft.AspNetCore.DataProtection;
using Microsoft.AspNetCore.DataProtection.KeyManagement;
using Microsoft.Extensions.DependencyInjection;

public class Program
{
    public static void Main(string[] args)
    {
        var serviceCollection = new ServiceCollection();
        serviceCollection.AddDataProtection()
            // point at a specific folder and use DPAPI to encrypt keys
            .PersistKeysToFileSystem(new DirectoryInfo(@"c:\temp-keys"))
            .ProtectKeysWithDpapi();
        var services = serviceCollection.BuildServiceProvider();

        // get a protector and perform a protect operation
        var protector = services.GetDataProtector("Sample.DangerousUnprotect");
        Console.Write("Input: ");
        byte[] input = Encoding.UTF8.GetBytes(Console.ReadLine());
        var protectedData = protector.Protect(input);
        Console.WriteLine($"Protected payload: {Convert.ToBase64String(protectedData)}");

        // demonstrate that the payload round-trips properly
        var roundTripped = protector.Unprotect(protectedData);
        Console.WriteLine($"Round-tripped payload: {Encoding.UTF8.GetString(roundTripped)}");

        // get a reference to the key manager and revoke all keys in the key ring
        var keyManager = services.GetService<IKeyManager>();
        Console.WriteLine("Revoking all keys in the key ring...");
        keyManager.RevokeAllKeys(DateTimeOffset.Now, "Sample revocation.");

        // try calling Protect - this should throw
        Console.WriteLine("Calling Unprotect...");
        try
        {
            var unprotectedPayload = protector.Unprotect(protectedData);
            Console.WriteLine($"Unprotected payload: {Encoding.UTF8.GetString(unprotectedPayload)}");
        }
        catch (Exception ex)
        {
            Console.WriteLine($"{ex.GetType().Name}: {ex.Message}");

Configure ASP.NET Core Data Protection

9/22/2020 • 11 minutes to read • Edit Online

When the Data Protection system is initialized, it applies default settings based on the operational environment. These settings are generally appropriate for apps running on a single machine. There are cases where a developer may want to change the default settings:

- The app is spread across multiple machines.
- For compliance reasons.

For these scenarios, the Data Protection system offers a rich configuration API.

> **WARNING**
>
> Similar to configuration files, the data protection key ring should be protected using appropriate permissions. You can choose to encrypt keys at rest, but this doesn't prevent attackers from creating new keys. Consequently, your app's security is impacted. The storage location configured with Data Protection should have its access limited to the app itself, similar to the way you would protect configuration files. For example, if you choose to store your key ring on disk, use file system permissions. Ensure only the identity under which your web app runs has read, write, and create access to that directory. If you use Azure Blob Storage, only the web app should have the ability to read, write, or create new entries in the blob store, etc.
>
> The extension method AddDataProtection returns an IDataProtectionBuilder. `IDataProtectionBuilder` exposes extension methods that you can chain together to configure Data Protection options.

The following NuGet packages are required for the Data Protection extensions used in this article:

- Azure.Extensions.AspNetCore.DataProtection.Blobs
- Azure.Extensions.AspNetCore.DataProtection.Keys

ProtectKeysWithAzureKeyVault

To store keys in Azure Key Vault, configure the system with ProtectKeysWithAzureKeyVault in the `Startup` class. `blobUriWithSasToken` is the full URI where the key file should be stored. The URI must contain the SAS token as a query string parameter:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .PersistKeysToAzureBlobStorage(new Uri("<blobUriWithSasToken>"))
        .ProtectKeysWithAzureKeyVault("<keyIdentifier>", "<clientId>", "<clientSecret>");
}
```

Set the key ring storage location (for example, PersistKeysToAzureBlobStorage). The location must be set because calling `ProtectKeysWithAzureKeyVault` implements an IXmlEncryptor that disables automatic data protection settings, including the key ring storage location. The preceding example uses Azure Blob Storage to persist the key ring. For more information, see Key storage providers: Azure Storage. You can also persist the key ring locally with PersistKeysToFileSystem.

The `keyIdentifier` is the key vault key identifier used for key encryption. For example, a key created in key vault named `dataprotection` in the `contosokeyvault` has the key identifier

`https://contosokeyvault.vault.azure.net/keys/dataprotection/`. Provide the app with **Unwrap Key** and **Wrap Key** permissions to the key vault.

`ProtectKeysWithAzureKeyVault` overloads:

- ProtectKeysWithAzureKeyVault(IDataProtectionBuilder, KeyVaultClient, String) permits the use of a KeyVaultClient to enable the data protection system to use the key vault.
- ProtectKeysWithAzureKeyVault(IDataProtectionBuilder, String, String, X509Certificate2) permits the use of a `ClientId` and X509Certificate to enable the data protection system to use the key vault.
- ProtectKeysWithAzureKeyVault(IDataProtectionBuilder, String, String, String) permits the use of a `ClientId` and `ClientSecret` to enable the data protection system to use the key vault.

If the app uses the prior Azure packages (`Microsoft.AspNetCore.DataProtection.AzureStorage` and `Microsoft.AspNetCore.DataProtection.AzureKeyVault`) and a combination of Azure Key Vault and Azure Storage to store and protect keys, System.UriFormatException is thrown if the blob for key storage doesn't exist. The blob can be manually created ahead of running the app in the Azure portal, or use the following procedure:

1. Remove the call to `ProtectKeysWithAzureKeyVault` for the first run to create the blob in place.
2. Add the call to `ProtectKeysWithAzureKeyVault` for subsequent runs.

Removing `ProtectKeysWithAzureKeyVault` for the first run is advised, as it ensures that the file is created with the proper schema and values in place.

We recommended upgrading to the Azure.Extensions.AspNetCore.DataProtection.Blobs and Azure.Extensions.AspNetCore.DataProtection.Keys packages because the API provided automatically creates the blob if it doesn't exist.

```
var storageAccount = CloudStorageAccount.Parse("<storage account connection string">);
var client = storageAccount.CreateCloudBlobClient();
var container = client.GetContainerReference("<key store container name>");

var azureServiceTokenProvider = new AzureServiceTokenProvider();
var keyVaultClient = new KeyVaultClient(new KeyVaultClient.AuthenticationCallback(
        azureServiceTokenProvider.KeyVaultTokenCallback));

services.AddDataProtection()
    //This blob must already exist before the application is run
    .PersistKeysToAzureBlobStorage(container, "<key store blob name>")
    //Removing this line below for an initial run will ensure the file is created correctly
    .ProtectKeysWithAzureKeyVault(keyVaultClient, "<keyIdentifier>");
```

PersistKeysToFileSystem

To store keys on a UNC share instead of at the *%LOCALAPPDATA%* default location, configure the system with PersistKeysToFileSystem:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .PersistKeysToFileSystem(new DirectoryInfo(@"\\server\share\directory\"));
}
```

WARNING

If you change the key persistence location, the system no longer automatically encrypts keys at rest, since it doesn't know whether DPAPI is an appropriate encryption mechanism.

ProtectKeysWith*

You can configure the system to protect keys at rest by calling any of the ProtectKeysWith* configuration APIs. Consider the example below, which stores keys on a UNC share and encrypts those keys at rest with a specific X.509 certificate:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .PersistKeysToFileSystem(new DirectoryInfo(@"\\server\share\directory\"))
        .ProtectKeysWithCertificate("thumbprint");
}
```

In ASP.NET Core 2.1 or later, you can provide an X509Certificate2 to ProtectKeysWithCertificate, such as a certificate loaded from a file:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .PersistKeysToFileSystem(new DirectoryInfo(@"\\server\share\directory\"))
        .ProtectKeysWithCertificate(
            new X509Certificate2("certificate.pfx", "password"));
}
```

See Key Encryption At Rest for more examples and discussion on the built-in key encryption mechanisms.

UnprotectKeysWithAnyCertificate

In ASP.NET Core 2.1 or later, you can rotate certificates and decrypt keys at rest using an array of X509Certificate2 certificates with UnprotectKeysWithAnyCertificate:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .PersistKeysToFileSystem(new DirectoryInfo(@"\\server\share\directory\"))
        .ProtectKeysWithCertificate(
            new X509Certificate2("certificate.pfx", "password"));
        .UnprotectKeysWithAnyCertificate(
            new X509Certificate2("certificate_old_1.pfx", "password_1"),
            new X509Certificate2("certificate_old_2.pfx", "password_2"));
}
```

SetDefaultKeyLifetime

To configure the system to use a key lifetime of 14 days instead of the default 90 days, use SetDefaultKeyLifetime:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .SetDefaultKeyLifetime(TimeSpan.FromDays(14));
}
```

SetApplicationName

By default, the Data Protection system isolates apps from one another based on their content root paths, even

if they're sharing the same physical key repository. This prevents the apps from understanding each other's protected payloads.

To share protected payloads among apps:

- Configure SetApplicationName in each app with the same value.
- Use the same version of the Data Protection API stack across the apps. Perform **either** of the following in the apps' project files:
  - Reference the same shared framework version via the Microsoft.AspNetCore.App metapackage.
  - Reference the same Data Protection package version.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .SetApplicationName("shared app name");
}
```

DisableAutomaticKeyGeneration

You may have a scenario where you don't want an app to automatically roll keys (create new keys) as they approach expiration. One example of this might be apps set up in a primary/secondary relationship, where only the primary app is responsible for key management concerns and secondary apps simply have a read-only view of the key ring. The secondary apps can be configured to treat the key ring as read-only by configuring the system with DisableAutomaticKeyGeneration:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .DisableAutomaticKeyGeneration();
}
```

Per-application isolation

When the Data Protection system is provided by an ASP.NET Core host, it automatically isolates apps from one another, even if those apps are running under the same worker process account and are using the same master keying material. This is somewhat similar to the IsolateApps modifier from System.Web's `<machineKey>` element.

The isolation mechanism works by considering each app on the local machine as a unique tenant, thus the IDataProtector rooted for any given app automatically includes the app ID as a discriminator. The app's unique ID is the app's physical path:

- For apps hosted in IIS, the unique ID is the IIS physical path of the app. If an app is deployed in a web farm environment, this value is stable assuming that the IIS environments are configured similarly across all machines in the web farm.
- For self-hosted apps running on the Kestrel server, the unique ID is the physical path to the app on disk.

The unique identifier is designed to survive resets—both of the individual app and of the machine itself.

This isolation mechanism assumes that the apps are not malicious. A malicious app can always impact any other app running under the same worker process account. In a shared hosting environment where apps are mutually untrusted, the hosting provider should take steps to ensure OS-level isolation between apps, including separating the apps' underlying key repositories.

If the Data Protection system isn't provided by an ASP.NET Core host (for example, if you instantiate it via the

`DataProtectionProvider` concrete type) app isolation is disabled by default. When app isolation is disabled, all apps backed by the same keying material can share payloads as long as they provide the appropriate purposes. To provide app isolation in this environment, call the SetApplicationName method on the configuration object and provide a unique name for each app.

Changing algorithms with UseCryptographicAlgorithms

The Data Protection stack allows you to change the default algorithm used by newly-generated keys. The simplest way to do this is to call UseCryptographicAlgorithms from the configuration callback:

```
services.AddDataProtection()
    .UseCryptographicAlgorithms(
        new AuthenticatedEncryptorConfiguration()
    {
        EncryptionAlgorithm = EncryptionAlgorithm.AES_256_CBC,
        ValidationAlgorithm = ValidationAlgorithm.HMACSHA256
    });
```

```
services.AddDataProtection()
    .UseCryptographicAlgorithms(
        new AuthenticatedEncryptionSettings()
    {
        EncryptionAlgorithm = EncryptionAlgorithm.AES_256_CBC,
        ValidationAlgorithm = ValidationAlgorithm.HMACSHA256
    });
```

The default EncryptionAlgorithm is AES-256-CBC, and the default ValidationAlgorithm is HMACSHA256. The default policy can be set by a system administrator via a machine-wide policy, but an explicit call to `UseCryptographicAlgorithms` overrides the default policy.

Calling `UseCryptographicAlgorithms` allows you to specify the desired algorithm from a predefined built-in list. You don't need to worry about the implementation of the algorithm. In the scenario above, the Data Protection system attempts to use the CNG implementation of AES if running on Windows. Otherwise, it falls back to the managed System.Security.Cryptography.Aes class.

You can manually specify an implementation via a call to UseCustomCryptographicAlgorithms.

> **TIP**
> Changing algorithms doesn't affect existing keys in the key ring. It only affects newly-generated keys.

Specifying custom managed algorithms

To specify custom managed algorithms, create a ManagedAuthenticatedEncryptorConfiguration instance that points to the implementation types:

```
serviceCollection.AddDataProtection()
    .UseCustomCryptographicAlgorithms(
        new ManagedAuthenticatedEncryptorConfiguration()
    {
        // A type that subclasses SymmetricAlgorithm
        EncryptionAlgorithmType = typeof(Aes),

        // Specified in bits
        EncryptionAlgorithmKeySize = 256,

        // A type that subclasses KeyedHashAlgorithm
        ValidationAlgorithmType = typeof(HMACSHA256)
    });
```

To specify custom managed algorithms, create a ManagedAuthenticatedEncryptionSettings instance that points to the implementation types:

```
serviceCollection.AddDataProtection()
    .UseCustomCryptographicAlgorithms(
        new ManagedAuthenticatedEncryptionSettings()
    {
        // A type that subclasses SymmetricAlgorithm
        EncryptionAlgorithmType = typeof(Aes),

        // Specified in bits
        EncryptionAlgorithmKeySize = 256,

        // A type that subclasses KeyedHashAlgorithm
        ValidationAlgorithmType = typeof(HMACSHA256)
    });
```

Generally the *Type properties must point to concrete, instantiable (via a public parameterless ctor) implementations of SymmetricAlgorithm and KeyedHashAlgorithm, though the system special-cases some values like `typeof(Aes)` for convenience.

> **NOTE**
>
> The SymmetricAlgorithm must have a key length of ≥ 128 bits and a block size of ≥ 64 bits, and it must support CBC-mode encryption with PKCS #7 padding. The KeyedHashAlgorithm must have a digest size of >= 128 bits, and it must support keys of length equal to the hash algorithm's digest length. The KeyedHashAlgorithm isn't strictly required to be HMAC.

Specifying custom Windows CNG algorithms

To specify a custom Windows CNG algorithm using CBC-mode encryption with HMAC validation, create a CngCbcAuthenticatedEncryptorConfiguration instance that contains the algorithmic information:

```
services.AddDataProtection()
    .UseCustomCryptographicAlgorithms(
        new CngCbcAuthenticatedEncryptorConfiguration()
    {
        // Passed to BCryptOpenAlgorithmProvider
        EncryptionAlgorithm = "AES",
        EncryptionAlgorithmProvider = null,

        // Specified in bits
        EncryptionAlgorithmKeySize = 256,

        // Passed to BCryptOpenAlgorithmProvider
        HashAlgorithm = "SHA256",
        HashAlgorithmProvider = null
    });
```

To specify a custom Windows CNG algorithm using CBC-mode encryption with HMAC validation, create a CngCbcAuthenticatedEncryptionSettings instance that contains the algorithmic information:

```
services.AddDataProtection()
    .UseCustomCryptographicAlgorithms(
        new CngCbcAuthenticatedEncryptionSettings()
    {
        // Passed to BCryptOpenAlgorithmProvider
        EncryptionAlgorithm = "AES",
        EncryptionAlgorithmProvider = null,

        // Specified in bits
        EncryptionAlgorithmKeySize = 256,

        // Passed to BCryptOpenAlgorithmProvider
        HashAlgorithm = "SHA256",
        HashAlgorithmProvider = null
    });
```

NOTE

The symmetric block cipher algorithm must have a key length of >= 128 bits, a block size of >= 64 bits, and it must support CBC-mode encryption with PKCS #7 padding. The hash algorithm must have a digest size of >= 128 bits and must support being opened with the BCRYPT_ALG_HANDLE_HMAC_FLAG flag. The *Provider properties can be set to null to use the default provider for the specified algorithm. See the BCryptOpenAlgorithmProvider documentation for more information.

To specify a custom Windows CNG algorithm using Galois/Counter Mode encryption with validation, create a CngGcmAuthenticatedEncryptorConfiguration instance that contains the algorithmic information:

```
services.AddDataProtection()
    .UseCustomCryptographicAlgorithms(
        new CngGcmAuthenticatedEncryptorConfiguration()
    {
        // Passed to BCryptOpenAlgorithmProvider
        EncryptionAlgorithm = "AES",
        EncryptionAlgorithmProvider = null,

        // Specified in bits
        EncryptionAlgorithmKeySize = 256
    });
```

To specify a custom Windows CNG algorithm using Galois/Counter Mode encryption with validation, create a

CngGcmAuthenticatedEncryptionSettings instance that contains the algorithmic information:

```
services.AddDataProtection()
    .UseCustomCryptographicAlgorithms(
        new CngGcmAuthenticatedEncryptionSettings()
    {
        // Passed to BCryptOpenAlgorithmProvider
        EncryptionAlgorithm = "AES",
        EncryptionAlgorithmProvider = null,

        // Specified in bits
        EncryptionAlgorithmKeySize = 256
    });
```

> **NOTE**
> The symmetric block cipher algorithm must have a key length of >= 128 bits, a block size of exactly 128 bits, and it must support GCM encryption. You can set the EncryptionAlgorithmProvider property to null to use the default provider for the specified algorithm. See the BCryptOpenAlgorithmProvider documentation for more information.

Specifying other custom algorithms

Though not exposed as a first-class API, the Data Protection system is extensible enough to allow specifying almost any kind of algorithm. For example, it's possible to keep all keys contained within a Hardware Security Module (HSM) and to provide a custom implementation of the core encryption and decryption routines. See IAuthenticatedEncryptor in Core cryptography extensibility for more information.

Persisting keys when hosting in a Docker container

When hosting in a Docker container, keys should be maintained in either:

- A folder that's a Docker volume that persists beyond the container's lifetime, such as a shared volume or a host-mounted volume.
- An external provider, such as Azure Key Vault or Redis.

Persisting keys with Redis

Only Redis versions supporting Redis Data Persistence should be used to store keys. Azure Blob storage is persistent and can be used to store keys. For more information, see this GitHub issue.

Data Protection key management and lifetime in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

By Rick Anderson

Key management

The app attempts to detect its operational environment and handle key configuration on its own.

1. If the app is hosted in Azure Apps, keys are persisted to the *%HOME%\ASP.NET\DataProtection-Keys* folder. This folder is backed by network storage and is synchronized across all machines hosting the app.

   - Keys aren't protected at rest.
   - The *DataProtection-Keys* folder supplies the key ring to all instances of an app in a single deployment slot.
   - Separate deployment slots, such as Staging and Production, don't share a key ring. When you swap between deployment slots, for example swapping Staging to Production or using A/B testing, any app using Data Protection won't be able to decrypt stored data using the key ring inside the previous slot. This leads to users being logged out of an app that uses the standard ASP.NET Core cookie authentication, as it uses Data Protection to protect its cookies. If you desire slot-independent key rings, use an external key ring provider, such as Azure Blob Storage, Azure Key Vault, a SQL store, or Redis cache.

2. If the user profile is available, keys are persisted to the *%LOCALAPPDATA%\ASP.NET\DataProtection-Keys* folder. If the operating system is Windows, the keys are encrypted at rest using DPAPI.

   The app pool's setProfileEnvironment attribute must also be enabled. The default value of `setProfileEnvironment` is `true`. In some scenarios (for example, Windows OS), `setProfileEnvironment` is set to `false`. If keys aren't stored in the user profile directory as expected:

   a. Navigate to the *%windir%/system32/inetsrv/config* folder.
   b. Open the *applicationHost.config* file.
   c. Locate the `<system.applicationHost><applicationPools><applicationPoolDefaults><processModel>` element.
   d. Confirm that the `setProfileEnvironment` attribute isn't present, which defaults the value to `true`, or explicitly set the attribute's value to `true`.

3. If the app is hosted in IIS, keys are persisted to the HKLM registry in a special registry key that's ACLed only to the worker process account. Keys are encrypted at rest using DPAPI.

4. If none of these conditions match, keys aren't persisted outside of the current process. When the process shuts down, all generated keys are lost.

The developer is always in full control and can override how and where keys are stored. The first three options above should provide good defaults for most apps similar to how the ASP.NET **<machineKey>** auto-generation routines worked in the past. The final, fallback option is the only scenario that requires the developer to specify configuration upfront if they want key persistence, but this fallback only occurs in rare situations.

When hosting in a Docker container, keys should be persisted in a folder that's a Docker volume (a shared volume or a host-mounted volume that persists beyond the container's lifetime) or in an external provider, such as Azure Key Vault or Redis. An external provider is also useful in web farm scenarios if apps can't access a shared network volume (see PersistKeysToFileSystem for more information).

> **WARNING**
>
> If the developer overrides the rules outlined above and points the Data Protection system at a specific key repository, automatic encryption of keys at rest is disabled. At-rest protection can be re-enabled via configuration.

Key lifetime

Keys have a 90-day lifetime by default. When a key expires, the app automatically generates a new key and sets the new key as the active key. As long as retired keys remain on the system, your app can decrypt any data protected with them. See key management for more information.

Default algorithms

The default payload protection algorithm used is AES-256-CBC for confidentiality and HMACSHA256 for authenticity. A 512-bit master key, changed every 90 days, is used to derive the two sub-keys used for these algorithms on a per-payload basis. See subkey derivation for more information.

Data Protection machine-wide policy support in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

By Rick Anderson

When running on Windows, the Data Protection system has limited support for setting a default machine-wide policy for all apps that consume ASP.NET Core Data Protection. The general idea is that an administrator might wish to change a default setting, such as the algorithms used or key lifetime, without the need to manually update every app on the machine.

> **WARNING**
> The system administrator can set default policy, but they can't enforce it. The app developer can always override any value with one of their own choosing. The default policy only affects apps where the developer hasn't specified an explicit value for a setting.

Setting default policy

To set default policy, an administrator can set known values in the system registry under the following registry key:

HKLM\SOFTWARE\Microsoft\DotNetPackages\Microsoft.AspNetCore.DataProtection

If you're on a 64-bit operating system and want to affect the behavior of 32-bit apps, remember to configure the Wow6432Node equivalent of the above key.

The supported values are shown below.

VALUE	TYPE	DESCRIPTION
EncryptionType	string	Specifies which algorithms should be used for data protection. The value must be CNG-CBC, CNG-GCM, or Managed and is described in more detail below.
DefaultKeyLifetime	DWORD	Specifies the lifetime for newly-generated keys. The value is specified in days and must be >= 7.
KeyEscrowSinks	string	Specifies the types that are used for key escrow. The value is a semicolon-delimited list of key escrow sinks, where each element in the list is the assembly-qualified name of a type that implements IKeyEscrowSink.

Encryption types

If EncryptionType is CNG-CBC, the system is configured to use a CBC-mode symmetric block cipher for

confidentiality and HMAC for authenticity with services provided by Windows CNG (see Specifying custom Windows CNG algorithms for more details). The following additional values are supported, each of which corresponds to a property on the CngCbcAuthenticatedEncryptionSettings type.

VALUE	TYPE	DESCRIPTION
EncryptionAlgorithm	string	The name of a symmetric block cipher algorithm understood by CNG. This algorithm is opened in CBC mode.
EncryptionAlgorithmProvider	string	The name of the CNG provider implementation that can produce the algorithm EncryptionAlgorithm.
EncryptionAlgorithmKeySize	DWORD	The length (in bits) of the key to derive for the symmetric block cipher algorithm.
HashAlgorithm	string	The name of a hash algorithm understood by CNG. This algorithm is opened in HMAC mode.
HashAlgorithmProvider	string	The name of the CNG provider implementation that can produce the algorithm HashAlgorithm.

If EncryptionType is CNG-GCM, the system is configured to use a Galois/Counter Mode symmetric block cipher for confidentiality and authenticity with services provided by Windows CNG (see Specifying custom Windows CNG algorithms for more details). The following additional values are supported, each of which corresponds to a property on the CngGcmAuthenticatedEncryptionSettings type.

VALUE	TYPE	DESCRIPTION
EncryptionAlgorithm	string	The name of a symmetric block cipher algorithm understood by CNG. This algorithm is opened in Galois/Counter Mode.
EncryptionAlgorithmProvider	string	The name of the CNG provider implementation that can produce the algorithm EncryptionAlgorithm.
EncryptionAlgorithmKeySize	DWORD	The length (in bits) of the key to derive for the symmetric block cipher algorithm.

If EncryptionType is Managed, the system is configured to use a managed SymmetricAlgorithm for confidentiality and KeyedHashAlgorithm for authenticity (see Specifying custom managed algorithms for more details). The following additional values are supported, each of which corresponds to a property on the ManagedAuthenticatedEncryptionSettings type.

VALUE	TYPE	DESCRIPTION
EncryptionAlgorithmType	string	The assembly-qualified name of a type that implements SymmetricAlgorithm.

VALUE	TYPE	DESCRIPTION
EncryptionAlgorithmKeySize	DWORD	The length (in bits) of the key to derive for the symmetric encryption algorithm.
ValidationAlgorithmType	string	The assembly-qualified name of a type that implements KeyedHashAlgorithm.

If EncryptionType has any other value other than null or empty, the Data Protection system throws an exception at startup.

> **WARNING**
> When configuring a default policy setting that involves type names (EncryptionAlgorithmType, ValidationAlgorithmType, KeyEscrowSinks), the types must be available to the app. This means that for apps running on Desktop CLR, the assemblies that contain these types should be present in the Global Assembly Cache (GAC). For ASP.NET Core apps running on .NET Core, the packages that contain these types should be installed.

Non-DI aware scenarios for Data Protection in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

By Rick Anderson

The ASP.NET Core Data Protection system is normally added to a service container and consumed by dependent components via dependency injection (DI). However, there are cases where this isn't feasible or desired, especially when importing the system into an existing app.

To support these scenarios, the Microsoft.AspNetCore.DataProtection.Extensions package provides a concrete type, DataProtectionProvider, which offers a simple way to use Data Protection without relying on DI. The `DataProtectionProvider` type implements IDataProtectionProvider. Constructing `DataProtectionProvider` only requires providing a DirectoryInfo instance to indicate where the provider's cryptographic keys should be stored, as seen in the following code sample:

```
using System;
using System.IO;
using Microsoft.AspNetCore.DataProtection;

public class Program
{
    public static void Main(string[] args)
    {
        // Get the path to %LOCALAPPDATA%\myapp-keys
        var destFolder = Path.Combine(
            System.Environment.GetEnvironmentVariable("LOCALAPPDATA"),
            "myapp-keys");

        // Instantiate the data protection system at this folder
        var dataProtectionProvider = DataProtectionProvider.Create(
            new DirectoryInfo(destFolder));

        var protector = dataProtectionProvider.CreateProtector("Program.No-DI");
        Console.Write("Enter input: ");
        var input = Console.ReadLine();

        // Protect the payload
        var protectedPayload = protector.Protect(input);
        Console.WriteLine($"Protect returned: {protectedPayload}");

        // Unprotect the payload
        var unprotectedPayload = protector.Unprotect(protectedPayload);
        Console.WriteLine($"Unprotect returned: {unprotectedPayload}");

        Console.WriteLine();
        Console.WriteLine("Press any key...");
        Console.ReadKey();
    }
}

/*
 * SAMPLE OUTPUT
 *
 * Enter input: Hello world!
 * Protect returned: CfDJ8FWbAn6...ch3hAPm1NJA
 * Unprotect returned: Hello world!
 *
 * Press any key...
*/
```

By default, the `DataProtectionProvider` concrete type doesn't encrypt raw key material before persisting it to the file system. This is to support scenarios where the developer points to a network share and the Data Protection system can't automatically deduce an appropriate at-rest key encryption mechanism.

Additionally, the `DataProtectionProvider` concrete type doesn't isolate apps by default. All apps using the same key directory can share payloads as long as their purpose parameters match.

The DataProtectionProvider constructor accepts an optional configuration callback that can be used to adjust the behaviors of the system. The sample below demonstrates restoring isolation with an explicit call to SetApplicationName. The sample also demonstrates configuring the system to automatically encrypt persisted keys using Windows DPAPI. If the directory points to a UNC share, you may wish to distribute a shared certificate across all relevant machines and to configure the system to use certificate-based encryption with a call to ProtectKeysWithCertificate.

```
using System;
using System.IO;
using Microsoft.AspNetCore.DataProtection;

public class Program
{
    public static void Main(string[] args)
    {
        // Get the path to %LOCALAPPDATA%\myapp-keys
        var destFolder = Path.Combine(
            System.Environment.GetEnvironmentVariable("LOCALAPPDATA"),
            "myapp-keys");

        // Instantiate the data protection system at this folder
        var dataProtectionProvider = DataProtectionProvider.Create(
            new DirectoryInfo(destFolder),
            configuration =>
            {
                configuration.SetApplicationName("my app name");
                configuration.ProtectKeysWithDpapi();
            });

        var protector = dataProtectionProvider.CreateProtector("Program.No-DI");
        Console.Write("Enter input: ");
        var input = Console.ReadLine();

        // Protect the payload
        var protectedPayload = protector.Protect(input);
        Console.WriteLine($"Protect returned: {protectedPayload}");

        // Unprotect the payload
        var unprotectedPayload = protector.Unprotect(protectedPayload);
        Console.WriteLine($"Unprotect returned: {unprotectedPayload}");

        Console.WriteLine();
        Console.WriteLine("Press any key...");
        Console.ReadKey();
    }
}
```

TIP

Instances of the `DataProtectionProvider` concrete type are expensive to create. If an app maintains multiple instances of this type and if they're all using the same key storage directory, app performance might degrade. If you use the `DataProtectionProvider` type, we recommend that you create this type once and reuse it as much as possible. The `DataProtectionProvider` type and all IDataProtector instances created from it are thread-safe for multiple callers.

ASP.NET Core Data Protection extensibility APIs

- Key management extensibility
- Miscellaneous APIs

Core cryptography extensibility in ASP.NET Core

9/22/2020 • 5 minutes to read • Edit Online

WARNING

Types that implement any of the following interfaces should be thread-safe for multiple callers.

IAuthenticatedEncryptor

The **IAuthenticatedEncryptor** interface is the basic building block of the cryptographic subsystem. There's generally one IAuthenticatedEncryptor per key, and the IAuthenticatedEncryptor instance wraps all cryptographic key material and algorithmic information necessary to perform cryptographic operations.

As its name suggests, the type is responsible for providing authenticated encryption and decryption services. It exposes the following two APIs.

- `Decrypt(ArraySegment<byte> ciphertext, ArraySegment<byte> additionalAuthenticatedData) : byte[]`
- `Encrypt(ArraySegment<byte> plaintext, ArraySegment<byte> additionalAuthenticatedData) : byte[]`

The Encrypt method returns a blob that includes the enciphered plaintext and an authentication tag. The authentication tag must encompass the additional authenticated data (AAD), though the AAD itself need not be recoverable from the final payload. The Decrypt method validates the authentication tag and returns the deciphered payload. All failures (except ArgumentNullException and similar) should be homogenized to CryptographicException.

NOTE

The IAuthenticatedEncryptor instance itself doesn't actually need to contain the key material. For example, the implementation could delegate to an HSM for all operations.

How to create an IAuthenticatedEncryptor

- ASP.NET Core 2.x
- ASP.NET Core 1.x

The **IAuthenticatedEncryptorFactory** interface represents a type that knows how to create an IAuthenticatedEncryptor instance. Its API is as follows.

- CreateEncryptorInstance(IKey key) : IAuthenticatedEncryptor

For any given IKey instance, any authenticated encryptors created by its CreateEncryptorInstance method should be considered equivalent, as in the below code sample.

```
// we have an IAuthenticatedEncryptorFactory instance and an IKey instance
IAuthenticatedEncryptorFactory factory = ...;
IKey key = ...;

// get an encryptor instance and perform an authenticated encryption operation
ArraySegment<byte> plaintext = new ArraySegment<byte>(Encoding.UTF8.GetBytes("plaintext"));
ArraySegment<byte> aad = new ArraySegment<byte>(Encoding.UTF8.GetBytes("AAD"));
var encryptor1 = factory.CreateEncryptorInstance(key);
byte[] ciphertext = encryptor1.Encrypt(plaintext, aad);

// get another encryptor instance and perform an authenticated decryption operation
var encryptor2 = factory.CreateEncryptorInstance(key);
byte[] roundTripped = encryptor2.Decrypt(new ArraySegment<byte>(ciphertext), aad);

// the 'roundTripped' and 'plaintext' buffers should be equivalent
```

IAuthenticatedEncryptorDescriptor (ASP.NET Core 2.x only)

- ASP.NET Core 2.x
- ASP.NET Core 1.x

The **IAuthenticatedEncryptorDescriptor** interface represents a type that knows how to export itself to XML. Its API is as follows.

- ExportToXml() : XmlSerializedDescriptorInfo

XML Serialization

The primary difference between IAuthenticatedEncryptor and IAuthenticatedEncryptorDescriptor is that the descriptor knows how to create the encryptor and supply it with valid arguments. Consider an IAuthenticatedEncryptor whose implementation relies on SymmetricAlgorithm and KeyedHashAlgorithm. The encryptor's job is to consume these types, but it doesn't necessarily know where these types came from, so it can't really write out a proper description of how to recreate itself if the application restarts. The descriptor acts as a higher level on top of this. Since the descriptor knows how to create the encryptor instance (e.g., it knows how to create the required algorithms), it can serialize that knowledge in XML form so that the encryptor instance can be recreated after an application reset.

The descriptor can be serialized via its ExportToXml routine. This routine returns an XmlSerializedDescriptorInfo which contains two properties: the XElement representation of the descriptor and the Type which represents an IAuthenticatedEncryptorDescriptorDeserializer which can be used to resurrect this descriptor given the corresponding XElement.

The serialized descriptor may contain sensitive information such as cryptographic key material. The data protection system has built-in support for encrypting information before it's persisted to storage. To take advantage of this, the descriptor should mark the element which contains sensitive information with the attribute name "requiresEncryption" (xmlns "http://schemas.asp.net/2015/03/dataProtection"), value "true".

> **TIP**
> There's a helper API for setting this attribute. Call the extension method XElement.MarkAsRequiresEncryption() located in namespace Microsoft.AspNetCore.DataProtection.AuthenticatedEncryption.ConfigurationModel.

There can also be cases where the serialized descriptor doesn't contain sensitive information. Consider again the case of a cryptographic key stored in an HSM. The descriptor cannot write out the key material when serializing itself since the HSM won't expose the material in plaintext form. Instead, the descriptor might write out the key-

wrapped version of the key (if the HSM allows export in this fashion) or the HSM's own unique identifier for the key.

IAuthenticatedEncryptorDescriptorDeserializer

The **IAuthenticatedEncryptorDescriptorDeserializer** interface represents a type that knows how to deserialize an IAuthenticatedEncryptorDescriptor instance from an XElement. It exposes a single method:

- ImportFromXml(XElement element) : IAuthenticatedEncryptorDescriptor

The ImportFromXml method takes the XElement that was returned by IAuthenticatedEncryptorDescriptor.ExportToXml and creates an equivalent of the original IAuthenticatedEncryptorDescriptor.

Types which implement IAuthenticatedEncryptorDescriptorDeserializer should have one of the following two public constructors:

- .ctor(IServiceProvider)
- .ctor()

> **NOTE**
> The IServiceProvider passed to the constructor may be null.

The top-level factory

- ASP.NET Core 2.x
- ASP.NET Core 1.x

The **AlgorithmConfiguration** class represents a type which knows how to create IAuthenticatedEncryptorDescriptor instances. It exposes a single API.

- CreateNewDescriptor() : IAuthenticatedEncryptorDescriptor

Think of AlgorithmConfiguration as the top-level factory. The configuration serves as a template. It wraps algorithmic information (e.g., this configuration produces descriptors with an AES-128-GCM master key), but it's not yet associated with a specific key.

When CreateNewDescriptor is called, fresh key material is created solely for this call, and a new IAuthenticatedEncryptorDescriptor is produced which wraps this key material and the algorithmic information required to consume the material. The key material could be created in software (and held in memory), it could be created and held within an HSM, and so on. The crucial point is that any two calls to CreateNewDescriptor should never create equivalent IAuthenticatedEncryptorDescriptor instances.

The AlgorithmConfiguration type serves as the entry point for key creation routines such as automatic key rolling. To change the implementation for all future keys, set the AuthenticatedEncryptorConfiguration property in KeyManagementOptions.

Key management extensibility in ASP.NET Core

9/22/2020 • 7 minutes to read • Edit Online

Read the key management section before reading this section, as it explains some of the fundamental concepts behind these APIs.

Warning: Types that implement any of the following interfaces should be thread-safe for multiple callers.

Key

The `IKey` interface is the basic representation of a key in cryptosystem. The term key is used here in the abstract sense, not in the literal sense of "cryptographic key material". A key has the following properties:

- Activation, creation, and expiration dates
- Revocation status
- Key identifier (a GUID)

Additionally, `IKey` exposes a `CreateEncryptor` method which can be used to create an IAuthenticatedEncryptor instance tied to this key.

Additionally, `IKey` exposes a `CreateEncryptorInstance` method which can be used to create an IAuthenticatedEncryptor instance tied to this key.

> **NOTE**
> There's no API to retrieve the raw cryptographic material from an `IKey` instance.

IKeyManager

The `IKeyManager` interface represents an object responsible for general key storage, retrieval, and manipulation. It exposes three high-level operations:

- Create a new key and persist it to storage.
- Get all keys from storage.
- Revoke one or more keys and persist the revocation information to storage.

> **WARNING**
> Writing an `IKeyManager` is a very advanced task, and the majority of developers shouldn't attempt it. Instead, most developers should take advantage of the facilities offered by the XmlKeyManager class.

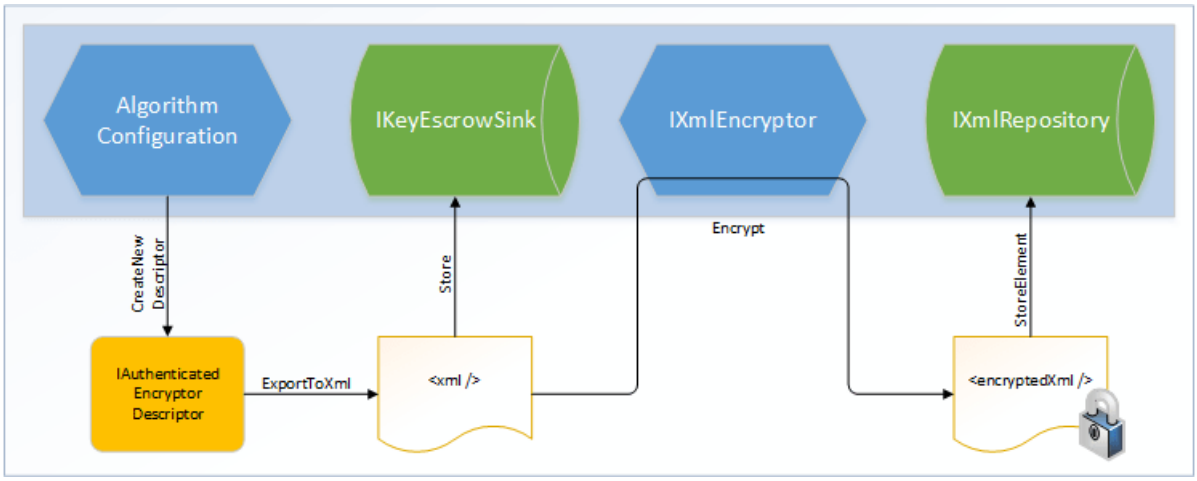
XmlKeyManager

The `XmlKeyManager` type is the in-box concrete implementation of `IKeyManager`. It provides several useful facilities, including key escrow and encryption of keys at rest. Keys in this system are represented as XML elements (specifically, XElement).

`XmlKeyManager` depends on several other components in the course of fulfilling its tasks:

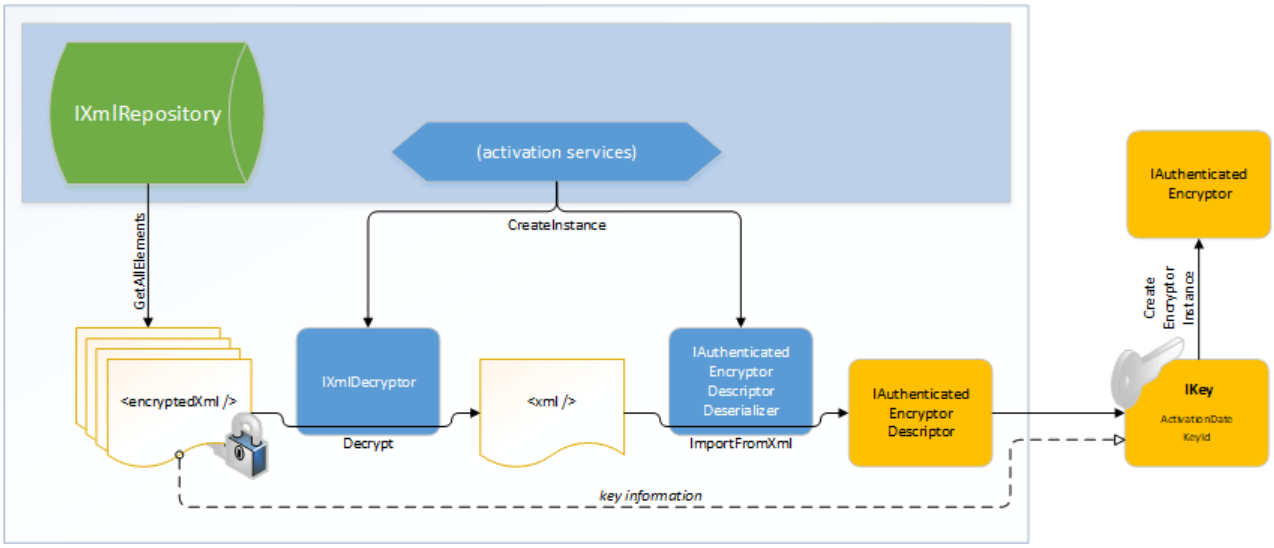
- `AlgorithmConfiguration`, which dictates the algorithms used by new keys.
- `IXmlRepository`, which controls where keys are persisted in storage.
- `IXmlEncryptor` [optional], which allows encrypting keys at rest.
- `IKeyEscrowSink` [optional], which provides key escrow services.
- `IXmlRepository`, which controls where keys are persisted in storage.
- `IXmlEncryptor` [optional], which allows encrypting keys at rest.
- `IKeyEscrowSink` [optional], which provides key escrow services.

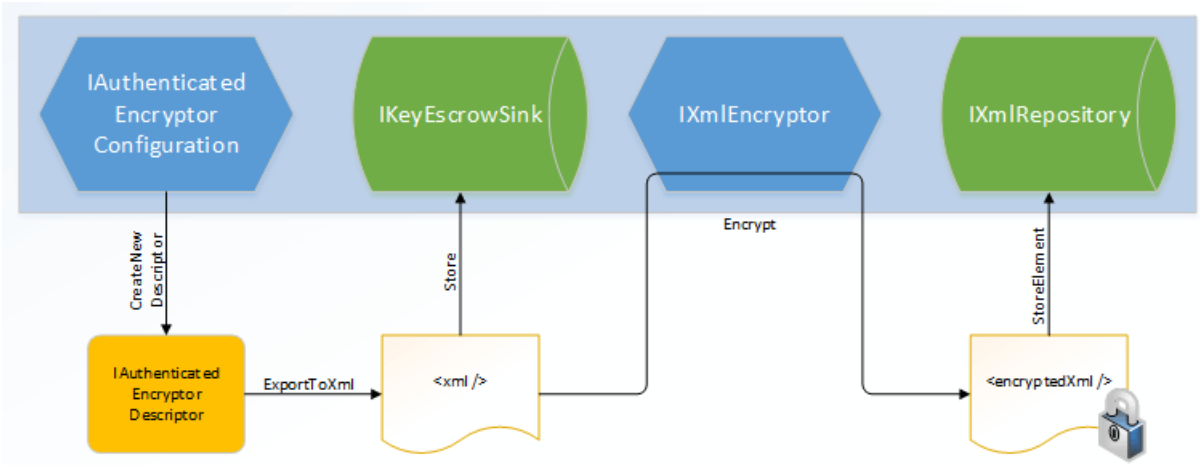
Below are high-level diagrams which indicate how these components are wired together within `XmlKeyManager`.



Key Creation / CreateNewKey

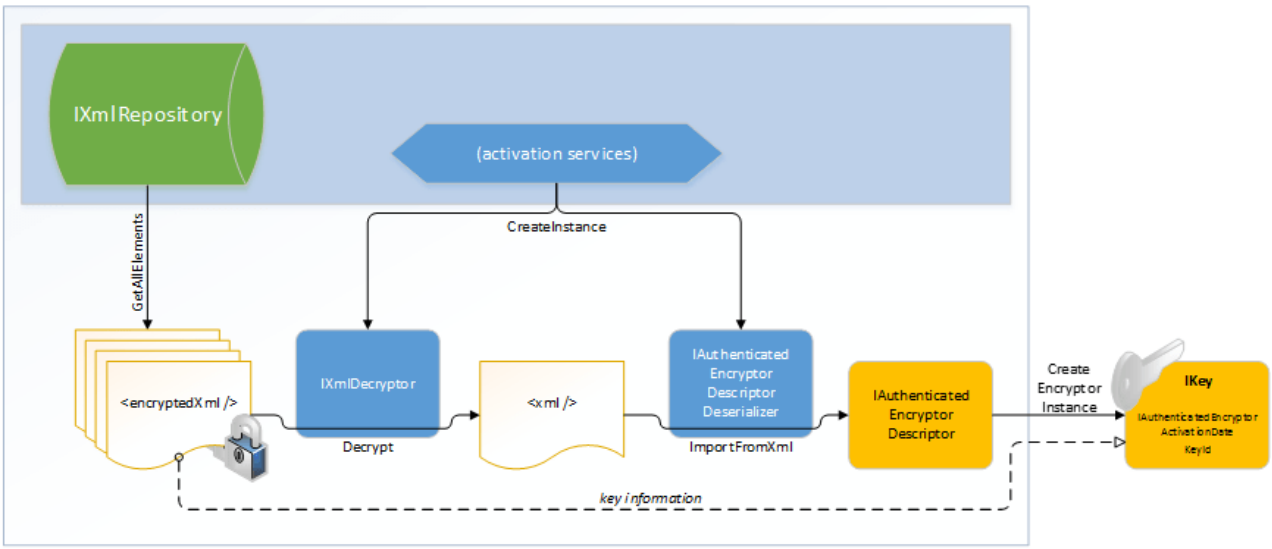
In the implementation of `CreateNewKey`, the `AlgorithmConfiguration` component is used to create a unique `IAuthenticatedEncryptorDescriptor`, which is then serialized as XML. If a key escrow sink is present, the raw (unencrypted) XML is provided to the sink for long-term storage. The unencrypted XML is then run through an `IXmlEncryptor` (if required) to generate the encrypted XML document. This encrypted document is persisted to long-term storage via the `IXmlRepository`. (If no `IXmlEncryptor` is configured, the unencrypted document is persisted in the `IXmlRepository`.)





Key Creation / CreateNewKey

In the implementation of `CreateNewKey`, the `IAuthenticatedEncryptorConfiguration` component is used to create a unique `IAuthenticatedEncryptorDescriptor`, which is then serialized as XML. If a key escrow sink is present, the raw (unencrypted) XML is provided to the sink for long-term storage. The unencrypted XML is then run through an `IXmlEncryptor` (if required) to generate the encrypted XML document. This encrypted document is persisted to long-term storage via the `IXmlRepository`. (If no `IXmlEncryptor` is configured, the unencrypted document is persisted in the `IXmlRepository`.)



Key Retrieval / GetAllKeys

In the implementation of `GetAllKeys`, the XML documents representing keys and revocations are read from the underlying `IXmlRepository`. If these documents are encrypted, the system will automatically decrypt them. `XmlKeyManager` creates the appropriate `IAuthenticatedEncryptorDescriptorDeserializer` instances to deserialize the documents back into `IAuthenticatedEncryptorDescriptor` instances, which are then wrapped in individual `IKey` instances. This collection of `IKey` instances is returned to the caller.

Further information on the particular XML elements can be found in the key storage format document.

IXmlRepository

The `IXmlRepository` interface represents a type that can persist XML to and retrieve XML from a backing store. It exposes two APIs:

- `GetAllElements` : `IReadOnlyCollection<XElement>`
- `StoreElement(XElement element, string friendlyName)`

Implementations of `IXmlRepository` don't need to parse the XML passing through them. They should treat the XML documents as opaque and let higher layers worry about generating and parsing the documents.

There are four built-in concrete types which implement `IXmlRepository`:

- FileSystemXmlRepository
- RegistryXmlRepository
- AzureStorage.AzureBlobXmlRepository
- RedisXmlRepository

- FileSystemXmlRepository
- RegistryXmlRepository
- AzureStorage.AzureBlobXmlRepository
- RedisXmlRepository

See the key storage providers document for more information.

Registering a custom `IXmlRepository` is appropriate when using a different backing store (for example, Azure Table Storage).

To change the default repository application-wide, register a custom `IXmlRepository` instance:

```
services.Configure<KeyManagementOptions>(options => options.XmlRepository = new MyCustomXmlRepository());
```

```
services.AddSingleton<IXmlRepository>(new MyCustomXmlRepository());
```

IXmlEncryptor

The `IXmlEncryptor` interface represents a type that can encrypt a plaintext XML element. It exposes a single API:

- Encrypt(XElement plaintextElement) : EncryptedXmlInfo

If a serialized `IAuthenticatedEncryptorDescriptor` contains any elements marked as "requires encryption", then `XmlKeyManager` will run those elements through the configured `IXmlEncryptor`'s `Encrypt` method, and it will persist the enciphered element rather than the plaintext element to the `IXmlRepository`. The output of the `Encrypt` method is an `EncryptedXmlInfo` object. This object is a wrapper which contains both the resultant enciphered `XElement` and the Type which represents an `IXmlDecryptor` which can be used to decipher the corresponding element.

There are four built-in concrete types which implement `IXmlEncryptor`:

- CertificateXmlEncryptor
- DpapiNGXmlEncryptor
- DpapiXmlEncryptor
- NullXmlEncryptor

See the key encryption at rest document for more information.

To change the default key-encryption-at-rest mechanism application-wide, register a custom `IXmlEncryptor` instance:

```
services.Configure<KeyManagementOptions>(options => options.XmlEncryptor = new MyCustomXmlEncryptor());
```

```
services.AddSingleton<IXmlEncryptor>(new MyCustomXmlEncryptor());
```

IXmlDecryptor

The `IXmlDecryptor` interface represents a type that knows how to decrypt an `XElement` that was enciphered via an `IXmlEncryptor`. It exposes a single API:

- Decrypt(XElement encryptedElement) : XElement

The `Decrypt` method undoes the encryption performed by `IXmlEncryptor.Encrypt`. Generally, each concrete `IXmlEncryptor` implementation will have a corresponding concrete `IXmlDecryptor` implementation.

Types which implement `IXmlDecryptor` should have one of the following two public constructors:

- .ctor(IServiceProvider)
- .ctor()

> **NOTE**
> The `IServiceProvider` passed to the constructor may be null.

IKeyEscrowSink

The `IKeyEscrowSink` interface represents a type that can perform escrow of sensitive information. Recall that serialized descriptors might contain sensitive information (such as cryptographic material), and this is what led to the introduction of the IXmlEncryptor type in the first place. However, accidents happen, and key rings can be deleted or become corrupted.

The escrow interface provides an emergency escape hatch, allowing access to the raw serialized XML before it's transformed by any configured IXmlEncryptor. The interface exposes a single API:

- Store(Guid keyId, XElement element)

It's up to the `IKeyEscrowSink` implementation to handle the provided element in a secure manner consistent with business policy. One possible implementation could be for the escrow sink to encrypt the XML element using a known corporate X.509 certificate where the certificate's private key has been escrowed; the `CertificateXmlEncryptor` type can assist with this. The `IKeyEscrowSink` implementation is also responsible for persisting the provided element appropriately.

By default no escrow mechanism is enabled, though server administrators can configure this globally. It can also be configured programmatically via the `IDataProtectionBuilder.AddKeyEscrowSink` method as shown in the sample below. The `AddKeyEscrowSink` method overloads mirror the `IServiceCollection.AddSingleton` and `IServiceCollection.AddInstance` overloads, as `IKeyEscrowSink` instances are intended to be singletons. If multiple `IKeyEscrowSink` instances are registered, each one will be called during key generation, so keys can be escrowed to multiple mechanisms simultaneously.

There's no API to read material from an `IKeyEscrowSink` instance. This is consistent with the design theory of the escrow mechanism: it's intended to make the key material accessible to a trusted authority, and since the application is itself not a trusted authority, it shouldn't have access to its own escrowed material.

The following sample code demonstrates creating and registering an `IKeyEscrowSink` where keys are escrowed such that only members of "CONTOSODomain Admins" can recover them.

NOTE

To run this sample, you must be on a domain-joined Windows 8 / Windows Server 2012 machine, and the domain controller must be Windows Server 2012 or later.

```
using System;

Miscellaneous ASP.NET Core Data Protection APIs

9/22/2020 • 2 minutes to read • Edit Online

WARNING

Types that implement any of the following interfaces should be thread-safe for multiple callers.

ISecret

The `ISecret` interface represents a secret value, such as cryptographic key material. It contains the following API surface:

- `Length` : `int`
- `Dispose()` : `void`
- `WriteSecretIntoBuffer(ArraySegment<byte> buffer)` : `void`

The `WriteSecretIntoBuffer` method populates the supplied buffer with the raw secret value. The reason this API takes the buffer as a parameter rather than returning a `byte[]` directly is that this gives the caller the opportunity to pin the buffer object, limiting secret exposure to the managed garbage collector.

The `Secret` type is a concrete implementation of `ISecret` where the secret value is stored in in-process memory. On Windows platforms, the secret value is encrypted via CryptProtectMemory.

ASP.NET Core Data Protection implementation

Authenticated encryption details in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

Calls to IDataProtector.Protect are authenticated encryption operations. The Protect method offers both confidentiality and authenticity, and it's tied to the purpose chain that was used to derive this particular IDataProtector instance from its root IDataProtectionProvider.

IDataProtector.Protect takes a byte[] plaintext parameter and produces a byte[] protected payload, whose format is described below. (There's also an extension method overload which takes a string plaintext parameter and returns a string protected payload. If this API is used the protected payload format will still have the below structure, but it will be base64url-encoded.)

Protected payload format

The protected payload format consists of three primary components:

- A 32-bit magic header that identifies the version of the data protection system.
- A 128-bit key id that identifies the key used to protect this particular payload.
- The remainder of the protected payload is specific to the encryptor encapsulated by this key. In the example below, the key represents an AES-256-CBC + HMACSHA256 encryptor, and the payload is further subdivided as follows:
  - A 128-bit key modifier.
  - A 128-bit initialization vector.
  - 48 bytes of AES-256-CBC output.
  - An HMACSHA256 authentication tag.

A sample protected payload is illustrated below.

```
09 F0 C9 F0 80 9C 81 0C 19 66 19 40 95 36 53 F8
AA FF EE 57 57 2F 40 4C 3F 7F CC 9D CC D9 32 3E
84 17 99 16 EC BA 1F 4A A1 18 45 1F 2D 13 7A 28
79 6B 86 9C F8 B7 84 F9 26 31 FC B1 86 0A F1 56
61 CF 14 58 D3 51 6F CF 36 50 85 82 08 2D 3F 73
5F B0 AD 9E 1A B2 AE 13 57 90 C8 F5 7C 95 4E 6A
8A AA 06 EF 43 CA 19 62 84 7C 11 B2 C8 71 9D AA
52 19 2E 5B 4C 1E 54 F0 55 BE 88 92 12 C1 4B 5E
52 C9 74 A0
```

From the payload format above the first 32 bits, or 4 bytes are the magic header identifying the version (09 F0 C9 F0)

The next 128 bits, or 16 bytes is the key identifier (80 9C 81 0C 19 66 19 40 95 36 53 F8 AA FF EE 57)

The remainder contains the payload and is specific to the format used.

WARNING

All payloads protected to a given key will begin with the same 20-byte (magic value, key id) header. Administrators can use this fact for diagnostic purposes to approximate when a payload was generated. For example, the payload above corresponds to key {0c819c80-6619-4019-9536-53f8aaffee57}. If after checking the key repository you find that this specific key's activation date was 2015-01-01 and its expiration date was 2015-03-01, then it's reasonable to assume that the payload (if not tampered with) was generated within that window, give or take a small fudge factor on either side.

Subkey derivation and authenticated encryption in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

Most keys in the key ring will contain some form of entropy and will have algorithmic information stating "CBC-mode encryption + HMAC validation" or "GCM encryption + validation". In these cases, we refer to the embedded entropy as the master keying material (or KM) for this key, and we perform a key derivation function to derive the keys that will be used for the actual cryptographic operations.

> **NOTE**
> Keys are abstract, and a custom implementation might not behave as below. If the key provides its own implementation of `IAuthenticatedEncryptor` rather than using one of our built-in factories, the mechanism described in this section no longer applies.

Additional authenticated data and subkey derivation

The `IAuthenticatedEncryptor` interface serves as the core interface for all authenticated encryption operations. Its `Encrypt` method takes two buffers: plaintext and additionalAuthenticatedData (AAD). The plaintext contents flow unchanged the call to `IDataProtector.Protect`, but the AAD is generated by the system and consists of three components:

1. The 32-bit magic header 09 F0 C9 F0 that identifies this version of the data protection system.
2. The 128-bit key id.
3. A variable-length string formed from the purpose chain that created the `IDataProtector` that's performing this operation.

Because the AAD is unique for the tuple of all three components, we can use it to derive new keys from KM instead of using KM itself in all of our cryptographic operations. For every call to `IAuthenticatedEncryptor.Encrypt`, the following key derivation process takes place:

```
( K_E, K_H ) = SP800_108_CTR_HMACSHA512(K_M, AAD, contextHeader || keyModifier)
```

Here, we're calling the NIST SP800-108 KDF in Counter Mode (see NIST SP800-108, Sec. 5.1) with the following parameters:

- Key derivation key (KDK) = `K_M`
- PRF = HMACSHA512
- label = additionalAuthenticatedData
- context = contextHeader || keyModifier

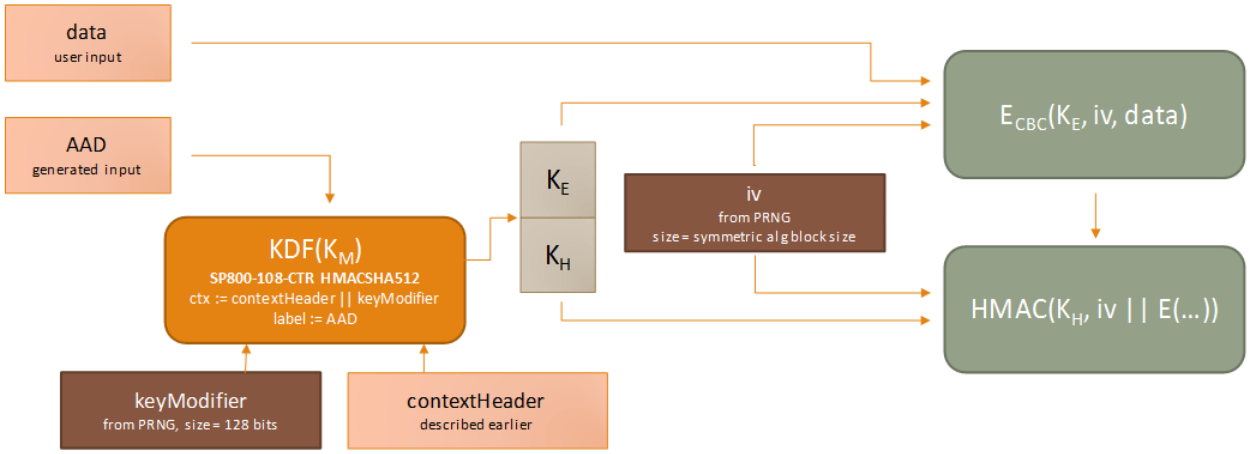
The context header is of variable length and essentially serves as a thumbprint of the algorithms for which we're deriving `K_E` and `K_H`. The key modifier is a 128-bit string randomly generated for each call to `Encrypt` and serves to ensure with overwhelming probability that KE and KH are unique for this specific authentication encryption operation, even if all other input to the KDF is constant.

For CBC-mode encryption + HMAC validation operations, `| K_E |` is the length of the symmetric block cipher key,

and `| K_H |` is the digest size of the HMAC routine. For GCM encryption + validation operations, `| K_H | = 0`.

CBC-mode encryption + HMAC validation

Once `K_E` is generated via the above mechanism, we generate a random initialization vector and run the symmetric block cipher algorithm to encipher the plaintext. The initialization vector and ciphertext are then run through the HMAC routine initialized with the key `K_H` to produce the MAC. This process and the return value is represented graphically below.

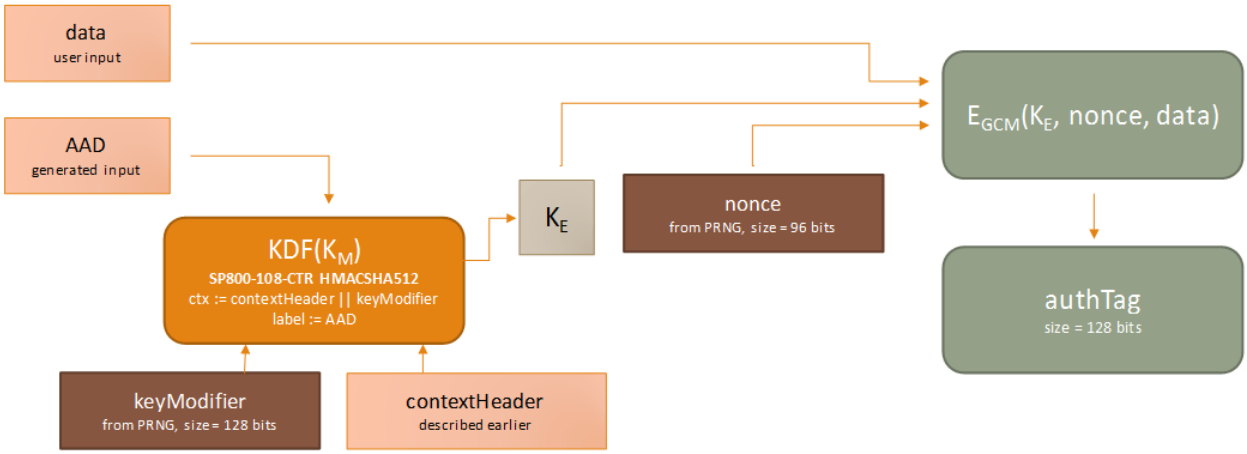


```
output:= keyModifier || iv || E_cbc (K_E,iv,data) || HMAC(K_H, iv || E_cbc (K_E,iv,data))
```

> **NOTE**
>
> The `IDataProtector.Protect` implementation will prepend the magic header and key id to output before returning it to the caller. Because the magic header and key id are implicitly part of AAD, and because the key modifier is fed as input to the KDF, this means that every single byte of the final returned payload is authenticated by the MAC.

Galois/Counter Mode encryption + validation

Once `K_E` is generated via the above mechanism, we generate a random 96-bit nonce and run the symmetric block cipher algorithm to encipher the plaintext and produce the 128-bit authentication tag.



```
output := keyModifier || nonce || E_gcm (K_E,nonce,data) || authTag
```

NOTE

Even though GCM natively supports the concept of AAD, we're still feeding AAD only to the original KDF, opting to pass an empty string into GCM for its AAD parameter. The reason for this is two-fold. First, to support agility we never want to use `K_M` directly as the encryption key. Additionally, GCM imposes very strict uniqueness requirements on its inputs. The probability that the GCM encryption routine is ever invoked on two or more distinct sets of input data with the same (key, nonce) pair must not exceed 2^32. If we fix `K_E` we cannot perform more than 2^32 encryption operations before we run afoul of the 2^-32 limit. This might seem like a very large number of operations, but a high-traffic web server can go through 4 billion requests in mere days, well within the normal lifetime for these keys. To stay compliant of the 2^-32 probability limit, we continue to use a 128-bit key modifier and 96-bit nonce, which radically extends the usable operation count for any given `K_M`. For simplicity of design we share the KDF code path between CBC and GCM operations, and since AAD is already considered in the KDF there's no need to forward it to the GCM routine.

Context headers in ASP.NET Core

9/22/2020 • 8 minutes to read • Edit Online

Background and theory

In the data protection system, a "key" means an object that can provide authenticated encryption services. Each key is identified by a unique id (a GUID), and it carries with it algorithmic information and entropic material. It's intended that each key carry unique entropy, but the system cannot enforce that, and we also need to account for developers who might change the key ring manually by modifying the algorithmic information of an existing key in the key ring. To achieve our security requirements given these cases the data protection system has a concept of cryptographic agility, which allows securely using a single entropic value across multiple cryptographic algorithms.

Most systems which support cryptographic agility do so by including some identifying information about the algorithm inside the payload. The algorithm's OID is generally a good candidate for this. However, one problem that we ran into is that there are multiple ways to specify the same algorithm: "AES" (CNG) and the managed Aes, AesManaged, AesCryptoServiceProvider, AesCng, and RijndaelManaged (given specific parameters) classes are all actually the same thing, and we'd need to maintain a mapping of all of these to the correct OID. If a developer wanted to provide a custom algorithm (or even another implementation of AES!), they'd have to tell us its OID. This extra registration step makes system configuration particularly painful.

Stepping back, we decided that we were approaching the problem from the wrong direction. An OID tells you what the algorithm is, but we don't actually care about this. If we need to use a single entropic value securely in two different algorithms, it's not necessary for us to know what the algorithms actually are. What we actually care about is how they behave. Any decent symmetric block cipher algorithm is also a strong pseudorandom permutation (PRP): fix the inputs (key, chaining mode, IV, plaintext) and the ciphertext output will with overwhelming probability be distinct from any other symmetric block cipher algorithm given the same inputs. Similarly, any decent keyed hash function is also a strong pseudorandom function (PRF), and given a fixed input set its output will overwhelmingly be distinct from any other keyed hash function.

We use this concept of strong PRPs and PRFs to build up a context header. This context header essentially acts as a stable thumbprint over the algorithms in use for any given operation, and it provides the cryptographic agility needed by the data protection system. This header is reproducible and is used later as part of the subkey derivation process. There are two different ways to build the context header depending on the modes of operation of the underlying algorithms.

CBC-mode encryption + HMAC authentication

The context header consists of the following components:

- [16 bits] The value 00 00, which is a marker meaning "CBC encryption + HMAC authentication".
- [32 bits] The key length (in bytes, big-endian) of the symmetric block cipher algorithm.
- [32 bits] The block size (in bytes, big-endian) of the symmetric block cipher algorithm.
- [32 bits] The key length (in bytes, big-endian) of the HMAC algorithm. (Currently the key size always matches the digest size.)
- [32 bits] The digest size (in bytes, big-endian) of the HMAC algorithm.
- `EncCBC(K_E, IV, "")`, which is the output of the symmetric block cipher algorithm given an empty string input and where IV is an all-zero vector. The construction of `K_E` is described below.

- `MAC(K_H, "")`, which is the output of the HMAC algorithm given an empty string input. The construction of `K_H` is described below.

Ideally, we could pass all-zero vectors for `K_E` and `K_H`. However, we want to avoid the situation where the underlying algorithm checks for the existence of weak keys before performing any operations (notably DES and 3DES), which precludes using a simple or repeatable pattern like an all-zero vector.

Instead, we use the NIST SP800-108 KDF in Counter Mode (see NIST SP800-108, Sec. 5.1) with a zero-length key, label, and context and HMACSHA512 as the underlying PRF. We derive `| K_E | + | K_H |` bytes of output, then decompose the result into `K_E` and `K_H` themselves. Mathematically, this is represented as follows.

```
( K_E || K_H ) = SP800_108_CTR(prf = HMACSHA512, key = "", label = "", context = "")
```

Example: AES-192-CBC + HMACSHA256

As an example, consider the case where the symmetric block cipher algorithm is AES-192-CBC and the validation algorithm is HMACSHA256. The system would generate the context header using the following steps.

First, let `( K_E || K_H ) = SP800_108_CTR(prf = HMACSHA512, key = "", label = "", context = "")`, where `| K_E | = 192 bits` and `| K_H | = 256 bits` per the specified algorithms. This leads to `K_E = 5BB6..21DD` and `K_H = A04A..00A9` in the example below:

```
5B B6 C9 83 13 78 22 1D 8E 10 73 CA CF 65 8E B0
61 62 42 71 CB 83 21 DD A0 4A 05 00 5B AB C0 A2
49 6F A5 61 E3 E2 49 87 AA 63 55 CD 74 0A DA C4
B7 92 3D BF 59 90 00 A9
```

Next, compute `Enc_CBC (K_E, IV, "")` for AES-192-CBC given `IV = 0*` and `K_E` as above.

```
result := F474B1872B3B53E4721DE19C0841DB6F
```

Next, compute `MAC(K_H, "")` for HMACSHA256 given `K_H` as above.

```
result := D4791184B996092EE1202F36E8608FA8FBD98ABDFF5402F264B1D7211536220C
```

This produces the full context header below:

```
00 00 00 00 00 18 00 00 00 10 00 00 00 20 00 00
00 20 F4 74 B1 87 2B 3B 53 E4 72 1D E1 9C 08 41
DB 6F D4 79 11 84 B9 96 09 2E E1 20 2F 36 E8 60
8F A8 FB D9 8A BD FF 54 02 F2 64 B1 D7 21 15 36
22 0C
```

This context header is the thumbprint of the authenticated encryption algorithm pair (AES-192-CBC encryption + HMACSHA256 validation). The components, as described above are:

- the marker `(00 00)`
- the block cipher key length `(00 00 00 18)`
- the block cipher block size `(00 00 00 10)`
- the HMAC key length `(00 00 00 20)`
- the HMAC digest size `(00 00 00 20)`
- the block cipher PRP output `(F4 74 - DB 6F)` and
- the HMAC PRF output `(D4 79 - end)`.

> **NOTE**
> The CBC-mode encryption + HMAC authentication context header is built the same way regardless of whether the algorithms implementations are provided by Windows CNG or by managed SymmetricAlgorithm and KeyedHashAlgorithm types. This allows applications running on different operating systems to reliably produce the same context header even though the implementations of the algorithms differ between OSes. (In practice, the KeyedHashAlgorithm doesn't have to be a proper HMAC. It can be any keyed hash algorithm type.)

Example: 3DES-192-CBC + HMACSHA1

First, let `( K_E || K_H ) = SP800_108_CTR(prf = HMACSHA512, key = "", label = "", context = "")`, where `| K_E | = 192 bits` and `| K_H | = 160 bits` per the specified algorithms. This leads to `K_E = A219..E2BB` and `K_H = DC4A..B464` in the example below:

```
A2 19 60 2F 83 A9 13 EA B0 61 3A 39 B8 A6 7E 22
61 D9 F8 6C 10 51 E2 BB DC 4A 00 D7 03 A2 48 3E
D1 F7 5A 34 EB 28 3E D7 D4 67 B4 64
```

Next, compute `Enc_CBC (K_E, IV, "")` for 3DES-192-CBC given `IV = 0*` and `K_E` as above.

`result := ABB100F81E53E10E`

Next, compute `MAC(K_H, "")` for HMACSHA1 given `K_H` as above.

`result := 76EB189B35CF03461DDF877CD9F4B1B4D63A7555`

This produces the full context header which is a thumbprint of the authenticated encryption algorithm pair (3DES-192-CBC encryption + HMACSHA1 validation), shown below:

```
00 00 00 00 00 18 00 00 00 08 00 00 00 14 00 00
00 14 AB B1 00 F8 1E 53 E1 0E 76 EB 18 9B 35 CF
03 46 1D DF 87 7C D9 F4 B1 B4 D6 3A 75 55
```

The components break down as follows:

- the marker `(00 00)`
- the block cipher key length `(00 00 00 18)`
- the block cipher block size `(00 00 00 08)`
- the HMAC key length `(00 00 00 14)`
- the HMAC digest size `(00 00 00 14)`
- the block cipher PRP output `(AB B1 - E1 0E)` and
- the HMAC PRF output `(76 EB - end)`.

Galois/Counter Mode encryption + authentication

The context header consists of the following components:

- [16 bits] The value 00 01, which is a marker meaning "GCM encryption + authentication".
- [32 bits] The key length (in bytes, big-endian) of the symmetric block cipher algorithm.
- [32 bits] The nonce size (in bytes, big-endian) used during authenticated encryption operations. (For our

system, this is fixed at nonce size = 96 bits.)

- [32 bits] The block size (in bytes, big-endian) of the symmetric block cipher algorithm. (For GCM, this is fixed at block size = 128 bits.)
- [32 bits] The authentication tag size (in bytes, big-endian) produced by the authenticated encryption function. (For our system, this is fixed at tag size = 128 bits.)
- [128 bits] The tag of `Enc_GCM (K_E, nonce, "")`, which is the output of the symmetric block cipher algorithm given an empty string input and where nonce is a 96-bit all-zero vector.

`K_E` is derived using the same mechanism as in the CBC encryption + HMAC authentication scenario. However, since there's no `K_H` in play here, we essentially have `| K_H | = 0`, and the algorithm collapses to the below form.

```
K_E = SP800_108_CTR(prf = HMACSHA512, key = "", label = "", context = "")
```

Example: AES-256-GCM

First, let `K_E = SP800_108_CTR(prf = HMACSHA512, key = "", label = "", context = "")`, where `| K_E | = 256 bits`.

```
K_E := 22BC6F1B171C08C4AE2F27444AF8FC8B3087A90006CAEA91FDCFB47C1B8733B8
```

Next, compute the authentication tag of `Enc_GCM (K_E, nonce, "")` for AES-256-GCM given `nonce = 096` and `K_E` as above.

```
result := E7DCCE66DF855A323A6BB7BD7A59BE45
```

This produces the full context header below:

```
00 01 00 00 00 20 00 00 00 0C 00 00 00 10 00 00
00 10 E7 DC CE 66 DF 85 5A 32 3A 6B B7 BD 7A 59
BE 45
```

The components break down as follows:

- the marker `(00 01)`
- the block cipher key length `(00 00 00 20)`
- the nonce size `(00 00 00 0C)`
- the block cipher block size `(00 00 00 10)`
- the authentication tag size `(00 00 00 10)` and
- the authentication tag from running the block cipher `(E7 DC - end)`.

Key management in ASP.NET Core

9/22/2020 • 6 minutes to read • Edit Online

The data protection system automatically manages the lifetime of master keys used to protect and unprotect payloads. Each key can exist in one of four stages:

- Created - the key exists in the key ring but has not yet been activated. The key shouldn't be used for new Protect operations until sufficient time has elapsed that the key has had a chance to propagate to all machines that are consuming this key ring.
- Active - the key exists in the key ring and should be used for all new Protect operations.
- Expired - the key has run its natural lifetime and should no longer be used for new Protect operations.
- Revoked - the key is compromised and must not be used for new Protect operations.

Created, active, and expired keys may all be used to unprotect incoming payloads. Revoked keys by default may not be used to unprotect payloads, but the application developer can override this behavior if necessary.

> **WARNING**
> The developer might be tempted to delete a key from the key ring (e.g., by deleting the corresponding file from the file system). At that point, all data protected by the key is permanently undecipherable, and there's no emergency override like there's with revoked keys. Deleting a key is truly destructive behavior, and consequently the data protection system exposes no first-class API for performing this operation.

Default key selection

When the data protection system reads the key ring from the backing repository, it will attempt to locate a "default" key from the key ring. The default key is used for new Protect operations.

The general heuristic is that the data protection system chooses the key with the most recent activation date as the default key. (There's a small fudge factor to allow for server-to-server clock skew.) If the key is expired or revoked, and if the application has not disabled automatic key generation, then a new key will be generated with immediate activation per the key expiration and rolling policy below.

The reason the data protection system generates a new key immediately rather than falling back to a different key is that new key generation should be treated as an implicit expiration of all keys that were activated prior to the new key. The general idea is that new keys may have been configured with different algorithms or encryption-at-rest mechanisms than old keys, and the system should prefer the current configuration over falling back.

There's an exception. If the application developer has disabled automatic key generation, then the data protection system must choose something as the default key. In this fallback scenario, the system will choose the non-revoked key with the most recent activation date, with preference given to keys that have had time to propagate to other machines in the cluster. The fallback system may end up choosing an expired default key as a result. The fallback system will never choose a revoked key as the default key, and if the key ring is empty or every key has been revoked then the system will produce an error upon initialization.

Key expiration and rolling

When a key is created, it's automatically given an activation date of { now + 2 days } and an expiration date of {

now + 90 days }. The 2-day delay before activation gives the key time to propagate through the system. That is, it allows other applications pointing at the backing store to observe the key at their next auto-refresh period, thus maximizing the chances that when the key ring does become active it has propagated to all applications that might need to use it.

If the default key will expire within 2 days and if the key ring doesn't already have a key that will be active upon expiration of the default key, then the data protection system will automatically persist a new key to the key ring. This new key has an activation date of { default key's expiration date } and an expiration date of { now + 90 days }. This allows the system to automatically roll keys on a regular basis with no interruption of service.

There might be circumstances where a key will be created with immediate activation. One example would be when the application hasn't run for a time and all keys in the key ring are expired. When this happens, the key is given an activation date of { now } without the normal 2-day activation delay.

The default key lifetime is 90 days, though this is configurable as in the following example.

```
services.AddDataProtection()
       // use 14-day lifetime instead of 90-day lifetime
       .SetDefaultKeyLifetime(TimeSpan.FromDays(14));
```

An administrator can also change the default system-wide, though an explicit call to `SetDefaultKeyLifetime` will override any system-wide policy. The default key lifetime cannot be shorter than 7 days.

Automatic key ring refresh

When the data protection system initializes, it reads the key ring from the underlying repository and caches it in memory. This cache allows Protect and Unprotect operations to proceed without hitting the backing store. The system will automatically check the backing store for changes approximately every 24 hours or when the current default key expires, whichever comes first.

> **WARNING**
>
> Developers should very rarely (if ever) need to use the key management APIs directly. The data protection system will perform automatic key management as described above.

The data protection system exposes an interface `IKeyManager` that can be used to inspect and make changes to the key ring. The DI system that provided the instance of `IDataProtectionProvider` can also provide an instance of `IKeyManager` for your consumption. Alternatively, you can pull the `IKeyManager` straight from the `IServiceProvider` as in the example below.

Any operation which modifies the key ring (creating a new key explicitly or performing a revocation) will invalidate the in-memory cache. The next call to `Protect` or `Unprotect` will cause the data protection system to reread the key ring and recreate the cache.

The sample below demonstrates using the `IKeyManager` interface to inspect and manipulate the key ring, including revoking existing keys and generating a new key manually.

```
using System;
using System.IO;
using System.Threading;
using Microsoft.AspNetCore.DataProtection;
using Microsoft.AspNetCore.DataProtection.KeyManagement;
using Microsoft.Extensions.DependencyInjection;

public class Program
{
    public static void Main(string[] args)
```

```
    public static void Main(string[] args)
    {
        var serviceCollection = new ServiceCollection();
        serviceCollection.AddDataProtection()
            // point at a specific folder and use DPAPI to encrypt keys
            .PersistKeysToFileSystem(new DirectoryInfo(@"c:\temp-keys"))
            .ProtectKeysWithDpapi();
        var services = serviceCollection.BuildServiceProvider();

        // perform a protect operation to force the system to put at least
        // one key in the key ring
        services.GetDataProtector("Sample.KeyManager.v1").Protect("payload");
        Console.WriteLine("Performed a protect operation.");
        Thread.Sleep(2000);

        // get a reference to the key manager
        var keyManager = services.GetService<IKeyManager>();

        // list all keys in the key ring
        var allKeys = keyManager.GetAllKeys();
        Console.WriteLine($"The key ring contains {allKeys.Count} key(s).");
        foreach (var key in allKeys)
        {
            Console.WriteLine($"Key {key.KeyId:B}: Created = {key.CreationDate:u}, IsRevoked =
{key.IsRevoked}");
        }

        // revoke all keys in the key ring
        keyManager.RevokeAllKeys(DateTimeOffset.Now, reason: "Revocation reason here.");
        Console.WriteLine("Revoked all existing keys.");

        // add a new key to the key ring with immediate activation and a 1-month expiration
        keyManager.CreateNewKey(
            activationDate: DateTimeOffset.Now,
            expirationDate: DateTimeOffset.Now.AddMonths(1));
        Console.WriteLine("Added a new key.");

        // list all keys in the key ring
        allKeys = keyManager.GetAllKeys();
        Console.WriteLine($"The key ring contains {allKeys.Count} key(s).");
        foreach (var key in allKeys)
        {
            Console.WriteLine($"Key {key.KeyId:B}: Created = {key.CreationDate:u}, IsRevoked =
{key.IsRevoked}");
        }
    }
}

/*
 * SAMPLE OUTPUT
 *
 * Performed a protect operation.
 * The key ring contains 1 key(s).
 * Key {1b948618-be1f-440b-b204-64ff5a152552}: Created = 2015-03-18 22:20:49Z, IsRevoked = False
 * Revoked all existing keys.
 * Added a new key.
 * The key ring contains 2 key(s).
 * Key {1b948618-be1f-440b-b204-64ff5a152552}: Created = 2015-03-18 22:20:49Z, IsRevoked = True
 * Key {2266fc40-e2fb-48c6-8ce2-5fde6b1493f7}: Created = 2015-03-18 22:20:51Z, IsRevoked = False
 */
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

Key storage

The data protection system has a heuristic whereby it attempts to deduce an appropriate key storage location and

encryption-at-rest mechanism automatically. The key persistence mechanism is also configurable by the app developer. The following documents discuss the in-box implementations of these mechanisms:

- Key storage providers in ASP.NET Core
- Key encryption at rest in Windows and Azure using ASP.NET Core

Key storage providers in ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

The data protection system employs a discovery mechanism by default to determine where cryptographic keys should be persisted. The developer can override the default discovery mechanism and manually specify the location.

> **WARNING**
> If you specify an explicit key persistence location, the data protection system deregisters the default key encryption at rest mechanism, so keys are no longer encrypted at rest. It's recommended that you additionally specify an explicit key encryption mechanism for production deployments.

File system

To configure a file system-based key repository, call the PersistKeysToFileSystem configuration routine as shown below. Provide a DirectoryInfo pointing to the repository where keys should be stored:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .PersistKeysToFileSystem(new DirectoryInfo(@"c:\temp-keys\"));
}
```

The `DirectoryInfo` can point to a directory on the local machine, or it can point to a folder on a network share. If pointing to a directory on the local machine (and the scenario is that only apps on the local machine require access to use this repository), consider using Windows DPAPI (on Windows) to encrypt the keys at rest. Otherwise, consider using an X.509 certificate to encrypt keys at rest.

Azure Storage

The Microsoft.AspNetCore.DataProtection.AzureStorage package allows storing data protection keys in Azure Blob Storage. Keys can be shared across several instances of a web app. Apps can share authentication cookies or CSRF protection across multiple servers.

To configure the Azure Blob Storage provider, call one of the PersistKeysToAzureBlobStorage overloads.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .PersistKeysToAzureBlobStorage(new Uri("<blob URI including SAS token>"));
}
```

If the web app is running as an Azure service, authentication tokens can be automatically created using Microsoft.Azure.Services.AppAuthentication.

```
var tokenProvider = new AzureServiceTokenProvider();
var token = await tokenProvider.GetAccessTokenAsync("https://storage.azure.com/");
var credentials = new StorageCredentials(new TokenCredential(token));
var storageAccount = new CloudStorageAccount(credentials, "mystorageaccount", "core.windows.net", useHttps:
true);
var client = storageAccount.CreateCloudBlobClient();
var container = client.GetContainerReference("my-key-container");

// optional - provision the container automatically
await container.CreateIfNotExistsAsync();

services.AddDataProtection()
    .PersistKeysToAzureBlobStorage(container, "keys.xml");
```

See more details about configuring service-to-service authentication.

Redis

The Microsoft.AspNetCore.DataProtection.StackExchangeRedis package allows storing data protection keys in a Redis cache. Keys can be shared across several instances of a web app. Apps can share authentication cookies or CSRF protection across multiple servers.

The Microsoft.AspNetCore.DataProtection.Redis package allows storing data protection keys in a Redis cache. Keys can be shared across several instances of a web app. Apps can share authentication cookies or CSRF protection across multiple servers.

To configure on Redis, call one of the PersistKeysToStackExchangeRedis overloads:

```
public void ConfigureServices(IServiceCollection services)
{
    var redis = ConnectionMultiplexer.Connect("<URI>");
    services.AddDataProtection()
        .PersistKeysToStackExchangeRedis(redis, "DataProtection-Keys");
}
```

To configure on Redis, call one of the PersistKeysToRedis overloads:

```
public void ConfigureServices(IServiceCollection services)
{
    var redis = ConnectionMultiplexer.Connect("<URI>");
    services.AddDataProtection()
        .PersistKeysToRedis(redis, "DataProtection-Keys");
}
```

For more information, see the following topics:

- StackExchange.Redis ConnectionMultiplexer
- Azure Redis Cache
- ASP.NET Core DataProtection samples

Registry

Only applies to Windows deployments.

Sometimes the app might not have write access to the file system. Consider a scenario where an app is running as a virtual service account (such as *w3wp.exe*'s app pool identity). In these cases, the administrator can provision a registry key that's accessible by the service account identity. Call the PersistKeysToRegistry extension

method as shown below. Provide a RegistryKey pointing to the location where cryptographic keys should be stored:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .PersistKeysToRegistry(Registry.CurrentUser.OpenSubKey(@"SOFTWARE\Sample\keys"));
}
```

> **IMPORTANT**
>
> We recommend using Windows DPAPI to encrypt the keys at rest.

Entity Framework Core

The Microsoft.AspNetCore.DataProtection.EntityFrameworkCore package provides a mechanism for storing data protection keys to a database using Entity Framework Core. The `Microsoft.AspNetCore.DataProtection.EntityFrameworkCore` NuGet package must be added to the project file, it's not part of the Microsoft.AspNetCore.App metapackage.

With this package, keys can be shared across multiple instances of a web app.

To configure the EF Core provider, call the PersistKeysToDbContext<TContext> method:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));

    // Add a DbContext to store your Database Keys
    services.AddDbContext<MyKeysContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("MyKeysConnection")));

    // using Microsoft.AspNetCore.DataProtection;
    services.AddDataProtection()
        .PersistKeysToDbContext<MyKeysContext>();

    services.AddDefaultIdentity<IdentityUser>()
        .AddDefaultUI(UIFramework.Bootstrap4)
        .AddEntityFrameworkStores<ApplicationDbContext>();
    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

The generic parameter, `TContext`, must inherit from DbContext and implement IDataProtectionKeyContext:

```
using Microsoft.AspNetCore.DataProtection.EntityFrameworkCore;
using Microsoft.EntityFrameworkCore;
using WebApp1.Data;

namespace WebApp1
{
    class MyKeysContext : DbContext, IDataProtectionKeyContext
    {
        // A recommended constructor overload when using EF Core
        // with dependency injection.
        public MyKeysContext(DbContextOptions<MyKeysContext> options)
            : base(options) { }

        // This maps to the table that stores keys.
        public DbSet<DataProtectionKey> DataProtectionKeys { get; set; }
    }
}
```

Create the `DataProtectionKeys` table.

- Visual Studio
- .NET Core CLI

Execute the following commands in the **Package Manager Console** (PMC) window:

```
Add-Migration AddDataProtectionKeys -Context MyKeysContext
Update-Database -Context MyKeysContext
```

`MyKeysContext` is the `DbContext` defined in the preceding code sample. If you're using a `DbContext` with a different name, substitute your `DbContext` name for `MyKeysContext`.

The `DataProtectionKeys` class/entity adopts the structure shown in the following table.

PROPERTY/FIELD	CLR TYPE	SQL TYPE
`Id`	`int`	`int`, PK, `IDENTITY(1,1)`, not null
`FriendlyName`	`string`	`nvarchar(MAX)`, null
`Xml`	`string`	`nvarchar(MAX)`, null

Custom key repository

If the in-box mechanisms aren't appropriate, the developer can specify their own key persistence mechanism by providing a custom IXmlRepository.

Key encryption at rest in Windows and Azure using ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

The data protection system employs a discovery mechanism by default to determine how cryptographic keys should be encrypted at rest. The developer can override the discovery mechanism and manually specify how keys should be encrypted at rest.

> **WARNING**
> If you specify an explicit key persistence location, the data protection system deregisters the default key encryption at rest mechanism. Consequently, keys are no longer encrypted at rest. We recommend that you specify an explicit key encryption mechanism for production deployments. The encryption-at-rest mechanism options are described in this topic.

Azure Key Vault

To store keys in Azure Key Vault, configure the system with ProtectKeysWithAzureKeyVault in the `Startup` class:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .PersistKeysToAzureBlobStorage(new Uri("<blobUriWithSasToken>"))
        .ProtectKeysWithAzureKeyVault("<keyIdentifier>", "<clientId>", "<clientSecret>");
}
```

For more information, see Configure ASP.NET Core Data Protection: ProtectKeysWithAzureKeyVault.

Windows DPAPI

Only applies to Windows deployments.

When Windows DPAPI is used, key material is encrypted with CryptProtectData before being persisted to storage. DPAPI is an appropriate encryption mechanism for data that's never read outside of the current machine (though it's possible to back these keys up to Active Directory; see DPAPI and Roaming Profiles). To configure DPAPI key-at-rest encryption, call one of the ProtectKeysWithDpapi extension methods:

```
public void ConfigureServices(IServiceCollection services)
{
    // Only the local user account can decrypt the keys
    services.AddDataProtection()
        .ProtectKeysWithDpapi();
}
```

If `ProtectKeysWithDpapi` is called with no parameters, only the current Windows user account can decipher the persisted key ring. You can optionally specify that any user account on the machine (not just the current user account) be able to decipher the key ring:

```
public void ConfigureServices(IServiceCollection services)
{
    // All user accounts on the machine can decrypt the keys
    services.AddDataProtection()
        .ProtectKeysWithDpapi(protectToLocalMachine: true);
}
```

X.509 certificate

If the app is spread across multiple machines, it may be convenient to distribute a shared X.509 certificate across the machines and configure the hosted apps to use the certificate for encryption of keys at rest:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .ProtectKeysWithCertificate("3BCE558E2AD3E0E34A7743EAB5AEA2A9BD2575A0");
}
```

Due to .NET Framework limitations, only certificates with CAPI private keys are supported. See the content below for possible workarounds to these limitations.

Windows DPAPI-NG

This mechanism is available only on Windows 8/Windows Server 2012 or later.

Beginning with Windows 8, Windows OS supports DPAPI-NG (also called CNG DPAPI). For more information, see About CNG DPAPI.

The principal is encoded as a protection descriptor rule. In the following example that calls ProtectKeysWithDpapiNG, only the domain-joined user with the specified SID can decrypt the key ring:

```
public void ConfigureServices(IServiceCollection services)
{
    // Uses the descriptor rule "SID=S-1-5-21-..."
    services.AddDataProtection()
        .ProtectKeysWithDpapiNG("SID=S-1-5-21-...",
        flags: DpapiNGProtectionDescriptorFlags.None);
}
```

There's also a parameterless overload of `ProtectKeysWithDpapiNG`. Use this convenience method to specify the rule "SID={CURRENT_ACCOUNT_SID}", where *CURRENT_ACCOUNT_SID* is the SID of the current Windows user account:

```
public void ConfigureServices(IServiceCollection services)
{
    // Use the descriptor rule "SID={current account SID}"
    services.AddDataProtection()
        .ProtectKeysWithDpapiNG();
}
```

In this scenario, the AD domain controller is responsible for distributing the encryption keys used by the DPAPI-NG operations. The target user can decipher the encrypted payload from any domain-joined machine (provided that the process is running under their identity).

Certificate-based encryption with Windows DPAPI-NG

If the app is running on Windows 8.1/Windows Server 2012 R2 or later, you can use Windows DPAPI-NG to perform certificate-based encryption. Use the rule descriptor string "CERTIFICATE=HashId:THUMBPRINT", where *THUMBPRINT* is the hex-encoded SHA1 thumbprint of the certificate:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .ProtectKeysWithDpapiNG("CERTIFICATE=HashId:3BCE558E2...B5AEA2A9BD2575A0",
            flags: DpapiNGProtectionDescriptorFlags.None);
}
```

Any app pointed at this repository must be running on Windows 8.1/Windows Server 2012 R2 or later to decipher the keys.

Custom key encryption

If the in-box mechanisms aren't appropriate, the developer can specify their own key encryption mechanism by providing a custom IXmlEncryptor.

Key immutability and key settings in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

Once an object is persisted to the backing store, its representation is forever fixed. New data can be added to the backing store, but existing data can never be mutated. The primary purpose of this behavior is to prevent data corruption.

One consequence of this behavior is that once a key is written to the backing store, it's immutable. Its creation, activation, and expiration dates can never be changed, though it can revoked by using `IKeyManager`. Additionally, its underlying algorithmic information, master keying material, and encryption at rest properties are also immutable.

If the developer changes any setting that affects key persistence, those changes won't go into effect until the next time a key is generated, either via an explicit call to `IKeyManager.CreateNewKey` or via the data protection system's own automatic key generation behavior. The settings that affect key persistence are as follows:

- The default key lifetime
- The key encryption at rest mechanism
- The algorithmic information contained within the key

If you need these settings to kick in earlier than the next automatic key rolling time, consider making an explicit call to `IKeyManager.CreateNewKey` to force the creation of a new key. Remember to provide an explicit activation date ({ now + 2 days } is a good rule of thumb to allow time for the change to propagate) and expiration date in the call.

> **TIP**
> All applications touching the repository should specify the same settings with the `IDataProtectionBuilder` extension methods. Otherwise, the properties of the persisted key will be dependent on the particular application that invoked the key generation routines.

Key storage format in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

Objects are stored at rest in XML representation. The default directory for key storage is:

- Windows: *%LOCALAPPDATA%\ASP.NET\DataProtection-Keys*
- macOS / Linux: *$HOME/.aspnet/DataProtection-Keys*

The <key> element

Keys exist as top-level objects in the key repository. By convention keys have the filename **key-{guid}.xml**, where {guid} is the id of the key. Each such file contains a single key. The format of the file is as follows.

```
<?xml version="1.0" encoding="utf-8"?>
<key id="80732141-ec8f-4b80-af9c-c4d2d1ff8901" version="1">
  <creationDate>2015-03-19T23:32:02.3949887Z</creationDate>
  <activationDate>2015-03-19T23:32:02.3839429Z</activationDate>
  <expirationDate>2015-06-17T23:32:02.3839429Z</expirationDate>
  <descriptor deserializerType="{deserializerType}">
    <descriptor>
      <encryption algorithm="AES_256_CBC" />
      <validation algorithm="HMACSHA256" />
      <enc:encryptedSecret decryptorType="{decryptorType}" xmlns:enc="...">
        <encryptedKey>
          <!-- This key is encrypted with Windows DPAPI. -->
          <value>AQAAANCM...8/zeP8lcwAg==</value>
        </encryptedKey>
      </enc:encryptedSecret>
    </descriptor>
  </descriptor>
</key>
```

The <key> element contains the following attributes and child elements:

- The key id. This value is treated as authoritative; the filename is simply a nicety for human readability.
- The version of the <key> element, currently fixed at 1.
- The key's creation, activation, and expiration dates.
- A <descriptor> element, which contains information on the authenticated encryption implementation contained within this key.

In the above example, the key's id is {80732141-ec8f-4b80-af9c-c4d2d1ff8901}, it was created and activated on March 19, 2015, and it has a lifetime of 90 days. (Occasionally the activation date might be slightly before the creation date as in this example. This is due to a nit in how the APIs work and is harmless in practice.)

The <descriptor> element

The outer <descriptor> element contains an attribute deserializerType, which is the assembly-qualified name of a type which implements IAuthenticatedEncryptorDescriptorDeserializer. This type is responsible for reading the inner <descriptor> element and for parsing the information contained within.

The particular format of the <descriptor> element depends on the authenticated encryptor implementation encapsulated by the key, and each deserializer type expects a slightly different format for this. In general, though,

this element will contain algorithmic information (names, types, OIDs, or similar) and secret key material. In the above example, the descriptor specifies that this key wraps AES-256-CBC encryption + HMACSHA256 validation.

The <encryptedSecret> element

An **<encryptedSecret>** element which contains the encrypted form of the secret key material may be present if encryption of secrets at rest is enabled. The attribute `decryptorType` is the assembly-qualified name of a type which implements IXmlDecryptor. This type is responsible for reading the inner **<encryptedKey>** element and decrypting it to recover the original plaintext.

As with `<descriptor>`, the particular format of the `<encryptedSecret>` element depends on the at-rest encryption mechanism in use. In the above example, the master key is encrypted using Windows DPAPI per the comment.

The <revocation> element

Revocations exist as top-level objects in the key repository. By convention revocations have the filename **revocation-{timestamp}.xml** (for revoking all keys before a specific date) or **revocation-{guid}.xml** (for revoking a specific key). Each file contains a single <revocation> element.

For revocations of individual keys, the file contents will be as below.

```
<?xml version="1.0" encoding="utf-8"?>
<revocation version="1">
  <revocationDate>2015-03-20T22:45:30.2616742Z</revocationDate>
  <key id="eb4fc299-8808-409d-8a34-23fc83d026c9" />
  <reason>human-readable reason</reason>
</revocation>
```

In this case, only the specified key is revoked. If the key id is "*", however, as in the below example, all keys whose creation date is prior to the specified revocation date are revoked.

```
<?xml version="1.0" encoding="utf-8"?>
<revocation version="1">
  <revocationDate>2015-03-20T15:45:45.7366491-07:00</revocationDate>
  <!-- All keys created before the revocation date are revoked. -->
  <key id="*" />
  <reason>human-readable reason</reason>
</revocation>
```

The <reason> element is never read by the system. It's simply a convenient place to store a human-readable reason for revocation.

Ephemeral data protection providers in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

There are scenarios where an application needs a throwaway `IDataProtectionProvider`. For example, the developer might just be experimenting in a one-off console application, or the application itself is transient (it's scripted or a unit test project). To support these scenarios the Microsoft.AspNetCore.DataProtection package includes a type `EphemeralDataProtectionProvider`. This type provides a basic implementation of `IDataProtectionProvider` whose key repository is held solely in-memory and isn't written out to any backing store.

Each instance of `EphemeralDataProtectionProvider` uses its own unique master key. Therefore, if an `IDataProtector` rooted at an `EphemeralDataProtectionProvider` generates a protected payload, that payload can only be unprotected by an equivalent `IDataProtector` (given the same purpose chain) rooted at the same `EphemeralDataProtectionProvider` instance.

The following sample demonstrates instantiating an `EphemeralDataProtectionProvider` and using it to protect and unprotect data.

```
using System;
using Microsoft.AspNetCore.DataProtection;

public class Program
{
    public static void Main(string[] args)
    {
        const string purpose = "Ephemeral.App.v1";

        // create an ephemeral provider and demonstrate that it can round-trip a payload
        var provider = new EphemeralDataProtectionProvider();
        var protector = provider.CreateProtector(purpose);
        Console.Write("Enter input: ");
        string input = Console.ReadLine();

        // protect the payload
        string protectedPayload = protector.Protect(input);
        Console.WriteLine($"Protect returned: {protectedPayload}");

        // unprotect the payload
        string unprotectedPayload = protector.Unprotect(protectedPayload);
        Console.WriteLine($"Unprotect returned: {unprotectedPayload}");

        // if I create a new ephemeral provider, it won't be able to unprotect existing
        // payloads, even if I specify the same purpose
        provider = new EphemeralDataProtectionProvider();
        protector = provider.CreateProtector(purpose);
        unprotectedPayload = protector.Unprotect(protectedPayload); // THROWS
    }
}

/*
* SAMPLE OUTPUT
*
* Enter input: Hello!
* Protect returned: CfDJ8AAAAAAAAAAAAAAAAAAA...uGoxWLjGKtm1SkNACQ
* Unprotect returned: Hello!
* << throws CryptographicException >>
*/
```

Compatibility in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

- Replacing ASP.NET <machineKey> in ASP.NET Core
- `Microsoft.AspNetCore.DataProtection` 3.1 not compatible with Azure function apps. For more information, see this GitHub issue

Replace the ASP.NET machineKey in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

The implementation of the `<machineKey>` element in ASP.NET is replaceable. This allows most calls to ASP.NET cryptographic routines to be routed through a replacement data protection mechanism, including the new data protection system.

Package installation

> **NOTE**
> The new data protection system can only be installed into an existing ASP.NET application targeting .NET 4.5.1 or later. Installation will fail if the application targets .NET 4.5 or lower.

To install the new data protection system into an existing ASP.NET 4.5.1+ project, install the package Microsoft.AspNetCore.DataProtection.SystemWeb. This will instantiate the data protection system using the default configuration settings.

When you install the package, it inserts a line into *Web.config* that tells ASP.NET to use it for most cryptographic operations, including forms authentication, view state, and calls to MachineKey.Protect. The line that's inserted reads as follows.

```
<machineKey compatibilityMode="Framework45" dataProtectorType="..." />
```

> **TIP**
> You can tell if the new data protection system is active by inspecting fields like `__VIEWSTATE`, which should begin with "CfDJ8" as in the example below. "CfDJ8" is the base64 representation of the magic "09 F0 C9 F0" header that identifies a payload protected by the data protection system.

```
<input type="hidden" name="__VIEWSTATE" id="__VIEWSTATE" value="CfDJ8AWPr2EQPTBGs3L2GCZOpk...">
```

Package configuration

The data protection system is instantiated with a default zero-setup configuration. However, since by default keys are persisted to the local file system, this won't work for applications which are deployed in a farm. To resolve this, you can provide configuration by creating a type which subclasses DataProtectionStartup and overrides its ConfigureServices method.

Below is an example of a custom data protection startup type which configured both where keys are persisted and how they're encrypted at rest. It also overrides the default app isolation policy by providing its own application name.

```
using System;
using System.IO;
using Microsoft.AspNetCore.DataProtection;
using Microsoft.AspNetCore.DataProtection.SystemWeb;
using Microsoft.Extensions.DependencyInjection;

namespace DataProtectionDemo
{
    public class MyDataProtectionStartup : DataProtectionStartup
    {
        public override void ConfigureServices(IServiceCollection services)
        {
            services.AddDataProtection()
                .SetApplicationName("my-app")
                .PersistKeysToFileSystem(new DirectoryInfo(@"\\server\share\myapp-keys\"))
                .ProtectKeysWithCertificate("thumbprint");
        }
    }
}
```

TIP

You can also use `<machineKey applicationName="my-app" ... />` in place of an explicit call to SetApplicationName. This is a convenience mechanism to avoid forcing the developer to create a DataProtectionStartup-derived type if all they wanted to configure was setting the application name.

To enable this custom configuration, go back to Web.config and look for the `<appSettings>` element that the package install added to the config file. It will look like the following markup:

```
<appSettings>
  <!--
  If you want to customize the behavior of the ASP.NET Core Data Protection stack, set the
  "aspnet:dataProtectionStartupType" switch below to be the fully-qualified name of a
  type which subclasses Microsoft.AspNetCore.DataProtection.SystemWeb.DataProtectionStartup.
  -->
  <add key="aspnet:dataProtectionStartupType" value="" />
</appSettings>
```

Fill in the blank value with the assembly-qualified name of the DataProtectionStartup-derived type you just created. If the name of the application is DataProtectionDemo, this would look like the below.

```
<add key="aspnet:dataProtectionStartupType"
     value="DataProtectionDemo.MyDataProtectionStartup, DataProtectionDemo" />
```

The newly-configured data protection system is now ready for use inside the application.

Safe storage of app secrets in development in ASP.NET Core

9/22/2020 • 15 minutes to read • Edit Online

By Rick Anderson, Kirk Larkin, Daniel Roth, and Scott Addie

View or download sample code (how to download)

This document explains techniques for storing and retrieving sensitive data during development of an ASP.NET Core app on a development machine. Never store passwords or other sensitive data in source code. Production secrets shouldn't be used for development or test. Secrets shouldn't be deployed with the app. Instead, secrets should be made available in the production environment through a controlled means like environment variables, Azure Key Vault, etc. You can store and protect Azure test and production secrets with the Azure Key Vault configuration provider.

Environment variables

Environment variables are used to avoid storage of app secrets in code or in local configuration files. Environment variables override configuration values for all previously specified configuration sources.

Consider an ASP.NET Core web app in which **Individual User Accounts** security is enabled. A default database connection string is included in the project's *appsettings.json* file with the key `DefaultConnection`. The default connection string is for LocalDB, which runs in user mode and doesn't require a password. During app deployment, the `DefaultConnection` key value can be overridden with an environment variable's value. The environment variable may store the complete connection string with sensitive credentials.

> **WARNING**
> Environment variables are generally stored in plain, unencrypted text. If the machine or process is compromised, environment variables can be accessed by untrusted parties. Additional measures to prevent disclosure of user secrets may be required.

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. `__`, the double underscore, is:

- Supported by all platforms. For example, the `:` separator is not supported by Bash, but `__` is.
- Automatically replaced by a `:`

Secret Manager

The Secret Manager tool stores sensitive data during the development of an ASP.NET Core project. In this context, a piece of sensitive data is an app secret. App secrets are stored in a separate location from the project tree. The app secrets are associated with a specific project or shared across several projects. The app secrets aren't checked into source control.

> **WARNING**
> The Secret Manager tool doesn't encrypt the stored secrets and shouldn't be treated as a trusted store. It's for development purposes only. The keys and values are stored in a JSON configuration file in the user profile directory.

How the Secret Manager tool works

The Secret Manager tool abstracts away the implementation details, such as where and how the values are stored. You can use the tool without knowing these implementation details. The values are stored in a JSON configuration file in a system-protected user profile folder on the local machine:

- Windows
- Linux / macOS

File system path:

```
%APPDATA%\Microsoft\UserSecrets\<user_secrets_id>\secrets.json
```

In the preceding file paths, replace `<user_secrets_id>` with the `UserSecretsId` value specified in the *.csproj* file.

Don't write code that depends on the location or format of data saved with the Secret Manager tool. These implementation details may change. For example, the secret values aren't encrypted, but could be in the future.

Enable secret storage

The Secret Manager tool operates on project-specific configuration settings stored in your user profile.

The Secret Manager tool includes an `init` command in .NET Core SDK 3.0.100 or later. To use user secrets, run the following command in the project directory:

```
dotnet user-secrets init
```

The preceding command adds a `UserSecretsId` element within a `PropertyGroup` of the *.csproj* file. By default, the inner text of `UserSecretsId` is a GUID. The inner text is arbitrary, but is unique to the project.

```
<PropertyGroup>
  <TargetFramework>netcoreapp3.1</TargetFramework>
  <UserSecretsId>79a3edd0-2092-40a2-a04d-dcb46d5ca9ed</UserSecretsId>
</PropertyGroup>
```

In Visual Studio, right-click the project in Solution Explorer, and select **Manage User Secrets** from the context menu. This gesture adds a `UserSecretsId` element, populated with a GUID, to the *.csproj* file.

Set a secret

Define an app secret consisting of a key and its value. The secret is associated with the project's `UserSecretsId` value. For example, run the following command from the directory in which the *.csproj* file exists:

```
dotnet user-secrets set "Movies:ServiceApiKey" "12345"
```

In the preceding example, the colon denotes that `Movies` is an object literal with a `ServiceApiKey` property.

The Secret Manager tool can be used from other directories too. Use the `--project` option to supply the file system path at which the *.csproj* file exists. For example:

```
dotnet user-secrets set "Movies:ServiceApiKey" "12345" --project "C:\apps\WebApp1\src\WebApp1"
```

JSON structure flattening in Visual Studio

Visual Studio's **Manage User Secrets** gesture opens a *secrets.json* file in the text editor. Replace the contents of *secrets.json* with the key-value pairs to be stored. For example:

```
{
  "Movies": {
    "ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
    "ServiceApiKey": "12345"
  }
}
```

The JSON structure is flattened after modifications via `dotnet user-secrets remove` or `dotnet user-secrets set`. For example, running `dotnet user-secrets remove "Movies:ConnectionString"` collapses the `Movies` object literal. The modified file resembles the following:

```
{
  "Movies:ServiceApiKey": "12345"
}
```

Set multiple secrets

A batch of secrets can be set by piping JSON to the `set` command. In the following example, the *input.json* file's contents are piped to the `set` command.

- Windows
- Linux / macOS

Open a command shell, and execute the following command:

```
type .\input.json | dotnet user-secrets set
```

Access a secret

The ASP.NET Core Configuration API provides access to Secret Manager secrets.

The user secrets configuration source is automatically added in development mode when the project calls CreateDefaultBuilder to initialize a new instance of the host with preconfigured defaults. `CreateDefaultBuilder` calls AddUserSecrets when the EnvironmentName is Development:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

When `CreateDefaultBuilder` isn't called, add the user secrets configuration source explicitly by calling AddUserSecrets. Call `AddUserSecrets` only when the app runs in the Development environment, as shown in the following example:

```
var host = new HostBuilder()
    .ConfigureAppConfiguration((hostContext, builder) =>
    {
        // Add other providers for JSON, etc.

        if (hostContext.HostingEnvironment.IsDevelopment())
        {
            builder.AddUserSecrets<Program>();
        }
    })
    .Build();
```

User secrets can be retrieved via the `Configuration` API:

```
public class Startup
{
    private string _moviesApiKey = null;

    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        _moviesApiKey = Configuration["Movies:ServiceApiKey"];
    }

    public void Configure(IApplicationBuilder app)
    {
        app.Run(async (context) =>
        {
            var result = string.IsNullOrEmpty(_moviesApiKey) ? "Null" : "Not Null";
            await context.Response.WriteAsync($"Secret is {result}");
        });
    }
}
```

Map secrets to a POCO

Mapping an entire object literal to a POCO (a simple .NET class with properties) is useful for aggregating related properties.

Assume the app's *secrets.json* file contains the following two secrets:

```
{
  "Movies:ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
  "Movies:ServiceApiKey": "12345"
}
```

To map the preceding secrets to a POCO, use the `Configuration` API's object graph binding feature. The following code binds to a custom `MovieSettings` POCO and accesses the `ServiceApiKey` property value:

```
var moviesConfig = Configuration.GetSection("Movies")
                                .Get<MovieSettings>();
_moviesApiKey = moviesConfig.ServiceApiKey;
```

The `Movies:ConnectionString` and `Movies:ServiceApiKey` secrets are mapped to the respective properties in `MovieSettings`:

```
public class MovieSettings
{
    public string ConnectionString { get; set; }

    public string ServiceApiKey { get; set; }
}
```

String replacement with secrets

Storing passwords in plain text is insecure. For example, a database connection string stored in *appsettings.json* may include a password for the specified user:

```
{
  "ConnectionStrings": {
    "Movies": "Server=(localdb)\\mssqllocaldb;Database=Movie-1;User
Id=johndoe;Password=pass123;MultipleActiveResultSets=true"
  }
}
```

A more secure approach is to store the password as a secret. For example:

```
dotnet user-secrets set "DbPassword" "pass123"
```

Remove the `Password` key-value pair from the connection string in *appsettings.json*. For example:

```
{
  "ConnectionStrings": {
    "Movies": "Server=(localdb)\\mssqllocaldb;Database=Movie-1;User
Id=johndoe;MultipleActiveResultSets=true"
  }
}
```

The secret's value can be set on a SqlConnectionStringBuilder object's Password property to complete the connection string:

```
public class Startup
{
    private string _connection = null;

    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        var builder = new SqlConnectionStringBuilder(
            Configuration.GetConnectionString("Movies"));
        builder.Password = Configuration["DbPassword"];
        _connection = builder.ConnectionString;
    }

    public void Configure(IApplicationBuilder app)
    {
        app.Run(async (context) =>
        {
            await context.Response.WriteAsync($"DB Connection: {_connection}");
        });
    }
}
```

List the secrets

Assume the app's *secrets.json* file contains the following two secrets:

```
{
  "Movies:ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
  "Movies:ServiceApiKey": "12345"
}
```

Run the following command from the directory in which the *.csproj* file exists:

```
dotnet user-secrets list
```

The following output appears:

```
Movies:ConnectionString = Server=(localdb)\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true
Movies:ServiceApiKey = 12345
```

In the preceding example, a colon in the key names denotes the object hierarchy within *secrets.json*.

Remove a single secret

Assume the app's *secrets.json* file contains the following two secrets:

```
{
  "Movies:ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
  "Movies:ServiceApiKey": "12345"
}
```

Run the following command from the directory in which the *.csproj* file exists:

```
dotnet user-secrets remove "Movies:ConnectionString"
```

The app's *secrets.json* file was modified to remove the key-value pair associated with the `MoviesConnectionString` key:

```
{
  "Movies": {
    "ServiceApiKey": "12345"
  }
}
```

`dotnet user-secrets list` displays the following message:

```
Movies:ServiceApiKey = 12345
```

Remove all secrets

Assume the app's *secrets.json* file contains the following two secrets:

```
{
  "Movies:ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
  "Movies:ServiceApiKey": "12345"
}
```

Run the following command from the directory in which the *.csproj* file exists:

```
dotnet user-secrets clear
```

All user secrets for the app have been deleted from the *secrets.json* file:

```
{}
```

Running `dotnet user-secrets list` displays the following message:

```
No secrets configured for this application.
```

View or download sample code (how to download)

This document explains techniques for storing and retrieving sensitive data during development of an ASP.NET Core app on a development machine. Never store passwords or other sensitive data in source code. Production secrets shouldn't be used for development or test. Secrets shouldn't be deployed with the app. Instead, secrets should be made available in the production environment through a controlled means like environment variables, Azure Key Vault, etc. You can store and protect Azure test and production secrets with the Azure Key Vault configuration provider.

Environment variables

Environment variables are used to avoid storage of app secrets in code or in local configuration files. Environment variables override configuration values for all previously specified configuration sources.

Consider an ASP.NET Core web app in which **Individual User Accounts** security is enabled. A default database connection string is included in the project's *appsettings.json* file with the key `DefaultConnection`. The default connection string is for LocalDB, which runs in user mode and doesn't require a password. During app deployment, the `DefaultConnection` key value can be overridden with an environment variable's value. The environment variable may store the complete connection string with sensitive credentials.

> **WARNING**
> Environment variables are generally stored in plain, unencrypted text. If the machine or process is compromised, environment variables can be accessed by untrusted parties. Additional measures to prevent disclosure of user secrets may be required.

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. `__`, the double underscore, is:

- Supported by all platforms. For example, the `:` separator is not supported by Bash, but `__` is.
- Automatically replaced by a `:`

Secret Manager

The Secret Manager tool stores sensitive data during the development of an ASP.NET Core project. In this context, a piece of sensitive data is an app secret. App secrets are stored in a separate location from the project tree. The app secrets are associated with a specific project or shared across several projects. The app secrets aren't checked into source control.

> **WARNING**
> The Secret Manager tool doesn't encrypt the stored secrets and shouldn't be treated as a trusted store. It's for development purposes only. The keys and values are stored in a JSON configuration file in the user profile directory.

How the Secret Manager tool works

The Secret Manager tool abstracts away the implementation details, such as where and how the values are stored. You can use the tool without knowing these implementation details. The values are stored in a JSON configuration file in a system-protected user profile folder on the local machine:

- Windows
- Linux / macOS

File system path:

```
%APPDATA%\Microsoft\UserSecrets\<user_secrets_id>\secrets.json
```

In the preceding file paths, replace `<user_secrets_id>` with the `UserSecretsId` value specified in the *.csproj* file.

Don't write code that depends on the location or format of data saved with the Secret Manager tool. These implementation details may change. For example, the secret values aren't encrypted, but could be in the future.

Enable secret storage

The Secret Manager tool operates on project-specific configuration settings stored in your user profile.

To use user secrets, define a `UserSecretsId` element within a `PropertyGroup` of the *.csproj* file. The inner text of `UserSecretsId` is arbitrary, but is unique to the project. Developers typically generate a GUID for the `UserSecretsId`.

```
<PropertyGroup>
  <TargetFramework>netcoreapp2.1</TargetFramework>
  <UserSecretsId>79a3edd0-2092-40a2-a04d-dcb46d5ca9ed</UserSecretsId>
</PropertyGroup>
```

> **TIP**
> In Visual Studio, right-click the project in Solution Explorer, and select **Manage User Secrets** from the context menu. This gesture adds a `UserSecretsId` element, populated with a GUID, to the *.csproj* file.

Set a secret

Define an app secret consisting of a key and its value. The secret is associated with the project's `UserSecretsId` value. For example, run the following command from the directory in which the *.csproj* file exists:

```
dotnet user-secrets set "Movies:ServiceApiKey" "12345"
```

In the preceding example, the colon denotes that `Movies` is an object literal with a `ServiceApiKey` property.

The Secret Manager tool can be used from other directories too. Use the `--project` option to supply the file system path at which the *.csproj* file exists. For example:

```
dotnet user-secrets set "Movies:ServiceApiKey" "12345" --project "C:\apps\WebApp1\src\WebApp1"
```

JSON structure flattening in Visual Studio

Visual Studio's **Manage User Secrets** gesture opens a *secrets.json* file in the text editor. Replace the contents of *secrets.json* with the key-value pairs to be stored. For example:

```
{
  "Movies": {
    "ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
    "ServiceApiKey": "12345"
  }
}
```

The JSON structure is flattened after modifications via `dotnet user-secrets remove` or `dotnet user-secrets set`. For example, running `dotnet user-secrets remove "Movies:ConnectionString"` collapses the `Movies` object literal. The modified file resembles the following:

```
{
  "Movies:ServiceApiKey": "12345"
}
```

Set multiple secrets

A batch of secrets can be set by piping JSON to the `set` command. In the following example, the *input.json* file's contents are piped to the `set` command.

- Windows
- Linux / macOS

Open a command shell, and execute the following command:

```
type .\input.json | dotnet user-secrets set
```

Access a secret

The ASP.NET Core Configuration API provides access to Secret Manager secrets.

If your project targets .NET Framework, install the Microsoft.Extensions.Configuration.UserSecrets NuGet package.

In ASP.NET Core 2.0 or later, the user secrets configuration source is automatically added in development mode when the project calls CreateDefaultBuilder to initialize a new instance of the host with preconfigured defaults. `CreateDefaultBuilder` calls AddUserSecrets when the EnvironmentName is Development:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>();
```

When `CreateDefaultBuilder` isn't called, add the user secrets configuration source explicitly by calling AddUserSecrets in the `Startup` constructor. Call `AddUserSecrets` only when the app runs in the Development environment, as shown in the following example:

```
public Startup(IHostingEnvironment env)
{
    var builder = new ConfigurationBuilder()
        .SetBasePath(env.ContentRootPath)
        .AddJsonFile("appsettings.json",
                     optional: false,
                     reloadOnChange: true)
        .AddEnvironmentVariables();

    if (env.IsDevelopment())
    {
        builder.AddUserSecrets<Startup>();
    }

    Configuration = builder.Build();
}
```

User secrets can be retrieved via the `Configuration` API:

```
public class Startup
{
    private string _moviesApiKey = null;

    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        _moviesApiKey = Configuration["Movies:ServiceApiKey"];
    }

    public void Configure(IApplicationBuilder app)
    {
        app.Run(async (context) =>
        {
            var result = string.IsNullOrEmpty(_moviesApiKey) ? "Null" : "Not Null";
            await context.Response.WriteAsync($"Secret is {result}");
        });
    }
}
```

Map secrets to a POCO

Mapping an entire object literal to a POCO (a simple .NET class with properties) is useful for aggregating related properties.

Assume the app's *secrets.json* file contains the following two secrets:

```
{
  "Movies:ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
  "Movies:ServiceApiKey": "12345"
}
```

To map the preceding secrets to a POCO, use the `Configuration` API's object graph binding feature. The following code binds to a custom `MovieSettings` POCO and accesses the `ServiceApiKey` property value:

```
var moviesConfig = Configuration.GetSection("Movies")
                                .Get<MovieSettings>();
_moviesApiKey = moviesConfig.ServiceApiKey;
```

The `Movies:ConnectionString` and `Movies:ServiceApiKey` secrets are mapped to the respective properties in `MovieSettings`:

```
public class MovieSettings
{
    public string ConnectionString { get; set; }

    public string ServiceApiKey { get; set; }
}
```

String replacement with secrets

Storing passwords in plain text is insecure. For example, a database connection string stored in *appsettings.json* may include a password for the specified user:

```
{
  "ConnectionStrings": {
    "Movies": "Server=(localdb)\\mssqllocaldb;Database=Movie-1;User
Id=johndoe;Password=pass123;MultipleActiveResultSets=true"
  }
}
```

A more secure approach is to store the password as a secret. For example:

```
dotnet user-secrets set "DbPassword" "pass123"
```

Remove the `Password` key-value pair from the connection string in *appsettings.json*. For example:

```
{
  "ConnectionStrings": {
    "Movies": "Server=(localdb)\\mssqllocaldb;Database=Movie-1;User
Id=johndoe;MultipleActiveResultSets=true"
  }
}
```

The secret's value can be set on a SqlConnectionStringBuilder object's Password property to complete the connection string:

```
public class Startup
{
    private string _connection = null;

    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        var builder = new SqlConnectionStringBuilder(
            Configuration.GetConnectionString("Movies"));
        builder.Password = Configuration["DbPassword"];
        _connection = builder.ConnectionString;
    }

    public void Configure(IApplicationBuilder app)
    {
        app.Run(async (context) =>
        {
            await context.Response.WriteAsync($"DB Connection: {_connection}");
        });
    }
}
```

List the secrets

Assume the app's *secrets.json* file contains the following two secrets:

```
{
  "Movies:ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
  "Movies:ServiceApiKey": "12345"
}
```

Run the following command from the directory in which the *.csproj* file exists:

```
dotnet user-secrets list
```

The following output appears:

```
Movies:ConnectionString = Server=(localdb)\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true
Movies:ServiceApiKey = 12345
```

In the preceding example, a colon in the key names denotes the object hierarchy within *secrets.json*.

Remove a single secret

Assume the app's *secrets.json* file contains the following two secrets:

```
{
  "Movies:ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
  "Movies:ServiceApiKey": "12345"
}
```

Run the following command from the directory in which the *.csproj* file exists:

```
dotnet user-secrets remove "Movies:ConnectionString"
```

The app's *secrets.json* file was modified to remove the key-value pair associated with the `MoviesConnectionString` key:

```
{
  "Movies": {
    "ServiceApiKey": "12345"
  }
}
```

Running `dotnet user-secrets list` displays the following message:

```
Movies:ServiceApiKey = 12345
```

Remove all secrets

Assume the app's *secrets.json* file contains the following two secrets:

```
{
  "Movies:ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
  "Movies:ServiceApiKey": "12345"
}
```

Run the following command from the directory in which the *.csproj* file exists:

```
dotnet user-secrets clear
```

All user secrets for the app have been deleted from the *secrets.json* file:

```
{}
```

Running `dotnet user-secrets list` displays the following message:

```
No secrets configured for this application.
```

Azure Key Vault Configuration Provider in ASP.NET Core

9/22/2020 • 29 minutes to read • Edit Online

By Andrew Stanton-Nurse

This document explains how to use the Microsoft Azure Key Vault Configuration Provider to load app configuration values from Azure Key Vault secrets. Azure Key Vault is a cloud-based service that assists in safeguarding cryptographic keys and secrets used by apps and services. Common scenarios for using Azure Key Vault with ASP.NET Core apps include:

- Controlling access to sensitive configuration data.
- Meeting the requirement for FIPS 140-2 Level 2 validated Hardware Security Modules (HSM's) when storing configuration data.

View or download sample code (how to download)

Packages

Add a package reference to the Microsoft.Extensions.Configuration.AzureKeyVault package.

Sample app

The sample app runs in either of two modes determined by the `#define` statement at the top of the *Program.cs* file:

- `Certificate`: Demonstrates the use of an Azure Key Vault Client ID and X.509 certificate to access secrets stored in Azure Key Vault. This version of the sample can be run from any location, deployed to Azure App Service or any host capable of serving an ASP.NET Core app.
- `Managed`: Demonstrates how to use Managed identities for Azure resources to authenticate the app to Azure Key Vault with Azure AD authentication without credentials stored in the app's code or configuration. When using managed identities to authenticate, an Azure AD Application ID and Password (Client Secret) aren't required. The `Managed` version of the sample must be deployed to Azure. Follow the guidance in the Use the Managed identities for Azure resources section.

For more information on how to configure a sample app using preprocessor directives (`#define`), see Introduction to ASP.NET Core.

Secret storage in the Development environment

Set secrets locally using the Secret Manager tool. When the sample app runs on the local machine in the Development environment, secrets are loaded from the local Secret Manager store.

The Secret Manager tool requires a `<UserSecretsId>` property in the app's project file. Set the property value (`{GUID}`) to any unique GUID:

```
<PropertyGroup>
  <UserSecretsId>{GUID}</UserSecretsId>
</PropertyGroup>
```

Secrets are created as name-value pairs. Hierarchical values (configuration sections) use a `:` (colon) as a separator in ASP.NET Core configuration key names.

The Secret Manager is used from a command shell opened to the project's content root, where `{SECRET NAME}` is the name and `{SECRET VALUE}` is the value:

```
dotnet user-secrets set "{SECRET NAME}" "{SECRET VALUE}"
```

Execute the following commands in a command shell from the project's content root to set the secrets for the sample app:

```
dotnet user-secrets set "SecretName" "secret_value_1_dev"
dotnet user-secrets set "Section:SecretName" "secret_value_2_dev"
```

When these secrets are stored in Azure Key Vault in the Secret storage in the Production environment with Azure Key Vault section, the `_dev` suffix is changed to `_prod`. The suffix provides a visual cue in the app's output indicating the source of the configuration values.

Secret storage in the Production environment with Azure Key Vault

The instructions provided by the Quickstart: Set and retrieve a secret from Azure Key Vault using Azure CLI topic are summarized here for creating an Azure Key Vault and storing secrets used by the sample app. Refer to the topic for further details.

1. Open Azure Cloud shell using any one of the following methods in the Azure portal:

   - Select **Try It** in the upper-right corner of a code block. Use the search string "Azure CLI" in the text box.
   - Open Cloud Shell in your browser with the **Launch Cloud Shell** button.
   - Select the **Cloud Shell** button on the menu in the upper-right corner of the Azure portal.

   For more information, see Azure CLI and Overview of Azure Cloud Shell.

2. If you aren't already authenticated, sign in with the `az login` command.

3. Create a resource group with the following command, where `{RESOURCE GROUP NAME}` is the resource group name for the new resource group and `{LOCATION}` is the Azure region (datacenter):

   ```
   az group create --name "{RESOURCE GROUP NAME}" --location {LOCATION}
   ```

4. Create a key vault in the resource group with the following command, where `{KEY VAULT NAME}` is the name for the new key vault and `{LOCATION}` is the Azure region (datacenter):

   ```
   az keyvault create --name {KEY VAULT NAME} --resource-group "{RESOURCE GROUP NAME}" --location
   {LOCATION}
   ```

5. Create secrets in the key vault as name-value pairs.

   Azure Key Vault secret names are limited to alphanumeric characters and dashes. Hierarchical values (configuration sections) use `--` (two dashes) as a separator. Colons, which are normally used to delimit a section from a subkey in ASP.NET Core configuration, aren't allowed in key vault secret names. Therefore, two dashes are used and swapped for a colon when the secrets are loaded into the app's configuration.

The following secrets are for use with the sample app. The values include a `_prod` suffix to distinguish them from the `_dev` suffix values loaded in the Development environment from User Secrets. Replace `{KEY VAULT NAME}` with the name of the key vault that you created in the prior step:

```
az keyvault secret set --vault-name {KEY VAULT NAME} --name "SecretName" --value
"secret_value_1_prod"
az keyvault secret set --vault-name {KEY VAULT NAME} --name "Section--SecretName" --value
"secret_value_2_prod"
```

Use Application ID and X.509 certificate for non-Azure-hosted apps

Configure Azure AD, Azure Key Vault, and the app to use an Azure Active Directory Application ID and X.509 certificate to authenticate to a key vault **when the app is hosted outside of Azure**. For more information, see About keys, secrets, and certificates.

> **NOTE**
>
> Although using an Application ID and X.509 certificate is supported for apps hosted in Azure, we recommend using Managed identities for Azure resources when hosting an app in Azure. Managed identities don't require storing a certificate in the app or in the development environment.

The sample app uses an Application ID and X.509 certificate when the `#define` statement at the top of the *Program.cs* file is set to `Certificate`.

1. Create a PKCS#12 archive (*.pfx*) certificate. Options for creating certificates include MakeCert on Windows and OpenSSL.
2. Install the certificate into the current user's personal certificate store. Marking the key as exportable is optional. Note the certificate's thumbprint, which is used later in this process.
3. Export the PKCS#12 archive (*.pfx*) certificate as a DER-encoded certificate (*.cer*).
4. Register the app with Azure AD (**App registrations**).
5. Upload the DER-encoded certificate (*.cer*) to Azure AD:
   a. Select the app in Azure AD.
   b. Navigate to **Certificates & secrets**.
   c. Select **Upload certificate** to upload the certificate, which contains the public key. A *.cer*, *.pem*, or *.crt* certificate is acceptable.
6. Store the key vault name, Application ID, and certificate thumbprint in the app's *appsettings.json* file.
7. Navigate to **Key vaults** in the Azure portal.
8. Select the key vault that you created in the Secret storage in the Production environment with Azure Key Vault section.
9. Select **Access policies**.
10. Select **Add Access Policy**.
11. Open **Secret permissions** and provide the app with **Get** and **List** permissions.
12. Select **Select principal** and select the registered app by name. Select the **Select** button.
13. Select **OK**.
14. Select **Save**.
15. Deploy the app.

The `Certificate` sample app obtains its configuration values from `IConfigurationRoot` with the same name as the secret name:

- Non-hierarchical values: The value for `SecretName` is obtained with `config["SecretName"]`.

- Hierarchical values (sections): Use `:` (colon) notation or the `GetSection` extension method. Use either of these approaches to obtain the configuration value:
  - `config["Section:SecretName"]`
  - `config.GetSection("Section")["SecretName"]`

The X.509 certificate is managed by the OS. The app calls AddAzureKeyVault with values supplied by the *appsettings.json* file:

```
// using System.Linq;
// using System.Security.Cryptography.X509Certificates;
// using Microsoft.Extensions.Configuration;

public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureAppConfiguration((context, config) =>
        {
            if (context.HostingEnvironment.IsProduction())
            {
                var builtConfig = config.Build();

                using (var store = new X509Store(StoreLocation.CurrentUser))
                {
                    store.Open(OpenFlags.ReadOnly);
                    var certs = store.Certificates
                        .Find(X509FindType.FindByThumbprint,
                            builtConfig["AzureADCertThumbprint"], false);

                    config.AddAzureKeyVault(
                        $"https://{builtConfig["KeyVaultName"]}.vault.azure.net/",
                        builtConfig["AzureADApplicationId"],
                        certs.OfType<X509Certificate2>().Single());

                    store.Close();
                }
            }
        })
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

Example values:

- Key vault name: `contosovault`
- Application ID: `627e911e-43cc-61d4-992e-12db9c81b413`
- Certificate thumbprint: `fe14593dd66b2406c5269d742d04b6e1ab03adb1`

appsettings.json:

```
{
  "KeyVaultName": "Key Vault Name",
  "AzureADApplicationId": "Azure AD Application ID",
  "AzureADCertThumbprint": "Azure AD Certificate Thumbprint"
}
```

When you run the app, a webpage shows the loaded secret values. In the Development environment, secret values load with the `_dev` suffix. In the Production environment, the values load with the `_prod` suffix.

Use Managed identities for Azure resources

An app deployed to Azure can take advantage of Managed identities for Azure resources, which allows the app to authenticate with Azure Key Vault using Azure AD authentication without credentials (Application ID and Password/Client Secret) stored in the app.

The sample app uses Managed identities for Azure resources when the `#define` statement at the top of the *Program.cs* file is set to `Managed`.

Enter the vault name into the app's *appsettings.json* file. The sample app doesn't require an Application ID and Password (Client Secret) when set to the `Managed` version, so you can ignore those configuration entries. The app is deployed to Azure, and Azure authenticates the app to access Azure Key Vault only using the vault name stored in the *appsettings.json* file.

Deploy the sample app to Azure App Service.

An app deployed to Azure App Service is automatically registered with Azure AD when the service is created. Obtain the Object ID from the deployment for use in the following command. The Object ID is shown in the Azure portal on the **Identity** panel of the App Service.

Using Azure CLI and the app's Object ID, provide the app with `list` and `get` permissions to access the key vault:

```
az keyvault set-policy --name {KEY VAULT NAME} --object-id {OBJECT ID} --secret-permissions get list
```

Restart the app using Azure CLI, PowerShell, or the Azure portal.

The sample app:

- Creates an instance of the `AzureServiceTokenProvider` class without a connection string. When a connection string isn't provided, the provider attempts to obtain an access token from Managed identities for Azure resources.
- A new KeyVaultClient is created with the `AzureServiceTokenProvider` instance token callback.
- The KeyVaultClient instance is used with a default implementation of IKeyVaultSecretManager that loads all secret values and replaces double-dashes (`--`) with colons (`:`) in key names.

```
// using Microsoft.Azure.KeyVault;
// using Microsoft.Azure.Services.AppAuthentication;
// using Microsoft.Extensions.Configuration.AzureKeyVault;

public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureAppConfiguration((context, config) =>
        {
            if (context.HostingEnvironment.IsProduction())
            {
                var builtConfig = config.Build();

                var azureServiceTokenProvider = new AzureServiceTokenProvider();
                var keyVaultClient = new KeyVaultClient(
                    new KeyVaultClient.AuthenticationCallback(
                        azureServiceTokenProvider.KeyVaultTokenCallback));

                config.AddAzureKeyVault(
                    $"https://{builtConfig["KeyVaultName"]}.vault.azure.net/",
                    keyVaultClient,
                    new DefaultKeyVaultSecretManager());
            }
        })
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

Key vault name example value: `contosovault`

appsettings.json:

```
{
  "KeyVaultName": "Key Vault Name"
}
```

When you run the app, a webpage shows the loaded secret values. In the Development environment, secret values have the `_dev` suffix because they're provided by User Secrets. In the Production environment, the values load with the `_prod` suffix because they're provided by Azure Key Vault.

If you receive an `Access denied` error, confirm that the app is registered with Azure AD and provided access to the key vault. Confirm that you've restarted the service in Azure.

For information on using the provider with a managed identity and an Azure DevOps pipeline, see Create an Azure Resource Manager service connection to a VM with a managed service identity.

Configuration options

AddAzureKeyVault can accept an AzureKeyVaultConfigurationOptions:

```
config.AddAzureKeyVault(
    new AzureKeyVaultConfigurationOptions()
    {
        ...
    });
```

PROPERTY	DESCRIPTION
`Client`	KeyVaultClient to use for retrieving values.
`Manager`	IKeyVaultSecretManager instance used to control secret loading.
`ReloadInterval`	`Timespan` to wait between attempts at polling the key vault for changes. The default value is `null` (configuration isn't reloaded).
`Vault`	Key vault URI.

Use a key name prefix

AddAzureKeyVault provides an overload that accepts an implementation of IKeyVaultSecretManager, which allows you to control how key vault secrets are converted into configuration keys. For example, you can implement the interface to load secret values based on a prefix value you provide at app startup. This allows you, for example, to load secrets based on the version of the app.

> **WARNING**
> Don't use prefixes on key vault secrets to place secrets for multiple apps into the same key vault or to place environmental secrets (for example, *development* versus *production* secrets) into the same vault. We recommend that different apps and development/production environments use separate key vaults to isolate app environments for the highest level of security.

In the following example, a secret is established in the key vault (and using the Secret Manager tool for the Development environment) for `5000-AppSecret` (periods aren't allowed in key vault secret names). This secret represents an app secret for version 5.0.0.0 of the app. For another version of the app, 5.1.0.0, a secret is added to the key vault (and using the Secret Manager tool) for `5100-AppSecret`. Each app version loads its versioned secret value into its configuration as `AppSecret`, stripping off the version as it loads the secret.

AddAzureKeyVault is called with a custom IKeyVaultSecretManager:

```
config.AddAzureKeyVault(
    $"https://{builtConfig["KeyVaultName"]}.vault.azure.net/",
    builtConfig["AzureADApplicationId"],
    certs.OfType<X509Certificate2>().Single(),
    new PrefixKeyVaultSecretManager(versionPrefix));
```

The IKeyVaultSecretManager implementation reacts to the version prefixes of secrets to load the proper secret into configuration:

- `Load` loads a secret when its name starts with the prefix. Other secrets aren't loaded.
- `GetKey`:
  - Removes the prefix from the secret name.
  - Replaces two dashes in any name with the `KeyDelimiter`, which is the delimiter used in configuration (usually a colon). Azure Key Vault doesn't allow a colon in secret names.

```
public class PrefixKeyVaultSecretManager : IKeyVaultSecretManager
{
    private readonly string _prefix;

    public PrefixKeyVaultSecretManager(string prefix)
    {
        _prefix = $"{prefix}-";
    }

    public bool Load(SecretItem secret)
    {
        return secret.Identifier.Name.StartsWith(_prefix);
    }

    public string GetKey(SecretBundle secret)
    {
        return secret.SecretIdentifier.Name
            .Substring(_prefix.Length)
            .Replace("--", ConfigurationPath.KeyDelimiter);
    }
}
```

The `Load` method is called by a provider algorithm that iterates through the vault secrets to find the ones that have the version prefix. When a version prefix is found with `Load`, the algorithm uses the `GetKey` method to return the configuration name of the secret name. It strips off the version prefix from the secret's name and returns the rest of the secret name for loading into the app's configuration name-value pairs.

When this approach is implemented:

1. The app's version specified in the app's project file. In the following example, the app's version is set to `5.0.0.0`:

   ```
   <PropertyGroup>
     <Version>5.0.0.0</Version>
   </PropertyGroup>
   ```

2. Confirm that a `<UserSecretsId>` property is present in the app's project file, where `{GUID}` is a user-supplied GUID:

   ```
   <PropertyGroup>
     <UserSecretsId>{GUID}</UserSecretsId>
   </PropertyGroup>
   ```

   Save the following secrets locally with the Secret Manager tool:

   ```
   dotnet user-secrets set "5000-AppSecret" "5.0.0.0_secret_value_dev"
   dotnet user-secrets set "5100-AppSecret" "5.1.0.0_secret_value_dev"
   ```

3. Secrets are saved in Azure Key Vault using the following Azure CLI commands:

   ```
   az keyvault secret set --vault-name {KEY VAULT NAME} --name "5000-AppSecret" --value
   "5.0.0.0_secret_value_prod"
   az keyvault secret set --vault-name {KEY VAULT NAME} --name "5100-AppSecret" --value
   "5.1.0.0_secret_value_prod"
   ```

4. When the app is run, the key vault secrets are loaded. The string secret for `5000-AppSecret` is matched to the app's version specified in the app's project file (`5.0.0.0`).

5. The version, `5000` (with the dash), is stripped from the key name. Throughout the app, reading configuration with the key `AppSecret` loads the secret value.

6. If the app's version is changed in the project file to `5.1.0.0` and the app is run again, the secret value returned is `5.1.0.0_secret_value_dev` in the Development environment and `5.1.0.0_secret_value_prod` in Production.

> **NOTE**
>
> You can also provide your own KeyVaultClient implementation to AddAzureKeyVault. A custom client permits sharing a single instance of the client across the app.

Bind an array to a class

The provider is capable of reading configuration values into an array for binding to a POCO array.

When reading from a configuration source that allows keys to contain colon (`:`) separators, a numeric key segment is used to distinguish the keys that make up an array (`:0:` , `:1:` , ... `:{n}:`). For more information, see Configuration: Bind an array to a class.

Azure Key Vault keys can't use a colon as a separator. The approach described in this topic uses double dashes (`--`) as a separator for hierarchical values (sections). Array keys are stored in Azure Key Vault with double dashes and numeric key segments (`--0--` , `--1--` , ... `--{n}--`).

Examine the following Serilog logging provider configuration provided by a JSON file. There are two object literals defined in the `WriteTo` array that reflect two Serilog *sinks*, which describe destinations for logging output:

```
"Serilog": {
  "WriteTo": [
    {
      "Name": "AzureTableStorage",
      "Args": {
        "storageTableName": "logs",
        "connectionString": "DefaultEnd...ountKey=Eby8...GMGw=="
      }
    },
    {
      "Name": "AzureDocumentDB",
      "Args": {
        "endpointUrl": "https://contoso.documents.azure.com:443",
        "authorizationKey": "Eby8...GMGw=="
      }
    }
  ]
}
```

The configuration shown in the preceding JSON file is stored in Azure Key Vault using double dash (`--`) notation and numeric segments:

KEY	VALUE
`Serilog--WriteTo--0--Name`	`AzureTableStorage`
`Serilog--WriteTo--0--Args--storageTableName`	`logs`

KEY	VALUE
`Serilog--WriteTo--0--Args--connectionString`	`DefaultEnd...ountKey=Eby8...GMGw==`
`Serilog--WriteTo--1--Name`	`AzureDocumentDB`
`Serilog--WriteTo--1--Args--endpointUrl`	`https://contoso.documents.azure.com:443`
`Serilog--WriteTo--1--Args--authorizationKey`	`Eby8...GMGw==`

Reload secrets

Secrets are cached until `IConfigurationRoot.Reload()` is called. Expired, disabled, and updated secrets in the key vault are not respected by the app until `Reload` is executed.

```
Configuration.Reload();
```

Disabled and expired secrets

Disabled and expired secrets throw a KeyVaultErrorException. To prevent the app from throwing, provide the configuration using a different configuration provider or update the disabled or expired secret.

Troubleshoot

When the app fails to load configuration using the provider, an error message is written to the ASP.NET Core Logging infrastructure. The following conditions will prevent configuration from loading:

- The app or certificate isn't configured correctly in Azure Active Directory.
- The key vault doesn't exist in Azure Key Vault.
- The app isn't authorized to access the key vault.
- The access policy doesn't include `Get` and `List` permissions.
- In the key vault, the configuration data (name-value pair) is incorrectly named, missing, disabled, or expired.
- The app has the wrong key vault name (`KeyVaultName`), Azure AD Application Id (`AzureADApplicationId`), or Azure AD certificate thumbprint (`AzureADCertThumbprint`).
- The configuration key (name) is incorrect in the app for the value you're trying to load.
- When adding the access policy for the app to the key vault, the policy was created, but the **Save** button wasn't selected in the **Access policies** UI.

Additional resources

- Configuration in ASP.NET Core
- Microsoft Azure: Key Vault
- Microsoft Azure: Key Vault Documentation
- How to generate and transfer HSM-protected keys for Azure Key Vault
- KeyVaultClient Class
- Quickstart: Set and retrieve a secret from Azure Key Vault by using a .NET web app
- Tutorial: How to use Azure Key Vault with Azure Windows Virtual Machine in .NET

This document explains how to use the Microsoft Azure Key Vault Configuration Provider to load app configuration values from Azure Key Vault secrets. Azure Key Vault is a cloud-based service that assists in

safeguarding cryptographic keys and secrets used by apps and services. Common scenarios for using Azure Key Vault with ASP.NET Core apps include:

- Controlling access to sensitive configuration data.
- Meeting the requirement for FIPS 140-2 Level 2 validated Hardware Security Modules (HSM's) when storing configuration data.

View or download sample code (how to download)

Packages

Add a package reference to the Microsoft.Extensions.Configuration.AzureKeyVault package.

Sample app

The sample app runs in either of two modes determined by the `#define` statement at the top of the *Program.cs* file:

- `Certificate`: Demonstrates the use of an Azure Key Vault Client ID and X.509 certificate to access secrets stored in Azure Key Vault. This version of the sample can be run from any location, deployed to Azure App Service or any host capable of serving an ASP.NET Core app.
- `Managed`: Demonstrates how to use Managed identities for Azure resources to authenticate the app to Azure Key Vault with Azure AD authentication without credentials stored in the app's code or configuration. When using managed identities to authenticate, an Azure AD Application ID and Password (Client Secret) aren't required. The `Managed` version of the sample must be deployed to Azure. Follow the guidance in the Use the Managed identities for Azure resources section.

For more information on how to configure a sample app using preprocessor directives (`#define`), see Introduction to ASP.NET Core.

Secret storage in the Development environment

Set secrets locally using the Secret Manager tool. When the sample app runs on the local machine in the Development environment, secrets are loaded from the local Secret Manager store.

The Secret Manager tool requires a `<UserSecretsId>` property in the app's project file. Set the property value (`{GUID}`) to any unique GUID:

```
<PropertyGroup>
  <UserSecretsId>{GUID}</UserSecretsId>
</PropertyGroup>
```

Secrets are created as name-value pairs. Hierarchical values (configuration sections) use a `:` (colon) as a separator in ASP.NET Core configuration key names.

The Secret Manager is used from a command shell opened to the project's content root, where `{SECRET NAME}` is the name and `{SECRET VALUE}` is the value:

```
dotnet user-secrets set "{SECRET NAME}" "{SECRET VALUE}"
```

Execute the following commands in a command shell from the project's content root to set the secrets for the sample app:

```
dotnet user-secrets set "SecretName" "secret_value_1_dev"
dotnet user-secrets set "Section:SecretName" "secret_value_2_dev"
```

When these secrets are stored in Azure Key Vault in the Secret storage in the Production environment with Azure Key Vault section, the `_dev` suffix is changed to `_prod`. The suffix provides a visual cue in the app's output indicating the source of the configuration values.

Secret storage in the Production environment with Azure Key Vault

The instructions provided by the Quickstart: Set and retrieve a secret from Azure Key Vault using Azure CLI topic are summarized here for creating an Azure Key Vault and storing secrets used by the sample app. Refer to the topic for further details.

1. Open Azure Cloud shell using any one of the following methods in the Azure portal:

   - Select **Try It** in the upper-right corner of a code block. Use the search string "Azure CLI" in the text box.
   - Open Cloud Shell in your browser with the **Launch Cloud Shell** button.
   - Select the **Cloud Shell** button on the menu in the upper-right corner of the Azure portal.

   For more information, see Azure CLI and Overview of Azure Cloud Shell.

2. If you aren't already authenticated, sign in with the `az login` command.

3. Create a resource group with the following command, where `{RESOURCE GROUP NAME}` is the resource group name for the new resource group and `{LOCATION}` is the Azure region (datacenter):

   ```
   az group create --name "{RESOURCE GROUP NAME}" --location {LOCATION}
   ```

4. Create a key vault in the resource group with the following command, where `{KEY VAULT NAME}` is the name for the new key vault and `{LOCATION}` is the Azure region (datacenter):

   ```
   az keyvault create --name {KEY VAULT NAME} --resource-group "{RESOURCE GROUP NAME}" --location
   {LOCATION}
   ```

5. Create secrets in the key vault as name-value pairs.

   Azure Key Vault secret names are limited to alphanumeric characters and dashes. Hierarchical values (configuration sections) use `--` (two dashes) as a separator. Colons, which are normally used to delimit a section from a subkey in ASP.NET Core configuration, aren't allowed in key vault secret names. Therefore, two dashes are used and swapped for a colon when the secrets are loaded into the app's configuration.

   The following secrets are for use with the sample app. The values include a `_prod` suffix to distinguish them from the `_dev` suffix values loaded in the Development environment from User Secrets. Replace `{KEY VAULT NAME}` with the name of the key vault that you created in the prior step:

   ```
   az keyvault secret set --vault-name {KEY VAULT NAME} --name "SecretName" --value
   "secret_value_1_prod"
   az keyvault secret set --vault-name {KEY VAULT NAME} --name "Section--SecretName" --value
   "secret_value_2_prod"
   ```

Use Application ID and X.509 certificate for non-Azure-hosted apps

Configure Azure AD, Azure Key Vault, and the app to use an Azure Active Directory Application ID and X.509 certificate to authenticate to a key vault **when the app is hosted outside of Azure**. For more information, see About keys, secrets, and certificates.

> **NOTE**
>
> Although using an Application ID and X.509 certificate is supported for apps hosted in Azure, we recommend using Managed identities for Azure resources when hosting an app in Azure. Managed identities don't require storing a certificate in the app or in the development environment.

The sample app uses an Application ID and X.509 certificate when the `#define` statement at the top of the *Program.cs* file is set to `Certificate`.

1. Create a PKCS#12 archive (*.pfx*) certificate. Options for creating certificates include MakeCert on Windows and OpenSSL.
2. Install the certificate into the current user's personal certificate store. Marking the key as exportable is optional. Note the certificate's thumbprint, which is used later in this process.
3. Export the PKCS#12 archive (*.pfx*) certificate as a DER-encoded certificate (*.cer*).
4. Register the app with Azure AD (**App registrations**).
5. Upload the DER-encoded certificate (*.cer*) to Azure AD:
   a. Select the app in Azure AD.
   b. Navigate to **Certificates & secrets**.
   c. Select **Upload certificate** to upload the certificate, which contains the public key. A *.cer*, *.pem*, or *.crt* certificate is acceptable.
6. Store the key vault name, Application ID, and certificate thumbprint in the app's *appsettings.json* file.
7. Navigate to **Key vaults** in the Azure portal.
8. Select the key vault that you created in the Secret storage in the Production environment with Azure Key Vault section.
9. Select **Access policies**.
10. Select **Add Access Policy**.
11. Open **Secret permissions** and provide the app with **Get** and **List** permissions.
12. Select **Select principal** and select the registered app by name. Select the **Select** button.
13. Select **OK**.
14. Select **Save**.
15. Deploy the app.

The `Certificate` sample app obtains its configuration values from `IConfigurationRoot` with the same name as the secret name:

- Non-hierarchical values: The value for `SecretName` is obtained with `config["SecretName"]`.
- Hierarchical values (sections): Use `:` (colon) notation or the `GetSection` extension method. Use either of these approaches to obtain the configuration value:
  - `config["Section:SecretName"]`
  - `config.GetSection("Section")["SecretName"]`

The X.509 certificate is managed by the OS. The app calls AddAzureKeyVault with values supplied by the *appsettings.json* file:

```
// using System.Linq;
// using System.Security.Cryptography.X509Certificates;
// using Microsoft.Extensions.Configuration;

public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .ConfigureAppConfiguration((context, config) =>
        {
            if (context.HostingEnvironment.IsProduction())
            {
                var builtConfig = config.Build();

                using (var store = new X509Store(StoreLocation.CurrentUser))
                {
                    store.Open(OpenFlags.ReadOnly);
                    var certs = store.Certificates
                        .Find(X509FindType.FindByThumbprint,
                            builtConfig["AzureADCertThumbprint"], false);

                    config.AddAzureKeyVault(
                        $"https://{builtConfig["KeyVaultName"]}.vault.azure.net/",
                        builtConfig["AzureADApplicationId"],
                        certs.OfType<X509Certificate2>().Single());

                    store.Close();
                }
            }
        })
        .UseStartup<Startup>();
```

Example values:

- Key vault name: `contosovault`
- Application ID: `627e911e-43cc-61d4-992e-12db9c81b413`
- Certificate thumbprint: `fe14593dd66b2406c5269d742d04b6e1ab03adb1`

appsettings.json:

```
{
  "KeyVaultName": "Key Vault Name",
  "AzureADApplicationId": "Azure AD Application ID",
  "AzureADCertThumbprint": "Azure AD Certificate Thumbprint"
}
```

When you run the app, a webpage shows the loaded secret values. In the Development environment, secret values load with the `_dev` suffix. In the Production environment, the values load with the `_prod` suffix.

Use Managed identities for Azure resources

An app deployed to Azure can take advantage of Managed identities for Azure resources, which allows the app to authenticate with Azure Key Vault using Azure AD authentication without credentials (Application ID and Password/Client Secret) stored in the app.

The sample app uses Managed identities for Azure resources when the `#define` statement at the top of the *Program.cs* file is set to `Managed`.

Enter the vault name into the app's *appsettings.json* file. The sample app doesn't require an Application ID and Password (Client Secret) when set to the `Managed` version, so you can ignore those configuration entries. The app is deployed to Azure, and Azure authenticates the app to access Azure Key Vault only using the vault name stored in the *appsettings.json* file.

Deploy the sample app to Azure App Service.

An app deployed to Azure App Service is automatically registered with Azure AD when the service is created. Obtain the Object ID from the deployment for use in the following command. The Object ID is shown in the Azure portal on the **Identity** panel of the App Service.

Using Azure CLI and the app's Object ID, provide the app with `list` and `get` permissions to access the key vault:

```
az keyvault set-policy --name {KEY VAULT NAME} --object-id {OBJECT ID} --secret-permissions get list
```

Restart the app using Azure CLI, PowerShell, or the Azure portal.

The sample app:

- Creates an instance of the `AzureServiceTokenProvider` class without a connection string. When a connection string isn't provided, the provider attempts to obtain an access token from Managed identities for Azure resources.
- A new KeyVaultClient is created with the `AzureServiceTokenProvider` instance token callback.
- The KeyVaultClient instance is used with a default implementation of IKeyVaultSecretManager that loads all secret values and replaces double-dashes (`--`) with colons (`:`) in key names.

```
// using Microsoft.Azure.KeyVault;
// using Microsoft.Azure.Services.AppAuthentication;
// using Microsoft.Extensions.Configuration.AzureKeyVault;

public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .ConfigureAppConfiguration((context, config) =>
        {
            if (context.HostingEnvironment.IsProduction())
            {
                var builtConfig = config.Build();

                var azureServiceTokenProvider = new AzureServiceTokenProvider();
                var keyVaultClient = new KeyVaultClient(
                    new KeyVaultClient.AuthenticationCallback(
                        azureServiceTokenProvider.KeyVaultTokenCallback));

                config.AddAzureKeyVault(
                    $"https://{builtConfig["KeyVaultName"]}.vault.azure.net/",
                    keyVaultClient,
                    new DefaultKeyVaultSecretManager());
            }
        })
        .UseStartup<Startup>();
```

Key vault name example value: `contosovault`

appsettings.json:

```
{
  "KeyVaultName": "Key Vault Name"
}
```

When you run the app, a webpage shows the loaded secret values. In the Development environment, secret values have the `_dev` suffix because they're provided by User Secrets. In the Production environment, the values load with the `_prod` suffix because they're provided by Azure Key Vault.

If you receive an `Access denied` error, confirm that the app is registered with Azure AD and provided access to the key vault. Confirm that you've restarted the service in Azure.

For information on using the provider with a managed identity and an Azure DevOps pipeline, see Create an Azure Resource Manager service connection to a VM with a managed service identity.

Use a key name prefix

AddAzureKeyVault provides an overload that accepts an implementation of IKeyVaultSecretManager, which allows you to control how key vault secrets are converted into configuration keys. For example, you can implement the interface to load secret values based on a prefix value you provide at app startup. This allows you, for example, to load secrets based on the version of the app.

> **WARNING**
> Don't use prefixes on key vault secrets to place secrets for multiple apps into the same key vault or to place environmental secrets (for example, *development* versus *production* secrets) into the same vault. We recommend that different apps and development/production environments use separate key vaults to isolate app environments for the highest level of security.

In the following example, a secret is established in the key vault (and using the Secret Manager tool for the Development environment) for `5000-AppSecret` (periods aren't allowed in key vault secret names). This secret represents an app secret for version 5.0.0.0 of the app. For another version of the app, 5.1.0.0, a secret is added to the key vault (and using the Secret Manager tool) for `5100-AppSecret`. Each app version loads its versioned secret value into its configuration as `AppSecret`, stripping off the version as it loads the secret.

AddAzureKeyVault is called with a custom IKeyVaultSecretManager:

```
config.AddAzureKeyVault(
    $"https://{builtConfig["KeyVaultName"]}.vault.azure.net/",
    builtConfig["AzureADApplicationId"],
    certs.OfType<X509Certificate2>().Single(),
    new PrefixKeyVaultSecretManager(versionPrefix));
```

The IKeyVaultSecretManager implementation reacts to the version prefixes of secrets to load the proper secret into configuration:

- `Load` loads a secret when its name starts with the prefix. Other secrets aren't loaded.
- `GetKey`:
  - Removes the prefix from the secret name.
  - Replaces two dashes in any name with the `KeyDelimiter`, which is the delimiter used in configuration (usually a colon). Azure Key Vault doesn't allow a colon in secret names.

```
public class PrefixKeyVaultSecretManager : IKeyVaultSecretManager
{
    private readonly string _prefix;

    public PrefixKeyVaultSecretManager(string prefix)
    {
        _prefix = $"{prefix}-";
    }

    public bool Load(SecretItem secret)
    {
        return secret.Identifier.Name.StartsWith(_prefix);
    }

    public string GetKey(SecretBundle secret)
    {
        return secret.SecretIdentifier.Name
            .Substring(_prefix.Length)
            .Replace("--", ConfigurationPath.KeyDelimiter);
    }
}
```

The `Load` method is called by a provider algorithm that iterates through the vault secrets to find the ones that have the version prefix. When a version prefix is found with `Load`, the algorithm uses the `GetKey` method to return the configuration name of the secret name. It strips off the version prefix from the secret's name and returns the rest of the secret name for loading into the app's configuration name-value pairs.

When this approach is implemented:

1. The app's version specified in the app's project file. In the following example, the app's version is set to `5.0.0.0`:

   ```
   <PropertyGroup>
     <Version>5.0.0.0</Version>
   </PropertyGroup>
   ```

2. Confirm that a `<UserSecretsId>` property is present in the app's project file, where `{GUID}` is a user-supplied GUID:

   ```
   <PropertyGroup>
     <UserSecretsId>{GUID}</UserSecretsId>
   </PropertyGroup>
   ```

   Save the following secrets locally with the Secret Manager tool:

   ```
   dotnet user-secrets set "5000-AppSecret" "5.0.0.0_secret_value_dev"
   dotnet user-secrets set "5100-AppSecret" "5.1.0.0_secret_value_dev"
   ```

3. Secrets are saved in Azure Key Vault using the following Azure CLI commands:

   ```
   az keyvault secret set --vault-name {KEY VAULT NAME} --name "5000-AppSecret" --value
   "5.0.0.0_secret_value_prod"
   az keyvault secret set --vault-name {KEY VAULT NAME} --name "5100-AppSecret" --value
   "5.1.0.0_secret_value_prod"
   ```

4. When the app is run, the key vault secrets are loaded. The string secret for `5000-AppSecret` is matched to the app's version specified in the app's project file (`5.0.0.0`).

5. The version, `5000` (with the dash), is stripped from the key name. Throughout the app, reading configuration with the key `AppSecret` loads the secret value.

6. If the app's version is changed in the project file to `5.1.0.0` and the app is run again, the secret value returned is `5.1.0.0_secret_value_dev` in the Development environment and `5.1.0.0_secret_value_prod` in Production.

> **NOTE**
>
> You can also provide your own KeyVaultClient implementation to AddAzureKeyVault. A custom client permits sharing a single instance of the client across the app.

Bind an array to a class

The provider is capable of reading configuration values into an array for binding to a POCO array.

When reading from a configuration source that allows keys to contain colon (`:`) separators, a numeric key segment is used to distinguish the keys that make up an array (`:0:` , `:1:` , ... `:{n}:`). For more information, see Configuration: Bind an array to a class.

Azure Key Vault keys can't use a colon as a separator. The approach described in this topic uses double dashes (`--`) as a separator for hierarchical values (sections). Array keys are stored in Azure Key Vault with double dashes and numeric key segments (`--0--` , `--1--` , ... `--{n}--`).

Examine the following Serilog logging provider configuration provided by a JSON file. There are two object literals defined in the `WriteTo` array that reflect two Serilog *sinks*, which describe destinations for logging output:

```
"Serilog": {
  "WriteTo": [
    {
      "Name": "AzureTableStorage",
      "Args": {
        "storageTableName": "logs",
        "connectionString": "DefaultEnd...ountKey=Eby8...GMGw=="
      }
    },
    {
      "Name": "AzureDocumentDB",
      "Args": {
        "endpointUrl": "https://contoso.documents.azure.com:443",
        "authorizationKey": "Eby8...GMGw=="
      }
    }
  ]
}
```

The configuration shown in the preceding JSON file is stored in Azure Key Vault using double dash (`--`) notation and numeric segments:

KEY	VALUE
`Serilog--WriteTo--0--Name`	`AzureTableStorage`
`Serilog--WriteTo--0--Args--storageTableName`	`logs`

KEY	VALUE
`Serilog--WriteTo--0--Args--connectionString`	`DefaultEnd...ountKey=Eby8...GMGw==`
`Serilog--WriteTo--1--Name`	`AzureDocumentDB`
`Serilog--WriteTo--1--Args--endpointUrl`	`https://contoso.documents.azure.com:443`
`Serilog--WriteTo--1--Args--authorizationKey`	`Eby8...GMGw==`

Reload secrets

Secrets are cached until `IConfigurationRoot.Reload()` is called. Expired, disabled, and updated secrets in the key vault are not respected by the app until `Reload` is executed.

```
Configuration.Reload();
```

Disabled and expired secrets

Disabled and expired secrets throw a KeyVaultErrorException. To prevent the app from throwing, provide the configuration using a different configuration provider or update the disabled or expired secret.

Troubleshoot

When the app fails to load configuration using the provider, an error message is written to the ASP.NET Core Logging infrastructure. The following conditions will prevent configuration from loading:

- The app or certificate isn't configured correctly in Azure Active Directory.
- The key vault doesn't exist in Azure Key Vault.
- The app isn't authorized to access the key vault.
- The access policy doesn't include `Get` and `List` permissions.
- In the key vault, the configuration data (name-value pair) is incorrectly named, missing, disabled, or expired.
- The app has the wrong key vault name (`KeyVaultName`), Azure AD Application Id (`AzureADApplicationId`), or Azure AD certificate thumbprint (`AzureADCertThumbprint`).
- The configuration key (name) is incorrect in the app for the value you're trying to load.
- When adding the access policy for the app to the key vault, the policy was created, but the **Save** button wasn't selected in the **Access policies** UI.

Enforce HTTPS in ASP.NET Core

9/22/2020 • 12 minutes to read • Edit Online

By Rick Anderson

This document shows how to:

- Require HTTPS for all requests.
- Redirect all HTTP requests to HTTPS.

No API can prevent a client from sending sensitive data on the first request.

WARNING

API projects

Do **not** use RequireHttpsAttribute on Web APIs that receive sensitive information. `RequireHttpsAttribute` uses HTTP status codes to redirect browsers from HTTP to HTTPS. API clients may not understand or obey redirects from HTTP to HTTPS. Such clients may send information over HTTP. Web APIs should either:

- Not listen on HTTP.
- Close the connection with status code 400 (Bad Request) and not serve the request.

HSTS and API projects

The default API projects don't include HSTS because HSTS is generally a browser only instruction. Other callers, such as phone or desktop apps, do **not** obey the instruction. Even within browsers, a single authenticated call to an API over HTTP has risks on insecure networks. The secure approach is to configure API projects to only listen to and respond over HTTPS.

WARNING

API projects

Do **not** use RequireHttpsAttribute on Web APIs that receive sensitive information. `RequireHttpsAttribute` uses HTTP status codes to redirect browsers from HTTP to HTTPS. API clients may not understand or obey redirects from HTTP to HTTPS. Such clients may send information over HTTP. Web APIs should either:

- Not listen on HTTP.
- Close the connection with status code 400 (Bad Request) and not serve the request.

Require HTTPS

We recommend that production ASP.NET Core web apps use:

- HTTPS Redirection Middleware (UseHttpsRedirection) to redirect HTTP requests to HTTPS.
- HSTS Middleware (UseHsts) to send HTTP Strict Transport Security Protocol (HSTS) headers to clients.

> **NOTE**
>
> Apps deployed in a reverse proxy configuration allow the proxy to handle connection security (HTTPS). If the proxy also handles HTTPS redirection, there's no need to use HTTPS Redirection Middleware. If the proxy server also handles writing HSTS headers (for example, native HSTS support in IIS 10.0 (1709) or later), HSTS Middleware isn't required by the app. For more information, see Opt-out of HTTPS/HSTS on project creation.

UseHttpsRedirection

The following code calls `UseHttpsRedirection` in the `Startup` class:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        // The default HSTS value is 30 days. You may want to change this for production scenarios, see
https://aka.ms/aspnetcore-hsts.
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseCookiePolicy();

    app.UseMvc();
}
```

The preceding highlighted code:

- Uses the default HttpsRedirectionOptions.RedirectStatusCode (Status307TemporaryRedirect).
- Uses the default HttpsRedirectionOptions.HttpsPort (null) unless overridden by the `ASPNETCORE_HTTPS_PORT`

environment variable or IServerAddressesFeature.

We recommend using temporary redirects rather than permanent redirects. Link caching can cause unstable behavior in development environments. If you prefer to send a permanent redirect status code when the app is in a non-Development environment, see the Configure permanent redirects in production section. We recommend using HSTS to signal to clients that only secure resource requests should be sent to the app (only in production).

Port configuration

A port must be available for the middleware to redirect an insecure request to HTTPS. If no port is available:

- Redirection to HTTPS doesn't occur.
- The middleware logs the warning "Failed to determine the https port for redirect."

Specify the HTTPS port using any of the following approaches:

- Set HttpsRedirectionOptions.HttpsPort.
- Set the `https_port` host setting:
  - In host configuration.
  - By setting the `ASPNETCORE_HTTPS_PORT` environment variable.
  - By adding a top-level entry in *appsettings.json*:

```
{
    "https_port": 443,
    "Logging": {
        "LogLevel": {
            "Default": "Information",
            "Microsoft": "Warning",
            "Microsoft.Hosting.Lifetime": "Information"
        }
    },
    "AllowedHosts": "*"
}
```

- Indicate a port with the secure scheme using the ASPNETCORE_URLS environment variable. The environment variable configures the server. The middleware indirectly discovers the HTTPS port via IServerAddressesFeature. This approach doesn't work in reverse proxy deployments.
- Set the `https_port` host setting:
  - In host configuration.
  - By setting the `ASPNETCORE_HTTPS_PORT` environment variable.
  - By adding a top-level entry in *appsettings.json*:

```
{
    "https_port": 443,
    "Logging": {
        "LogLevel": {
            "Default": "Warning"
        }
    },
    "AllowedHosts": "*"
}
```

- Indicate a port with the secure scheme using the ASPNETCORE_URLS environment variable. The environment variable configures the server. The middleware indirectly discovers the HTTPS port via IServerAddressesFeature. This approach doesn't work in reverse proxy deployments.
- In development, set an HTTPS URL in *launchsettings.json*. Enable HTTPS when IIS Express is used.
- Configure an HTTPS URL endpoint for a public-facing edge deployment of Kestrel server or HTTP.sys server. Only **one HTTPS port** is used by the app. The middleware discovers the port via IServerAddressesFeature.

> **NOTE**
> When an app is run in a reverse proxy configuration, IServerAddressesFeature isn't available. Set the port using one of the other approaches described in this section.

Edge deployments

When Kestrel or HTTP.sys is used as a public-facing edge server, Kestrel or HTTP.sys must be configured to listen on both:

- The secure port where the client is redirected (typically, 443 in production and 5001 in development).
- The insecure port (typically, 80 in production and 5000 in development).

The insecure port must be accessible by the client in order for the app to receive an insecure request and redirect the client to the secure port.

For more information, see Kestrel endpoint configuration or HTTP.sys web server implementation in ASP.NET Core.

Deployment scenarios

Any firewall between the client and server must also have communication ports open for traffic.

If requests are forwarded in a reverse proxy configuration, use Forwarded Headers Middleware before calling HTTPS Redirection Middleware. Forwarded Headers Middleware updates the `Request.Scheme`, using the `X-Forwarded-Proto` header. The middleware permits redirect URIs and other security policies to work correctly. When Forwarded Headers Middleware isn't used, the backend app might not receive the correct scheme and end up in a redirect loop. A common end user error message is that too many redirects have occurred.

When deploying to Azure App Service, follow the guidance in Tutorial: Bind an existing custom SSL certificate to Azure Web Apps.

Options

The following highlighted code calls AddHttpsRedirection to configure middleware options:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();

    services.AddHsts(options =>
    {
        options.Preload = true;
        options.IncludeSubDomains = true;
        options.MaxAge = TimeSpan.FromDays(60);
        options.ExcludedHosts.Add("example.com");
        options.ExcludedHosts.Add("www.example.com");
    });

    services.AddHttpsRedirection(options =>
    {
        options.RedirectStatusCode = StatusCodes.Status307TemporaryRedirect;
        options.HttpsPort = 5001;
    });
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc();

    services.AddHsts(options =>
    {
        options.Preload = true;
        options.IncludeSubDomains = true;
        options.MaxAge = TimeSpan.FromDays(60);
        options.ExcludedHosts.Add("example.com");
        options.ExcludedHosts.Add("www.example.com");
    });

    services.AddHttpsRedirection(options =>
    {
        options.RedirectStatusCode = StatusCodes.Status307TemporaryRedirect;
        options.HttpsPort = 5001;
    });
}
```

Calling `AddHttpsRedirection` is only necessary to change the values of `HttpsPort` or `RedirectStatusCode`.

The preceding highlighted code:

- Sets HttpsRedirectionOptions.RedirectStatusCode to Status307TemporaryRedirect, which is the default value. Use the fields of the StatusCodes class for assignments to `RedirectStatusCode`.
- Sets the HTTPS port to 5001.

Configure permanent redirects in production

The middleware defaults to sending a Status307TemporaryRedirect with all redirects. If you prefer to send a permanent redirect status code when the app is in a non-Development environment, wrap the middleware options configuration in a conditional check for a non-Development environment.

When configuring services in *Startup.cs*:

```
public void ConfigureServices(IServiceCollection services)
{
    // IWebHostEnvironment (stored in _env) is injected into the Startup class.
    if (!_env.IsDevelopment())
    {
        services.AddHttpsRedirection(options =>
        {
            options.RedirectStatusCode = StatusCodes.Status308PermanentRedirect;
            options.HttpsPort = 443;
        });
    }
}
```

When configuring services in *Startup.cs*:

```
public void ConfigureServices(IServiceCollection services)
{
    // IHostingEnvironment (stored in _env) is injected into the Startup class.
    if (!_env.IsDevelopment())
    {
        services.AddHttpsRedirection(options =>
        {
            options.RedirectStatusCode = StatusCodes.Status308PermanentRedirect;
            options.HttpsPort = 443;
        });
    }
}
```

HTTPS Redirection Middleware alternative approach

An alternative to using HTTPS Redirection Middleware (`UseHttpsRedirection`) is to use URL Rewriting Middleware (`AddRedirectToHttps`). `AddRedirectToHttps` can also set the status code and port when the redirect is executed. For more information, see URL Rewriting Middleware.

When redirecting to HTTPS without the requirement for additional redirect rules, we recommend using HTTPS Redirection Middleware (`UseHttpsRedirection`) described in this topic.

HTTP Strict Transport Security Protocol (HSTS)

Per OWASP, HTTP Strict Transport Security (HSTS) is an opt-in security enhancement that's specified by a web app through the use of a response header. When a browser that supports HSTS receives this header:

- The browser stores configuration for the domain that prevents sending any communication over HTTP. The browser forces all communication over HTTPS.
- The browser prevents the user from using untrusted or invalid certificates. The browser disables prompts that allow a user to temporarily trust such a certificate.

Because HSTS is enforced by the client, it has some limitations:

- The client must support HSTS.
- HSTS requires at least one successful HTTPS request to establish the HSTS policy.
- The application must check every HTTP request and redirect or reject the HTTP request.

ASP.NET Core 2.1 and later implements HSTS with the `UseHsts` extension method. The following code calls `UseHsts` when the app isn't in development mode:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        // The default HSTS value is 30 days. You may want to change this for production scenarios, see
https://aka.ms/aspnetcore-hsts.
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseCookiePolicy();

    app.UseMvc();
}
```

`UseHsts` isn't recommended in development because the HSTS settings are highly cacheable by browsers. By default, `UseHsts` excludes the local loopback address.

For production environments that are implementing HTTPS for the first time, set the initial HstsOptions.MaxAge to a small value using one of the TimeSpan methods. Set the value from hours to no more than a single day in case you need to revert the HTTPS infrastructure to HTTP. After you're confident in the sustainability of the HTTPS configuration, increase the HSTS `max-age` value; a commonly used value is one year.

The following code:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();

    services.AddHsts(options =>
    {
        options.Preload = true;
        options.IncludeSubDomains = true;
        options.MaxAge = TimeSpan.FromDays(60);
        options.ExcludedHosts.Add("example.com");
        options.ExcludedHosts.Add("www.example.com");
    });

    services.AddHttpsRedirection(options =>
    {
        options.RedirectStatusCode = StatusCodes.Status307TemporaryRedirect;
        options.HttpsPort = 5001;
    });
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc();

    services.AddHsts(options =>
    {
        options.Preload = true;
        options.IncludeSubDomains = true;
        options.MaxAge = TimeSpan.FromDays(60);
        options.ExcludedHosts.Add("example.com");
        options.ExcludedHosts.Add("www.example.com");
    });

    services.AddHttpsRedirection(options =>
    {
        options.RedirectStatusCode = StatusCodes.Status307TemporaryRedirect;
        options.HttpsPort = 5001;
    });
}
```

- Sets the preload parameter of the `Strict-Transport-Security` header. Preload isn't part of the RFC HSTS specification, but is supported by web browsers to preload HSTS sites on fresh install. For more information, see https://hstspreload.org/.
- Enables includeSubDomain, which applies the HSTS policy to Host subdomains.
- Explicitly sets the `max-age` parameter of the `Strict-Transport-Security` header to 60 days. If not set, defaults to 30 days. For more information, see the max-age directive.
- Adds `example.com` to the list of hosts to exclude.

`UseHsts` excludes the following loopback hosts:

- `localhost` : The IPv4 loopback address.
- `127.0.0.1` : The IPv4 loopback address.
- `[::1]` : The IPv6 loopback address.

Opt-out of HTTPS/HSTS on project creation

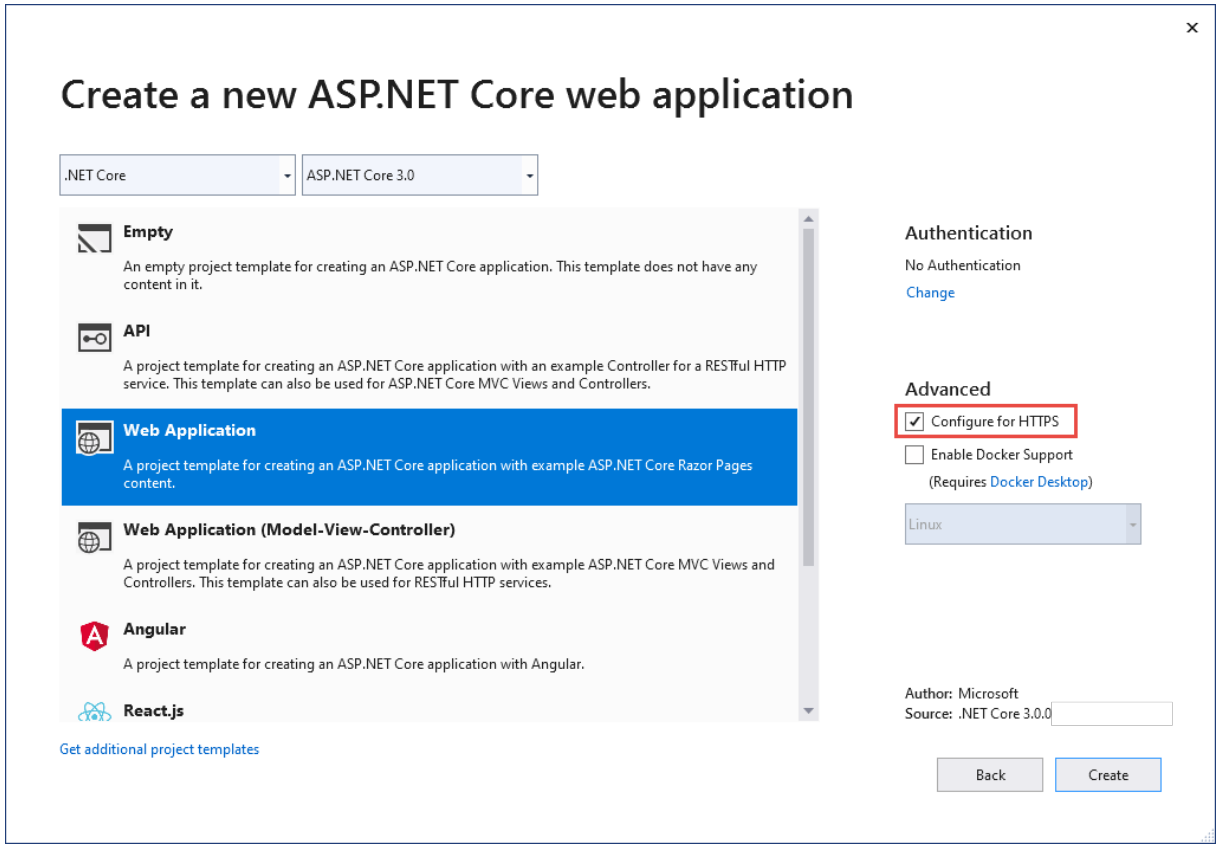
In some backend service scenarios where connection security is handled at the public-facing edge of the network, configuring connection security at each node isn't required. Web apps that are generated from the templates in Visual Studio or from the dotnet new command enable HTTPS redirection and HSTS. For

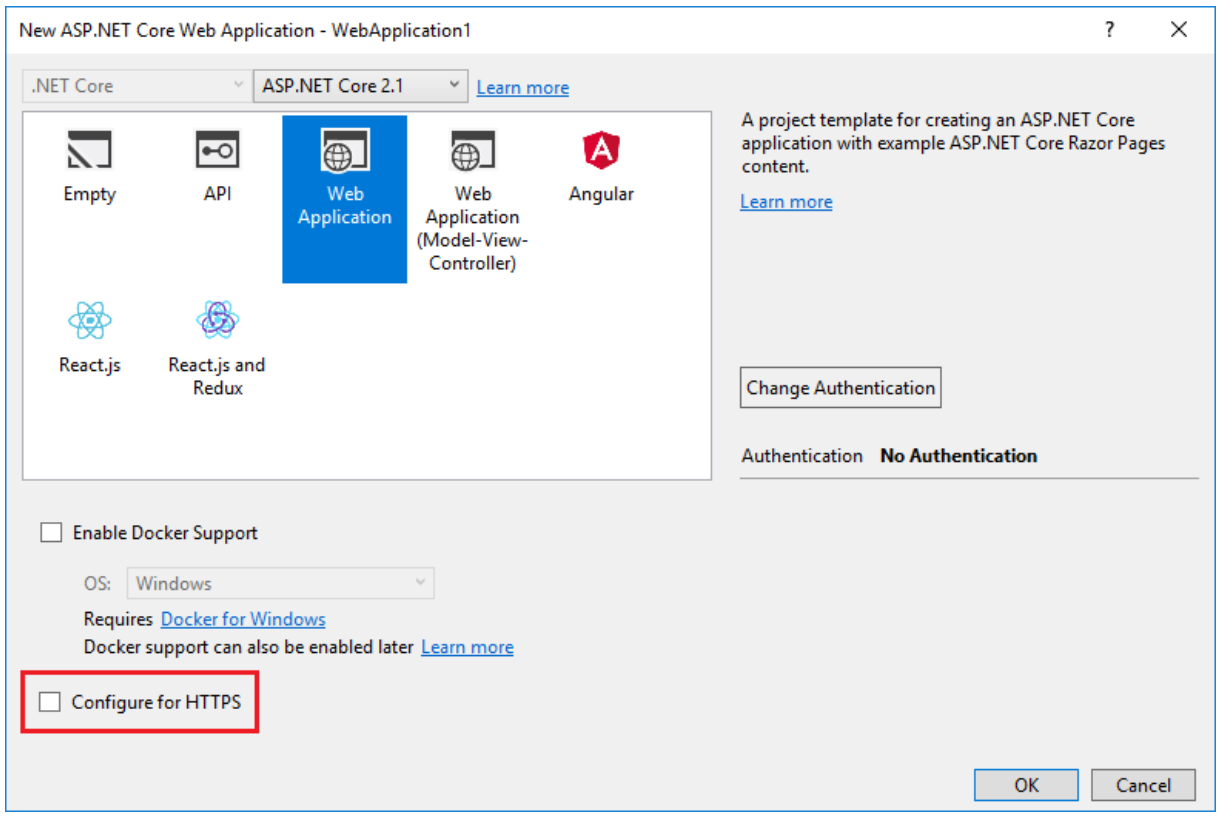
deployments that don't require these scenarios, you can opt-out of HTTPS/HSTS when the app is created from the template.

To opt-out of HTTPS/HSTS:

- Visual Studio
- .NET Core CLI

Uncheck the **Configure for HTTPS** check box.





Trust the ASP.NET Core HTTPS development certificate on Windows and macOS

The .NET Core SDK includes an HTTPS development certificate. The certificate is installed as part of the first-run experience. For example, `dotnet --info` produces a variation of the following output:

```
ASP.NET Core
------------
Successfully installed the ASP.NET Core HTTPS Development Certificate.
To trust the certificate run 'dotnet dev-certs https --trust' (Windows and macOS only).
For establishing trust on other platforms refer to the platform specific documentation.
For more information on configuring HTTPS see https://go.microsoft.com/fwlink/?linkid=848054.
```

Installing the .NET Core SDK installs the ASP.NET Core HTTPS development certificate to the local user certificate store. The certificate has been installed, but it's not trusted. To trust the certificate, perform the one-time step to run the dotnet `dev-certs` tool:

```
dotnet dev-certs https --trust
```

The following command provides help on the `dev-certs` tool:

```
dotnet dev-certs https --help
```

How to set up a developer certificate for Docker

See this GitHub issue.

Trust HTTPS certificate on Linux

For instructions on Linux, refer to the distribution documentation.

Trust HTTPS certificate from Windows Subsystem for Linux

The Windows Subsystem for Linux (WSL) generates an HTTPS self-signed cert. To configure the Windows certificate store to trust the WSL certificate:

- Run the following command to export the WSL-generated certificate:

  ```
  dotnet dev-certs https -ep %USERPROFILE%\.aspnet\https\aspnetapp.pfx -p <cryptic-password>
  ```

- In a WSL window, run the following command:

  ```
    ASPNETCORE_Kestrel__Certificates__Default__Password="<cryptic-password>"
    ASPNETCORE_Kestrel__Certificates__Default__Path=/mnt/c/Users/user-
  name/.aspnet/https/aspnetapp.pfx
    dotnet watch run
  ```

  The preceding command sets the environment variables so Linux uses the Windows trusted certificate.

Troubleshoot certificate problems

This section provides help when the ASP.NET Core HTTPS development certificate has been installed and

trusted, but you still have browser warnings that the certificate is not trusted. The ASP.NET Core HTTPS development certificate is used by Kestrel.

All platforms - certificate not trusted

Run the following commands:

```
dotnet dev-certs https --clean
dotnet dev-certs https --trust
```

Close any browser instances open. Open a new browser window to app. Certificate trust is cached by browsers.

The preceding commands solve most browser trust issues. If the browser is still not trusting the certificate, follow the platform-specific suggestions that follow.

Docker - certificate not trusted

- Delete the *C:\Users{USER}\AppData\Roaming\ASP.NET\Https* folder.
- Clean the solution. Delete the *bin* and *obj* folders.
- Restart the development tool. For example, Visual Studio, Visual Studio Code, or Visual Studio for Mac.

Windows - certificate not trusted

- Check the certificates in the certificate store. There should be a `localhost` certificate with the `ASP.NET Core HTTPS development certificate` friendly name both under `Current User > Personal > Certificates` and `Current User > Trusted root certification authorities > Certificates`
- Remove all the found certificates from both Personal and Trusted root certification authorities. Do **not** remove the IIS Express localhost certificate.
- Run the following commands:

```
dotnet dev-certs https --clean
dotnet dev-certs https --trust
```

Close any browser instances open. Open a new browser window to app.

OS X - certificate not trusted

- Open KeyChain Access.
- Select the System keychain.
- Check for the presence of a localhost certificate.
- Check that it contains a `+` symbol on the icon to indicate it's trusted for all users.
- Remove the certificate from the system keychain.
- Run the following commands:

```
dotnet dev-certs https --clean
dotnet dev-certs https --trust
```

Close any browser instances open. Open a new browser window to app.

See HTTPS Error using IIS Express (dotnet/AspNetCore #16892) for troubleshooting certificate issues with Visual Studio.

IIS Express SSL certificate used with Visual Studio

To fix problems with the IIS Express certificate, select **Repair** from the Visual Studio installer. For more

information, see this GitHub issue.

Hosting ASP.NET Core images with Docker over HTTPS

9/22/2020 • 2 minutes to read • Edit Online

By Rick Anderson

ASP.NET Core uses HTTPS by default. HTTPS relies on certificates for trust, identity, and encryption.

This document explains how to run pre-built container images with HTTPS.

See Developing ASP.NET Core Applications with Docker over HTTPS for development scenarios.

This sample requires Docker 17.06 or later of the Docker client.

Prerequisites

The .NET Core 2.2 SDK or later is required for some of the instructions in this document.

Certificates

A certificate from a certificate authority is required for production hosting for a domain. Let's Encrypt is a certificate authority that offers free certificates.

This document uses self-signed development certificates for hosting pre-built images over `localhost`. The instructions are similar to using production certificates.

For production certs:

- The `dotnet dev-certs` tool is not required.
- Certificates do not need to be stored in the location used in the instructions. Any location should work, although storing certs within your site directory is not recommended.

The instructions contained in the following section volume mount certificates into containers using Docker's `-v` command-line option. You could add certificates into container images with a `COPY` command in a *Dockerfile*, but it's not recommended. Copying certificates into an image isn't recommended for the following reasons:

- It makes difficult to use the same image for testing with developer certificates.
- It makes difficult to use the same image for Hosting with production certificates.
- There is significant risk of certificate disclosure.

Running pre-built container images with HTTPS

Use the following instructions for your operating system configuration.

Windows using Linux containers

Generate certificate and configure local machine:

```
dotnet dev-certs https -ep %USERPROFILE%\.aspnet\https\aspnetapp.pfx -p { password here }
dotnet dev-certs https --trust
```

In the preceding commands, replace `{ password here }` with a password.

Run the container image with ASP.NET Core configured for HTTPS in a command shell:

```
docker pull mcr.microsoft.com/dotnet/core/samples:aspnetapp
docker run --rm -it -p 8000:80 -p 8001:443 -e ASPNETCORE_URLS="https://+;http://+" -e
ASPNETCORE_HTTPS_PORT=8001 -e ASPNETCORE_Kestrel__Certificates__Default__Password="password" -e
ASPNETCORE_Kestrel__Certificates__Default__Path=/https/aspnetapp.pfx -v %USERPROFILE%\.aspnet\https:/https/
mcr.microsoft.com/dotnet/core/samples:aspnetapp
```

When using PowerShell, replace `%USERPROFILE%` with `$env:USERPROFILE`.

The password must match the password used for the certificate.

macOS or Linux

Generate certificate and configure local machine:

```
dotnet dev-certs https -ep ${HOME}/.aspnet/https/aspnetapp.pfx -p { password here }
dotnet dev-certs https --trust
```

`dotnet dev-certs https --trust` is only supported on macOS and Windows. You need to trust certs on Linux in the way that is supported by your distribution. It is likely that you need to trust the certificate in your browser.

In the preceding commands, replace `{ password here }` with a password.

Run the container image with ASP.NET Core configured for HTTPS:

```
docker pull mcr.microsoft.com/dotnet/core/samples:aspnetapp
docker run --rm -it -p 8000:80 -p 8001:443 -e ASPNETCORE_URLS="https://+;http://+" -e
ASPNETCORE_HTTPS_PORT=8001 -e ASPNETCORE_Kestrel__Certificates__Default__Password="password" -e
ASPNETCORE_Kestrel__Certificates__Default__Path=/https/aspnetapp.pfx -v ${HOME}/.aspnet/https:/https/
mcr.microsoft.com/dotnet/core/samples:aspnetapp
```

The password must match the password used for the certificate.

Windows using Windows containers

Generate certificate and configure local machine:

```
dotnet dev-certs https -ep %USERPROFILE%\.aspnet\https\aspnetapp.pfx -p { password here }
dotnet dev-certs https --trust
```

In the preceding commands, replace `{ password here }` with a password. When using PowerShell, replace `%USERPROFILE%` with `$env:USERPROFILE`.

Run the container image with ASP.NET Core configured for HTTPS:

```
docker pull mcr.microsoft.com/dotnet/core/samples:aspnetapp
docker run --rm -it -p 8000:80 -p 8001:443 -e ASPNETCORE_URLS="https://+;http://+" -e
ASPNETCORE_HTTPS_PORT=8001 -e ASPNETCORE_Kestrel__Certificates__Default__Password="password" -e
ASPNETCORE_Kestrel__Certificates__Default__Path=\https\aspnetapp.pfx -v %USERPROFILE%\.aspnet\https:C:\https\
mcr.microsoft.com/dotnet/core/samples:aspnetapp
```

The password must match the password used for the certificate. When using PowerShell, replace `%USERPROFILE%` with `$env:USERPROFILE`.

Hosting ASP.NET Core images with Docker Compose over HTTPS

9/22/2020 • 2 minutes to read • Edit Online

ASP.NET Core uses HTTPS by default. HTTPS relies on certificates for trust, identity, and encryption.

This document explains how to run pre-built container images with HTTPS.

See Developing ASP.NET Core Applications with Docker over HTTPS for development scenarios.

This sample requires Docker 17.06 or later of the Docker client.

Prerequisites

The .NET Core 2.2 SDK or later is required for some of the instructions in this document.

Certificates

A certificate from a certificate authority is required for production hosting for a domain. Let's Encrypt is a certificate authority that offers free certificates.

This document uses self-signed development certificates for hosting pre-built images over `localhost`. The instructions are similar to using production certificates.

For production certificates:

- The `dotnet dev-certs` tool is not required.
- Certificates don't need to be stored in the location used in the instructions. Store the certificates in any location outside the site directory.

The instructions contained in the following section volume mount certificates into containers using the `volumes` property in *docker-compose.yml*. You could add certificates into container images with a `COPY` command in a *Dockerfile*, but it's not recommended. Copying certificates into an image isn't recommended for the following reasons:

- It makes it difficult to use the same image for testing with developer certificates.
- It makes it difficult to use the same image for Hosting with production certificates.
- There is significant risk of certificate disclosure.

Starting a container with https support using docker compose

Use the following instructions for your operating system configuration.

Windows using Linux containers

Generate certificate and configure local machine:

```
dotnet dev-certs https -ep %USERPROFILE%\.aspnet\https\aspnetapp.pfx -p { password here }
dotnet dev-certs https --trust
```

In the preceding commands, replace `{ password here }` with a password.

Create a *docker-compose.debug.yml* file with the following content:

```
version: '3.4'

services:
  webapp:
    image: mcr.microsoft.com/dotnet/core/samples:aspnetapp
    ports:
      - 80
      - 443
    environment:
      - ASPNETCORE_ENVIRONMENT=Development
      - ASPNETCORE_URLS=https://+:443;http://+:80
      - ASPNETCORE_Kestrel__Certificates__Default__Password=password
      - ASPNETCORE_Kestrel__Certificates__Default__Path=/https/aspnetapp.pfx
    volumes:
      - ~/.aspnet/https:/https:ro
```

The password specified in the docker compose file must match the password used for the certificate.

Start the container with ASP.NET Core configured for HTTPS:

```
docker-compose -f "docker-compose.debug.yml" up -d
```

macOS or Linux

Generate certificate and configure local machine:

```
dotnet dev-certs https -ep ${HOME}/.aspnet/https/aspnetapp.pfx -p { password here }
dotnet dev-certs https --trust
```

`dotnet dev-certs https --trust` is only supported on macOS and Windows. You need to trust certificates on Linux in the way that is supported by your distribution. It is likely that you need to trust the certificate in your browser.

In the preceding commands, replace `{ password here }` with a password.

Create a *docker-compose.debug.yml* file with the following content:

```
version: '3.4'

services:
  webapp:
    image: mcr.microsoft.com/dotnet/core/samples:aspnetapp
    ports:
      - 80
      - 443
    environment:
      - ASPNETCORE_ENVIRONMENT=Development
      - ASPNETCORE_URLS=https://+:443;http://+:80
      - ASPNETCORE_Kestrel__Certificates__Default__Password=password
      - ASPNETCORE_Kestrel__Certificates__Default__Path=/https/aspnetapp.pfx
    volumes:
      - ~/.aspnet/https:/https:ro
```

The password specified in the docker compose file must match the password used for the certificate.

Start the container with ASP.NET Core configured for HTTPS:

```
docker-compose -f "docker-compose.debug.yml" up -d
```

Windows using Windows containers

Generate certificate and configure local machine:

```
dotnet dev-certs https -ep %USERPROFILE%\.aspnet\https\aspnetapp.pfx -p { password here }
dotnet dev-certs https --trust
```

In the preceding commands, replace `{ password here }` with a password.

Create a *docker-compose.debug.yml* file with the following content:

```
version: '3.4'

services:
  webapp:
    image: mcr.microsoft.com/dotnet/core/samples:aspnetapp
    ports:
      - 80
      - 443
    environment:
      - ASPNETCORE_ENVIRONMENT=Development
      - ASPNETCORE_URLS=https://+:443;http://+:80
      - ASPNETCORE_Kestrel__Certificates__Default__Password=password
      - ASPNETCORE_Kestrel__Certificates__Default__Path=C:\https\aspnetapp.pfx
    volumes:
      - ${USERPROFILE}\.aspnet\https:C:\https:ro
```

The password specified in the docker compose file must match the password used for the certificate.

Start the container with ASP.NET Core configured for HTTPS:

```
docker-compose -f "docker-compose.debug.yml" up -d
```

EU General Data Protection Regulation (GDPR) support in ASP.NET Core

9/22/2020 • 7 minutes to read • Edit Online

By Rick Anderson

ASP.NET Core provides APIs and templates to help meet some of the EU General Data Protection Regulation (GDPR) requirements:

- The project templates include extension points and stubbed markup that you can replace with your privacy and cookie use policy.
- The *Pages/Privacy.cshtml* page or *Views/Home/Privacy.cshtml* view provides a page to detail your site's privacy policy.

To enable the default cookie consent feature like that found in the ASP.NET Core 2.2 templates in an ASP.NET Core 3.0 template generated app:

- Add `using Microsoft.AspNetCore.Http` to the list of using directives.
- Add CookiePolicyOptions to `Startup.ConfigureServices` and UseCookiePolicy to `Startup.Configure`:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.Configure<CookiePolicyOptions>(options =>
        {
            // This lambda determines whether user consent for non-essential
            // cookies is needed for a given request.
            options.CheckConsentNeeded = context => true;
            // requires using Microsoft.AspNetCore.Http;
            options.MinimumSameSitePolicy = SameSiteMode.None;
        });

        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseCookiePolicy();

        app.UseRouting();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapRazorPages();
        });
    }
}
```

- Add the cookie consent partial to the *_Layout.cshtml* file:

```
        @*Previous markup removed for brevity*@
    </header>
    <div class="container">
        <partial name="_CookieConsentPartial" />
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2019 - RPCC - <a asp-area="" asp-page="/Privacy">Privacy</a>
        </div>
    </footer>

    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>

    @RenderSection("Scripts", required: false)
</body>
</html>
```

- Add the *_CookieConsentPartial.cshtml* file to the project:

```
@using Microsoft.AspNetCore.Http.Features

@{
    var consentFeature = Context.Features.Get<ITrackingConsentFeature>();
    var showBanner = !consentFeature?.CanTrack ?? false;
    var cookieString = consentFeature?.CreateConsentCookie();
}

@if (showBanner)
{
    <div id="cookieConsent" class="alert alert-info alert-dismissible fade show" role="alert">
        Use this space to summarize your privacy and cookie use policy. <a asp-
page="/Privacy">Learn More</a>.
        <button type="button" class="accept-policy close" data-dismiss="alert" aria-
label="Close" data-cookie-string="@cookieString">
            <span aria-hidden="true">Accept</span>
        </button>
    </div>
    <script>
        (function () {
            var button = document.querySelector("#cookieConsent button[data-cookie-string]");
            button.addEventListener("click", function (event) {
                document.cookie = button.dataset.cookieString;
            }, false);
        })();
    </script>
}
```

- Select the ASP.NET Core 2.2 version of this article to read about the cookie consent feature.

- The project templates include extension points and stubbed markup that you can replace with your privacy and cookie use policy.
- A cookie consent feature allows you to ask for (and track) consent from your users for storing personal information. If a user hasn't consented to data collection and the app has CheckConsentNeeded set to `true`, non-essential cookies aren't sent to the browser.
- Cookies can be marked as essential. Essential cookies are sent to the browser even when the user hasn't

consented and tracking is disabled.

- TempData and Session cookies aren't functional when tracking is disabled.
- The Identity manage page provides a link to download and delete user data.

The sample app allows you test most of the GDPR extension points and APIs added to the ASP.NET Core 2.1 templates. See the ReadMe file for testing instructions.

View or download sample code (how to download)

ASP.NET Core GDPR support in template-generated code

Razor Pages and MVC projects created with the project templates include the following GDPR support:

- CookiePolicyOptions and UseCookiePolicy are set in the `Startup` class.
- The *_CookieConsentPartial.cshtml* partial view. An **Accept** button is included in this file. When the user clicks the **Accept** button, consent to store cookies is provided.
- The *Pages/Privacy.cshtml* page or *Views/Home/Privacy.cshtml* view provides a page to detail your site's privacy policy. The *_CookieConsentPartial.cshtml* file generates a link to the Privacy page.
- For apps created with individual user accounts, the Manage page provides links to download and delete personal user data.

CookiePolicyOptions and UseCookiePolicy

CookiePolicyOptions are initialized in `Startup.ConfigureServices`:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    // This method gets called by the runtime. Use this method to add services
    // to the container.
    public void ConfigureServices(IServiceCollection services)
    {
        services.Configure<CookiePolicyOptions>(options =>
        {
            // This lambda determines whether user consent for non-essential cookies
            // is needed for a given request.
            options.CheckConsentNeeded = context => true;
            options.MinimumSameSitePolicy = SameSiteMode.None;
        });

        services.AddDbContext<ApplicationDbContext>(options =>
            options.UseSqlServer(
                Configuration.GetConnectionString("DefaultConnection")));
        services.AddDefaultIdentity<IdentityUser>()
            .AddEntityFrameworkStores<ApplicationDbContext>();

        // If the app uses session state, call AddSession.
        // services.AddSession();

        services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
    }

    // This method gets called by the runtime. Use this method to configure the
    // HTTP request pipeline.
    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
            app.UseDatabaseErrorPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseCookiePolicy();

        app.UseAuthentication();

        // If the app uses session state, call Session Middleware after Cookie
        // Policy Middleware and before MVC Middleware.
        // app.UseSession();

        app.UseMvc();
    }
}
```

UseCookiePolicy is called in `Startup.Configure`:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    // This method gets called by the runtime. Use this method to add services
    // to the container.
    public void ConfigureServices(IServiceCollection services)
    {
        services.Configure<CookiePolicyOptions>(options =>
        {
            // This lambda determines whether user consent for non-essential cookies
            // is needed for a given request.
            options.CheckConsentNeeded = context => true;
            options.MinimumSameSitePolicy = SameSiteMode.None;
        });

        services.AddDbContext<ApplicationDbContext>(options =>
            options.UseSqlServer(
                Configuration.GetConnectionString("DefaultConnection")));
        services.AddDefaultIdentity<IdentityUser>()
            .AddEntityFrameworkStores<ApplicationDbContext>();

        // If the app uses session state, call AddSession.
        // services.AddSession();

        services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
    }

    // This method gets called by the runtime. Use this method to configure the
    // HTTP request pipeline.
    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
            app.UseDatabaseErrorPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseCookiePolicy();

        app.UseAuthentication();

        // If the app uses session state, call Session Middleware after Cookie
        // Policy Middleware and before MVC Middleware.
        // app.UseSession();

        app.UseMvc();
    }
}
```

_CookieConsentPartial.cshtml partial view

The *_CookieConsentPartial.cshtml* partial view:

```
@using Microsoft.AspNetCore.Http.Features

@{
    var consentFeature = Context.Features.Get<ITrackingConsentFeature>();
    var showBanner = !consentFeature?.CanTrack ?? false;
    var cookieString = consentFeature?.CreateConsentCookie();
}

@if (showBanner)
{
    <nav id="cookieConsent" class="navbar navbar-default navbar-fixed-top" role="alert">
        <div class="container">
            <div class="navbar-header">
                <button type="button" class="navbar-toggle" data-toggle="collapse" data-
target="#cookieConsent .navbar-collapse">
                    <span class="sr-only">Toggle cookie consent banner</span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                </button>
                <span class="navbar-brand"><span class="glyphicon glyphicon-info-sign" aria-
hidden="true"></span></span>
            </div>
            <div class="collapse navbar-collapse">
                <p class="navbar-text">
                    Use this space to summarize your privacy and cookie use policy.
                </p>
                <div class="navbar-right">
                    <a asp-page="/Privacy" class="btn btn-info navbar-btn">Learn More</a>
                    <button type="button" class="btn btn-default navbar-btn" data-cookie-
string="@cookieString">Accept</button>
                </div>
            </div>
        </div>
    </nav>
    <script>
        (function () {
            document.querySelector("#cookieConsent button[data-cookie-
string]").addEventListener("click", function (el) {
                document.cookie = el.target.dataset.cookieString;
                document.querySelector("#cookieConsent").classList.add("hidden");
            }, false);
        })();
    </script>
}
```

This partial:

- Obtains the state of tracking for the user. If the app is configured to require consent, the user must consent before cookies can be tracked. If consent is required, the cookie consent panel is fixed at top of the navigation bar created by the *_Layout.cshtml* file.
- Provides an HTML `<p>` element to summarize your privacy and cookie use policy.
- Provides a link to Privacy page or view where you can detail your site's privacy policy.

Essential cookies

If consent to store cookies hasn't been provided, only cookies marked essential are sent to the browser. The following code makes a cookie essential:

```
public IActionResult OnPostCreateEssentialAsync()
{
    HttpContext.Response.Cookies.Append(Constants.EssentialSec,
        DateTime.Now.Second.ToString(),
        new CookieOptions() { IsEssential = true });

    ResponseCookies = Response.Headers[HeaderNames.SetCookie].ToString();

    return RedirectToPage("./Index");
}
```

TempData provider and session state cookies aren't essential

The TempData provider cookie isn't essential. If tracking is disabled, the TempData provider isn't functional. To enable the TempData provider when tracking is disabled, mark the TempData cookie as essential in `Startup.ConfigureServices`:

```
// The TempData provider cookie is not essential. Make it essential
// so TempData is functional when tracking is disabled.
services.Configure<CookieTempDataProviderOptions>(options => {
    options.Cookie.IsEssential = true;
});
```

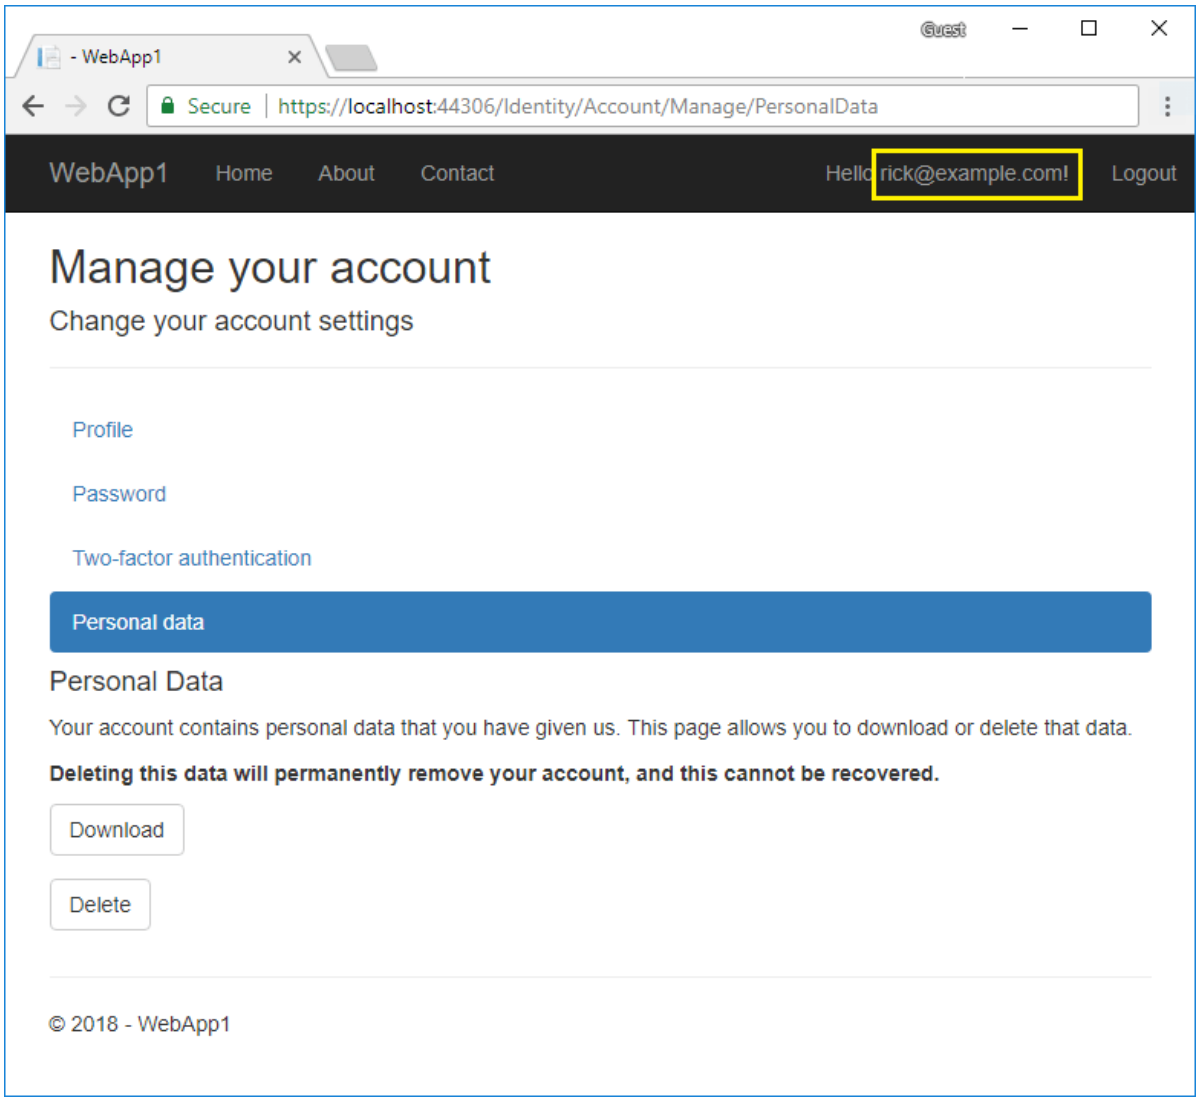
Session state cookies are not essential. Session state isn't functional when tracking is disabled. The following code makes session cookies essential:

```
services.AddSession(options =>
{
    options.Cookie.IsEssential = true;
});
```

Personal data

ASP.NET Core apps created with individual user accounts include code to download and delete personal data.

Select the user name and then select **Personal data**:



Notes:

- To generate the `Account/Manage` code, see Scaffold Identity.
- The **Delete** and **Download** links only act on the default identity data. Apps that create custom user data must be extended to delete/download the custom user data. For more information, see Add, download, and delete custom user data to Identity.
- Saved tokens for the user that are stored in the Identity database table `AspNetUserTokens` are deleted when the user is deleted via the cascading delete behavior due to the foreign key.
- External provider authentication, such as Facebook and Google, isn't available before the cookie policy is accepted.

Encryption at rest

Some databases and storage mechanisms allow for encryption at rest. Encryption at rest:

- Encrypts stored data automatically.
- Encrypts without configuration, programming, or other work for the software that accesses the data.
- Is the easiest and safest option.
- Allows the database to manage keys and encryption.

For example:

- Microsoft SQL and Azure SQL provide Transparent Data Encryption (TDE).
- SQL Azure encrypts the database by default
- Azure Blobs, Files, Table, and Queue Storage are encrypted by default.

For databases that don't provide built-in encryption at rest, you may be able to use disk encryption to provide the same protection. For example:

- BitLocker for Windows Server
- Linux:
  - eCryptfs
  - EncFS.

Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core

9/22/2020 • 14 minutes to read • Edit Online

By Rick Anderson, Fiyaz Hasan, and Steve Smith

Cross-site request forgery (also known as XSRF or CSRF) is an attack against web-hosted apps whereby a malicious web app can influence the interaction between a client browser and a web app that trusts that browser. These attacks are possible because web browsers send some types of authentication tokens automatically with every request to a website. This form of exploit is also known as a *one-click attack* or *session riding* because the attack takes advantage of the user's previously authenticated session.

An example of a CSRF attack:

1. A user signs into `www.good-banking-site.com` using forms authentication. The server authenticates the user and issues a response that includes an authentication cookie. The site is vulnerable to attack because it trusts any request that it receives with a valid authentication cookie.

2. The user visits a malicious site, `www.bad-crook-site.com`.

   The malicious site, `www.bad-crook-site.com`, contains an HTML form similar to the following:

   ```
   <h1>Congratulations! You're a Winner!</h1>
   <form action="http://good-banking-site.com/api/account" method="post">
       <input type="hidden" name="Transaction" value="withdraw">
       <input type="hidden" name="Amount" value="1000000">
       <input type="submit" value="Click to collect your prize!">
   </form>
   ```

   Notice that the form's `action` posts to the vulnerable site, not to the malicious site. This is the "cross-site" part of CSRF.

3. The user selects the submit button. The browser makes the request and automatically includes the authentication cookie for the requested domain, `www.good-banking-site.com`.

4. The request runs on the `www.good-banking-site.com` server with the user's authentication context and can perform any action that an authenticated user is allowed to perform.

In addition to the scenario where the user selects the button to submit the form, the malicious site could:

- Run a script that automatically submits the form.
- Send the form submission as an AJAX request.
- Hide the form using CSS.

These alternative scenarios don't require any action or input from the user other than initially visiting the malicious site.

Using HTTPS doesn't prevent a CSRF attack. The malicious site can send an `https://www.good-banking-site.com/` request just as easily as it can send an insecure request.

Some attacks target endpoints that respond to GET requests, in which case an image tag can be used to perform the action. This form of attack is common on forum sites that permit images but block JavaScript. Apps that change state on GET requests, where variables or resources are altered, are vulnerable to

malicious attacks. **GET requests that change state are insecure. A best practice is to never change state on a GET request.**

CSRF attacks are possible against web apps that use cookies for authentication because:

- Browsers store cookies issued by a web app.
- Stored cookies include session cookies for authenticated users.
- Browsers send all of the cookies associated with a domain to the web app every request regardless of how the request to app was generated within the browser.

However, CSRF attacks aren't limited to exploiting cookies. For example, Basic and Digest authentication are also vulnerable. After a user signs in with Basic or Digest authentication, the browser automatically sends the credentials until the session† ends.

†In this context, *session* refers to the client-side session during which the user is authenticated. It's unrelated to server-side sessions or ASP.NET Core Session Middleware.

Users can guard against CSRF vulnerabilities by taking precautions:

- Sign off of web apps when finished using them.
- Clear browser cookies periodically.

However, CSRF vulnerabilities are fundamentally a problem with the web app, not the end user.

Authentication fundamentals

Cookie-based authentication is a popular form of authentication. Token-based authentication systems are growing in popularity, especially for Single Page Applications (SPAs).

Cookie-based authentication

When a user authenticates using their username and password, they're issued a token, containing an authentication ticket that can be used for authentication and authorization. The token is stored as a cookie that accompanies every request the client makes. Generating and validating this cookie is performed by the Cookie Authentication Middleware. The middleware serializes a user principal into an encrypted cookie. On subsequent requests, the middleware validates the cookie, recreates the principal, and assigns the principal to the User property of HttpContext.

Token-based authentication

When a user is authenticated, they're issued a token (not an antiforgery token). The token contains user information in the form of claims or a reference token that points the app to user state maintained in the app. When a user attempts to access a resource requiring authentication, the token is sent to the app with an additional authorization header in form of Bearer token. This makes the app stateless. In each subsequent request, the token is passed in the request for server-side validation. This token isn't *encrypted*; it's *encoded*. On the server, the token is decoded to access its information. To send the token on subsequent requests, store the token in the browser's local storage. Don't be concerned about CSRF vulnerability if the token is stored in the browser's local storage. CSRF is a concern when the token is stored in a cookie. For more information, see the GitHub issue SPA code sample adds two cookies.

Multiple apps hosted at one domain

Shared hosting environments are vulnerable to session hijacking, login CSRF, and other attacks.

Although `example1.contoso.net` and `example2.contoso.net` are different hosts, there's an implicit trust relationship between hosts under the `*.contoso.net` domain. This implicit trust relationship allows potentially untrusted hosts to affect each other's cookies (the same-origin policies that govern AJAX requests don't necessarily apply to HTTP cookies).

Attacks that exploit trusted cookies between apps hosted on the same domain can be prevented by not sharing domains. When each app is hosted on its own domain, there is no implicit cookie trust relationship to exploit.

ASP.NET Core antiforgery configuration

> **WARNING**
> ASP.NET Core implements antiforgery using ASP.NET Core Data Protection. The data protection stack must be configured to work in a server farm. See Configuring data protection for more information.

Antiforgery middleware is added to the Dependency injection container when one of the following APIs is called in `Startup.ConfigureServices`:

- AddMvc
- MapRazorPages
- MapControllerRoute
- MapBlazorHub

Antiforgery middleware is added to the Dependency injection container when AddMvc is called in `Startup.ConfigureServices`

In ASP.NET Core 2.0 or later, the FormTagHelper injects antiforgery tokens into HTML form elements. The following markup in a Razor file automatically generates antiforgery tokens:

```
<form method="post">
    ...
</form>
```

Similarly, IHtmlHelper.BeginForm generates antiforgery tokens by default if the form's method isn't GET.

The automatic generation of antiforgery tokens for HTML form elements happens when the `<form>` tag contains the `method="post"` attribute and either of the following are true:

- The action attribute is empty (`action=""`).
- The action attribute isn't supplied (`<form method="post">`).

Automatic generation of antiforgery tokens for HTML form elements can be disabled:

- Explicitly disable antiforgery tokens with the `asp-antiforgery` attribute:

  ```
  <form method="post" asp-antiforgery="false">
      ...
  </form>
  ```

- The form element is opted-out of Tag Helpers by using the Tag Helper ! opt-out symbol:

  ```
  <!form method="post">
      ...
  </!form>
  ```

- Remove the `FormTagHelper` from the view. The `FormTagHelper` can be removed from a view by adding the following directive to the Razor view:

```
@removeTagHelper Microsoft.AspNetCore.Mvc.TagHelpers.FormTagHelper,
Microsoft.AspNetCore.Mvc.TagHelpers
```

> **NOTE**
>
> Razor Pages are automatically protected from XSRF/CSRF. For more information, see XSRF/CSRF and Razor Pages.

The most common approach to defending against CSRF attacks is to use the *Synchronizer Token Pattern* (STP). STP is used when the user requests a page with form data:

1. The server sends a token associated with the current user's identity to the client.
2. The client sends back the token to the server for verification.
3. If the server receives a token that doesn't match the authenticated user's identity, the request is rejected.

The token is unique and unpredictable. The token can also be used to ensure proper sequencing of a series of requests (for example, ensuring the request sequence of: page 1 > page 2 > page 3). All of the forms in ASP.NET Core MVC and Razor Pages templates generate antiforgery tokens. The following pair of view examples generate antiforgery tokens:

```
<form asp-controller="Manage" asp-action="ChangePassword" method="post">
    ...
</form>

@using (Html.BeginForm("ChangePassword", "Manage"))
{
    ...
}
```

Explicitly add an antiforgery token to a `<form>` element without using Tag Helpers with the HTML helper `@Html.AntiForgeryToken`:

```
<form action="/" method="post">
    @Html.AntiForgeryToken()
</form>
```

In each of the preceding cases, ASP.NET Core adds a hidden form field similar to the following:

```
<input name="__RequestVerificationToken" type="hidden" value="CfDJ8NrAkS ... s2-m9Yw">
```

ASP.NET Core includes three filters for working with antiforgery tokens:

- ValidateAntiForgeryToken
- AutoValidateAntiforgeryToken
- IgnoreAntiforgeryToken

Antiforgery options

Customize antiforgery options in `Startup.ConfigureServices`:

```
services.AddAntiforgery(options =>
{
    // Set Cookie properties using CookieBuilder properties†.
    options.FormFieldName = "AntiforgeryFieldname";
    options.HeaderName = "X-CSRF-TOKEN-HEADERNAME";
    options.SuppressXFrameOptionsHeader = false;
});
```

†Set the antiforgery `Cookie` properties using the properties of the CookieBuilder class.

OPTION	DESCRIPTION
Cookie	Determines the settings used to create the antiforgery cookies.
FormFieldName	The name of the hidden form field used by the antiforgery system to render antiforgery tokens in views.
HeaderName	The name of the header used by the antiforgery system. If `null`, the system considers only form data.
SuppressXFrameOptionsHeader	Specifies whether to suppress generation of the `X-Frame-Options` header. By default, the header is generated with a value of "SAMEORIGIN". Defaults to `false`.

```
services.AddAntiforgery(options =>
{
    options.CookieDomain = "contoso.com";
    options.CookieName = "X-CSRF-TOKEN-COOKIENAME";
    options.CookiePath = "Path";
    options.FormFieldName = "AntiforgeryFieldname";
    options.HeaderName = "X-CSRF-TOKEN-HEADERNAME";
    options.RequireSsl = false;
    options.SuppressXFrameOptionsHeader = false;
});
```

OPTION	DESCRIPTION
Cookie	Determines the settings used to create the antiforgery cookies.
CookieDomain	The domain of the cookie. Defaults to `null`. This property is obsolete and will be removed in a future version. The recommended alternative is Cookie.Domain.
CookieName	The name of the cookie. If not set, the system generates a unique name beginning with the DefaultCookiePrefix (".AspNetCore.Antiforgery."). This property is obsolete and will be removed in a future version. The recommended alternative is Cookie.Name.
CookiePath	The path set on the cookie. This property is obsolete and will be removed in a future version. The recommended alternative is Cookie.Path.

OPTION	DESCRIPTION
FormFieldName	The name of the hidden form field used by the antiforgery system to render antiforgery tokens in views.
HeaderName	The name of the header used by the antiforgery system. If `null`, the system considers only form data.
RequireSsl	Specifies whether HTTPS is required by the antiforgery system. If `true`, non-HTTPS requests fail. Defaults to `false`. This property is obsolete and will be removed in a future version. The recommended alternative is to set Cookie.SecurePolicy.
SuppressXFrameOptionsHeader	Specifies whether to suppress generation of the `X-Frame-Options` header. By default, the header is generated with a value of "SAMEORIGIN". Defaults to `false`.

For more information, see CookieAuthenticationOptions.

Configure antiforgery features with IAntiforgery

IAntiforgery provides the API to configure antiforgery features. `IAntiforgery` can be requested in the `Configure` method of the `Startup` class. The following example uses middleware from the app's home page to generate an antiforgery token and send it in the response as a cookie (using the default Angular naming convention described later in this topic):

```
public void Configure(IApplicationBuilder app, IAntiforgery antiforgery)
{
    app.Use(next => context =>
    {
        string path = context.Request.Path.Value;

        if (
            string.Equals(path, "/", StringComparison.OrdinalIgnoreCase) ||
            string.Equals(path, "/index.html", StringComparison.OrdinalIgnoreCase))
        {
            // The request token can be sent as a JavaScript-readable cookie,
            // and Angular uses it by default.
            var tokens = antiforgery.GetAndStoreTokens(context);
            context.Response.Cookies.Append("XSRF-TOKEN", tokens.RequestToken,
                new CookieOptions() { HttpOnly = false });
        }

        return next(context);
    });
}
```

Require antiforgery validation

ValidateAntiForgeryToken is an action filter that can be applied to an individual action, a controller, or globally. Requests made to actions that have this filter applied are blocked unless the request includes a valid antiforgery token.

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> RemoveLogin(RemoveLoginViewModel account)
{
    ManageMessageId? message = ManageMessageId.Error;
    var user = await GetCurrentUserAsync();

    if (user != null)
    {
        var result =
            await _userManager.RemoveLoginAsync(
                user, account.LoginProvider, account.ProviderKey);

        if (result.Succeeded)
        {
            await _signInManager.SignInAsync(user, isPersistent: false);
            message = ManageMessageId.RemoveLoginSuccess;
        }
    }

    return RedirectToAction(nameof(ManageLogins), new { Message = message });
}
```

The `ValidateAntiForgeryToken` attribute requires a token for requests to the action methods it marks, including HTTP GET requests. If the `ValidateAntiForgeryToken` attribute is applied across the app's controllers, it can be overridden with the `IgnoreAntiforgeryToken` attribute.

> **NOTE**
> ASP.NET Core doesn't support adding antiforgery tokens to GET requests automatically.

Automatically validate antiforgery tokens for unsafe HTTP methods only

ASP.NET Core apps don't generate antiforgery tokens for safe HTTP methods (GET, HEAD, OPTIONS, and TRACE). Instead of broadly applying the `ValidateAntiForgeryToken` attribute and then overriding it with `IgnoreAntiforgeryToken` attributes, the AutoValidateAntiforgeryToken attribute can be used. This attribute works identically to the `ValidateAntiForgeryToken` attribute, except that it doesn't require tokens for requests made using the following HTTP methods:

- GET
- HEAD
- OPTIONS
- TRACE

We recommend use of `AutoValidateAntiforgeryToken` broadly for non-API scenarios. This ensures POST actions are protected by default. The alternative is to ignore antiforgery tokens by default, unless `ValidateAntiForgeryToken` is applied to individual action methods. It's more likely in this scenario for a POST action method to be left unprotected by mistake, leaving the app vulnerable to CSRF attacks. All POSTs should send the antiforgery token.

APIs don't have an automatic mechanism for sending the non-cookie part of the token. The implementation probably depends on the client code implementation. Some examples are shown below:

Class-level example:

```
[Authorize]
[AutoValidateAntiforgeryToken]
public class ManageController : Controller
{
```

Global example:

services.AddMvc(options => options.Filters.Add(new AutoValidateAntiforgeryTokenAttribute()));

```
services.AddControllersWithViews(options =>
    options.Filters.Add(new AutoValidateAntiforgeryTokenAttribute()));
```

Override global or controller antiforgery attributes

The IgnoreAntiforgeryToken filter is used to eliminate the need for an antiforgery token for a given action (or controller). When applied, this filter overrides `ValidateAntiForgeryToken` and `AutoValidateAntiforgeryToken` filters specified at a higher level (globally or on a controller).

```
[Authorize]
[AutoValidateAntiforgeryToken]
public class ManageController : Controller
{
    [HttpPost]
    [IgnoreAntiforgeryToken]
    public async Task<IActionResult> DoSomethingSafe(SomeViewModel model)
    {
        // no antiforgery token required
    }
}
```

Refresh tokens after authentication

Tokens should be refreshed after the user is authenticated by redirecting the user to a view or Razor Pages page.

JavaScript, AJAX, and SPAs

In traditional HTML-based apps, antiforgery tokens are passed to the server using hidden form fields. In modern JavaScript-based apps and SPAs, many requests are made programmatically. These AJAX requests may use other techniques (such as request headers or cookies) to send the token.

If cookies are used to store authentication tokens and to authenticate API requests on the server, CSRF is a potential problem. If local storage is used to store the token, CSRF vulnerability might be mitigated because values from local storage aren't sent automatically to the server with every request. Thus, using local storage to store the antiforgery token on the client and sending the token as a request header is a recommended approach.

JavaScript

Using JavaScript with views, the token can be created using a service from within the view. Inject the Microsoft.AspNetCore.Antiforgery.IAntiforgery service into the view and call GetAndStoreTokens:

```
@{
    ViewData["Title"] = "AJAX Demo";
}
@inject Microsoft.AspNetCore.Antiforgery.IAntiforgery Xsrf
@functions{
    public string GetAntiXsrfRequestToken()
    {
        return Xsrf.GetAndStoreTokens(Context).RequestToken;
    }
}

<input type="hidden" id="RequestVerificationToken"
       name="RequestVerificationToken" value="@GetAntiXsrfRequestToken()">

<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<div class="row">
    <p><input type="button" id="antiforgery" value="Antiforgery"></p>
    <script>
        var xhttp = new XMLHttpRequest();
        xhttp.onreadystatechange = function() {
            if (xhttp.readyState == XMLHttpRequest.DONE) {
                if (xhttp.status == 200) {
                    alert(xhttp.responseText);
                } else {
                    alert('There was an error processing the AJAX request.');
                }
            }
        };

        document.addEventListener('DOMContentLoaded', function() {
            document.getElementById("antiforgery").onclick = function () {
                xhttp.open('POST', '@Url.Action("Antiforgery", "Home")', true);
                xhttp.setRequestHeader("RequestVerificationToken",
                    document.getElementById('RequestVerificationToken').value);
                xhttp.send();
            }
        });
    </script>
</div>
```

This approach eliminates the need to deal directly with setting cookies from the server or reading them from the client.

The preceding example uses JavaScript to read the hidden field value for the AJAX POST header.

JavaScript can also access tokens in cookies and use the cookie's contents to create a header with the token's value.

```
context.Response.Cookies.Append("CSRF-TOKEN", tokens.RequestToken,
    new Microsoft.AspNetCore.Http.CookieOptions { HttpOnly = false });
```

Assuming the script requests to send the token in a header called `X-CSRF-TOKEN`, configure the antiforgery service to look for the `X-CSRF-TOKEN` header:

```
services.AddAntiforgery(options => options.HeaderName = "X-CSRF-TOKEN");
```

The following example uses JavaScript to make an AJAX request with the appropriate header:

```
function getCookie(cname) {
    var name = cname + "=";
    var decodedCookie = decodeURIComponent(document.cookie);
    var ca = decodedCookie.split(';');
    for(var i = 0; i <ca.length; i++) {
        var c = ca[i];
        while (c.charAt(0) == ' ') {
            c = c.substring(1);
        }
        if (c.indexOf(name) == 0) {
            return c.substring(name.length, c.length);
        }
    }
    return "";
}

var csrfToken = getCookie("CSRF-TOKEN");

var xhttp = new XMLHttpRequest();
xhttp.onreadystatechange = function() {
    if (xhttp.readyState == XMLHttpRequest.DONE) {
        if (xhttp.status == 200) {
            alert(xhttp.responseText);
        } else {
            alert('There was an error processing the AJAX request.');
        }
    }
};
xhttp.open('POST', '/api/password/changepassword', true);
xhttp.setRequestHeader("Content-type", "application/json");
xhttp.setRequestHeader("X-CSRF-TOKEN", csrfToken);
xhttp.send(JSON.stringify({ "newPassword": "ReallySecurePassword999$$$" }));
```

AngularJS

AngularJS uses a convention to address CSRF. If the server sends a cookie with the name `XSRF-TOKEN`, the AngularJS `$http` service adds the cookie value to a header when it sends a request to the server. This process is automatic. The header doesn't need to be set in the client explicitly. The header name is `X-XSRF-TOKEN`. The server should detect this header and validate its contents.

For ASP.NET Core API to work with this convention in your application startup:

- Configure your app to provide a token in a cookie called `XSRF-TOKEN`.
- Configure the antiforgery service to look for a header named `X-XSRF-TOKEN`.

```
public void Configure(IApplicationBuilder app, IAntiforgery antiforgery)
{
    app.Use(next => context =>
    {
        string path = context.Request.Path.Value;

        if (
            string.Equals(path, "/", StringComparison.OrdinalIgnoreCase) ||
            string.Equals(path, "/index.html", StringComparison.OrdinalIgnoreCase))
        {
            // The request token can be sent as a JavaScript-readable cookie,
            // and Angular uses it by default.
            var tokens = antiforgery.GetAndStoreTokens(context);
            context.Response.Cookies.Append("XSRF-TOKEN", tokens.RequestToken,
                new CookieOptions() { HttpOnly = false });
        }

        return next(context);
    });
}

public void ConfigureServices(IServiceCollection services)
{
    // Angular's default header name for sending the XSRF token.
    services.AddAntiforgery(options => options.HeaderName = "X-XSRF-TOKEN");
}
```

View or download sample code (how to download)

Extend antiforgery

The IAntiForgeryAdditionalDataProvider type allows developers to extend the behavior of the anti-CSRF system by round-tripping additional data in each token. The GetAdditionalData method is called each time a field token is generated, and the return value is embedded within the generated token. An implementer could return a timestamp, a nonce, or any other value and then call ValidateAdditionalData to validate this data when the token is validated. The client's username is already embedded in the generated tokens, so there's no need to include this information. If a token includes supplemental data but no `IAntiForgeryAdditionalDataProvider` is configured, the supplemental data isn't validated.

Prevent open redirect attacks in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

A web app that redirects to a URL that's specified via the request such as the querystring or form data can potentially be tampered with to redirect users to an external, malicious URL. This tampering is called an open redirection attack.

Whenever your application logic redirects to a specified URL, you must verify that the redirection URL hasn't been tampered with. ASP.NET Core has built-in functionality to help protect apps from open redirect (also known as open redirection) attacks.

What is an open redirect attack?

Web applications frequently redirect users to a login page when they access resources that require authentication. The redirection typically includes a `returnUrl` querystring parameter so that the user can be returned to the originally requested URL after they have successfully logged in. After the user authenticates, they're redirected to the URL they had originally requested.

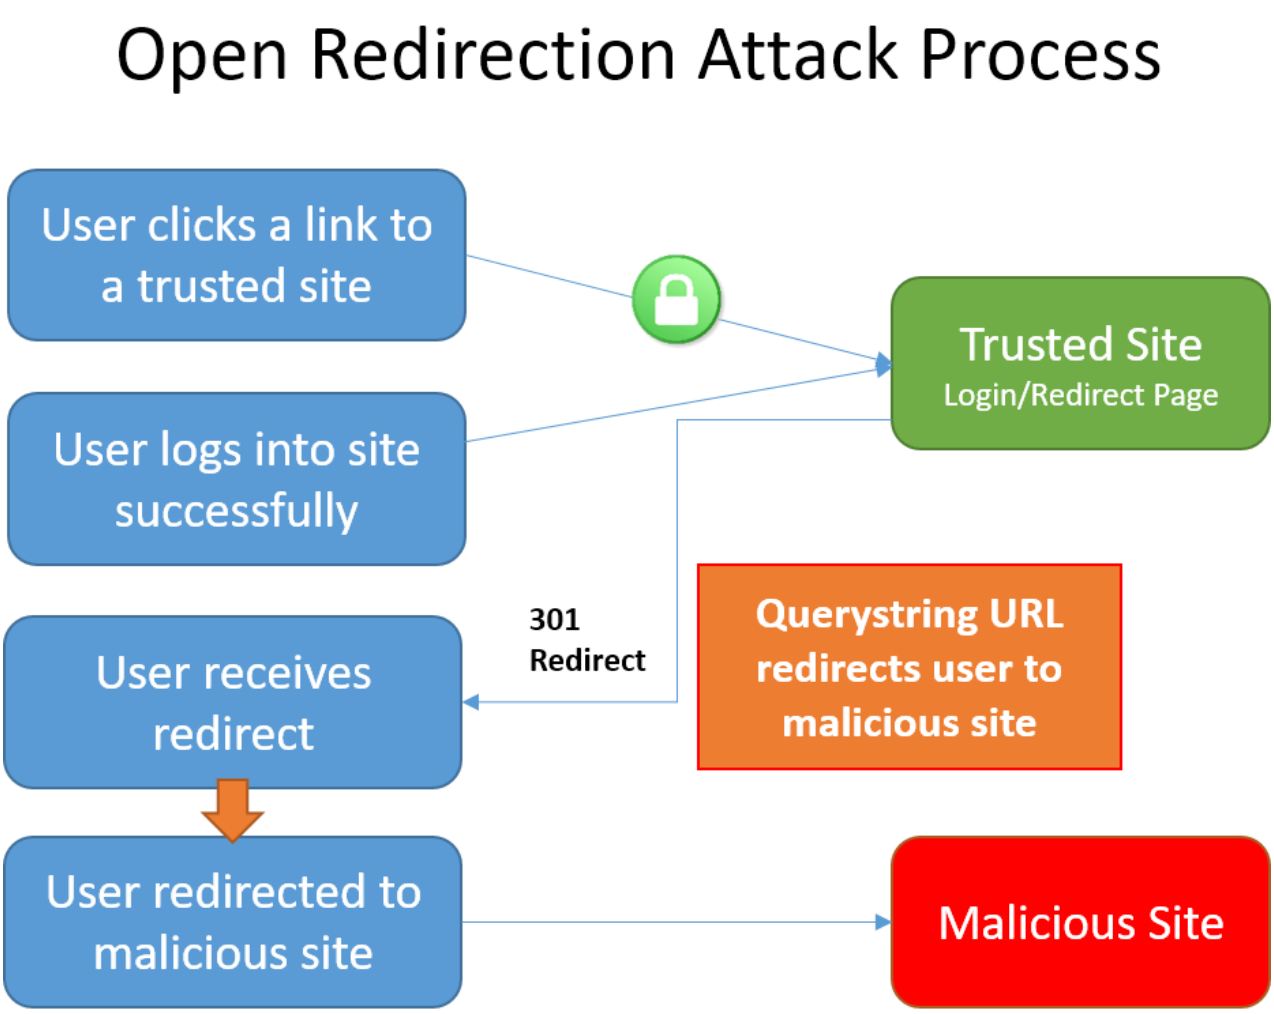
Because the destination URL is specified in the querystring of the request, a malicious user could tamper with the querystring. A tampered querystring could allow the site to redirect the user to an external, malicious site. This technique is called an open redirect (or redirection) attack.

An example attack

A malicious user can develop an attack intended to allow the malicious user access to a user's credentials or sensitive information. To begin the attack, the malicious user convinces the user to click a link to your site's login page with a `returnUrl` querystring value added to the URL. For example, consider an app at `contoso.com` that includes a login page at `http://contoso.com/Account/LogOn?returnUrl=/Home/About`. The attack follows these steps:

1. The user clicks a malicious link to `http://contoso.com/Account/LogOn?returnUrl=http://contoso1.com/Account/LogOn` (the second URL is "contoso**1**.com", not "contoso.com").
2. The user logs in successfully.
3. The user is redirected (by the site) to `http://contoso1.com/Account/LogOn` (a malicious site that looks exactly like real site).
4. The user logs in again (giving malicious site their credentials) and is redirected back to the real site.

The user likely believes that their first attempt to log in failed and that their second attempt is successful. The user most likely remains unaware that their credentials are compromised.



In addition to login pages, some sites provide redirect pages or endpoints. Imagine your app has a page with an open redirect, `/Home/Redirect`. An attacker could create, for example, a link in an email that goes to `[yoursite]/Home/Redirect?url=http://phishingsite.com/Home/Login`. A typical user will look at the URL and see it begins with your site name. Trusting that, they will click the link. The open redirect would then send the user to the phishing site, which looks identical to yours, and the user would likely login to what they believe is your site.

Protecting against open redirect attacks

When developing web applications, treat all user-provided data as untrustworthy. If your application has functionality that redirects the user based on the contents of the URL, ensure that such redirects are only done locally within your app (or to a known URL, not any URL that may be supplied in the querystring).

LocalRedirect

Use the `LocalRedirect` helper method from the base `Controller` class:

```
public IActionResult SomeAction(string redirectUrl)
{
    return LocalRedirect(redirectUrl);
}
```

`LocalRedirect` will throw an exception if a non-local URL is specified. Otherwise, it behaves just like the `Redirect` method.

IsLocalUrl

Use the IsLocalUrl method to test URLs before redirecting:

The following example shows how to check whether a URL is local before redirecting.

```
private IActionResult RedirectToLocal(string returnUrl)
{
    if (Url.IsLocalUrl(returnUrl))
    {
        return Redirect(returnUrl);
    }
    else
    {
        return RedirectToAction(nameof(HomeController.Index), "Home");
    }
}
```

The `IsLocalUrl` method protects users from being inadvertently redirected to a malicious site. You can log the details of the URL that was provided when a non-local URL is supplied in a situation where you expected a local URL. Logging redirect URLs may help in diagnosing redirection attacks.

Prevent Cross-Site Scripting (XSS) in ASP.NET Core

9/22/2020 • 7 minutes to read • Edit Online

By Rick Anderson

Cross-Site Scripting (XSS) is a security vulnerability which enables an attacker to place client side scripts (usually JavaScript) into web pages. When other users load affected pages the attacker's scripts will run, enabling the attacker to steal cookies and session tokens, change the contents of the web page through DOM manipulation or redirect the browser to another page. XSS vulnerabilities generally occur when an application takes user input and outputs it to a page without validating, encoding or escaping it.

Protecting your application against XSS

At a basic level XSS works by tricking your application into inserting a `<script>` tag into your rendered page, or by inserting an `On*` event into an element. Developers should use the following prevention steps to avoid introducing XSS into their application.

1. Never put untrusted data into your HTML input, unless you follow the rest of the steps below. Untrusted data is any data that may be controlled by an attacker, HTML form inputs, query strings, HTTP headers, even data sourced from a database as an attacker may be able to breach your database even if they cannot breach your application.
2. Before putting untrusted data inside an HTML element ensure it's HTML encoded. HTML encoding takes characters such as < and changes them into a safe form like <
3. Before putting untrusted data into an HTML attribute ensure it's HTML encoded. HTML attribute encoding is a superset of HTML encoding and encodes additional characters such as " and '.
4. Before putting untrusted data into JavaScript place the data in an HTML element whose contents you retrieve at runtime. If this isn't possible, then ensure the data is JavaScript encoded. JavaScript encoding takes dangerous characters for JavaScript and replaces them with their hex, for example < would be encoded as `\u003C`.
5. Before putting untrusted data into a URL query string ensure it's URL encoded.

HTML Encoding using Razor

The Razor engine used in MVC automatically encodes all output sourced from variables, unless you work really hard to prevent it doing so. It uses HTML attribute encoding rules whenever you use the @ directive. As HTML attribute encoding is a superset of HTML encoding this means you don't have to concern yourself with whether you should use HTML encoding or HTML attribute encoding. You must ensure that you only use @ in an HTML context, not when attempting to insert untrusted input directly into JavaScript. Tag helpers will also encode input you use in tag parameters.

Take the following Razor view:

```
@{
        var untrustedInput = "<\"123\">";
    }

    @untrustedInput
```

This view outputs the contents of the *untrustedInput* variable. This variable includes some characters which are used in XSS attacks, namely <, " and >. Examining the source shows the rendered output encoded as:

```
&lt;&quot;123&quot;&gt;
```

WARNING

ASP.NET Core MVC provides an `HtmlString` class which isn't automatically encoded upon output. This should never be used in combination with untrusted input as this will expose an XSS vulnerability.

JavaScript Encoding using Razor

There may be times you want to insert a value into JavaScript to process in your view. There are two ways to do this. The safest way to insert values is to place the value in a data attribute of a tag and retrieve it in your JavaScript. For example:

```
@{
    var untrustedInput = "<script>alert(1)</script>";
}

<div id="injectedData"
     data-untrustedinput="@untrustedInput" />

<div id="scriptedWrite" />
<div id="scriptedWrite-html5" />

<script>
    var injectedData = document.getElementById("injectedData");

    // All clients
    var clientSideUntrustedInputOldStyle =
        injectedData.getAttribute("data-untrustedinput");

    // HTML 5 clients only
    var clientSideUntrustedInputHtml5 =
        injectedData.dataset.untrustedinput;

    // Put the injected, untrusted data into the scriptedWrite div tag.
    // Do NOT use document.write() on dynamically generated data as it
    // can lead to XSS.

    document.getElementById("scriptedWrite").innerText += clientSideUntrustedInputOldStyle;

    // Or you can use createElement() to dynamically create document elements
    // This time we're using textContent to ensure the data is properly encoded.
    var x = document.createElement("div");
    x.textContent = clientSideUntrustedInputHtml5;
    document.body.appendChild(x);

    // You can also use createTextNode on an element to ensure data is properly encoded.
    var y = document.createElement("div");
    y.appendChild(document.createTextNode(clientSideUntrustedInputHtml5));
    document.body.appendChild(y);

</script>
```

The preceding markup generates the following HTML:

```
<div id="injectedData"
     data-untrustedinput="&lt;script&gt;alert(1)&lt;/script&gt;" />

<div id="scriptedWrite" />
<div id="scriptedWrite-html5" />

<script>
    var injectedData = document.getElementById("injectedData");

    // All clients
    var clientSideUntrustedInputOldStyle =
        injectedData.getAttribute("data-untrustedinput");

    // HTML 5 clients only
    var clientSideUntrustedInputHtml5 =
        injectedData.dataset.untrustedinput;

    // Put the injected, untrusted data into the scriptedWrite div tag.
    // Do NOT use document.write() on dynamically generated data as it can
    // lead to XSS.

    document.getElementById("scriptedWrite").innerText += clientSideUntrustedInputOldStyle;

    // Or you can use createElement() to dynamically create document elements
    // This time we're using textContent to ensure the data is properly encoded.
    var x = document.createElement("div");
    x.textContent = clientSideUntrustedInputHtml5;
    document.body.appendChild(x);

    // You can also use createTextNode on an element to ensure data is properly encoded.
    var y = document.createElement("div");
    y.appendChild(document.createTextNode(clientSideUntrustedInputHtml5));
    document.body.appendChild(y);

</script>
```

The preceding code generates the following output:

```
<script>alert(1)</script>
<script>alert(1)</script>
<script>alert(1)</script>
```

WARNING

Do ***NOT*** concatenate untrusted input in JavaScript to create DOM elements or use `document.write()` on dynamically generated content.

Use one of the following approaches to prevent code from being exposed to DOM-based XSS:

- `createElement()` and assign property values with appropriate methods or properties such as `node.textContent=` or node.InnerText=`.
- `document.CreateTextNode()` and append it in the appropriate DOM location.
- `element.SetAttribute()`
- `element[attribute]=`

Accessing encoders in code

The HTML, JavaScript and URL encoders are available to your code in two ways, you can inject them via dependency injection or you can use the default encoders contained in the `System.Text.Encodings.Web` namespace. If you use the default encoders then any you applied to character ranges to be treated as safe won't take effect -

the default encoders use the safest encoding rules possible.

To use the configurable encoders via DI your constructors should take an *HtmlEncoder*, *JavaScriptEncoder* and *UrlEncoder* parameter as appropriate. For example;

```
public class HomeController : Controller
   {
       HtmlEncoder _htmlEncoder;
       JavaScriptEncoder _javaScriptEncoder;
       UrlEncoder _urlEncoder;

       public HomeController(HtmlEncoder htmlEncoder,
                             JavaScriptEncoder javascriptEncoder,
                             UrlEncoder urlEncoder)
       {
           _htmlEncoder = htmlEncoder;
           _javaScriptEncoder = javascriptEncoder;
           _urlEncoder = urlEncoder;
       }
   }
```

Encoding URL Parameters

If you want to build a URL query string with untrusted input as a value use the `UrlEncoder` to encode the value. For example,

```
var example = "\"Quoted Value with spaces and &\"";
   var encodedValue = _urlEncoder.Encode(example);
```

After encoding the encodedValue variable will contain `%22Quoted%20Value%20with%20spaces%20and%20%26%22`. Spaces, quotes, punctuation and other unsafe characters will be percent encoded to their hexadecimal value, for example a space character will become %20.

> **WARNING**
> Don't use untrusted input as part of a URL path. Always pass untrusted input as a query string value.

Customizing the Encoders

By default encoders use a safe list limited to the Basic Latin Unicode range and encode all characters outside of that range as their character code equivalents. This behavior also affects Razor TagHelper and HtmlHelper rendering as it will use the encoders to output your strings.

The reasoning behind this is to protect against unknown or future browser bugs (previous browser bugs have tripped up parsing based on the processing of non-English characters). If your web site makes heavy use of non-Latin characters, such as Chinese, Cyrillic or others this is probably not the behavior you want.

You can customize the encoder safe lists to include Unicode ranges appropriate to your application during startup, in `ConfigureServices()`.

For example, using the default configuration you might use a Razor HtmlHelper like so;

```
<p>This link text is in Chinese: @Html.ActionLink("汉语/漢語", "Index")</p>
```

When you view the source of the web page you will see it has been rendered as follows, with the Chinese text

encoded;

```
<p>This link text is in Chinese: <a href="/">&#x6C49;&#x8BED;/&#x6F22;&#x8A9E;</a></p>
```

To widen the characters treated as safe by the encoder you would insert the following line into the `ConfigureServices()` method in `startup.cs`;

```
services.AddSingleton<HtmlEncoder>(
     HtmlEncoder.Create(allowedRanges: new[] { UnicodeRanges.BasicLatin,
                                               UnicodeRanges.CjkUnifiedIdeographs }));
```

This example widens the safe list to include the Unicode Range CjkUnifiedIdeographs. The rendered output would now become

```
<p>This link text is in Chinese: <a href="/">汉语/漢語</a></p>
```

Safe list ranges are specified as Unicode code charts, not languages. The Unicode standard has a list of code charts you can use to find the chart containing your characters. Each encoder, Html, JavaScript and Url, must be configured separately.

> **NOTE**
>
> Customization of the safe list only affects encoders sourced via DI. If you directly access an encoder via `System.Text.Encodings.Web.*Encoder.Default` then the default, Basic Latin only safelist will be used.

Where should encoding take place?

The general accepted practice is that encoding takes place at the point of output and encoded values should never be stored in a database. Encoding at the point of output allows you to change the use of data, for example, from HTML to a query string value. It also enables you to easily search your data without having to encode values before searching and allows you to take advantage of any changes or bug fixes made to encoders.

Validation as an XSS prevention technique

Validation can be a useful tool in limiting XSS attacks. For example, a numeric string containing only the characters 0-9 won't trigger an XSS attack. Validation becomes more complicated when accepting HTML in user input. Parsing HTML input is difficult, if not impossible. Markdown, coupled with a parser that strips embedded HTML, is a safer option for accepting rich input. Never rely on validation alone. Always encode untrusted input before output, no matter what validation or sanitization has been performed.

Enable Cross-Origin Requests (CORS) in ASP.NET Core

9/22/2020 • 33 minutes to read • Edit Online

By Rick Anderson and Kirk Larkin

This article shows how to enable CORS in an ASP.NET Core app.

Browser security prevents a web page from making requests to a different domain than the one that served the web page. This restriction is called the *same-origin policy*. The same-origin policy prevents a malicious site from reading sensitive data from another site. Sometimes, you might want to allow other sites to make cross-origin requests to your app. For more information, see the Mozilla CORS article.

Cross Origin Resource Sharing (CORS):

- Is a W3C standard that allows a server to relax the same-origin policy.
- Is **not** a security feature, CORS relaxes security. An API is not safer by allowing CORS. For more information, see How CORS works.
- Allows a server to explicitly allow some cross-origin requests while rejecting others.
- Is safer and more flexible than earlier techniques, such as JSONP.

View or download sample code (how to download)

Same origin

Two URLs have the same origin if they have identical schemes, hosts, and ports (RFC 6454).

These two URLs have the same origin:

- `https://example.com/foo.html`
- `https://example.com/bar.html`

These URLs have different origins than the previous two URLs:

- `https://example.net`: Different domain
- `https://www.example.com/foo.html`: Different subdomain
- `http://example.com/foo.html`: Different scheme
- `https://example.com:9000/foo.html`: Different port

Enable CORS

There are three ways to enable CORS:

- In middleware using a named policy or default policy.
- Using endpoint routing.
- With the [EnableCors] attribute.

Using the [EnableCors] attribute with a named policy provides the finest control in limiting endpoints that support CORS.

WARNING

UseCors must be called before UseResponseCaching when using `UseResponseCaching`.

Each approach is detailed in the following sections.

CORS with named policy and middleware

CORS Middleware handles cross-origin requests. The following code applies a CORS policy to all the app's endpoints with the specified origins:

```
public class Startup
{
    readonly string MyAllowSpecificOrigins = "_myAllowSpecificOrigins";

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddCors(options =>
        {
            options.AddPolicy(name: MyAllowSpecificOrigins,
                              builder =>
                              {
                                  builder.WithOrigins("http://example.com",
                                                      "http://www.contoso.com");
                              });
        });

        // services.AddResponseCaching();
        services.AddControllers();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseRouting();

        app.UseCors(MyAllowSpecificOrigins);

        // app.UseResponseCaching();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapControllers();
        });
    }
}
```

The preceding code:

- Sets the policy name to `_myAllowSpecificOrigins`. The policy name is arbitrary.
- Calls the UseCors extension method and specifies the `_myAllowSpecificOrigins` CORS policy. `UseCors` adds the CORS middleware. The call to `UseCors` must be placed after `UseRouting`, but before `UseAuthorization`. For more information, see Middleware order.

- Calls AddCors with a lambda expression. The lambda takes a CorsPolicyBuilder object. Configuration options, such as `WithOrigins`, are described later in this article.
- Enables the `_myAllowSpecificOrigins` CORS policy for all controller endpoints. See endpoint routing to apply a CORS policy to specific endpoints.
- When using Response Caching Middleware, call UseCors before UseResponseCaching.

With endpoint routing, the CORS middleware **must** be configured to execute between the calls to `UseRouting` and `UseEndpoints`.

See Test CORS for instructions on testing code similar to the preceding code.

The AddCors method call adds CORS services to the app's service container:

```
public class Startup
{
    readonly string MyAllowSpecificOrigins = "_myAllowSpecificOrigins";

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddCors(options =>
        {
            options.AddPolicy(name: MyAllowSpecificOrigins,
                              builder =>
                              {
                                  builder.WithOrigins("http://example.com",
                                                      "http://www.contoso.com");
                              });
        });

        // services.AddResponseCaching();
        services.AddControllers();
    }
```

For more information, see CORS policy options in this document.

The CorsPolicyBuilder methods can be chained, as shown in the following code:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddCors(options =>
    {
        options.AddPolicy(MyAllowSpecificOrigins,
                          builder =>
                          {
                              builder.WithOrigins("http://example.com",
                                                  "http://www.contoso.com")
                                                  .AllowAnyHeader()
                                                  .AllowAnyMethod();
                          });
    });

    services.AddControllers();
}
```

Note: The specified URL must **not** contain a trailing slash (`/`). If the URL terminates with `/`, the comparison returns `false` and no header is returned.

CORS with default policy and middleware

The following highlighted code enables the default CORS policy:

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddCors(options =>
        {
            options.AddDefaultPolicy(
                builder =>
                {
                    builder.WithOrigins("http://example.com",
                                        "http://www.contoso.com");
                });
        });

        services.AddControllers();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseRouting();

        app.UseCors();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapControllers();
        });
    }
}
```

The preceding code applies the default CORS policy to all controller endpoints.

Enable Cors with endpoint routing

Enabling CORS on a per-endpoint basis using `RequireCors` currently does **not** support automatic preflight requests. For more information, see this GitHub issue and Test CORS with endpoint routing and [HttpOptions].

With endpoint routing, CORS can be enabled on a per-endpoint basis using the RequireCors set of extension methods:

```
public class Startup
{
    readonly string MyAllowSpecificOrigins = "_myAllowSpecificOrigins";

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddCors(options =>
        {
            options.AddPolicy(name: MyAllowSpecificOrigins,
                              builder =>
                              {
                                  builder.WithOrigins("http://example.com",
                                                      "http://www.contoso.com");
                              });
        });

        services.AddControllers();
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseRouting();

        app.UseCors();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapGet("/echo",
                context => context.Response.WriteAsync("echo"))
                .RequireCors(MyAllowSpecificOrigins);

            endpoints.MapControllers()
                     .RequireCors(MyAllowSpecificOrigins);

            endpoints.MapGet("/echo2",
                context => context.Response.WriteAsync("echo2"));

            endpoints.MapRazorPages();
        });
    }
}
```

In the preceding code:

- `app.UseCors` enables the CORS middleware. Because a default policy hasn't been configured, `app.UseCors()` alone doesn't enable CORS.
- The `/echo` and controller endpoints allow cross-origin requests using the specified policy.
- The `/echo2` and Razor Pages endpoints do **not** allow cross-origin requests because no default policy was specified.

The [DisableCors] attribute does **not** disable CORS that has been enabled by endpoint routing with `RequireCors`.

See Test CORS with endpoint routing and [HttpOptions] for instructions on testing code similar to the

preceding.

Enable CORS with attributes

Enabling CORS with the [EnableCors] attribute and applying a named policy to only those endpoints that require CORS provides the finest control.

The [EnableCors] attribute provides an alternative to applying CORS globally. The `[EnableCors]` attribute enables CORS for selected endpoints, rather than all endpoints:

- `[EnableCors]` specifies the default policy.
- `[EnableCors("{Policy String}")]` specifies a named policy.

The `[EnableCors]` attribute can be applied to:

- Razor Page `PageModel`
- Controller
- Controller action method

Different policies can be applied to controllers, page models, or action methods with the `[EnableCors]` attribute. When the `[EnableCors]` attribute is applied to a controller, page model, or action method, and CORS is enabled in middleware, **both** policies are applied. **We recommend against combining policies. Use the `[EnableCors]` attribute or middleware, not both in the same app.**

The following code applies a different policy to each method:

```
[Route("api/[controller]")]
[ApiController]
public class WidgetController : ControllerBase
{
    // GET api/values
    [EnableCors("AnotherPolicy")]
    [HttpGet]
    public ActionResult<IEnumerable<string>> Get()
    {
        return new string[] { "green widget", "red widget" };
    }

    // GET api/values/5
    [EnableCors("Policy1")]
    [HttpGet("{id}")]
    public ActionResult<string> Get(int id)
    {
        return id switch
        {
            1 => "green widget",
            2 => "red widget",
            _ => NotFound(),
        };
    }
}
```

The following code creates two CORS policies:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddCors(options =>
        {
            options.AddPolicy("Policy1",
                builder =>
                {
                    builder.WithOrigins("http://example.com",
                                        "http://www.contoso.com");
                });

            options.AddPolicy("AnotherPolicy",
                builder =>
                {
                    builder.WithOrigins("http://www.contoso.com")
                                        .AllowAnyHeader()
                                        .AllowAnyMethod();
                });
        });

        services.AddControllers();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        app.UseHttpsRedirection();

        app.UseRouting();

        app.UseCors();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapControllers();
        });
    }
}
```

For the finest control of limiting CORS requests:

- Use `[EnableCors("MyPolicy")]` with a named policy.
- Don't define a default policy.
- Don't use endpoint routing.

The code in the next section meets the preceding list.

See Test CORS for instructions on testing code similar to the preceding code.

Disable CORS

The [DisableCors] attribute does **not** disable CORS that has been enabled by endpoint routing.

The following code defines the CORS policy `"MyPolicy"`:

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddCors(options =>
        {
            options.AddPolicy(name: "MyPolicy",
                builder =>
                {
                    builder.WithOrigins("http://example.com",
                                        "http://www.contoso.com")
                           .WithMethods("PUT", "DELETE", "GET");
                });
        });

        services.AddControllers();
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseRouting();

        app.UseCors();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapControllers();
            endpoints.MapRazorPages();
        });
    }
}
```

The following code disables CORS for the `GetValues2` action:

```
[EnableCors("MyPolicy")]
[Route("api/[controller]")]
[ApiController]
public class ValuesController : ControllerBase
{
    // GET api/values
    [HttpGet]
    public IActionResult Get() =>
        ControllerContext.MyDisplayRouteInfo();

    // GET api/values/5
    [HttpGet("{id}")]
    public IActionResult Get(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);

    // PUT api/values/5
    [HttpPut("{id}")]
    public IActionResult Put(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);

    // GET: api/values/GetValues2
    [DisableCors]
    [HttpGet("{action}")]
    public IActionResult GetValues2() =>
        ControllerContext.MyDisplayRouteInfo();

}
```

The preceding code:

- Doesn't enable CORS with endpoint routing.
- Doesn't define a default CORS policy.
- Uses [EnableCors("MyPolicy")] to enable the `"MyPolicy"` CORS policy for the controller.
- Disables CORS for the `GetValues2` method.

See Test CORS for instructions on testing the preceding code.

CORS policy options

This section describes the various options that can be set in a CORS policy:

- Set the allowed origins
- Set the allowed HTTP methods
- Set the allowed request headers
- Set the exposed response headers
- Credentials in cross-origin requests
- Set the preflight expiration time

AddPolicy is called in `Startup.ConfigureServices`. For some options, it may be helpful to read the How CORS works section first.

Set the allowed origins

AllowAnyOrigin: Allows CORS requests from all origins with any scheme (`http` or `https`). `AllowAnyOrigin` is insecure because *any website* can make cross-origin requests to the app.

> **NOTE**
>
> Specifying `AllowAnyOrigin` and `AllowCredentials` is an insecure configuration and can result in cross-site request forgery. The CORS service returns an invalid CORS response when an app is configured with both methods.

`AllowAnyOrigin` affects preflight requests and the `Access-Control-Allow-Origin` header. For more information, see the Preflight requests section.

SetIsOriginAllowedToAllowWildcardSubdomains: Sets the IsOriginAllowed property of the policy to be a function that allows origins to match a configured wildcard domain when evaluating if the origin is allowed.

```
options.AddPolicy("MyAllowSubdomainPolicy",
    builder =>
    {
        builder.WithOrigins("https://*.example.com")
            .SetIsOriginAllowedToAllowWildcardSubdomains();
    });
```

Set the allowed HTTP methods

AllowAnyMethod:

- Allows any HTTP method:
- Affects preflight requests and the `Access-Control-Allow-Methods` header. For more information, see the Preflight requests section.

Set the allowed request headers

To allow specific headers to be sent in a CORS request, called author request headers, call WithHeaders and specify the allowed headers:

```
options.AddPolicy("MyAllowHeadersPolicy",
    builder =>
    {
        // requires using Microsoft.Net.Http.Headers;
        builder.WithOrigins("http://example.com")
               .WithHeaders(HeaderNames.ContentType, "x-custom-header");
    });
```

To allow all author request headers, call AllowAnyHeader:

```
options.AddPolicy("MyAllowAllHeadersPolicy",
    builder =>
    {
        builder.WithOrigins("https://*.example.com")
               .AllowAnyHeader();
    });
```

`AllowAnyHeader` affects preflight requests and the Access-Control-Request-Headers header. For more information, see the Preflight requests section.

A CORS Middleware policy match to specific headers specified by `WithHeaders` is only possible when the headers sent in `Access-Control-Request-Headers` exactly match the headers stated in `WithHeaders`.

For instance, consider an app configured as follows:

```
app.UseCors(policy => policy.WithHeaders(HeaderNames.CacheControl));
```

CORS Middleware declines a preflight request with the following request header because `Content-Language` (HeaderNames.ContentLanguage) isn't listed in `WithHeaders`:

```
Access-Control-Request-Headers: Cache-Control, Content-Language
```

The app returns a *200 OK* response but doesn't send the CORS headers back. Therefore, the browser doesn't attempt the cross-origin request.

Set the exposed response headers

By default, the browser doesn't expose all of the response headers to the app. For more information, see W3C Cross-Origin Resource Sharing (Terminology): Simple Response Header.

The response headers that are available by default are:

- `Cache-Control`
- `Content-Language`
- `Content-Type`
- `Expires`
- `Last-Modified`
- `Pragma`

The CORS specification calls these headers *simple response headers*. To make other headers available to the app, call WithExposedHeaders:

```
options.AddPolicy("MyExposeResponseHeadersPolicy",
    builder =>
    {
        builder.WithOrigins("https://*.example.com")
               .WithExposedHeaders("x-custom-header");
    });
```

Credentials in cross-origin requests

Credentials require special handling in a CORS request. By default, the browser doesn't send credentials with a cross-origin request. Credentials include cookies and HTTP authentication schemes. To send credentials with a cross-origin request, the client must set `XMLHttpRequest.withCredentials` to `true`.

Using `XMLHttpRequest` directly:

```
var xhr = new XMLHttpRequest();
xhr.open('get', 'https://www.example.com/api/test');
xhr.withCredentials = true;
```

Using jQuery:

```
$.ajax({
  type: 'get',
  url: 'https://www.example.com/api/test',
  xhrFields: {
    withCredentials: true
  }
});
```

Using the Fetch API:

```
fetch('https://www.example.com/api/test', {
    credentials: 'include'
});
```

The server must allow the credentials. To allow cross-origin credentials, call AllowCredentials:

```
options.AddPolicy("MyMyAllowCredentialsPolicy",
    builder =>
    {
        builder.WithOrigins("http://example.com")
               .AllowCredentials();
    });
```

The HTTP response includes an `Access-Control-Allow-Credentials` header, which tells the browser that the server allows credentials for a cross-origin request.

If the browser sends credentials but the response doesn't include a valid `Access-Control-Allow-Credentials` header, the browser doesn't expose the response to the app, and the cross-origin request fails.

Allowing cross-origin credentials is a security risk. A website at another domain can send a signed-in user's credentials to the app on the user's behalf without the user's knowledge.

The CORS specification also states that setting origins to `"*"` (all origins) is invalid if the `Access-Control-Allow-Credentials` header is present.

Preflight requests

For some CORS requests, the browser sends an additional OPTIONS request before making the actual request. This request is called a preflight request. The browser can skip the preflight request if **all** the following conditions are true:

- The request method is GET, HEAD, or POST.
- The app doesn't set request headers other than `Accept`, `Accept-Language`, `Content-Language`, `Content-Type`, or `Last-Event-ID`.
- The `Content-Type` header, if set, has one of the following values:
  - `application/x-www-form-urlencoded`
  - `multipart/form-data`
  - `text/plain`

The rule on request headers set for the client request applies to headers that the app sets by calling `setRequestHeader` on the `XMLHttpRequest` object. The CORS specification calls these headers author request headers. The rule doesn't apply to headers the browser can set, such as `User-Agent`, `Host`, or `Content-Length`.

The following is an example response similar to the preflight request made from the **[Put test]** button in the Test CORS section of this document.

```
General:
Request URL: https://cors3.azurewebsites.net/api/values/5
Request Method: OPTIONS
Status Code: 204 No Content

Response Headers:
Access-Control-Allow-Methods: PUT,DELETE,GET
Access-Control-Allow-Origin: https://cors1.azurewebsites.net
Server: Microsoft-IIS/10.0
Set-Cookie: ARRAffinity=8f8...8;Path=/;HttpOnly;Domain=cors1.azurewebsites.net
Vary: Origin

Request Headers:
Accept: */*
Accept-Encoding: gzip, deflate, br
Accept-Language: en-US,en;q=0.9
Access-Control-Request-Method: PUT
Connection: keep-alive
Host: cors3.azurewebsites.net
Origin: https://cors1.azurewebsites.net
Referer: https://cors1.azurewebsites.net/
Sec-Fetch-Dest: empty
Sec-Fetch-Mode: cors
Sec-Fetch-Site: cross-site
User-Agent: Mozilla/5.0
```

The preflight request uses the HTTP OPTIONS method. It may include the following headers:

- Access-Control-Request-Method: The HTTP method that will be used for the actual request.
- Access-Control-Request-Headers: A list of request headers that the app sets on the actual request. As stated earlier, this doesn't include headers that the browser sets, such as `User-Agent`.
- Access-Control-Allow-Methods

If the preflight request is denied, the app returns a `200 OK` response but doesn't set the CORS headers. Therefore, the browser doesn't attempt the cross-origin request. For an example of a denied preflight request, see the Test CORS section of this document.

Using the F12 tools, the console app shows an error similar to one of the following, depending on the browser:

- Firefox: Cross-Origin Request Blocked: The Same Origin Policy disallows reading the remote resource at `https://cors1.azurewebsites.net/api/TodoItems1/MyDelete2/5`. (Reason: CORS request did not succeed). Learn More
- Chromium based: Access to fetch at 'https://cors1.azurewebsites.net/api/TodoItems1/MyDelete2/5' from origin 'https://cors3.azurewebsites.net' has been blocked by CORS policy: Response to preflight request doesn't pass access control check: No 'Access-Control-Allow-Origin' header is present on the requested resource. If an opaque response serves your needs, set the request's mode to 'no-cors' to fetch the resource with CORS disabled.

To allow specific headers, call WithHeaders:

```
options.AddPolicy("MyAllowHeadersPolicy",
    builder =>
    {
        // requires using Microsoft.Net.Http.Headers;
        builder.WithOrigins("http://example.com")
               .WithHeaders(HeaderNames.ContentType, "x-custom-header");
    });
```

To allow all author request headers, call AllowAnyHeader:

```
options.AddPolicy("MyAllowAllHeadersPolicy",
    builder =>
    {
        builder.WithOrigins("https://*.example.com")
               .AllowAnyHeader();
    });
```

Browsers aren't consistent in how they set `Access-Control-Request-Headers`. If either:

- Headers are set to anything other than `"*"`
- AllowAnyHeader is called: Include at least `Accept`, `Content-Type`, and `Origin`, plus any custom headers that you want to support.

Automatic preflight request code

When the CORS policy is applied either:

- Globally by calling `app.UseCors` in `Startup.Configure`.
- Using the `[EnableCors]` attribute.

ASP.NET Core responds to the preflight OPTIONS request.

Enabling CORS on a per-endpoint basis using `RequireCors` currently does **not** support automatic preflight requests.

The Test CORS section of this document demonstrates this behavior.

[HttpOptions] attribute for preflight requests

When CORS is enabled with the appropriate policy, ASP.NET Core generally responds to CORS preflight requests automatically. In some scenarios, this may not be the case. For example, using CORS with endpoint routing.

The following code uses the [HttpOptions] attribute to create endpoints for OPTIONS requests:

```
[Route("api/[controller]")]
[ApiController]
public class TodoItems2Controller : ControllerBase
{
    // OPTIONS: api/TodoItems2/5
    [HttpOptions("{id}")]
    public IActionResult PreflightRoute(int id)
    {
        return NoContent();
    }

    // OPTIONS: api/TodoItems2
    [HttpOptions]
    public IActionResult PreflightRoute()
    {
        return NoContent();
    }

    [HttpPut("{id}")]
    public IActionResult PutTodoItem(int id)
    {
        if (id < 1)
        {
            return BadRequest();
        }

        return ControllerContext.MyDisplayRouteInfo(id);
    }
```

See Test CORS with endpoint routing and [HttpOptions] for instructions on testing the preceding code.

Set the preflight expiration time

The `Access-Control-Max-Age` header specifies how long the response to the preflight request can be cached. To set this header, call SetPreflightMaxAge:

```
options.AddPolicy("MySetPreflightExpirationPolicy",
    builder =>
    {
        builder.WithOrigins("http://example.com")
               .SetPreflightMaxAge(TimeSpan.FromSeconds(2520));
    });
```

How CORS works

This section describes what happens in a CORS request at the level of the HTTP messages.

- CORS is **not** a security feature. CORS is a W3C standard that allows a server to relax the same-origin policy.
  - For example, a malicious actor could use Cross-Site Scripting (XSS) against your site and execute a cross-site request to their CORS enabled site to steal information.
- An API isn't safer by allowing CORS.
  - It's up to the client (browser) to enforce CORS. The server executes the request and returns the response, it's the client that returns an error and blocks the response. For example, any of the following tools will display the server response:
    - Fiddler
    - Postman
    - .NET HttpClient
    - A web browser by entering the URL in the address bar.
- It's a way for a server to allow browsers to execute a cross-origin XHR or Fetch API request that otherwise

would be forbidden.

- Browsers without CORS can't do cross-origin requests. Before CORS, JSONP was used to circumvent this restriction. JSONP doesn't use XHR, it uses the `<script>` tag to receive the response. Scripts are allowed to be loaded cross-origin.

The CORS specification introduced several new HTTP headers that enable cross-origin requests. If a browser supports CORS, it sets these headers automatically for cross-origin requests. Custom JavaScript code isn't required to enable CORS.

The PUT test button on the deployed sample

The following is an example of a cross-origin request from the Values test button to `https://cors1.azurewebsites.net/api/values`. The `Origin` header:

- Provides the domain of the site that's making the request.
- Is required and must be different from the host.

General headers

```
Request URL: https://cors1.azurewebsites.net/api/values
Request Method: GET
Status Code: 200 OK
```

Response headers

```
Content-Encoding: gzip
Content-Type: text/plain; charset=utf-8
Server: Microsoft-IIS/10.0
Set-Cookie: ARRAffinity=8f...;Path=/;HttpOnly;Domain=cors1.azurewebsites.net
Transfer-Encoding: chunked
Vary: Accept-Encoding
X-Powered-By: ASP.NET
```

Request headers

```
Accept: */*
Accept-Encoding: gzip, deflate, br
Accept-Language: en-US,en;q=0.9
Connection: keep-alive
Host: cors1.azurewebsites.net
Origin: https://cors3.azurewebsites.net
Referer: https://cors3.azurewebsites.net/
Sec-Fetch-Dest: empty
Sec-Fetch-Mode: cors
Sec-Fetch-Site: cross-site
User-Agent: Mozilla/5.0 ...
```

In `OPTIONS` requests, the server sets the **Response headers** `Access-Control-Allow-Origin: {allowed origin}` header in the response. For example, the deployed sample, Delete [EnableCors] button `OPTIONS` request contains the following headers:

General headers

```
Request URL: https://cors3.azurewebsites.net/api/TodoItems2/MyDelete2/5
Request Method: OPTIONS
Status Code: 204 No Content
```

Response headers

```
Access-Control-Allow-Headers: Content-Type,x-custom-header
Access-Control-Allow-Methods: PUT,DELETE,GET,OPTIONS
Access-Control-Allow-Origin: https://cors1.azurewebsites.net
Server: Microsoft-IIS/10.0
Set-Cookie: ARRAffinity=8f...;Path=/;HttpOnly;Domain=cors3.azurewebsites.net
Vary: Origin
X-Powered-By: ASP.NET
```

Request headers

```
Accept: */*
Accept-Encoding: gzip, deflate, br
Accept-Language: en-US,en;q=0.9
Access-Control-Request-Headers: content-type
Access-Control-Request-Method: DELETE
Connection: keep-alive
Host: cors3.azurewebsites.net
Origin: https://cors1.azurewebsites.net
Referer: https://cors1.azurewebsites.net/test?number=2
Sec-Fetch-Dest: empty
Sec-Fetch-Mode: cors
Sec-Fetch-Site: cross-site
User-Agent: Mozilla/5.0
```

In the preceding **Response headers**, the server sets the Access-Control-Allow-Origin header in the response. The `https://cors1.azurewebsites.net` value of this header matches the `Origin` header from the request.

If AllowAnyOrigin is called, the `Access-Control-Allow-Origin: *`, the wildcard value, is returned. `AllowAnyOrigin` allows any origin.

If the response doesn't include the `Access-Control-Allow-Origin` header, the cross-origin request fails. Specifically, the browser disallows the request. Even if the server returns a successful response, the browser doesn't make the response available to the client app.

Display OPTIONS requests

By default, the Chrome and Edge browsers don't show OPTIONS requests on the network tab of the F12 tools. To display OPTIONS requests in these browsers:

- `chrome://flags/#out-of-blink-cors` or `edge://flags/#out-of-blink-cors`
- disable the flag.
- restart.

Firefox shows OPTIONS requests by default.

CORS in IIS

When deploying to IIS, CORS has to run before Windows Authentication if the server isn't configured to allow anonymous access. To support this scenario, the IIS CORS module needs to be installed and configured for the app.

Test CORS

The sample download has code to test CORS. See how to download. The sample is an API project with Razor Pages added:

```
public class StartupTest2
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddCors(options =>
        {
            options.AddPolicy(name: "MyPolicy",
                builder =>
                {
                    builder.WithOrigins("http://example.com",
                        "http://www.contoso.com",
                        "https://cors1.azurewebsites.net",
                        "https://cors3.azurewebsites.net",
                        "https://localhost:44398",
                        "https://localhost:5001")
                            .WithMethods("PUT", "DELETE", "GET");
                });
        });

        services.AddControllers();
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app)
    {
        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseRouting();

        app.UseCors();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapControllers();
            endpoints.MapRazorPages();
        });
    }
}
```

WARNING

`WithOrigins("https://localhost:<port>");` should only be used for testing a sample app similar to the download sample code.

The following `ValuesController` provides the endpoints for testing:

```
[EnableCors("MyPolicy")]
[Route("api/[controller]")]
[ApiController]
public class ValuesController : ControllerBase
{
    // GET api/values
    [HttpGet]
    public IActionResult Get() =>
        ControllerContext.MyDisplayRouteInfo();

    // GET api/values/5
    [HttpGet("{id}")]
    public IActionResult Get(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);

    // PUT api/values/5
    [HttpPut("{id}")]
    public IActionResult Put(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);

    // GET: api/values/GetValues2
    [DisableCors]
    [HttpGet("{action}")]
    public IActionResult GetValues2() =>
        ControllerContext.MyDisplayRouteInfo();

}
```

MyDisplayRouteInfo is provided by the Rick.Docs.Samples.RouteInfo NuGet package and displays route information.

Test the preceding sample code by using one of the following approaches:

- Use the deployed sample app at https://cors3.azurewebsites.net/. There is no need to download the sample.
- Run the sample with `dotnet run` using the default URL of `https://localhost:5001`.
- Run the sample from Visual Studio with the port set to 44398 for a URL of `https://localhost:44398`.

Using a browser with the F12 tools:

- Select the **Values** button and review the headers in the **Network** tab.
- Select the **PUT test** button. See Display OPTIONS requests for instructions on displaying the OPTIONS request. The **PUT test** creates two requests, an OPTIONS preflight request and the PUT request.
- Select the `GetValues2 [DisableCors]` button to trigger a failed CORS request. As mentioned in the document, the response returns 200 success, but the CORS request is not made. Select the **Console** tab to see the CORS error. Depending on the browser, an error similar to the following is displayed:

  Access to fetch at `'https://cors1.azurewebsites.net/api/values/GetValues2'` from origin `'https://cors3.azurewebsites.net'` has been blocked by CORS policy: No 'Access-Control-Allow-Origin' header is present on the requested resource. If an opaque response serves your needs, set the request's mode to 'no-cors' to fetch the resource with CORS disabled.

CORS-enabled endpoints can be tested with a tool, such as curl, Fiddler, or Postman. When using a tool, the origin of the request specified by the `Origin` header must differ from the host receiving the request. If the request isn't *cross-origin* based on the value of the `Origin` header:

- There's no need for CORS Middleware to process the request.
- CORS headers aren't returned in the response.

The following command uses `curl` to issue an OPTIONS request with information:

```
curl -X OPTIONS https://cors3.azurewebsites.net/api/TodoItems2/5 -i
```

Test CORS with endpoint routing and [HttpOptions]

Enabling CORS on a per-endpoint basis using `RequireCors` currently does **not** support automatic preflight requests. Consider the following code which uses endpoint routing to enable CORS:

```
public class StartupEndPointBugTest
{
    readonly string MyPolicy = "_myPolicy";

    // .WithHeaders(HeaderNames.ContentType, "x-custom-header")
    // forces browsers to require a preflight request with GET

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddCors(options =>
        {
            options.AddPolicy(name: MyPolicy,
                builder =>
                {
                    builder.WithOrigins("http://example.com",
                                        "http://www.contoso.com",
                                        "https://cors1.azurewebsites.net",
                                        "https://cors3.azurewebsites.net",
                                        "https://localhost:44398",
                                        "https://localhost:5001")
                           .WithHeaders(HeaderNames.ContentType, "x-custom-header")
                           .WithMethods("PUT", "DELETE", "GET", "OPTIONS");
                });
        });

        services.AddControllers();
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseRouting();

        app.UseCors();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapControllers().RequireCors(MyPolicy);
            endpoints.MapRazorPages();
        });
    }
}
```

The following `TodoItems1Controller` provides endpoints for testing:

```
[Route("api/[controller]")]
[ApiController]
public class TodoItems1Controller : ControllerBase
{
    // PUT: api/TodoItems1/5
    [HttpPut("{id}")]
    public IActionResult PutTodoItem(int id)
    {
        if (id < 1)
        {
            return Content($"ID = {id}");
        }

        return ControllerContext.MyDisplayRouteInfo(id);
    }

    // Delete: api/TodoItems1/5
    [HttpDelete("{id}")]
    public IActionResult MyDelete(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);

    // GET: api/TodoItems1
    [HttpGet]
    public IActionResult GetTodoItems() =>
        ControllerContext.MyDisplayRouteInfo();

    [EnableCors]
    [HttpGet("{action}")]
    public IActionResult GetTodoItems2() =>
        ControllerContext.MyDisplayRouteInfo();

    // Delete: api/TodoItems1/MyDelete2/5
    [EnableCors]
    [HttpDelete("{action}/{id}")]
    public IActionResult MyDelete2(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);
}
```

Test the preceding code from the test page of the deployed sample.

The **Delete [EnableCors]** and **GET [EnableCors]** buttons succeed, because the endpoints have `[EnableCors]` and respond to preflight requests. The other endpoints fails. The **GET** button fails, because the JavaScript sends:

```
 headers: {
      "Content-Type": "x-custom-header"
 },
```

The following `TodoItems2Controller` provides similar endpoints, but includes explicit code to respond to OPTIONS requests:

```
[Route("api/[controller]")]
[ApiController]
public class TodoItems2Controller : ControllerBase
{
    // OPTIONS: api/TodoItems2/5
    [HttpOptions("{id}")]
    public IActionResult PreflightRoute(int id)
    {
        return NoContent();
    }

    // OPTIONS: api/TodoItems2
    [HttpOptions]
    public IActionResult PreflightRoute()
    {
        return NoContent();
    }

    [HttpPut("{id}")]
    public IActionResult PutTodoItem(int id)
    {
        if (id < 1)
        {
            return BadRequest();
        }

        return ControllerContext.MyDisplayRouteInfo(id);
    }

    // [EnableCors] // Not needed as OPTIONS path provided
    [HttpDelete("{id}")]
    public IActionResult MyDelete(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);

    [EnableCors]  // Rquired for this path
    [HttpGet]
    public IActionResult GetTodoItems() =>
        ControllerContext.MyDisplayRouteInfo();

    [HttpGet("{action}")]
    public IActionResult GetTodoItems2() =>
        ControllerContext.MyDisplayRouteInfo();

    [EnableCors]  // Rquired for this path
    [HttpDelete("{action}/{id}")]
    public IActionResult MyDelete2(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);
}
```

Test the preceding code from the test page of the deployed sample. In the **Controller** drop down list, select **Preflight** and then **Set Controller**. All the CORS calls to the `TodoItems2Controller` endpoints succeed.

Additional resources

- Cross-Origin Resource Sharing (CORS)
- Getting started with the IIS CORS module

By Rick Anderson

This article shows how to enable CORS in an ASP.NET Core app.

Browser security prevents a web page from making requests to a different domain than the one that served the web page. This restriction is called the *same-origin policy*. The same-origin policy prevents a malicious site from reading sensitive data from another site. Sometimes, you might want to allow other sites make cross-

origin requests to your app. For more information, see the Mozilla CORS article.

Cross Origin Resource Sharing (CORS):

- Is a W3C standard that allows a server to relax the same-origin policy.
- Is **not** a security feature, CORS relaxes security. An API is not safer by allowing CORS. For more information, see How CORS works.
- Allows a server to explicitly allow some cross-origin requests while rejecting others.
- Is safer and more flexible than earlier techniques, such as JSONP.

View or download sample code (how to download)

Same origin

Two URLs have the same origin if they have identical schemes, hosts, and ports (RFC 6454).

These two URLs have the same origin:

- `https://example.com/foo.html`
- `https://example.com/bar.html`

These URLs have different origins than the previous two URLs:

- `https://example.net`: Different domain
- `https://www.example.com/foo.html`: Different subdomain
- `http://example.com/foo.html`: Different scheme
- `https://example.com:9000/foo.html`: Different port

Internet Explorer doesn't consider the port when comparing origins.

CORS with named policy and middleware

CORS Middleware handles cross-origin requests. The following code enables CORS for the entire app with the specified origin:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    readonly string MyAllowSpecificOrigins = "_myAllowSpecificOrigins";

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddCors(options =>
        {
            options.AddPolicy(MyAllowSpecificOrigins,
            builder =>
            {
                builder.WithOrigins("http://example.com",
                                    "http://www.contoso.com");
            });
        });

        services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseHsts();
        }

        app.UseCors(MyAllowSpecificOrigins);

        app.UseHttpsRedirection();
        app.UseMvc();
    }
}
```

The preceding code:

- Sets the policy name to "_myAllowSpecificOrigins". The policy name is arbitrary.
- Calls the UseCors extension method, which enables CORS.
- Calls AddCors with a lambda expression. The lambda takes a CorsPolicyBuilder object. Configuration options, such as `WithOrigins`, are described later in this article.

The AddCors method call adds CORS services to the app's service container:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddCors(options =>
    {
        options.AddPolicy(MyAllowSpecificOrigins,
        builder =>
        {
            builder.WithOrigins("http://example.com",
                                "http://www.contoso.com");
        });
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

For more information, see CORS policy options in this document .

The CorsPolicyBuilder method can chain methods, as shown in the following code:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddCors(options =>
    {
        options.AddPolicy(MyAllowSpecificOrigins,
        builder =>
        {
            builder.WithOrigins("http://example.com",
                                "http://www.contoso.com")
                                .AllowAnyHeader()
                                .AllowAnyMethod();
        });
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

Note: The URL must **not** contain a trailing slash (`/`). If the URL terminates with `/`, the comparison returns `false` and no header is returned.

The following code applies CORS policies to all the apps endpoints via CORS Middleware:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseHsts();
    }

    app.UseCors();

    app.UseHttpsRedirection();
    app.UseMvc();
}
```

Note: `UseCors` must be called before `UseMvc`.

See Enable CORS in Razor Pages, controllers, and action methods to apply CORS policy at the page/controller/action level.

See Test CORS for instructions on testing code similar to the preceding code.

Enable CORS with attributes

The [EnableCors] attribute provides an alternative to applying CORS globally. The `[EnableCors]` attribute enables CORS for selected end points, rather than all end points.

Use `[EnableCors]` to specify the default policy and `[EnableCors("{Policy String}")]` to specify a policy.

The `[EnableCors]` attribute can be applied to:

- Razor Page `PageModel`
- Controller
- Controller action method

You can apply different policies to controller/page-model/action with the `[EnableCors]` attribute. When the `[EnableCors]` attribute is applied to a controllers/page model/action method, and CORS is enabled in middleware, **both** policies are applied. We recommend **not** combining policies. Use the `[EnableCors]` attribute or middleware, **not both**. When using `[EnableCors]`, do **not** define a default policy.

The following code applies a different policy to each method:

```
[Route("api/[controller]")]
[ApiController]
public class WidgetController : ControllerBase
{
    // GET api/values
    [EnableCors("AnotherPolicy")]
    [HttpGet]
    public ActionResult<IEnumerable<string>> Get()
    {
        return new string[] { "green widget", "red widget" };
    }

    // GET api/values/5
    [EnableCors]        // Default policy.
    [HttpGet("{id}")]
    public ActionResult<string> Get(int id)
    {
        switch (id)
        {
            case 1:
                return "green widget";
            case 2:
                return "red widget";
            default:
                return NotFound();
        }
    }
}
```

The following code creates a CORS default policy and a policy named `"AnotherPolicy"`:

```
public class StartupMultiPolicy
{
    public StartupMultiPolicy(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddCors(options =>
        {
            options.AddDefaultPolicy(
                builder =>
                {

                    builder.WithOrigins("http://example.com",
                                        "http://www.contoso.com");
                });

            options.AddPolicy("AnotherPolicy",
                builder =>
                {
                    builder.WithOrigins("http://www.contoso.com")
                                        .AllowAnyHeader()
                                        .AllowAnyMethod();
                });

        });

        services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseMvc();
    }
}
```

Disable CORS

The [DisableCors] attribute disables CORS for the controller/page-model/action.

CORS policy options

This section describes the various options that can be set in a CORS policy:

- Set the allowed origins
- Set the allowed HTTP methods
- Set the allowed request headers
- Set the exposed response headers
- Credentials in cross-origin requests

- Set the preflight expiration time

AddPolicy is called in `Startup.ConfigureServices`. For some options, it may be helpful to read the How CORS works section first.

Set the allowed origins

AllowAnyOrigin: Allows CORS requests from all origins with any scheme (`http` or `https`). `AllowAnyOrigin` is insecure because *any website* can make cross-origin requests to the app.

> **NOTE**
> Specifying `AllowAnyOrigin` and `AllowCredentials` is an insecure configuration and can result in cross-site request forgery. For a secure app, specify an exact list of origins if the client must authorize itself to access server resources.

`AllowAnyOrigin` affects preflight requests and the `Access-Control-Allow-Origin` header. For more information, see the Preflight requests section.

SetIsOriginAllowedToAllowWildcardSubdomains: Sets the IsOriginAllowed property of the policy to be a function that allows origins to match a configured wildcard domain when evaluating if the origin is allowed.

```
options.AddPolicy("AllowSubdomain",
    builder =>
    {
        builder.WithOrigins("https://*.example.com")
            .SetIsOriginAllowedToAllowWildcardSubdomains();
    });
```

Set the allowed HTTP methods

AllowAnyMethod:

- Allows any HTTP method:
- Affects preflight requests and the `Access-Control-Allow-Methods` header. For more information, see the Preflight requests section.

Set the allowed request headers

To allow specific headers to be sent in a CORS request, called *author request headers*, call WithHeaders and specify the allowed headers:

```
options.AddPolicy("AllowHeaders",
    builder =>
    {
        builder.WithOrigins("http://example.com")
               .WithHeaders(HeaderNames.ContentType, "x-custom-header");
    });
```

To allow all author request headers, call AllowAnyHeader:

```
options.AddPolicy("AllowAllHeaders",
    builder =>
    {
        builder.WithOrigins("http://example.com")
               .AllowAnyHeader();
    });
```

This setting affects preflight requests and the `Access-Control-Request-Headers` header. For more information, see the Preflight requests section.

CORS Middleware always allows four headers in the `Access-Control-Request-Headers` to be sent regardless of the values configured in CorsPolicy.Headers. This list of headers includes:

- `Accept`
- `Accept-Language`
- `Content-Language`
- `Origin`

For instance, consider an app configured as follows:

```
app.UseCors(policy => policy.WithHeaders(HeaderNames.CacheControl));
```

CORS Middleware responds successfully to a preflight request with the following request header because `Content-Language` is always permitted:

```
Access-Control-Request-Headers: Cache-Control, Content-Language
```

Set the exposed response headers

By default, the browser doesn't expose all of the response headers to the app. For more information, see W3C Cross-Origin Resource Sharing (Terminology): Simple Response Header.

The response headers that are available by default are:

- `Cache-Control`
- `Content-Language`
- `Content-Type`
- `Expires`
- `Last-Modified`
- `Pragma`

The CORS specification calls these headers *simple response headers*. To make other headers available to the app, call WithExposedHeaders:

```
options.AddPolicy("ExposeResponseHeaders",
    builder =>
    {
        builder.WithOrigins("http://example.com")
               .WithExposedHeaders("x-custom-header");
    });
```

Credentials in cross-origin requests

Credentials require special handling in a CORS request. By default, the browser doesn't send credentials with a cross-origin request. Credentials include cookies and HTTP authentication schemes. To send credentials with a cross-origin request, the client must set `XMLHttpRequest.withCredentials` to `true`.

Using `XMLHttpRequest` directly:

```
var xhr = new XMLHttpRequest();
xhr.open('get', 'https://www.example.com/api/test');
xhr.withCredentials = true;
```

Using jQuery:

```
$.ajax({
  type: 'get',
  url: 'https://www.example.com/api/test',
  xhrFields: {
    withCredentials: true
  }
});
```

Using the Fetch API:

```
fetch('https://www.example.com/api/test', {
    credentials: 'include'
});
```

The server must allow the credentials. To allow cross-origin credentials, call AllowCredentials:

```
options.AddPolicy("AllowCredentials",
    builder =>
    {
        builder.WithOrigins("http://example.com")
               .AllowCredentials();
    });
```

The HTTP response includes an `Access-Control-Allow-Credentials` header, which tells the browser that the server allows credentials for a cross-origin request.

If the browser sends credentials but the response doesn't include a valid `Access-Control-Allow-Credentials` header, the browser doesn't expose the response to the app, and the cross-origin request fails.

Allowing cross-origin credentials is a security risk. A website at another domain can send a signed-in user's credentials to the app on the user's behalf without the user's knowledge.

The CORS specification also states that setting origins to `"*"` (all origins) is invalid if the `Access-Control-Allow-Credentials` header is present.

Preflight requests

For some CORS requests, the browser sends an additional request before making the actual request. This request is called a *preflight request*. The browser can skip the preflight request if the following conditions are true:

- The request method is GET, HEAD, or POST.
- The app doesn't set request headers other than `Accept`, `Accept-Language`, `Content-Language`, `Content-Type`, or `Last-Event-ID`.
- The `Content-Type` header, if set, has one of the following values:
  - `application/x-www-form-urlencoded`
  - `multipart/form-data`
  - `text/plain`

The rule on request headers set for the client request applies to headers that the app sets by calling

`setRequestHeader` on the `XMLHttpRequest` object. The CORS specification calls these headers *author request headers*. The rule doesn't apply to headers the browser can set, such as `User-Agent`, `Host`, or `Content-Length`.

The following is an example of a preflight request:

```
OPTIONS https://myservice.azurewebsites.net/api/test HTTP/1.1
Accept: */*
Origin: https://myclient.azurewebsites.net
Access-Control-Request-Method: PUT
Access-Control-Request-Headers: accept, x-my-custom-header
Accept-Encoding: gzip, deflate
User-Agent: Mozilla/5.0 (compatible; MSIE 10.0; Windows NT 6.2; WOW64; Trident/6.0)
Host: myservice.azurewebsites.net
Content-Length: 0
```

The pre-flight request uses the HTTP OPTIONS method. It includes two special headers:

- `Access-Control-Request-Method`: The HTTP method that will be used for the actual request.
- `Access-Control-Request-Headers`: A list of request headers that the app sets on the actual request. As stated earlier, this doesn't include headers that the browser sets, such as `User-Agent`.

When CORS is enabled with the appropriate policy, ASP.NET Core generally automatically responds to CORS preflight requests. See [HttpOptions] attribute for preflight requests.

A CORS preflight request might include an `Access-Control-Request-Headers` header, which indicates to the server the headers that are sent with the actual request.

To allow specific headers, call WithHeaders:

```
options.AddPolicy("AllowHeaders",
    builder =>
    {
        builder.WithOrigins("http://example.com")
               .WithHeaders(HeaderNames.ContentType, "x-custom-header");
    });
```

To allow all author request headers, call AllowAnyHeader:

```
options.AddPolicy("AllowAllHeaders",
    builder =>
    {
        builder.WithOrigins("http://example.com")
               .AllowAnyHeader();
    });
```

Browsers aren't entirely consistent in how they set `Access-Control-Request-Headers`. If you set headers to anything other than `"*"` (or use AllowAnyHeader), you should include at least `Accept`, `Content-Type`, and `Origin`, plus any custom headers that you want to support.

The following is an example response to the preflight request (assuming that the server allows the request):

```
HTTP/1.1 200 OK
Cache-Control: no-cache
Pragma: no-cache
Content-Length: 0
Access-Control-Allow-Origin: https://myclient.azurewebsites.net
Access-Control-Allow-Headers: x-my-custom-header
Access-Control-Allow-Methods: PUT
Date: Wed, 20 May 2015 06:33:22 GMT
```

The response includes an `Access-Control-Allow-Methods` header that lists the allowed methods and optionally an `Access-Control-Allow-Headers` header, which lists the allowed headers. If the preflight request succeeds, the browser sends the actual request.

If the preflight request is denied, the app returns a *200 OK* response but doesn't send the CORS headers back. Therefore, the browser doesn't attempt the cross-origin request.

Set the preflight expiration time

The `Access-Control-Max-Age` header specifies how long the response to the preflight request can be cached. To set this header, call SetPreflightMaxAge:

```
options.AddPolicy("SetPreflightExpiration",
    builder =>
    {
        builder.WithOrigins("http://example.com")
               .SetPreflightMaxAge(TimeSpan.FromSeconds(2520));
    });
```

How CORS works

This section describes what happens in a CORS request at the level of the HTTP messages.

- CORS is **not** a security feature. CORS is a W3C standard that allows a server to relax the same-origin policy.
  - For example, a malicious actor could use Prevent Cross-Site Scripting (XSS) against your site and execute a cross-site request to their CORS enabled site to steal information.
- Your API is not safer by allowing CORS.
  - It's up to the client (browser) to enforce CORS. The server executes the request and returns the response, it's the client that returns an error and blocks the response. For example, any of the following tools will display the server response:
    - Fiddler
    - Postman
    - .NET HttpClient
    - A web browser by entering the URL in the address bar.
- It's a way for a server to allow browsers to execute a cross-origin XHR or Fetch API request that otherwise would be forbidden.
  - Browsers (without CORS) can't do cross-origin requests. Before CORS, JSONP was used to circumvent this restriction. JSONP doesn't use XHR, it uses the `<script>` tag to receive the response. Scripts are allowed to be loaded cross-origin.

The CORS specification introduced several new HTTP headers that enable cross-origin requests. If a browser supports CORS, it sets these headers automatically for cross-origin requests. Custom JavaScript code isn't required to enable CORS.

The following is an example of a cross-origin request. The `Origin` header provides the domain of the site that's making the request. The `Origin` header is required and must be different from the host.

```
GET https://myservice.azurewebsites.net/api/test HTTP/1.1
Referer: https://myclient.azurewebsites.net/
Accept: */*
Accept-Language: en-US
Origin: https://myclient.azurewebsites.net
Accept-Encoding: gzip, deflate
User-Agent: Mozilla/5.0 (compatible; MSIE 10.0; Windows NT 6.2; WOW64; Trident/6.0)
Host: myservice.azurewebsites.net
```

If the server allows the request, it sets the `Access-Control-Allow-Origin` header in the response. The value of this header either matches the `Origin` header from the request or is the wildcard value `"*"`, meaning that any origin is allowed:

```
HTTP/1.1 200 OK
Cache-Control: no-cache
Pragma: no-cache
Content-Type: text/plain; charset=utf-8
Access-Control-Allow-Origin: https://myclient.azurewebsites.net
Date: Wed, 20 May 2015 06:27:30 GMT
Content-Length: 12

Test message
```

If the response doesn't include the `Access-Control-Allow-Origin` header, the cross-origin request fails. Specifically, the browser disallows the request. Even if the server returns a successful response, the browser doesn't make the response available to the client app.

Test CORS

To test CORS:

1. Create an API project. Alternatively, you can download the sample.
2. Enable CORS using one of the approaches in this document. For example:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseHsts();
    }

    // Shows UseCors with CorsPolicyBuilder.
    app.UseCors(builder =>
    {
        builder.WithOrigins("http://example.com",
                            "http://www.contoso.com",
                            "https://localhost:44375",
                            "https://localhost:5001");
    });

    app.UseHttpsRedirection();
    app.UseMvc();
}
```

WARNING

`WithOrigins("https://localhost:<port>");` should only be used for testing a sample app similar to the download sample code.

1. Create a web app project (Razor Pages or MVC). The sample uses Razor Pages. You can create the web app in the same solution as the API project.
2. Add the following highlighted code to the *Index.cshtml* file:

```
@page
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

<div class="text-center">
    <h1 class="display-4">CORS Test</h1>
</div>

<div>
    <input type="button" value="Test"
           onclick="requestVal('https://<web app>.azurewebsites.net/api/values')" />
    <span id='result'></span>
</div>

<script>
    function requestVal(uri) {
        const resultSpan = document.getElementById('result');

        fetch(uri)
            .then(response => response.json())
            .then(data => resultSpan.innerText = data)
            .catch(error => resultSpan.innerText = 'See F12 Console for error');
    }
</script>
```

1. In the preceding code, replace `url: 'https://<web app>.azurewebsites.net/api/values/1',` with the URL to the deployed app.
2. Deploy the API project. For example, deploy to Azure.
3. Run the Razor Pages or MVC app from the desktop and click on the **Test** button. Use the F12 tools to review error messages.
4. Remove the localhost origin from `WithOrigins` and deploy the app. Alternatively, run the client app with a different port. For example, run from Visual Studio.
5. Test with the client app. CORS failures return an error, but the error message isn't available to JavaScript. Use the console tab in the F12 tools to see the error. Depending on the browser, you get an error (in the F12 tools console) similar to the following:

   - Using Microsoft Edge:

     SEC7120: [CORS] The origin `https://localhost:44375` did not find `https://localhost:44375` in the Access-Control-Allow-Origin response header for cross-origin resource at `https://webapi.azurewebsites.net/api/values/1`

   - Using Chrome:

     Access to XMLHttpRequest at `https://webapi.azurewebsites.net/api/values/1` from origin

> `https://localhost:44375` **has been blocked by CORS policy: No 'Access-Control-Allow-Origin' header is present on the requested resource.**

CORS-enabled endpoints can be tested with a tool, such as Fiddler or Postman. When using a tool, the origin of the request specified by the `Origin` header must differ from the host receiving the request. If the request isn't *cross-origin* based on the value of the `Origin` header:

- There's no need for CORS Middleware to process the request.
- CORS headers aren't returned in the response.

CORS in IIS

When deploying to IIS, CORS has to run before Windows Authentication if the server isn't configured to allow anonymous access. To support this scenario, the IIS CORS module needs to be installed and configured for the app.

Share authentication cookies among ASP.NET apps

9/22/2020 • 5 minutes to read • Edit Online

By Rick Anderson

Websites often consist of individual web apps working together. To provide a single sign-on (SSO) experience, web apps within a site must share authentication cookies. To support this scenario, the data protection stack allows sharing Katana cookie authentication and ASP.NET Core cookie authentication tickets.

In the examples that follow:

- The authentication cookie name is set to a common value of `.AspNet.SharedCookie`.
- The `AuthenticationType` is set to `Identity.Application` either explicitly or by default.
- A common app name is used to enable the data protection system to share data protection keys (`SharedCookieApp`).
- `Identity.Application` is used as the authentication scheme. Whatever scheme is used, it must be used consistently *within and across* the shared cookie apps either as the default scheme or by explicitly setting it. The scheme is used when encrypting and decrypting cookies, so a consistent scheme must be used across apps.
- A common data protection key storage location is used.
  - In ASP.NET Core apps, PersistKeysToFileSystem is used to set the key storage location.
  - In .NET Framework apps, Cookie Authentication Middleware uses an implementation of DataProtectionProvider. `DataProtectionProvider` provides data protection services for the encryption and decryption of authentication cookie payload data. The `DataProtectionProvider` instance is isolated from the data protection system used by other parts of the app. DataProtectionProvider.Create(System.IO.DirectoryInfo, Action<IDataProtectionBuilder>) accepts a DirectoryInfo to specify the location for data protection key storage.
- `DataProtectionProvider` requires the Microsoft.AspNetCore.DataProtection.Extensions NuGet package:
  - In ASP.NET Core 2.x apps, reference the Microsoft.AspNetCore.App metapackage.
  - In .NET Framework apps, add a package reference to Microsoft.AspNetCore.DataProtection.Extensions.
- SetApplicationName sets the common app name.

Share authentication cookies with ASP.NET Core Identity

When using ASP.NET Core Identity:

- Data protection keys and the app name must be shared among apps. A common key storage location is provided to the PersistKeysToFileSystem method in the following examples. Use SetApplicationName to configure a common shared app name (`SharedCookieApp` in the following examples). For more information, see Configure ASP.NET Core Data Protection.
- Use the ConfigureApplicationCookie extension method to set up the data protection service for cookies.
- The default authentication type is `Identity.Application`.

In `Startup.ConfigureServices`:

```
services.AddDataProtection()
    .PersistKeysToFileSystem("{PATH TO COMMON KEY RING FOLDER}")
    .SetApplicationName("SharedCookieApp");

services.ConfigureApplicationCookie(options => {
    options.Cookie.Name = ".AspNet.SharedCookie";
});
```

Share authentication cookies without ASP.NET Core Identity

When using cookies directly without ASP.NET Core Identity, configure data protection and authentication in `Startup.ConfigureServices`. In the following example, the authentication type is set to `Identity.Application`:

```
services.AddDataProtection()
    .PersistKeysToFileSystem("{PATH TO COMMON KEY RING FOLDER}")
    .SetApplicationName("SharedCookieApp");

services.AddAuthentication("Identity.Application")
    .AddCookie("Identity.Application", options =>
    {
        options.Cookie.Name = ".AspNet.SharedCookie";
    });
```

Share cookies across different base paths

An authentication cookie uses the HttpRequest.PathBase as its default Cookie.Path. If the app's cookie must be shared across different base paths, `Path` must be overridden:

```
services.AddDataProtection()
    .PersistKeysToFileSystem("{PATH TO COMMON KEY RING FOLDER}")
    .SetApplicationName("SharedCookieApp");

services.ConfigureApplicationCookie(options => {
    options.Cookie.Name = ".AspNet.SharedCookie";
    options.Cookie.Path = "/";
});
```

Share cookies across subdomains

When hosting apps that share cookies across subdomains, specify a common domain in the Cookie.Domain property. To share cookies across apps at `contoso.com`, such as `first_subdomain.contoso.com` and `second_subdomain.contoso.com`, specify the `Cookie.Domain` as `.contoso.com`:

```
options.Cookie.Domain = ".contoso.com";
```

Encrypt data protection keys at rest

For production deployments, configure the `DataProtectionProvider` to encrypt keys at rest with DPAPI or an X509Certificate. For more information, see Key encryption at rest in Windows and Azure using ASP.NET Core. In the following example, a certificate thumbprint is provided to ProtectKeysWithCertificate:

```
services.AddDataProtection()
    .ProtectKeysWithCertificate("{CERTIFICATE THUMBPRINT}");
```

Share authentication cookies between ASP.NET 4.x and ASP.NET Core apps

ASP.NET 4.x apps that use Katana Cookie Authentication Middleware can be configured to generate authentication cookies that are compatible with the ASP.NET Core Cookie Authentication Middleware. This allows upgrading a large site's individual apps in several steps while providing a smooth SSO experience across the site.

When an app uses Katana Cookie Authentication Middleware, it calls `UseCookieAuthentication` in the project's *Startup.Auth.cs* file. ASP.NET 4.x web app projects created with Visual Studio 2013 and later use the Katana Cookie Authentication Middleware by default. Although `UseCookieAuthentication` is obsolete and unsupported for ASP.NET Core apps, calling `UseCookieAuthentication` in an ASP.NET 4.x app that uses Katana Cookie Authentication Middleware is valid.

An ASP.NET 4.x app must target .NET Framework 4.5.1 or later. Otherwise, the necessary NuGet packages fail to install.

To share authentication cookies between an ASP.NET 4.x app and an ASP.NET Core app, configure the ASP.NET Core app as stated in the Share authentication cookies among ASP.NET Core apps section, then configure the ASP.NET 4.x app as follows.

Confirm that the app's packages are updated to the latest releases. Install the Microsoft.Owin.Security.Interop package into each ASP.NET 4.x app.

Locate and modify the call to `UseCookieAuthentication`:

- Change the cookie name to match the name used by the ASP.NET Core Cookie Authentication Middleware (`.AspNet.SharedCookie` in the example).
- In the following example, the authentication type is set to `Identity.Application`.
- Provide an instance of a `DataProtectionProvider` initialized to the common data protection key storage location.
- Confirm that the app name is set to the common app name used by all apps that share authentication cookies (`SharedCookieApp` in the example).

If not setting `http://schemas.xmlsoap.org/ws/2005/05/identity/claims/nameidentifier` and `http://schemas.microsoft.com/accesscontrolservice/2010/07/claims/identityprovider`, set UniqueClaimTypeIdentifier to a claim that distinguishes unique users.

App_Start/Startup.Auth.cs:

```
app.UseCookieAuthentication(new CookieAuthenticationOptions
{
    AuthenticationType = "Identity.Application",
    CookieName = ".AspNet.SharedCookie",
    LoginPath = new PathString("/Account/Login"),
    Provider = new CookieAuthenticationProvider
    {
        OnValidateIdentity =
            SecurityStampValidator
                .OnValidateIdentity<ApplicationUserManager, ApplicationUser>(
                    validateInterval: TimeSpan.FromMinutes(30),
                    regenerateIdentity: (manager, user) =>
                        user.GenerateUserIdentityAsync(manager))
    },
    TicketDataFormat = new AspNetTicketDataFormat(
        new DataProtectorShim(
            DataProtectionProvider.Create("{PATH TO COMMON KEY RING FOLDER}",
                (builder) => { builder.SetApplicationName("SharedCookieApp"); })
            .CreateProtector(
                "Microsoft.AspNetCore.Authentication.Cookies." +
                    "CookieAuthenticationMiddleware",
                "Identity.Application",
                "v2"))),
    CookieManager = new ChunkingCookieManager()
});

System.Web.Helpers.AntiForgeryConfig.UniqueClaimTypeIdentifier =
    "http://schemas.xmlsoap.org/ws/2005/05/identity/claims/name";
```

When generating a user identity, the authentication type (`Identity.Application`) must match the type defined in `AuthenticationType` set with `UseCookieAuthentication` in *App_Start/Startup.Auth.cs*.

Models/IdentityModels.cs:

```
public class ApplicationUser : IdentityUser
{
    public async Task<ClaimsIdentity> GenerateUserIdentityAsync(
        UserManager<ApplicationUser> manager)
    {
        // The authenticationType must match the one defined in
        // CookieAuthenticationOptions.AuthenticationType
        var userIdentity =
            await manager.CreateIdentityAsync(this, "Identity.Application");

        // Add custom user claims here

        return userIdentity;
    }
}
```

Use a common user database

When apps use the same Identity schema (same version of Identity), confirm that the Identity system for each app is pointed at the same user database. Otherwise, the identity system produces failures at runtime when it attempts to match the information in the authentication cookie against the information in its database.

When the Identity schema is different among apps, usually because apps are using different Identity versions, sharing a common database based on the latest version of Identity isn't possible without remapping and adding columns in other app's Identity schemas. It's often more efficient to upgrade the other apps to use the latest Identity version so that a common database can be shared by the apps.

Work with SameSite cookies in ASP.NET Core

9/22/2020 • 10 minutes to read • Edit Online

By Rick Anderson

SameSite is an IETF draft standard designed to provide some protection against cross-site request forgery (CSRF) attacks. Originally drafted in 2016, the draft standard was updated in 2019. The updated standard is not backward compatible with the previous standard, with the following being the most noticeable differences:

- Cookies without SameSite header are treated as `SameSite=Lax` by default.
- `SameSite=None` must be used to allow cross-site cookie use.
- Cookies that assert `SameSite=None` must also be marked as `Secure`.
- Applications that use `<iframe>` may experience issues with `sameSite=Lax` or `sameSite=Strict` cookies because `<iframe>` is treated as cross-site scenarios.
- The value `SameSite=None` is not allowed by the 2016 standard and causes some implementations to treat such cookies as `SameSite=Strict`. See Supporting older browsers in this document.

The `SameSite=Lax` setting works for most application cookies. Some forms of authentication like OpenID Connect (OIDC) and WS-Federation default to POST based redirects. The POST based redirects trigger the SameSite browser protections, so SameSite is disabled for these components. Most OAuth logins are not affected due to differences in how the request flows.

Each ASP.NET Core component that emits cookies needs to decide if SameSite is appropriate.

SameSite and Identity

ASP.NET Core Identity is largely unaffected by SameSite cookies except for advanced scenarios like `IFrames` or `OpenIdConnect` integration.

When using `Identity`, do ***not*** add any cookie providers or call `services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)`, `Identity` takes care of that.

SameSite test sample code

The following samples can be downloaded and tested:

SAMPLE	DOCUMENT
.NET Core MVC	ASP.NET Core 2.1 MVC SameSite cookie sample
.NET Core Razor Pages	ASP.NET Core 2.1 Razor Pages SameSite cookie sample

The following sample can be downloaded and tested:

SAMPLE	DOCUMENT
.NET Core Razor Pages	ASP.NET Core 3.1 Razor Pages SameSite cookie sample

.NET Core support for the sameSite attribute

.NET Core 2.2 and later support the 2019 draft standard for SameSite since the release of updates in December 2019. Developers are able to programmatically control the value of the sameSite attribute using the `HttpCookie.SameSite` property. Setting the `SameSite` property to Strict, Lax, or None results in those values being written on the network with the cookie. Setting it equal to `(SameSiteMode)(-1)` indicates that no sameSite attribute should be included on the network with the cookie

```
var cookieOptions = new CookieOptions
{
    // Set the secure flag, which Chrome's changes will require for SameSite none.
    // Note this will also require you to be running on HTTPS.
    Secure = true,

    // Set the cookie to HTTP only which is good practice unless you really do need
    // to access it client side in scripts.
    HttpOnly = true,

    // Add the SameSite attribute, this will emit the attribute with a value of none.
    // To not emit the attribute at all set
    // SameSite = (SameSiteMode)(-1)
    SameSite = SameSiteMode.None
};

// Add the cookie to the response cookie collection
Response.Cookies.Append("MyCookie", "cookieValue", cookieOptions);
```

.NET Core 3.0 and later support the updated SameSite values and adds an extra enum value, `SameSiteMode.Unspecified` to the `SameSiteMode` enum. This new value indicates no sameSite should be sent with the cookie.

December patch behavior changes

The specific behavior change for .NET Framework and .NET Core 2.1 is how the `SameSite` property interprets the `None` value. Before the patch a value of `None` meant "Do not emit the attribute at all", after the patch it means "Emit the attribute with a value of `None`". After the patch a `SameSite` value of `(SameSiteMode)(-1)` causes the attribute not to be emitted.

The default SameSite value for forms authentication and session state cookies was changed from `None` to `Lax`.

API usage with SameSite

HttpContext.Response.Cookies.Append defaults to `Unspecified`, meaning no SameSite attribute added to the cookie and the client will use its default behavior (Lax for new browsers, None for old ones). The following code shows how to change the cookie SameSite value to `SameSiteMode.Lax`:

```
HttpContext.Response.Cookies.Append(
                    "name", "value",
                    new CookieOptions() { SameSite = SameSiteMode.Lax });
```

All ASP.NET Core components that emit cookies override the preceding defaults with settings appropriate for their scenarios. The overridden preceding default values haven't changed.

COMPONENT	COOKIE	DEFAULT
CookieBuilder	SameSite	`Unspecified`
Session	SessionOptions.Cookie	`Lax`

COMPONENT	COOKIE	DEFAULT
CookieTempDataProvider	CookieTempDataProviderOptions.Cookie	`Lax`
IAntiforgery	AntiforgeryOptions.Cookie	`Strict`
Cookie Authentication	CookieAuthenticationOptions.Cookie	`Lax`
AddTwitter	TwitterOptions.StateCookie	`Lax`
RemoteAuthenticationHandler<TOptions>	RemoteAuthenticationOptions.CorrelationCookie	`None`
AddOpenIdConnect	OpenIdConnectOptions.NonceCookie	`None`
HttpContext.Response.Cookies.Append	CookieOptions	`Unspecified`

ASP.NET Core 3.1 and later provides the following SameSite support:

- Redefines the behavior of `SameSiteMode.None` to emit `SameSite=None`
- Adds a new value `SameSiteMode.Unspecified` to omit the SameSite attribute.
- All cookies APIs default to `Unspecified`. Some components that use cookies set values more specific to their scenarios. See the table above for examples.

In ASP.NET Core 3.0 and later the SameSite defaults were changed to avoid conflicting with inconsistent client defaults. The following APIs have changed the default from `SameSiteMode.Lax` to `-1` to avoid emitting a SameSite attribute for these cookies:

- CookieOptions used with HttpContext.Response.Cookies.Append
- CookieBuilder used as a factory for `CookieOptions`
- CookiePolicyOptions.MinimumSameSitePolicy

History and changes

SameSite support was first implemented in ASP.NET Core in 2.0 using the 2016 draft standard. The 2016 standard was opt-in. ASP.NET Core opted-in by setting several cookies to `Lax` by default. After encountering several issues with authentication, most SameSite usage was disabled.

Patches were issued in November 2019 to update from the 2016 standard to the 2019 standard. The 2019 draft of the SameSite specification:

- Is **not** backwards compatible with the 2016 draft. For more information, see Supporting older browsers in this document.
- Specifies cookies are treated as `SameSite=Lax` by default.
- Specifies cookies that explicitly assert `SameSite=None` in order to enable cross-site delivery should be marked as `Secure`. `None` is a new entry to opt out.
- Is supported by patches issued for ASP.NET Core 2.1, 2.2, and 3.0. ASP.NET Core 3.1 has additional SameSite support.
- Is scheduled to be enabled by Chrome by default in Feb 2020. Browsers started moving to this standard in 2019.

APIs impacted by the change from the 2016 SameSite draft standard to the 2019 draft standard

- Http.SameSiteMode
- CookieOptions.SameSite
- CookieBuilder.SameSite
- CookiePolicyOptions.MinimumSameSitePolicy
- Microsoft.Net.Http.Headers.SameSiteMode
- Microsoft.Net.Http.Headers.SetCookieHeaderValue.SameSite

Supporting older browsers

The 2016 SameSite standard mandated that unknown values must be treated as `SameSite=Strict` values. Apps accessed from older browsers which support the 2016 SameSite standard may break when they get a SameSite property with a value of `None`. Web apps must implement browser detection if they intend to support older browsers. ASP.NET Core doesn't implement browser detection because User-Agents values are highly volatile and change frequently. An extension point in Microsoft.AspNetCore.CookiePolicy allows plugging in User-Agent specific logic.

In `Startup.Configure`, add code that calls UseCookiePolicy before calling UseAuthentication or *any* method that writes cookies:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseCookiePolicy();
    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

In `Startup.ConfigureServices`, add code similar to the following:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.MinimumSameSitePolicy = SameSiteMode.Unspecified;
        options.OnAppendCookie = cookieContext =>
            CheckSameSite(cookieContext.Context, cookieContext.CookieOptions);
        options.OnDeleteCookie = cookieContext =>
            CheckSameSite(cookieContext.Context, cookieContext.CookieOptions);
    });

    services.AddRazorPages();
}

private void CheckSameSite(HttpContext httpContext, CookieOptions options)
{
    if (options.SameSite == SameSiteMode.None)
    {
        var userAgent = httpContext.Request.Headers["User-Agent"].ToString();
        if (MyUserAgentDetectionLib.DisallowsSameSiteNone(userAgent))
        {
            options.SameSite = SameSiteMode.Unspecified;
        }
    }
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.MinimumSameSitePolicy = (SameSiteMode)(-1);
        options.OnAppendCookie = cookieContext =>
            CheckSameSite(cookieContext.Context, cookieContext.CookieOptions);
        options.OnDeleteCookie = cookieContext =>
            CheckSameSite(cookieContext.Context, cookieContext.CookieOptions);
    });

    services.AddRazorPages();
}

private void CheckSameSite(HttpContext httpContext, CookieOptions options)
{
    if (options.SameSite == SameSiteMode.None)
    {
        var userAgent = httpContext.Request.Headers["User-Agent"].ToString();
        if (MyUserAgentDetectionLib.DisallowsSameSiteNone(userAgent))
        {
            options.SameSite = (SameSiteMode)(-1);
        }

    }
}
```

In the preceding sample, `MyUserAgentDetectionLib.DisallowsSameSiteNone` is a user supplied library that detects if the user agent doesn't support SameSite `None`:

```
if (MyUserAgentDetectionLib.DisallowsSameSiteNone(userAgent))
{
    options.SameSite = SameSiteMode.Unspecified;
}
```

The following code shows a sample `DisallowsSameSiteNone` method:

WARNING

The following code is for demonstration only:

- It should not be considered complete.
- It is not maintained or supported.

```
public static bool DisallowsSameSiteNone(string userAgent)
{
    // Check if a null or empty string has been passed in, since this
    // will cause further interrogation of the useragent to fail.
     if (String.IsNullOrWhiteSpace(userAgent))
        return false;

    // Cover all iOS based browsers here. This includes:
    // - Safari on iOS 12 for iPhone, iPod Touch, iPad
    // - WkWebview on iOS 12 for iPhone, iPod Touch, iPad
    // - Chrome on iOS 12 for iPhone, iPod Touch, iPad
    // All of which are broken by SameSite=None, because they use the iOS networking
    // stack.
    if (userAgent.Contains("CPU iPhone OS 12") ||
        userAgent.Contains("iPad; CPU OS 12"))
    {
        return true;
    }

    // Cover Mac OS X based browsers that use the Mac OS networking stack.
    // This includes:
    // - Safari on Mac OS X.
    // This does not include:
    // - Chrome on Mac OS X
    // Because they do not use the Mac OS networking stack.
    if (userAgent.Contains("Macintosh; Intel Mac OS X 10_14") &&
        userAgent.Contains("Version/") && userAgent.Contains("Safari"))
    {
        return true;
    }

    // Cover Chrome 50-69, because some versions are broken by SameSite=None,
    // and none in this range require it.
    // Note: this covers some pre-Chromium Edge versions,
    // but pre-Chromium Edge does not require SameSite=None.
    if (userAgent.Contains("Chrome/5") || userAgent.Contains("Chrome/6"))
    {
        return true;
    }

    return false;
}
```

Test apps for SameSite problems

Apps that interact with remote sites such as through third-party login need to:

- Test the interaction on multiple browsers.
- Apply the CookiePolicy browser detection and mitigation discussed in this document.

Test web apps using a client version that can opt-in to the new SameSite behavior. Chrome, Firefox, and Chromium Edge all have new opt-in feature flags that can be used for testing. After your app applies the SameSite patches, test it with older client versions, especially Safari. For more information, see Supporting older browsers in this document.

Test with Chrome

Chrome 78+ gives misleading results because it has a temporary mitigation in place. The Chrome 78+ temporary mitigation allows cookies less than two minutes old. Chrome 76 or 77 with the appropriate test flags enabled provides more accurate results. To test the new SameSite behavior toggle `chrome://flags/#same-site-by-default-cookies` to **Enabled**. Older versions of Chrome (75 and below) are reported to fail with the new `None` setting. See Supporting older browsers in this document.

Google does not make older chrome versions available. Follow the instructions at Download Chromium to test older versions of Chrome. Do **not** download Chrome from links provided by searching for older versions of chrome.

- Chromium 76 Win64
- Chromium 74 Win64

Starting in Canary version `80.0.3975.0`, the Lax+POST temporary mitigation can be disabled for testing purposes using the new flag `--enable-features=SameSiteDefaultChecksMethodRigorously` to allow testing of sites and services in the eventual end state of the feature where the mitigation has been removed. For more information, see The Chromium Projects SameSite Updates

Test with Safari

Safari 12 strictly implemented the prior draft and fails when the new `None` value is in a cookie. `None` is avoided via the browser detection code Supporting older browsers in this document. Test Safari 12, Safari 13, and WebKit based OS style logins using MSAL, ADAL or whatever library you are using. The problem is dependent on the underlying OS version. OSX Mojave (10.14) and iOS 12 are known to have compatibility problems with the new SameSite behavior. Upgrading the OS to OSX Catalina (10.15) or iOS 13 fixes the problem. Safari does not currently have an opt-in flag for testing the new spec behavior.

Test with Firefox

Firefox support for the new standard can be tested on version 68+ by opting in on the `about:config` page with the feature flag `network.cookie.sameSite.laxByDefault`. There haven't been reports of compatibility issues with older versions of Firefox.

Test with Edge browser

Edge supports the old SameSite standard. Edge version 44 doesn't have any known compatibility problems with the new standard.

Test with Edge (Chromium)

SameSite flags are set on the `edge://flags/#same-site-by-default-cookies` page. No compatibility issues were discovered with Edge Chromium.

Test with Electron

Versions of Electron include older versions of Chromium. For example, the version of Electron used by Teams is Chromium 66, which exhibits the older behavior. You must perform your own compatibility testing with the version of Electron your product uses. See Supporting older browsers in the following section.

ASP.NET Core 2.1 Razor Pages SameSite cookie sample

9/22/2020 • 3 minutes to read • Edit Online

This sample targets .NET Framework Targeted

ASP.NET Core 2.1 has built-in support for the SameSite attribute, but it was written to the original standard. The patched behavior changed the meaning of `SameSite.None` to emit the sameSite attribute with a value of `None`, rather than not emit the value at all. If you want to not emit the value you can set the `SameSite` property on a cookie to -1.

ASP.NET Core Identity is largely unaffected by SameSite cookies except for advanced scenarios like `IFrames` or `OpenIdConnect` integration.

When using `Identity`, do ***not*** add any cookie providers or call `services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)`, `Identity` takes care of that.

Writing the SameSite attribute

The following code is an example of how to write a SameSite attribute on a cookie:

```
var cookieOptions = new CookieOptions
{
    // Set the secure flag, which Chrome's changes will require for SameSite none.
    // Note this will also require you to be running on HTTPS
    Secure = true,

    // Set the cookie to HTTP only which is good practice unless you really do need
    // to access it client side in scripts.
    HttpOnly = true,

    // Add the SameSite attribute, this will emit the attribute with a value of none.
    // To not emit the attribute at all set the SameSite property to (SameSiteMode)(-1).
    SameSite = SameSiteMode.None
};

// Add the cookie to the response cookie collection
Response.Cookies.Append(CookieName, "cookieValue", cookieOptions);
```

Setting Cookie Authentication and Session State cookies

Cookie authentication, session state and various other components set their sameSite options via Cookie options, for example

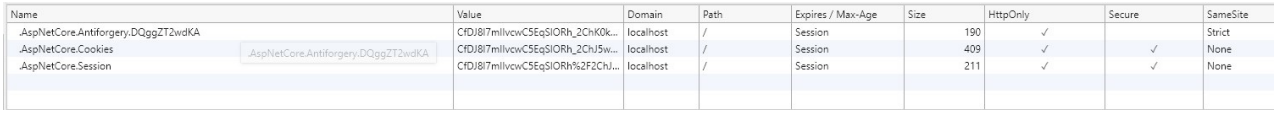
```
services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
    .AddCookie(options =>
    {
        options.Cookie.SameSite = SameSiteMode.None;
        options.Cookie.SecurePolicy = CookieSecurePolicy.Always;
        options.Cookie.IsEssential = true;
    });

services.AddSession(options =>
{
    options.Cookie.SameSite = SameSiteMode.None;
    options.Cookie.SecurePolicy = CookieSecurePolicy.Always;
    options.Cookie.IsEssential = true;
});
```

In the preceding code, both cookie authentication and session state set their sameSite attribute to `None`, emitting the attribute with a `None` value, and also set the Secure attribute to `true`.

Run the sample

If you run the sample project, load your browser debugger on the initial page and use it to view the cookie collection for the site. To do so in Edge and Chrome press `F12` then select the `Application` tab and click the site URL under the `Cookies` option in the `Storage` section.



Name	Value	Domain	Path	Expires / Max-Age	Size	HttpOnly	Secure	SameSite
.AspNetCore.Antiforgery.DQggZT2wdKA	CfDJ8I7mIlvcwC5EqSIORh_2ChK0k...	localhost	/	Session	190	✓		Strict
.AspNetCore.Cookies	CfDJ8I7mIlvcwC5EqSIORh_2ChJ5w...	localhost	/	Session	409	✓	✓	None
.AspNetCore.Session	CfDJ8I7mIlvcwC5EqSIORh%2F2ChJ...	localhost	/	Session	211	✓	✓	None

You can see from the image above that the cookie created by the sample when you click the "Create SameSite Cookie" button has a SameSite attribute value of `Lax`, matching the value set in the sample code.

Intercepting cookies

In order to intercept cookies, to adjust the none value according to its support in the user's browser agent you must use the `CookiePolicy` middleware. This must be placed into the http request pipeline **before** any components that write cookies and configured within `ConfigureServices()`.

To insert it into the pipeline use `app.UseCookiePolicy()` in the `Configure(IApplicationBuilder, IHostingEnvironment)` method in your Startup.cs. For example

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
       app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseCookiePolicy();
    app.UseAuthentication();
    app.UseSession();

    app.UseMvc(routes =>
    {
        routes.MapRoute(
            name: "default",
            template: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

Then in the `ConfigureServices(IServiceCollection services)` configure the cookie policy to call out to a helper class when cookies are appended or deleted, like so;

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
        options.OnAppendCookie = cookieContext =>
            CheckSameSite(cookieContext.Context, cookieContext.CookieOptions);
        options.OnDeleteCookie = cookieContext =>
            CheckSameSite(cookieContext.Context, cookieContext.CookieOptions);
    });
}

private void CheckSameSite(HttpContext httpContext, CookieOptions options)
{
    if (options.SameSite == SameSiteMode.None)
    {
        var userAgent = httpContext.Request.Headers["User-Agent"].ToString();
        if (SameSite.BrowserDetection.DisallowsSameSiteNone(userAgent))
        {
            options.SameSite = (SameSiteMode)(-1);
        }
    }
}
```

The helper function `CheckSameSite(HttpContext, CookieOptions)`:

- Is called when cookies are appended to the request or deleted from the request.
- Checks to see if the `SameSite` property is set to `None`.
- If `SameSite` is set to `None` and the current user agent is known to not support the none attribute value. The check is done using the SameSiteSupport class:
  - Sets `SameSite` to not emit the value by setting the property to `(SameSiteMode)(-1)`

Targeting .NET Framework

ASP.NET Core and System.Web (ASP.NET Classic) have independent implementations of SameSite. The SameSite KB patches for .NET Framework are not required if using ASP.NET Core nor does the System.Web SameSite minimum framework version requirement (.NET 4.7.2) apply to ASP.NET Core.

ASP.NET Core on .NET requires updating NuGet package dependencies to get the appropriate fixes.

To get the ASP.NET Core changes for .NET Framework ensure that you have a direct reference to the patched packages and versions (2.1.14 or later 2.1 versions).

```
<PackageReference Include="Microsoft.Net.Http.Headers" Version="2.1.14" />
<PackageReference Include="Microsoft.AspNetCore.CookiePolicy" Version="2.1.14" />
```

Chrome Updates ASP.NET Core SameSite Documentation ASP.NET Core 2.1 SameSite Change Announcement

ASP.NET Core 3.1 Razor Pages SameSite cookie sample

9/22/2020 • 3 minutes to read • Edit Online

ASP.NET Core 3.0 has built-in support for the SameSite attribute, including a `SameSiteMode` attribute value of `Unspecified` to suppress writing the attribute.

ASP.NET Core Identity is largely unaffected by SameSite cookies except for advanced scenarios like `IFrames` or `OpenIdConnect` integration.

When using `Identity`, do ***not*** add any cookie providers or call `services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)`, `Identity` takes care of that.

Writing the SameSite attribute

Following is an example of how to write a SameSite attribute on a cookie;

```
var cookieOptions = new CookieOptions
{
    // Set the secure flag, which Chrome's changes will require for SameSite none.
    // Note this will also require you to be running on HTTPS
    Secure = true,

    // Set the cookie to HTTP only which is good practice unless you really do need
    // to access it client side in scripts.
    HttpOnly = true,

    // Add the SameSite attribute, this will emit the attribute with a value of none.
    // To not emit the attribute at all set the SameSite property to SameSiteMode.Unspecified.
    SameSite = SameSiteMode.None
};

// Add the cookie to the response cookie collection
Response.Cookies.Append(CookieName, "cookieValue", cookieOptions);
```

Setting Cookie Authentication and Session State cookies

Cookie authentication, session state and various other components set their sameSite options via Cookie options, for example

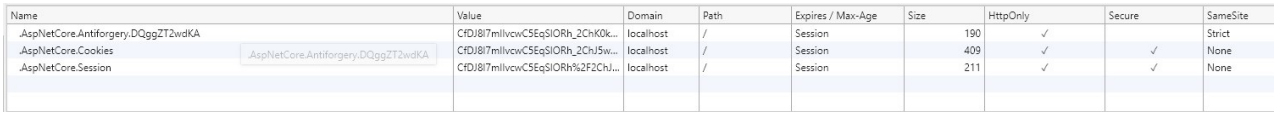
```
services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
    .AddCookie(options =>
    {
        options.Cookie.SameSite = SameSiteMode.None;
        options.Cookie.SecurePolicy = CookieSecurePolicy.Always;
        options.Cookie.IsEssential = true;
    });

services.AddSession(options =>
{
    options.Cookie.SameSite = SameSiteMode.None;
    options.Cookie.SecurePolicy = CookieSecurePolicy.Always;
    options.Cookie.IsEssential = true;
});
```

In the code shown above both cookie authentication and session state set their sameSite attribute to None, emitting the attribute with a `None` value, and also set the Secure attribute to true.

Run the sample

If you run the sample project, load your browser debugger on the initial page and use it to view the cookie collection for the site. To do so in Edge and Chrome press `F12` then select the `Application` tab and click the site URL under the `Cookies` option in the `Storage` section.



You can see from the image above that the cookie created by the sample when you click the "Create SameSite Cookie" button has a SameSite attribute value of `Lax`, matching the value set in the sample code.

Intercepting cookies

In order to intercept cookies, to adjust the none value according to its support in the user's browser agent you must use the `CookiePolicy` middleware. This must be placed into the http request pipeline **before** any components that write cookies and configured within `ConfigureServices()`.

To insert it into the pipeline use `app.UseCookiePolicy()` in the `Configure(IApplicationBuilder, IHostingEnvironment)` method in your Startup.cs. For example

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
       app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseCookiePolicy();
    app.UseAuthentication();
    app.UseSession();

    app.UseMvc(routes =>
    {
        routes.MapRoute(
            name: "default",
            template: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

Then in the `ConfigureServices(IServiceCollection services)` configure the cookie policy to call out to a helper class when cookies are appended or deleted, like so;

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
        options.OnAppendCookie = cookieContext =>
            CheckSameSite(cookieContext.Context, cookieContext.CookieOptions);
        options.OnDeleteCookie = cookieContext =>
            CheckSameSite(cookieContext.Context, cookieContext.CookieOptions);
    });
}

private void CheckSameSite(HttpContext httpContext, CookieOptions options)
{
    if (options.SameSite == SameSiteMode.None)
    {
        var userAgent = httpContext.Request.Headers["User-Agent"].ToString();
        if (SameSite.BrowserDetection.DisallowsSameSiteNone(userAgent))
        {
            options.SameSite = SameSiteMode.Unspecified;
        }
    }
}
```

The helper function `CheckSameSite(HttpContext, CookieOptions)`:

- Is called when cookies are appended to the request or deleted from the request.
- Checks to see if the `SameSite` property is set to `None`.
- If `SameSite` is set to `None` and the current user agent is known to not support the none attribute value. The check is done using the SameSiteSupport class:
  - Sets `SameSite` to not emit the value by setting the property to `(SameSiteMode)(-1)`

ASP.NET Core 2.1 MVC SameSite cookie sample

9/22/2020 • 3 minutes to read • Edit Online

ASP.NET Core 2.1 has built-in support for the SameSite attribute, but it was written to the original standard. The patched behavior changed the meaning of `SameSite.None` to emit the sameSite attribute with a value of `None`, rather than not emit the value at all. If you want to not emit the value you can set the `SameSite` property on a cookie to -1.

ASP.NET Core Identity is largely unaffected by SameSite cookies except for advanced scenarios like `IFrames` or `OpenIdConnect` integration.

When using `Identity`, do ***not*** add any cookie providers or call `services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)`, `Identity` takes care of that.

Writing the SameSite attribute

Following is an example of how to write a SameSite attribute on a cookie:

```
var cookieOptions = new CookieOptions
{
    // Set the secure flag, which Chrome's changes will require for SameSite none.
    // Note this will also require you to be running on HTTPS
    Secure = true,

    // Set the cookie to HTTP only which is good practice unless you really do need
    // to access it client side in scripts.
    HttpOnly = true,

    // Add the SameSite attribute, this will emit the attribute with a value of none.
    // To not emit the attribute at all set the SameSite property to (SameSiteMode)(-1).
    SameSite = SameSiteMode.None
};

// Add the cookie to the response cookie collection
Response.Cookies.Append(CookieName, "cookieValue", cookieOptions);
```

Setting Cookie Authentication and Session State cookies

Cookie authentication, session state and various other components set their sameSite options via Cookie options, for example

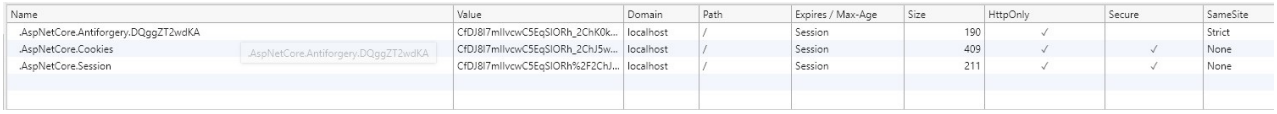
```
services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
    .AddCookie(options =>
    {
        options.Cookie.SameSite = SameSiteMode.None;
        options.Cookie.SecurePolicy = CookieSecurePolicy.Always;
        options.Cookie.IsEssential = true;
    });

services.AddSession(options =>
{
    options.Cookie.SameSite = SameSiteMode.None;
    options.Cookie.SecurePolicy = CookieSecurePolicy.Always;
    options.Cookie.IsEssential = true;
});
```

In the preceding code, both cookie authentication and session state set their sameSite attribute to `None`, emitting the attribute with a `None` value, and also set the Secure attribute to true.

Run the sample

If you run the sample project, load your browser debugger on the initial page and use it to view the cookie collection for the site. To do so in Edge and Chrome press `F12` then select the `Application` tab and click the site URL under the `Cookies` option in the `Storage` section.



Name	Value	Domain	Path	Expires / Max-Age	Size	HttpOnly	Secure	SameSite
.AspNetCore.Antiforgery.DQggZT2wdKA	CfDJ8I7mIlvcwC5EqSIORh_2ChK0k...	localhost	/	Session	190	✓		Strict
.AspNetCore.Cookies	CfDJ8I7mIlvcwC5EqSIORh_2ChJ5w...	localhost	/	Session	409	✓	✓	None
.AspNetCore.Session	CfDJ8I7mIlvcwC5EqSIORh%2F2ChJ...	localhost	/	Session	211	✓	✓	None

You can see from the image above that the cookie created by the sample when you click the "Create SameSite Cookie" button has a SameSite attribute value of `Lax`, matching the value set in the sample code.

Intercepting cookies

In order to intercept cookies, to adjust the none value according to its support in the user's browser agent you must use the `CookiePolicy` middleware. This must be placed into the http request pipeline **before** any components that write cookies and configured within `ConfigureServices()`.

To insert it into the pipeline use `app.UseCookiePolicy()` in the `Configure(IApplicationBuilder, IHostingEnvironment)` method in Startup.cs. For example:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
       app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseCookiePolicy();
    app.UseAuthentication();
    app.UseSession();

    app.UseMvc(routes =>
    {
        routes.MapRoute(
            name: "default",
            template: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

Then in the `ConfigureServices(IServiceCollection services)` configure the cookie policy to call out to a helper class when cookies are appended or deleted. For example:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
        options.OnAppendCookie = cookieContext =>
            CheckSameSite(cookieContext.Context, cookieContext.CookieOptions);
        options.OnDeleteCookie = cookieContext =>
            CheckSameSite(cookieContext.Context, cookieContext.CookieOptions);
    });
}

private void CheckSameSite(HttpContext httpContext, CookieOptions options)
{
    if (options.SameSite == SameSiteMode.None)
    {
        var userAgent = httpContext.Request.Headers["User-Agent"].ToString();
        if (SameSite.BrowserDetection.DisallowsSameSiteNone(userAgent))
        {
            options.SameSite = (SameSiteMode)(-1);
        }
    }
}
```

The helper function `CheckSameSite(HttpContext, CookieOptions)`:

- Is called when cookies are appended to the request or deleted from the request.
- Checks to see if the `SameSite` property is set to `None`.
- If `SameSite` is set to `None` and the current user agent is known to not support the none attribute value. The check is done using the SameSiteSupport class:
  - Sets `SameSite` to not emit the value by setting the property to `(SameSiteMode)(-1)`

Targeting .NET Framework

ASP.NET Core and System.Web (ASP.NET Classic) have independent implementations of SameSite. The SameSite KB patches for .NET Framework are not required if using ASP.NET Core nor does the System.Web SameSite minimum framework version requirement (.NET 4.7.2) apply to ASP.NET Core.

ASP.NET Core on .NET requires updating nuget package dependencies to get the appropriate fixes.

To get the ASP.NET Core changes for .NET Framework ensure that you have a direct reference to the patched packages and versions (2.1.14 or later 2.1 versions).

```
<PackageReference Include="Microsoft.Net.Http.Headers" Version="2.1.14" />
<PackageReference Include="Microsoft.AspNetCore.CookiePolicy" Version="2.1.14" />
```

Client IP safelist for ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

By Damien Bowden and Tom Dykstra

This article shows three ways to implement an IP address safelist (also known as an allow list) in an ASP.NET Core app. An accompanying sample app demonstrates all three approaches. You can use:

- Middleware to check the remote IP address of every request.
- MVC action filters to check the remote IP address of requests for specific controllers or action methods.
- Razor Pages filters to check the remote IP address of requests for Razor pages.

In each case, a string containing approved client IP addresses is stored in an app setting. The middleware or filter:

- Parses the string into an array.
- Checks if the remote IP address exists in the array.

Access is allowed if the array contains the IP address. Otherwise, an HTTP 403 Forbidden status code is returned.

View or download sample code (how to download)

IP address safelist

In the sample app, the IP address safelist is:

- Defined by the `AdminSafeList` property in the *appsettings.json* file.
- A semicolon-delimited string that may contain both Internet Protocol version 4 (IPv4) and Internet Protocol version 6 (IPv6) addresses.

```
{
  "AdminSafeList": "127.0.0.1;192.168.1.5;::1",
  "Logging": {
```

In the preceding example, the IPv4 addresses of `127.0.0.1` and `192.168.1.5` and the IPv6 loopback address of `::1` (compressed format for `0:0:0:0:0:0:0:1`) are allowed.

Middleware

The `Startup.Configure` method adds the custom `AdminSafeListMiddleware` middleware type to the app's request pipeline. The safelist is retrieved with the .NET Core configuration provider and is passed as a constructor parameter.

```
app.UseMiddleware<AdminSafeListMiddleware>(Configuration["AdminSafeList"]);
```

The middleware parses the string into an array and searches for the remote IP address in the array. If the remote IP address isn't found, the middleware returns HTTP 403 Forbidden. This validation process is bypassed for HTTP GET requests.

```
public class AdminSafeListMiddleware
{
    private readonly RequestDelegate _next;
    private readonly ILogger<AdminSafeListMiddleware> _logger;
    private readonly string _safelist;

    public AdminSafeListMiddleware(
        RequestDelegate next,
        ILogger<AdminSafeListMiddleware> logger,
        string safelist)
    {
        _safelist = safelist;
        _next = next;
        _logger = logger;
    }

    public async Task Invoke(HttpContext context)
    {
        if (context.Request.Method != HttpMethod.Get.Method)
        {
            var remoteIp = context.Connection.RemoteIpAddress;
            _logger.LogDebug("Request from Remote IP address: {RemoteIp}", remoteIp);

            string[] ip = _safelist.Split(';');

            var bytes = remoteIp.GetAddressBytes();
            var badIp = true;
            foreach (var address in ip)
            {
                var testIp = IPAddress.Parse(address);
                if (testIp.GetAddressBytes().SequenceEqual(bytes))
                {
                    badIp = false;
                    break;
                }
            }

            if (badIp)
            {
                _logger.LogWarning(
                    "Forbidden Request from Remote IP address: {RemoteIp}", remoteIp);
                context.Response.StatusCode = StatusCodes.Status403Forbidden;
                return;
            }
        }

        await _next.Invoke(context);
    }
}
```

Action filter

If you want safelist-driven access control for specific MVC controllers or action methods, use an action filter. For example:

```
public class ClientIpCheckActionFilter : ActionFilterAttribute
{
    private readonly ILogger _logger;
    private readonly string _safelist;

    public ClientIpCheckActionFilter(string safelist, ILogger logger)
    {
        _safelist = safelist;
        _logger = logger;
    }

    public override void OnActionExecuting(ActionExecutingContext context)
    {
        var remoteIp = context.HttpContext.Connection.RemoteIpAddress;
        _logger.LogDebug("Remote IpAddress: {RemoteIp}", remoteIp);
        var ip = _safelist.Split(';');
        var badIp = true;

        if (remoteIp.IsIPv4MappedToIPv6)
        {
            remoteIp = remoteIp.MapToIPv4();
        }

        foreach (var address in ip)
        {
            var testIp = IPAddress.Parse(address);

            if (testIp.Equals(remoteIp))
            {
                badIp = false;
                break;
            }
        }

        if (badIp)
        {
            _logger.LogWarning("Forbidden Request from IP: {RemoteIp}", remoteIp);
            context.Result = new StatusCodeResult(StatusCodes.Status403Forbidden);
            return;
        }

        base.OnActionExecuting(context);
    }
}
```

In `Startup.ConfigureServices`, add the action filter to the MVC filters collection. In the following example, a `ClientIpCheckActionFilter` action filter is added. A safelist and a console logger instance are passed as constructor parameters.

```
services.AddScoped<ClientIpCheckActionFilter>(container =>
{
    var loggerFactory = container.GetRequiredService<ILoggerFactory>();
    var logger = loggerFactory.CreateLogger<ClientIpCheckActionFilter>();

    return new ClientIpCheckActionFilter(
        Configuration["AdminSafeList"], logger);
});
```

```
services.AddScoped<ClientIpCheckActionFilter>(_ =>
{
    var logger = _loggerFactory.CreateLogger<ClientIpCheckActionFilter>();

    return new ClientIpCheckActionFilter(
        Configuration["AdminSafeList"], logger);
});
```

The action filter can then be applied to a controller or action method with the [ServiceFilter] attribute:

```
[ServiceFilter(typeof(ClientIpCheckActionFilter))]
[HttpGet]
public IEnumerable<string> Get()
```

In the sample app, the action filter is applied to the controller's `Get` action method. When you test the app by sending:

- An HTTP GET request, the `[ServiceFilter]` attribute validates the client IP address. If access is allowed to the `Get` action method, a variation of the following console output is produced by the action filter and action method:

  ```
  dbug: ClientIpSafelistComponents.Filters.ClientIpCheckActionFilter[0]
        Remote IpAddress: ::1
  dbug: ClientIpAspNetCore.Controllers.ValuesController[0]
        successful HTTP GET
  ```

- An HTTP request verb other than GET, the `AdminSafeListMiddleware` middleware validates the client IP address.

Razor Pages filter

If you want safelist-driven access control for a Razor Pages app, use a Razor Pages filter. For example:

```
public class ClientIpCheckPageFilter : IPageFilter
{
    private readonly ILogger _logger;
    private readonly string _safelist;

    public ClientIpCheckPageFilter(
        string safelist,
        ILogger logger)
    {
        _safelist = safelist;
        _logger = logger;
    }

    public void OnPageHandlerExecuting(PageHandlerExecutingContext context)
    {
        var remoteIp = context.HttpContext.Connection.RemoteIpAddress;
        _logger.LogDebug(
            "Remote IpAddress: {RemoteIp}", remoteIp);

        string[] ip = _safelist.Split(';');

        var badIp = true;
        foreach (var address in ip)
        {
            if (remoteIp.IsIPv4MappedToIPv6)
            {
                remoteIp = remoteIp.MapToIPv4();
            }
            var testIp = IPAddress.Parse(address);
            if (testIp.Equals(remoteIp))
            {
                badIp = false;
                break;
            }
        }

        if (badIp)
        {
            _logger.LogWarning(
                "Forbidden Request from Remote IP address: {RemoteIp}", remoteIp);
            context.Result = new StatusCodeResult(StatusCodes.Status403Forbidden);
            return;
        }
    }

    public void OnPageHandlerExecuted(PageHandlerExecutedContext context)
    {
    }

    public void OnPageHandlerSelected(PageHandlerSelectedContext context)
    {
    }
}
```

In `Startup.ConfigureServices`, enable the Razor Pages filter by adding it to the MVC filters collection. In the following example, a `ClientIpCheckPageFilter` Razor Pages filter is added. A safelist and a console logger instance are passed as constructor parameters.

```
services.AddRazorPages()
    .AddMvcOptions(options =>
    {
        var logger = LoggerFactory.Create(builder => builder.AddConsole())
                        .CreateLogger<ClientIpCheckPageFilter>();
        var filter = new ClientIpCheckPageFilter(
            Configuration["AdminSafeList"], logger);

        options.Filters.Add(filter);
    });
```

```
services.AddMvc(options =>
{
    var logger = _loggerFactory.CreateLogger<ClientIpCheckPageFilter>();
    var clientIpCheckPageFilter = new ClientIpCheckPageFilter(
        Configuration["AdminSafeList"], logger);

    options.Filters.Add(clientIpCheckPageFilter);
}).SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
```

When the sample app's *Index* Razor page is requested, the Razor Pages filter validates the client IP address. The filter produces a variation of the following console output:

```
dbug: ClientIpSafelistComponents.Filters.ClientIpCheckPageFilter[0]
      Remote IpAddress: ::1
```

ASP.NET Core Performance Best Practices

9/22/2020 • 17 minutes to read • Edit Online

By Mike Rousos

This article provides guidelines for performance best practices with ASP.NET Core.

Cache aggressively

Caching is discussed in several parts of this document. For more information, see Response caching in ASP.NET Core.

Understand hot code paths

In this document, a *hot code path* is defined as a code path that is frequently called and where much of the execution time occurs. Hot code paths typically limit app scale-out and performance and are discussed in several parts of this document.

Avoid blocking calls

ASP.NET Core apps should be designed to process many requests simultaneously. Asynchronous APIs allow a small pool of threads to handle thousands of concurrent requests by not waiting on blocking calls. Rather than waiting on a long-running synchronous task to complete, the thread can work on another request.

A common performance problem in ASP.NET Core apps is blocking calls that could be asynchronous. Many synchronous blocking calls lead to Thread Pool starvation and degraded response times.

Do not:

- Block asynchronous execution by calling Task.Wait or Task.Result.
- Acquire locks in common code paths. ASP.NET Core apps are most performant when architected to run code in parallel.
- Call Task.Run and immediately await it. ASP.NET Core already runs app code on normal Thread Pool threads, so calling Task.Run only results in extra unnecessary Thread Pool scheduling. Even if the scheduled code would block a thread, Task.Run does not prevent that.

Do:

- Make hot code paths asynchronous.
- Call data access, I/O, and long-running operations APIs asynchronously if an asynchronous API is available. Do **not** use Task.Run to make a synchronous API asynchronous.
- Make controller/Razor Page actions asynchronous. The entire call stack is asynchronous in order to benefit from async/await patterns.

A profiler, such as PerfView, can be used to find threads frequently added to the Thread Pool. The `Microsoft-Windows-DotNETRuntime/ThreadPoolWorkerThread/Start` event indicates a thread added to the thread pool.

Return IEnumerable<T> or IAsyncEnumerable<T>

Returning `IEnumerable<T>` from an action results in synchronous collection iteration by the serializer. The result is the blocking of calls and a potential for thread pool starvation. To avoid synchronous enumeration, use

`ToListAsync` before returning the enumerable.

Beginning with ASP.NET Core 3.0, `IAsyncEnumerable<T>` can be used as an alternative to `IEnumerable<T>` that enumerates asynchronously. For more information, see Controller action return types.

Minimize large object allocations

The .NET Core garbage collector manages allocation and release of memory automatically in ASP.NET Core apps. Automatic garbage collection generally means that developers don't need to worry about how or when memory is freed. However, cleaning up unreferenced objects takes CPU time, so developers should minimize allocating objects in hot code paths. Garbage collection is especially expensive on large objects (> 85 K bytes). Large objects are stored on the large object heap and require a full (generation 2) garbage collection to clean up. Unlike generation 0 and generation 1 collections, a generation 2 collection requires a temporary suspension of app execution. Frequent allocation and de-allocation of large objects can cause inconsistent performance.

Recommendations:

- **Do** consider caching large objects that are frequently used. Caching large objects prevents expensive allocations.
- **Do** pool buffers by using an ArrayPool<T> to store large arrays.
- **Do not** allocate many, short-lived large objects on hot code paths.

Memory issues, such as the preceding, can be diagnosed by reviewing garbage collection (GC) stats in PerfView and examining:

- Garbage collection pause time.
- What percentage of the processor time is spent in garbage collection.
- How many garbage collections are generation 0, 1, and 2.

For more information, see Garbage Collection and Performance.

Optimize data access and I/O

Interactions with a data store and other remote services are often the slowest parts of an ASP.NET Core app. Reading and writing data efficiently is critical for good performance.

Recommendations:

- **Do** call all data access APIs asynchronously.
- **Do not** retrieve more data than is necessary. Write queries to return just the data that's necessary for the current HTTP request.
- **Do** consider caching frequently accessed data retrieved from a database or remote service if slightly out-of-date data is acceptable. Depending on the scenario, use a MemoryCache or a DistributedCache. For more information, see Response caching in ASP.NET Core.
- **Do** minimize network round trips. The goal is to retrieve the required data in a single call rather than several calls.
- **Do** use no-tracking queries in Entity Framework Core when accessing data for read-only purposes. EF Core can return the results of no-tracking queries more efficiently.
- **Do** filter and aggregate LINQ queries (with `.Where`, `.Select`, or `.Sum` statements, for example) so that the filtering is performed by the database.
- **Do** consider that EF Core resolves some query operators on the client, which may lead to inefficient query execution. For more information, see Client evaluation performance issues.
- **Do not** use projection queries on collections, which can result in executing "N + 1" SQL queries. For more information, see Optimization of correlated subqueries.

See EF High Performance for approaches that may improve performance in high-scale apps:

- DbContext pooling
- Explicitly compiled queries

We recommend measuring the impact of the preceding high-performance approaches before committing the code base. The additional complexity of compiled queries may not justify the performance improvement.

Query issues can be detected by reviewing the time spent accessing data with Application Insights or with profiling tools. Most databases also make statistics available concerning frequently executed queries.

Pool HTTP connections with HttpClientFactory

Although HttpClient implements the `IDisposable` interface, it's designed for reuse. Closed `HttpClient` instances leave sockets open in the `TIME_WAIT` state for a short period of time. If a code path that creates and disposes of `HttpClient` objects is frequently used, the app may exhaust available sockets. HttpClientFactory was introduced in ASP.NET Core 2.1 as a solution to this problem. It handles pooling HTTP connections to optimize performance and reliability.

Recommendations:

- **Do not** create and dispose of `HttpClient` instances directly.
- **Do** use HttpClientFactory to retrieve `HttpClient` instances. For more information, see Use HttpClientFactory to implement resilient HTTP requests.

Keep common code paths fast

You want all of your code to be fast. Frequently-called code paths are the most critical to optimize. These include:

- Middleware components in the app's request processing pipeline, especially middleware run early in the pipeline. These components have a large impact on performance.
- Code that's executed for every request or multiple times per request. For example, custom logging, authorization handlers, or initialization of transient services.

Recommendations:

- **Do not** use custom middleware components with long-running tasks.
- **Do** use performance profiling tools, such as Visual Studio Diagnostic Tools or PerfView), to identify hot code paths.

Complete long-running Tasks outside of HTTP requests

Most requests to an ASP.NET Core app can be handled by a controller or page model calling necessary services and returning an HTTP response. For some requests that involve long-running tasks, it's better to make the entire request-response process asynchronous.

Recommendations:

- **Do not** wait for long-running tasks to complete as part of ordinary HTTP request processing.
- **Do** consider handling long-running requests with background services or out of process with an Azure Function. Completing work out-of-process is especially beneficial for CPU-intensive tasks.
- **Do** use real-time communication options, such as SignalR, to communicate with clients asynchronously.

Minify client assets

ASP.NET Core apps with complex front-ends frequently serve many JavaScript, CSS, or image files. Performance of

initial load requests can be improved by:

- Bundling, which combines multiple files into one.
- Minifying, which reduces the size of files by removing whitespace and comments.

Recommendations:

- **Do** use ASP.NET Core's built-in support for bundling and minifying client assets.
- **Do** consider other third-party tools, such as Webpack, for complex client asset management.

Compress responses

Reducing the size of the response usually increases the responsiveness of an app, often dramatically. One way to reduce payload sizes is to compress an app's responses. For more information, see Response compression.

Use the latest ASP.NET Core release

Each new release of ASP.NET Core includes performance improvements. Optimizations in .NET Core and ASP.NET Core mean that newer versions generally outperform older versions. For example, .NET Core 2.1 added support for compiled regular expressions and benefitted from Span<T>. ASP.NET Core 2.2 added support for HTTP/2. ASP.NET Core 3.0 adds many improvements that reduce memory usage and improve throughput. If performance is a priority, consider upgrading to the current version of ASP.NET Core.

Minimize exceptions

Exceptions should be rare. Throwing and catching exceptions is slow relative to other code flow patterns. Because of this, exceptions shouldn't be used to control normal program flow.

Recommendations:

- **Do not** use throwing or catching exceptions as a means of normal program flow, especially in hot code paths.
- **Do** include logic in the app to detect and handle conditions that would cause an exception.
- **Do** throw or catch exceptions for unusual or unexpected conditions.

App diagnostic tools, such as Application Insights, can help to identify common exceptions in an app that may affect performance.

Performance and reliability

The following sections provide performance tips and known reliability problems and solutions.

Avoid synchronous read or write on HttpRequest/HttpResponse body

All I/O in ASP.NET Core is asynchronous. Servers implement the `Stream` interface, which has both synchronous and asynchronous overloads. The asynchronous ones should be preferred to avoid blocking thread pool threads. Blocking threads can lead to thread pool starvation.

Do not do this: The following example uses the ReadToEnd. It blocks the current thread to wait for the result. This is an example of sync over async.

```
public class BadStreamReaderController : Controller
{
    [HttpGet("/contoso")]
    public ActionResult<ContosoData> Get()
    {
        var json = new StreamReader(Request.Body).ReadToEnd();

        return JsonSerializer.Deserialize<ContosoData>(json);
    }
}
```

In the preceding code, `Get` synchronously reads the entire HTTP request body into memory. If the client is slowly uploading, the app is doing sync over async. The app does sync over async because Kestrel does **NOT** support synchronous reads.

Do this: The following example uses ReadToEndAsync and does not block the thread while reading.

```
public class GoodStreamReaderController : Controller
{
    [HttpGet("/contoso")]
    public async Task<ActionResult<ContosoData>> Get()
    {
        var json = await new StreamReader(Request.Body).ReadToEndAsync();

        return JsonSerializer.Deserialize<ContosoData>(json);
    }

}
```

The preceding code asynchronously reads the entire HTTP request body into memory.

> **WARNING**
> If the request is large, reading the entire HTTP request body into memory could lead to an out of memory (OOM) condition. OOM can result in a Denial Of Service. For more information, see Avoid reading large request bodies or response bodies into memory in this document.

Do this: The following example is fully asynchronous using a non buffered request body:

```
public class GoodStreamReaderController : Controller
{
    [HttpGet("/contoso")]
    public async Task<ActionResult<ContosoData>> Get()
    {
        return await JsonSerializer.DeserializeAsync<ContosoData>(Request.Body);
    }
}
```

The preceding code asynchronously de-serializes the request body into a C# object.

Prefer ReadFormAsync over Request.Form

Use `HttpContext.Request.ReadFormAsync` instead of `HttpContext.Request.Form`. `HttpContext.Request.Form` can be safely read only with the following conditions:

- The form has been read by a call to `ReadFormAsync`, and
- The cached form value is being read using `HttpContext.Request.Form`

Do not do this: The following example uses `HttpContext.Request.Form`. `HttpContext.Request.Form` uses sync over async and can lead to thread pool starvation.

```
public class BadReadController : Controller
{
    [HttpPost("/form-body")]
    public IActionResult Post()
    {
        var form =  HttpContext.Request.Form;

        Process(form["id"], form["name"]);

        return Accepted();
    }
```

Do this: The following example uses `HttpContext.Request.ReadFormAsync` to read the form body asynchronously.

```
public class GoodReadController : Controller
{
    [HttpPost("/form-body")]
    public async Task<IActionResult> Post()
    {
       var form = await HttpContext.Request.ReadFormAsync();

        Process(form["id"], form["name"]);

        return Accepted();
    }
```

Avoid reading large request bodies or response bodies into memory

In .NET, every object allocation greater than 85 KB ends up in the large object heap (LOH). Large objects are expensive in two ways:

- The allocation cost is high because the memory for a newly allocated large object has to be cleared. The CLR guarantees that memory for all newly allocated objects is cleared.
- LOH is collected with the rest of the heap. LOH requires a full garbage collection or Gen2 collection.

This blog post describes the problem succinctly:

> When a large object is allocated, it's marked as Gen 2 object. Not Gen 0 as for small objects. The consequences are that if you run out of memory in LOH, GC cleans up the whole managed heap, not only LOH. So it cleans up Gen 0, Gen 1 and Gen 2 including LOH. This is called full garbage collection and is the most time-consuming garbage collection. For many applications, it can be acceptable. But definitely not for high-performance web servers, where few big memory buffers are needed to handle an average web request (read from a socket, decompress, decode JSON & more).

Naively storing a large request or response body into a single `byte[]` or `string`:

- May result in quickly running out of space in the LOH.
- May cause performance issues for the app because of full GCs running.

Working with a synchronous data processing API

When using a serializer/de-serializer that only supports synchronous reads and writes (for example, JSON.NET):

- Buffer the data into memory asynchronously before passing it into the serializer/de-serializer.

> **WARNING**
> If the request is large, it could lead to an out of memory (OOM) condition. OOM can result in a Denial Of Service. For more information, see Avoid reading large request bodies or response bodies into memory in this document.

ASP.NET Core 3.0 uses System.Text.Json by default for JSON serialization. System.Text.Json:

- Reads and writes JSON asynchronously.
- Is optimized for UTF-8 text.
- Typically higher performance than `Newtonsoft.Json`.

Do not store IHttpContextAccessor.HttpContext in a field

The IHttpContextAccessor.HttpContext returns the `HttpContext` of the active request when accessed from the request thread. The `IHttpContextAccessor.HttpContext` should **not** be stored in a field or variable.

Do not do this: The following example stores the `HttpContext` in a field and then attempts to use it later.

```
public class MyBadType
{
    private readonly HttpContext _context;
    public MyBadType(IHttpContextAccessor accessor)
    {
        _context = accessor.HttpContext;
    }

    public void CheckAdmin()
    {
        if (!_context.User.IsInRole("admin"))
        {
            throw new UnauthorizedAccessException("The current user isn't an admin");
        }
    }
}
```

The preceding code frequently captures a null or incorrect `HttpContext` in the constructor.

Do this: The following example:

- Stores the IHttpContextAccessor in a field.
- Uses the `HttpContext` field at the correct time and checks for `null`.

```
public class MyGoodType
{
    private readonly IHttpContextAccessor _accessor;
    public MyGoodType(IHttpContextAccessor accessor)
    {
        _accessor = accessor;
    }

    public void CheckAdmin()
    {
        var context = _accessor.HttpContext;
        if (context != null && !context.User.IsInRole("admin"))
        {
            throw new UnauthorizedAccessException("The current user isn't an admin");
        }
    }
}
```

Do not access HttpContext from multiple threads

`HttpContext` is *NOT* thread-safe. Accessing `HttpContext` from multiple threads in parallel can result in undefined behavior such as hangs, crashes, and data corruption.

Do not do this: The following example makes three parallel requests and logs the incoming request path before and after the outgoing HTTP request. The request path is accessed from multiple threads, potentially in parallel.

```
public class AsyncBadSearchController : Controller
{
    [HttpGet("/search")]
    public async Task<SearchResults> Get(string query)
    {
        var query1 = SearchAsync(SearchEngine.Google, query);
        var query2 = SearchAsync(SearchEngine.Bing, query);
        var query3 = SearchAsync(SearchEngine.DuckDuckGo, query);

        await Task.WhenAll(query1, query2, query3);

        var results1 = await query1;
        var results2 = await query2;
        var results3 = await query3;

        return SearchResults.Combine(results1, results2, results3);
    }

    private async Task<SearchResults> SearchAsync(SearchEngine engine, string query)
    {
        var searchResults = _searchService.Empty();
        try
        {
            _logger.LogInformation("Starting search query from {path}.",
                                   HttpContext.Request.Path);
            searchResults = _searchService.Search(engine, query);
            _logger.LogInformation("Finishing search query from {path}.",
                                   HttpContext.Request.Path);
        }
        catch (Exception ex)
        {
            _logger.LogError(ex, "Failed query from {path}",
                             HttpContext.Request.Path);
        }

        return await searchResults;
    }
```

Do this: The following example copies all data from the incoming request before making the three parallel requests.

```
public class AsyncGoodSearchController : Controller
{
    [HttpGet("/search")]
    public async Task<SearchResults> Get(string query)
    {
        string path = HttpContext.Request.Path;
        var query1 = SearchAsync(SearchEngine.Google, query,
                                 path);
        var query2 = SearchAsync(SearchEngine.Bing, query, path);
        var query3 = SearchAsync(SearchEngine.DuckDuckGo, query, path);

        await Task.WhenAll(query1, query2, query3);

        var results1 = await query1;
        var results2 = await query2;
        var results3 = await query3;

        return SearchResults.Combine(results1, results2, results3);
    }

    private async Task<SearchResults> SearchAsync(SearchEngine engine, string query,
                                                  string path)
    {
        var searchResults = _searchService.Empty();
        try
        {
            _logger.LogInformation("Starting search query from {path}.",
                                   path);
            searchResults = await _searchService.SearchAsync(engine, query);
            _logger.LogInformation("Finishing search query from {path}.", path);
        }
        catch (Exception ex)
        {
            _logger.LogError(ex, "Failed query from {path}", path);
        }

        return await searchResults;
    }
```

Do not use the HttpContext after the request is complete

`HttpContext` is only valid as long as there is an active HTTP request in the ASP.NET Core pipeline. The entire ASP.NET Core pipeline is an asynchronous chain of delegates that executes every request. When the `Task` returned from this chain completes, the `HttpContext` is recycled.

Do not do this: The following example uses `async void` which makes the HTTP request complete when the first `await` is reached:

- Which is **ALWAYS** a bad practice in ASP.NET Core apps.
- Accesses the `HttpResponse` after the HTTP request is complete.
- Crashes the process.

```
public class AsyncBadVoidController : Controller
{
    [HttpGet("/async")]
    public async void Get()
    {
        await Task.Delay(1000);

        // The following line will crash the process because of writing after the
        // response has completed on a background thread. Notice async void Get()

        await Response.WriteAsync("Hello World");
    }
}
```

Do this: The following example returns a `Task` to the framework, so the HTTP request doesn't complete until the action completes.

```
public class AsyncGoodTaskController : Controller
{
    [HttpGet("/async")]
    public async Task Get()
    {
        await Task.Delay(1000);

        await Response.WriteAsync("Hello World");
    }
}
```

Do not capture the HttpContext in background threads

Do not do this: The following example shows a closure is capturing the `HttpContext` from the `Controller` property. This is a bad practice because the work item could:

- Run outside of the request scope.
- Attempt to read the wrong `HttpContext`.

```
[HttpGet("/fire-and-forget-1")]
public IActionResult BadFireAndForget()
{
    _ = Task.Run(async () =>
    {
        await Task.Delay(1000);

        var path = HttpContext.Request.Path;
        Log(path);
    });

    return Accepted();
}
```

Do this: The following example:

- Copies the data required in the background task during the request.
- Doesn't reference anything from the controller.

```
[HttpGet("/fire-and-forget-3")]
public IActionResult GoodFireAndForget()
{
    string path = HttpContext.Request.Path;
    _ = Task.Run(async () =>
    {
        await Task.Delay(1000);

        Log(path);
    });

    return Accepted();
}
```

Background tasks should be implemented as hosted services. For more information, see Background tasks with hosted services.

Do not capture services injected into the controllers on background threads

Do not do this: The following example shows a closure is capturing the `DbContext` from the `Controller` action parameter. This is a bad practice. The work item could run outside of the request scope. The `ContosoDbContext` is scoped to the request, resulting in an `ObjectDisposedException`.

```
[HttpGet("/fire-and-forget-1")]
public IActionResult FireAndForget1([FromServices]ContosoDbContext context)
{
    _ = Task.Run(async () =>
    {
        await Task.Delay(1000);

        context.Contoso.Add(new Contoso());
        await context.SaveChangesAsync();
    });

    return Accepted();
}
```

Do this: The following example:

- Injects an IServiceScopeFactory in order to create a scope in the background work item. `IServiceScopeFactory` is a singleton.
- Creates a new dependency injection scope in the background thread.
- Doesn't reference anything from the controller.
- Doesn't capture the `ContosoDbContext` from the incoming request.

```
[HttpGet("/fire-and-forget-3")]
public IActionResult FireAndForget3([FromServices]IServiceScopeFactory
                                    serviceScopeFactory)
{
    _ = Task.Run(async () =>
    {
        await Task.Delay(1000);

        using (var scope = serviceScopeFactory.CreateScope())
        {
            var context = scope.ServiceProvider.GetRequiredService<ContosoDbContext>();

            context.Contoso.Add(new Contoso());

            await context.SaveChangesAsync();
        }
    });

    return Accepted();
}
```

The following highlighted code:

- Creates a scope for the lifetime of the background operation and resolves services from it.
- Uses `ContosoDbContext` from the correct scope.

```
[HttpGet("/fire-and-forget-3")]
public IActionResult FireAndForget3([FromServices]IServiceScopeFactory
                                    serviceScopeFactory)
{
    _ = Task.Run(async () =>
    {
        await Task.Delay(1000);

        using (var scope = serviceScopeFactory.CreateScope())
        {
            var context = scope.ServiceProvider.GetRequiredService<ContosoDbContext>();

            context.Contoso.Add(new Contoso());

            await context.SaveChangesAsync();
        }
    });

    return Accepted();
}
```

Do not modify the status code or headers after the response body has started

ASP.NET Core does not buffer the HTTP response body. The first time the response is written:

- The headers are sent along with that chunk of the body to the client.
- It's no longer possible to change response headers.

Do not do this: The following code tries to add response headers after the response has already started:

```
app.Use(async (context, next) =>
{
    await next();

    context.Response.Headers["test"] = "test value";
});
```

In the preceding code, `context.Response.Headers["test"] = "test value";` will throw an exception if `next()` has written to the response.

Do this: The following example checks if the HTTP response has started before modifying the headers.

```
app.Use(async (context, next) =>
{
    await next();

    if (!context.Response.HasStarted)
    {
        context.Response.Headers["test"] = "test value";
    }
});
```

Do this: The following example uses `HttpResponse.OnStarting` to set the headers before the response headers are flushed to the client.

Checking if the response has not started allows registering a callback that will be invoked just before response headers are written. Checking if the response has not started:

- Provides the ability to append or override headers just in time.
- Doesn't require knowledge of the next middleware in the pipeline.

```
app.Use(async (context, next) =>
{
    context.Response.OnStarting(() =>
    {
        context.Response.Headers["someheader"] = "somevalue";
        return Task.CompletedTask;
    });

    await next();
});
```

Do not call next() if you have already started writing to the response body

Components only expect to be called if it's possible for them to handle and manipulate the response.

Use In-process hosting with IIS

Using in-process hosting, an ASP.NET Core app runs in the same process as its IIS worker process. In-process hosting provides improved performance over out-of-process hosting because requests aren't proxied over the loopback adapter. The loopback adapter is a network interface that returns outgoing network traffic back to the same machine. IIS handles process management with the Windows Process Activation Service (WAS).

Projects default to the in-process hosting model in ASP.NET Core 3.0 and later.

For more information, see Host ASP.NET Core on Windows with IIS

Memory management and garbage collection (GC) in ASP.NET Core

9/22/2020 • 12 minutes to read • Edit Online

By Sébastien Ros and Rick Anderson

Memory management is complex, even in a managed framework like .NET. Analyzing and understanding memory issues can be challenging. This article:

- Was motivated by many *memory leak* and *GC not working* issues. Most of these issues were caused by not understanding how memory consumption works in .NET Core, or not understanding how it's measured.
- Demonstrates problematic memory use, and suggests alternative approaches.

How garbage collection (GC) works in .NET Core

The GC allocates heap segments where each segment is a contiguous range of memory. Objects placed in the heap are categorized into one of 3 generations: 0, 1, or 2. The generation determines the frequency the GC attempts to release memory on managed objects that are no longer referenced by the app. Lower numbered generations are GC'd more frequently.

Objects are moved from one generation to another based on their lifetime. As objects live longer, they are moved into a higher generation. As mentioned previously, higher generations are GC'd less often. Short term lived objects always remain in generation 0. For example, objects that are referenced during the life of a web request are short lived. Application level singletons generally migrate to generation 2.

When an ASP.NET Core app starts, the GC:

- Reserves some memory for the initial heap segments.
- Commits a small portion of memory when the runtime is loaded.

The preceding memory allocations are done for performance reasons. The performance benefit comes from heap segments in contiguous memory.

Call GC.Collect

Calling GC.Collect explicitly:

- Should **not** be done by production ASP.NET Core apps.
- Is useful when investigating memory leaks.
- When investigating, verifies the GC has removed all dangling objects from memory so memory can be measured.

Analyzing the memory usage of an app

Dedicated tools can help analyzing memory usage:

- Counting object references
- Measuring how much impact the GC has on CPU usage
- Measuring memory space used for each generation

Use the following tools to analyze memory usage:

- dotnet-trace: Can be used on production machines.

- Analyze memory usage without the Visual Studio debugger
- Profile memory usage in Visual Studio

Detecting memory issues

Task Manager can be used to get an idea of how much memory an ASP.NET app is using. The Task Manager memory value:

- Represents the amount of memory that is used by the ASP.NET process.
- Includes the app's living objects and other memory consumers such as native memory usage.

If the Task Manager memory value increases indefinitely and never flattens out, the app has a memory leak. The following sections demonstrate and explain several memory usage patterns.

Sample display memory usage app

The MemoryLeak sample app is available on GitHub. The MemoryLeak app:

- Includes a diagnostic controller that gathers real-time memory and GC data for the app.
- Has an Index page that displays the memory and GC data. The Index page is refreshed every second.
- Contains an API controller that provides various memory load patterns.
- Is not a supported tool, however, it can be used to display memory usage patterns of ASP.NET Core apps.

Run MemoryLeak. Allocated memory slowly increases until a GC occurs. Memory increases because the tool allocates custom object to capture data. The following image shows the MemoryLeak Index page when a Gen 0 GC occurs. The chart shows 0 RPS (Requests per second) because no API endpoints from the API controller have been called.

The chart displays two values for the memory usage:

- Allocated: the amount of memory occupied by managed objects
- Working set: The set of pages in the virtual address space of the process that are currently resident in physical memory. The working set shown is the same value Task Manager displays.

Transient objects

The following API creates a 10-KB String instance and returns it to the client. On each request, a new object is

allocated in memory and written to the response. Strings are stored as UTF-16 characters in .NET so each character takes 2 bytes in memory.

```
[HttpGet("bigstring")]
public ActionResult<string> GetBigString()
{
    return new String('x', 10 * 1024);
}
```

The following graph is generated with a relatively small load in to show how memory allocations are impacted by the GC.

The preceding chart shows:

- 4K RPS (Requests per second).
- Generation 0 GC collections occur about every two seconds.
- The working set is constant at approximately 500 MB.
- CPU is 12%.
- The memory consumption and release (through GC) is stable.

The following chart is taken at the max throughput that can be handled by the machine.

The preceding chart shows:

- 22K RPS
- Generation 0 GC collections occur several times per second.
- Generation 1 collections are triggered because the app allocated significantly more memory per second.
- The working set is constant at approximately 500 MB.
- CPU is 33%.
- The memory consumption and release (through GC) is stable.
- The CPU (33%) is not over-utilized, therefore the garbage collection can keep up with a high number of allocations.

Workstation GC vs. Server GC

The .NET Garbage Collector has two different modes:

- **Workstation GC**: Optimized for the desktop.
- **Server GC**. The default GC for ASP.NET Core apps. Optimized for the server.

The GC mode can be set explicitly in the project file or in the *runtimeconfig.json* file of the published app. The following markup shows setting `ServerGarbageCollection` in the project file:

```
<PropertyGroup>
  <ServerGarbageCollection>true</ServerGarbageCollection>
</PropertyGroup>
```

Changing `ServerGarbageCollection` in the project file requires the app to be rebuilt.

Note: Server garbage collection is **not** available on machines with a single core. For more information, see IsServerGC.

The following image shows the memory profile under a 5K RPS using the Workstation GC.

The differences between this chart and the server version are significant:

- The working set drops from 500 MB to 70 MB.
- The GC does generation 0 collections multiple times per second instead of every two seconds.
- GC drops from 300 MB to 10 MB.

On a typical web server environment, CPU usage is more important than memory, therefore the Server GC is better. If memory utilization is high and CPU usage is relatively low, the Workstation GC might be more performant. For example, high density hosting several web apps where memory is scarce.

GC using Docker and small containers

When multiple containerized apps are running on one machine, Workstation GC might be more preformant than Server GC. For more information, see Running with Server GC in a Small Container and Running with Server GC in a Small Container Scenario Part 1 – Hard Limit for the GC Heap.

Persistent object references

The GC cannot free objects that are referenced. Objects that are referenced but no longer needed result in a memory leak. If the app frequently allocates objects and fails to free them after they are no longer needed, memory usage will increase over time.

The following API creates a 10-KB String instance and returns it to the client. The difference with the previous example is that this instance is referenced by a static member, which means it's never available for collection.

```
private static ConcurrentBag<string> _staticStrings = new ConcurrentBag<string>();

[HttpGet("staticstring")]
public ActionResult<string> GetStaticString()
{
    var bigString = new String('x', 10 * 1024);
    _staticStrings.Add(bigString);
    return bigString;
}
```

The preceding code:

- Is an example of a typical memory leak.
- With frequent calls, causes app memory to increases until the process crashes with an `OutOfMemory` exception.

In the preceding image:

- Load testing the `/api/staticstring` endpoint causes a linear increase in memory.
- The GC tries to free memory as the memory pressure grows, by calling a generation 2 collection.
- The GC cannot free the leaked memory. Allocated and working set increase with time.

Some scenarios, such as caching, require object references to be held until memory pressure forces them to be released. The WeakReference class can be used for this type of caching code. A `WeakReference` object is collected under memory pressures. The default implementation of IMemoryCache uses `WeakReference`.

Native memory

Some .NET Core objects rely on native memory. Native memory can **not** be collected by the GC. The .NET object using native memory must free it using native code.

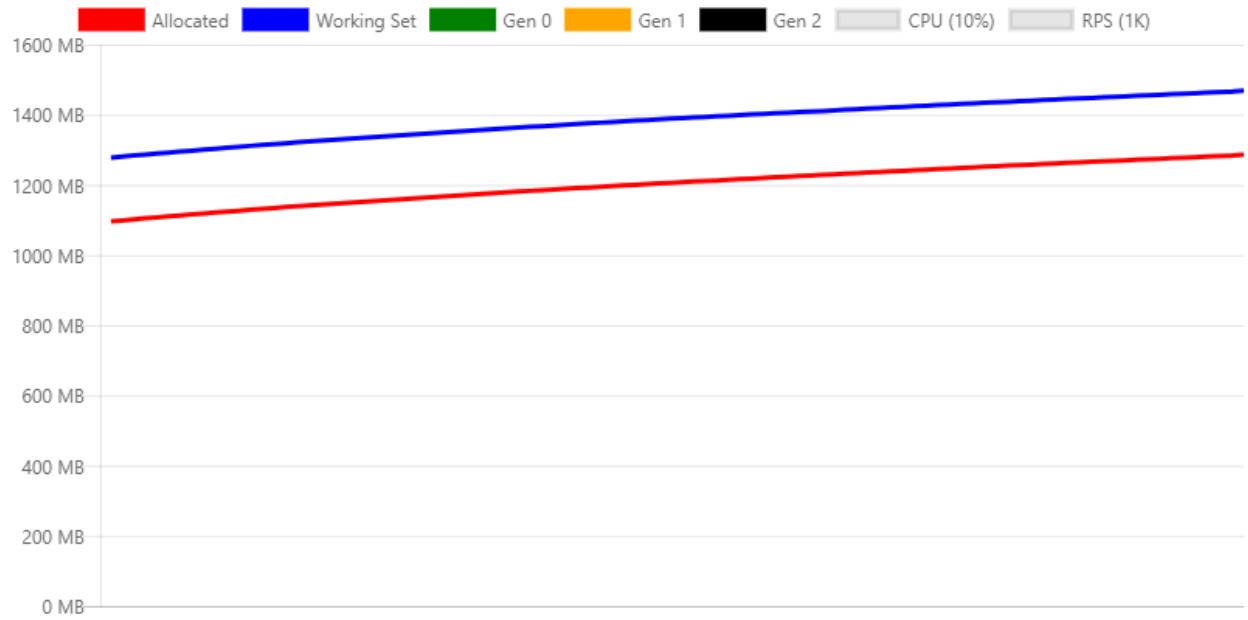
.NET provides the IDisposable interface to let developers release native memory. Even if Dispose is not called, correctly implemented classes call `Dispose` when the finalizer runs.

Consider the following code:

```
[HttpGet("fileprovider")]
public void GetFileProvider()
{
    var fp = new PhysicalFileProvider(TempPath);
    fp.Watch("*.*");
}
```

PhysicalFileProvider is a managed class, so any instance will be collected at the end of the request.

The following image shows the memory profile while invoking the `fileprovider` API continuously.



The preceding chart shows an obvious issue with the implementation of this class, as it keeps increasing memory usage. This is a known problem that is being tracked in this issue.

The same leak could be happen in user code, by one of the following:

- Not releasing the class correctly.
- Forgetting to invoke the `Dispose` method of the dependent objects that should be disposed.

Large objects heap

Frequent memory allocation/free cycles can fragment memory, especially when allocating large chunks of memory. Objects are allocated in contiguous blocks of memory. To mitigate fragmentation, when the GC frees memory, it tries to defragment it. This process is called **compaction**. Compaction involves moving objects. Moving large objects imposes a performance penalty. For this reason the GC creates a special memory zone for *large* objects, called the large object heap (LOH). Objects that are greater than 85,000 bytes (approximately 83 KB) are:

- Placed on the LOH.
- Not compacted.
- Collected during generation 2 GCs.

When the LOH is full, the GC will trigger a generation 2 collection. Generation 2 collections:

- Are inherently slow.
- Additionally incur the cost of triggering a collection on all other generations.

The following code compacts the LOH immediately:

```
GCSettings.LargeObjectHeapCompactionMode = GCLargeObjectHeapCompactionMode.CompactOnce;
GC.Collect();
```

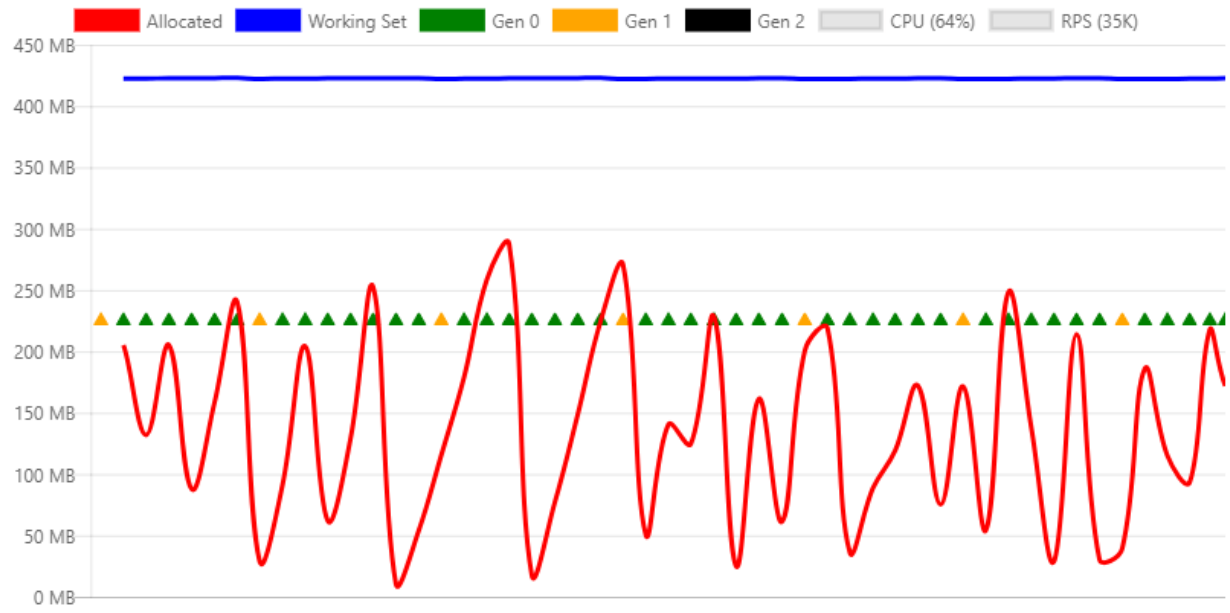
See LargeObjectHeapCompactionMode for information on compacting the LOH.

In containers using .NET Core 3.0 and later, the LOH is automatically compacted.

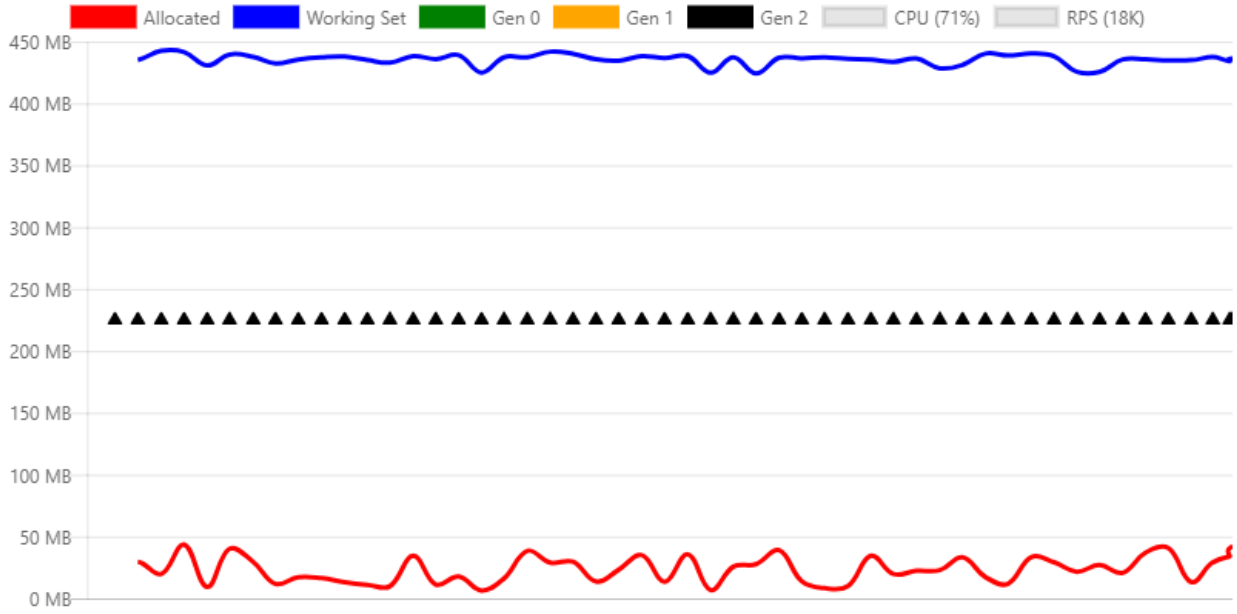
The following API that illustrates this behavior:

```
[HttpGet("loh/{size=85000}")]
public int GetLOH1(int size)
{
   return new byte[size].Length;
}
```

The following chart shows the memory profile of calling the `/api/loh/84975` endpoint, under maximum load:



The following chart shows the memory profile of calling the `/api/loh/84976` endpoint, allocating *just one more byte*:



Note: The `byte[]` structure has overhead bytes. That's why 84,976 bytes triggers the 85,000 limit.

Comparing the two preceding charts:

- The working set is similar for both scenarios, about 450 MB.
- The under LOH requests (84,975 bytes) shows mostly generation 0 collections.
- The over LOH requests generate constant generation 2 collections. Generation 2 collections are expensive. More CPU is required and throughput drops almost 50%.

Temporary large objects are particularly problematic because they cause gen2 GCs.

For maximum performance, large object use should be minimized. If possible, split up large objects. For example, Response Caching middleware in ASP.NET Core split the cache entries into blocks less than 85,000 bytes.

The following links show the ASP.NET Core approach to keeping objects under the LOH limit:

- ResponseCaching/Streams/StreamUtilities.cs
- ResponseCaching/MemoryResponseCache.cs

For more information, see:

- Large Object Heap Uncovered
- Large object heap

HttpClient

Incorrectly using HttpClient can result in a resource leak. System resources, such as database connections, sockets, file handles, etc.:

- Are more scarce than memory.
- Are more problematic when leaked than memory.

Experienced .NET developers know to call Dispose on objects that implement IDisposable. Not disposing objects that implement `IDisposable` typically results in leaked memory or leaked system resources.

`HttpClient` implements `IDisposable`, but should **not** be disposed on every invocation. Rather, `HttpClient` should be reused.

The following endpoint creates and disposes a new `HttpClient` instance on every request:

```
[HttpGet("httpclient1")]
public async Task<int> GetHttpClient1(string url)
{
    using (var httpClient = new HttpClient())
    {
        var result = await httpClient.GetAsync(url);
        return (int)result.StatusCode;
    }
}
```

Under load, the following error messages are logged:

```
fail: Microsoft.AspNetCore.Server.Kestrel[13]
      Connection id "0HLG70PBE1CR1", Request id "0HLG70PBE1CR1:00000031":
      An unhandled exception was thrown by the application.
System.Net.Http.HttpRequestException: Only one usage of each socket address
    (protocol/network address/port) is normally permitted --->
    System.Net.Sockets.SocketException: Only one usage of each socket address
    (protocol/network address/port) is normally permitted
   at System.Net.Http.ConnectHelper.ConnectAsync(String host, Int32 port,
    CancellationToken cancellationToken)
```

Even though the `HttpClient` instances are disposed, the actual network connection takes some time to be released by the operating system. By continuously creating new connections, *ports exhaustion* occurs. Each client connection requires its own client port.

One way to prevent port exhaustion is to reuse the same `HttpClient` instance:

```
private static readonly HttpClient _httpClient = new HttpClient();

[HttpGet("httpclient2")]
public async Task<int> GetHttpClient2(string url)
{
    var result = await _httpClient.GetAsync(url);
    return (int)result.StatusCode;
}
```

The `HttpClient` instance is released when the app stops. This example shows that not every disposable resource should be disposed after each use.

See the following for a better way to handle the lifetime of an `HttpClient` instance:

- HttpClient and lifetime management
- HTTPClient factory blog

Object pooling

The previous example showed how the `HttpClient` instance can be made static and reused by all requests. Reuse prevents running out of resources.

Object pooling:

- Uses the reuse pattern.
- Is designed for objects that are expensive to create.

A pool is a collection of pre-initialized objects that can be reserved and released across threads. Pools can define allocation rules such as limits, predefined sizes, or growth rate.

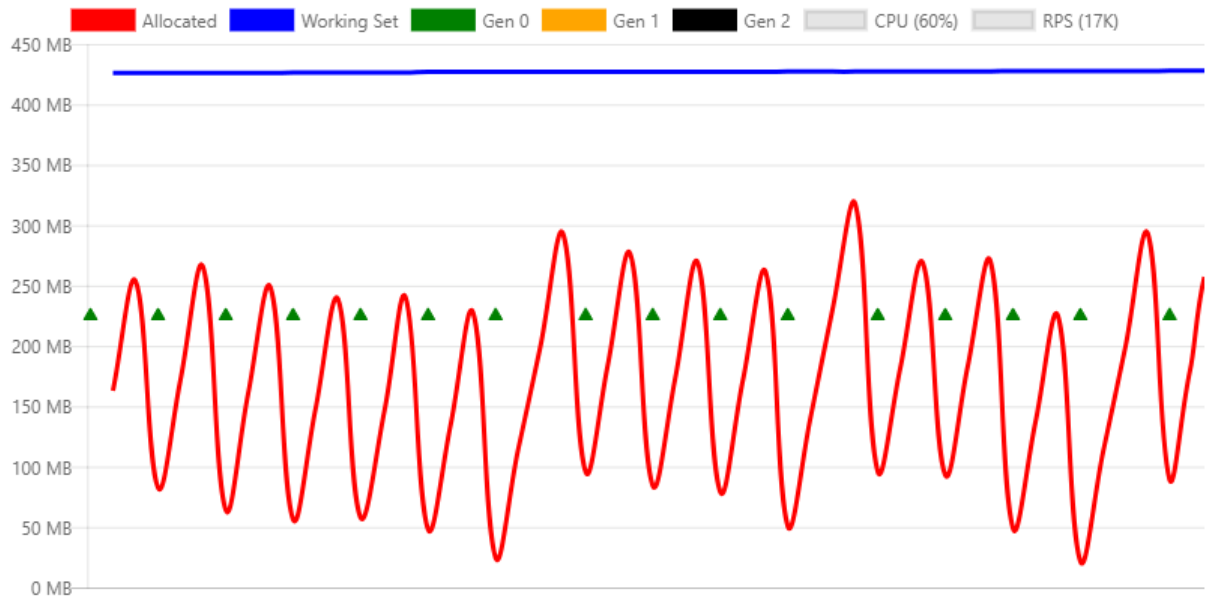
The NuGet package Microsoft.Extensions.ObjectPool contains classes that help to manage such pools.

The following API endpoint instantiates a `byte` buffer that is filled with random numbers on each request:

```
        [HttpGet("array/{size}")]
        public byte[] GetArray(int size)
        {
            var random = new Random();
            var array = new byte[size];
            random.NextBytes(array);

            return array;
        }
```

The following chart display calling the preceding API with moderate load:



In the preceding chart, generation 0 collections happen approximately once per second.

The preceding code can be optimized by pooling the `byte` buffer by using ArrayPool<T>. A static instance is reused across requests.

What's different with this approach is that a pooled object is returned from the API. That means:

- The object is out of your control as soon as you return from the method.
- You can't release the object.

To set up disposal of the object:

- Encapsulate the pooled array in a disposable object.
- Register the pooled object with HttpContext.Response.RegisterForDispose.

`RegisterForDispose` will take care of calling `Dispose` on the target object so that it's only released when the HTTP request is complete.

```
private static ArrayPool<byte> _arrayPool = ArrayPool<byte>.Create();

private class PooledArray : IDisposable
{
    public byte[] Array { get; private set; }

    public PooledArray(int size)
    {
        Array = _arrayPool.Rent(size);
    }

    public void Dispose()
    {
        _arrayPool.Return(Array);
    }
}

[HttpGet("pooledarray/{size}")]
public byte[] GetPooledArray(int size)
{
    var pooledArray = new PooledArray(size);

    var random = new Random();
    random.NextBytes(pooledArray.Array);

    HttpContext.Response.RegisterForDispose(pooledArray);

    return pooledArray.Array;
}
```

Applying the same load as the non-pooled version results in the following chart:

The main difference is allocated bytes, and as a consequence much fewer generation 0 collections.

Response caching in ASP.NET Core

9/22/2020 • 8 minutes to read • Edit Online

By John Luo, Rick Anderson, and Steve Smith

View or download sample code (how to download)

Response caching reduces the number of requests a client or proxy makes to a web server. Response caching also reduces the amount of work the web server performs to generate a response. Response caching is controlled by headers that specify how you want client, proxy, and middleware to cache responses.

The ResponseCache attribute participates in setting response caching headers. Clients and intermediate proxies should honor the headers for caching responses under the HTTP 1.1 Caching specification.

For server-side caching that follows the HTTP 1.1 Caching specification, use Response Caching Middleware. The middleware can use the ResponseCacheAttribute properties to influence server-side caching behavior.

HTTP-based response caching

The HTTP 1.1 Caching specification describes how Internet caches should behave. The primary HTTP header used for caching is Cache-Control, which is used to specify cache *directives*. The directives control caching behavior as requests make their way from clients to servers and as responses make their way from servers back to clients. Requests and responses move through proxy servers, and proxy servers must also conform to the HTTP 1.1 Caching specification.

Common `Cache-Control` directives are shown in the following table.

DIRECTIVE	ACTION
public	A cache may store the response.
private	The response must not be stored by a shared cache. A private cache may store and reuse the response.
max-age	The client doesn't accept a response whose age is greater than the specified number of seconds. Examples: `max-age=60` (60 seconds), `max-age=2592000` (1 month)
no-cache	**On requests**: A cache must not use a stored response to satisfy the request. The origin server regenerates the response for the client, and the middleware updates the stored response in its cache. **On responses**: The response must not be used for a subsequent request without validation on the origin server.
no-store	**On requests**: A cache must not store the request. **On responses**: A cache must not store any part of the response.

Other cache headers that play a role in caching are shown in the following table.

HEADER	FUNCTION
Age	An estimate of the amount of time in seconds since the response was generated or successfully validated at the origin server.
Expires	The time after which the response is considered stale.
Pragma	Exists for backwards compatibility with HTTP/1.0 caches for setting `no-cache` behavior. If the `Cache-Control` header is present, the `Pragma` header is ignored.
Vary	Specifies that a cached response must not be sent unless all of the `Vary` header fields match in both the cached response's original request and the new request.

HTTP-based caching respects request Cache-Control directives

The HTTP 1.1 Caching specification for the Cache-Control header requires a cache to honor a valid `Cache-Control` header sent by the client. A client can make requests with a `no-cache` header value and force the server to generate a new response for every request.

Always honoring client `Cache-Control` request headers makes sense if you consider the goal of HTTP caching. Under the official specification, caching is meant to reduce the latency and network overhead of satisfying requests across a network of clients, proxies, and servers. It isn't necessarily a way to control the load on an origin server.

There's no developer control over this caching behavior when using the Response Caching Middleware because the middleware adheres to the official caching specification. Planned enhancements to the middleware are an opportunity to configure the middleware to ignore a request's `Cache-Control` header when deciding to serve a cached response. Planned enhancements provide an opportunity to better control server load.

Other caching technology in ASP.NET Core

In-memory caching

In-memory caching uses server memory to store cached data. This type of caching is suitable for a single server or multiple servers using *sticky sessions*. Sticky sessions means that the requests from a client are always routed to the same server for processing.

For more information, see Cache in-memory in ASP.NET Core.

Distributed Cache

Use a distributed cache to store data in memory when the app is hosted in a cloud or server farm. The cache is shared across the servers that process requests. A client can submit a request that's handled by any server in the group if cached data for the client is available. ASP.NET Core works with SQL Server, Redis, and NCache distributed caches.

For more information, see Distributed caching in ASP.NET Core.

Cache Tag Helper

Cache the content from an MVC view or Razor Page with the Cache Tag Helper. The Cache Tag Helper uses in-memory caching to store data.

For more information, see Cache Tag Helper in ASP.NET Core MVC.

Distributed Cache Tag Helper

Cache the content from an MVC view or Razor Page in distributed cloud or web farm scenarios with the Distributed Cache Tag Helper. The Distributed Cache Tag Helper uses SQL Server, Redis, or NCache to store data.

For more information, see Distributed Cache Tag Helper in ASP.NET Core.

ResponseCache attribute

The ResponseCacheAttribute specifies the parameters necessary for setting appropriate headers in response caching.

> **WARNING**
> Disable caching for content that contains information for authenticated clients. Caching should only be enabled for content that doesn't change based on a user's identity or whether a user is signed in.

VaryByQueryKeys varies the stored response by the values of the given list of query keys. When a single value of `*` is provided, the middleware varies responses by all request query string parameters.

Response Caching Middleware must be enabled to set the VaryByQueryKeys property. Otherwise, a runtime exception is thrown. There isn't a corresponding HTTP header for the VaryByQueryKeys property. The property is an HTTP feature handled by Response Caching Middleware. For the middleware to serve a cached response, the query string and query string value must match a previous request. For example, consider the sequence of requests and results shown in the following table.

REQUEST	RESULT
`http://example.com?key1=value1`	Returned from the server.
`http://example.com?key1=value1`	Returned from middleware.
`http://example.com?key1=value2`	Returned from the server.

The first request is returned by the server and cached in middleware. The second request is returned by middleware because the query string matches the previous request. The third request isn't in the middleware cache because the query string value doesn't match a previous request.

The ResponseCacheAttribute is used to configure and create (via IFilterFactory) a `Microsoft.AspNetCore.Mvc.Internal.ResponseCacheFilter`. The `ResponseCacheFilter` performs the work of updating the appropriate HTTP headers and features of the response. The filter:

- Removes any existing headers for `Vary`, `Cache-Control`, and `Pragma`.
- Writes out the appropriate headers based on the properties set in the ResponseCacheAttribute.
- Updates the response caching HTTP feature if VaryByQueryKeys is set.

Vary

This header is only written when the VaryByHeader property is set. The property set to the `Vary` property's value. The following sample uses the VaryByHeader property:

```
[ResponseCache(VaryByHeader = "User-Agent", Duration = 30)]
public class Cache1Model : PageModel
{
```

Using the sample app, view the response headers with the browser's network tools. The following response

headers are sent with the Cache1 page response:

```
Cache-Control: public,max-age=30
Vary: User-Agent
```

NoStore and Location.None

NoStore overrides most of the other properties. When this property is set to `true`, the `Cache-Control` header is set to `no-store`. If Location is set to `None`:

- `Cache-Control` is set to `no-store,no-cache`.
- `Pragma` is set to `no-cache`.

If NoStore is `false` and Location is `None`, `Cache-Control`, and `Pragma` are set to `no-cache`.

NoStore is typically set to `true` for error pages. The Cache2 page in the sample app produces response headers that instruct the client not to store the response.

```
[ResponseCache(Duration = 0, Location = ResponseCacheLocation.None, NoStore = true)]
public class Cache2Model : PageModel
{
```

The sample app returns the Cache2 page with the following headers:

```
Cache-Control: no-store,no-cache
Pragma: no-cache
```

Location and Duration

To enable caching, Duration must be set to a positive value and Location must be either `Any` (the default) or `Client`. The framework sets the `Cache-Control` header to the location value followed by the `max-age` of the response.

Location's options of `Any` and `Client` translate into `Cache-Control` header values of `public` and `private`, respectively. As noted in the NoStore and Location.None section, setting Location to `None` sets both `Cache-Control` and `Pragma` headers to `no-cache`.

`Location.Any` (`Cache-Control` set to `public`) indicates that the *client or any intermediate proxy* may cache the value, including Response Caching Middleware.

`Location.Client` (`Cache-Control` set to `private`) indicates that *only the client* may cache the value. No intermediate cache should cache the value, including Response Caching Middleware.

Cache control headers merely provide guidance to clients and intermediary proxies when and how to cache responses. There's no guarantee that clients and proxies will honor the HTTP 1.1 Caching specification. Response Caching Middleware always follows the caching rules laid out by the specification.

The following example shows the Cache3 page model from the sample app and the headers produced by setting Duration and leaving the default Location value:

```
[ResponseCache(Duration = 10, Location = ResponseCacheLocation.Any, NoStore = false)]
public class Cache3Model : PageModel
{
```

The sample app returns the Cache3 page with the following header:

```
Cache-Control: public,max-age=10
```

Cache profiles

Instead of duplicating response cache settings on many controller action attributes, cache profiles can be configured as options when setting up MVC/Razor Pages in `Startup.ConfigureServices`. Values found in a referenced cache profile are used as the defaults by the ResponseCacheAttribute and are overridden by any properties specified on the attribute.

Set up a cache profile. The following example shows a 30 second cache profile in the sample app's `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();
    services.AddMvc(options =>
    {
        options.CacheProfiles.Add("Default30",
            new CacheProfile()
            {
                Duration = 30
            });
    });
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc(options =>
    {
        options.CacheProfiles.Add("Default30",
            new CacheProfile()
            {
                Duration = 30
            });
    }).SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

The sample app's Cache4 page model references the `Default30` cache profile:

```
[ResponseCache(CacheProfileName = "Default30")]
public class Cache4Model : PageModel
{
```

The ResponseCacheAttribute can be applied to:

- Razor Pages: Attributes can't be applied to handler methods.
- MVC controllers.
- MVC action methods: Method-level attributes override the settings specified in class-level attributes.

The resulting header applied to the Cache4 page response by the `Default30` cache profile:

```
Cache-Control: public,max-age=30

Cache in-memory in ASP.NET Core

9/22/2020 • 21 minutes to read • Edit Online

By Rick Anderson, John Luo, and Steve Smith

View or download sample code (how to download)

Caching basics

Caching can significantly improve the performance and scalability of an app by reducing the work required to generate content. Caching works best with data that changes infrequently **and** is expensive to generate. Caching makes a copy of data that can be returned much faster than from the source. Apps should be written and tested to **never** depend on cached data.

ASP.NET Core supports several different caches. The simplest cache is based on the IMemoryCache. `IMemoryCache` represents a cache stored in the memory of the web server. Apps running on a server farm (multiple servers) should ensure sessions are sticky when using the in-memory cache. Sticky sessions ensure that subsequent requests from a client all go to the same server. For example, Azure Web apps use Application Request Routing (ARR) to route all subsequent requests to the same server.

Non-sticky sessions in a web farm require a distributed cache to avoid cache consistency problems. For some apps, a distributed cache can support higher scale-out than an in-memory cache. Using a distributed cache offloads the cache memory to an external process.

The in-memory cache can store any object. The distributed cache interface is limited to `byte[]`. The in-memory and distributed cache store cache items as key-value pairs.

System.Runtime.Caching/MemoryCache

System.Runtime.Caching/MemoryCache (NuGet package) can be used with:

- .NET Standard 2.0 or later.
- Any .NET implementation that targets .NET Standard 2.0 or later. For example, ASP.NET Core 2.0 or later.
- .NET Framework 4.5 or later.

Microsoft.Extensions.Caching.Memory/ `IMemoryCache` (described in this article) is recommended over `System.Runtime.Caching` / `MemoryCache` because it's better integrated into ASP.NET Core. For example, `IMemoryCache` works natively with ASP.NET Core dependency injection.

Use `System.Runtime.Caching` / `MemoryCache` as a compatibility bridge when porting code from ASP.NET 4.x to ASP.NET Core.

Cache guidelines

- Code should always have a fallback option to fetch data and **not** depend on a cached value being available.
- The cache uses a scarce resource, memory. Limit cache growth:
  - Do **not** use external input as cache keys.
  - Use expirations to limit cache growth.
  - Use SetSize, Size, and SizeLimit to limit cache size. The ASP.NET Core runtime does **not** limit cache size based on memory pressure. It's up to the developer to limit cache size.

Use IMemoryCache

> **WARNING**
>
> Using a *shared* memory cache from Dependency Injection and calling `SetSize`, `Size`, or `SizeLimit` to limit cache size can cause the app to fail. When a size limit is set on a cache, all entries must specify a size when being added. This can lead to issues since developers may not have full control on what uses the shared cache. For example, Entity Framework Core uses the shared cache and does not specify a size. If an app sets a cache size limit and uses EF Core, the app throws an `InvalidOperationException`. When using `SetSize`, `Size`, or `SizeLimit` to limit cache, create a cache singleton for caching. For more information and an example, see Use SetSize, Size, and SizeLimit to limit cache size. A shared cache is one shared by other frameworks or libraries. For example, EF Core uses the shared cache and does not specify a size.

In-memory caching is a *service* that's referenced from an app using Dependency Injection. Request the `IMemoryCache` instance in the constructor:

```
public class HomeController : Controller
{
    private IMemoryCache _cache;

    public HomeController(IMemoryCache memoryCache)
    {
        _cache = memoryCache;
    }
```

The following code uses TryGetValue to check if a time is in the cache. If a time isn't cached, a new entry is created and added to the cache with Set. The `CacheKeys` class is part of the download sample.

```
public static class CacheKeys
{
    public static string Entry { get { return "_Entry"; } }
    public static string CallbackEntry { get { return "_Callback"; } }
    public static string CallbackMessage { get { return "_CallbackMessage"; } }
    public static string Parent { get { return "_Parent"; } }
    public static string Child { get { return "_Child"; } }
    public static string DependentMessage { get { return "_DependentMessage"; } }
    public static string DependentCTS { get { return "_DependentCTS"; } }
    public static string Ticks { get { return "_Ticks"; } }
    public static string CancelMsg { get { return "_CancelMsg"; } }
    public static string CancelTokenSource { get { return "_CancelTokenSource"; } }
}
```

```
public IActionResult CacheTryGetValueSet()
{
    DateTime cacheEntry;

    // Look for cache key.
    if (!_cache.TryGetValue(CacheKeys.Entry, out cacheEntry))
    {
        // Key not in cache, so get data.
        cacheEntry = DateTime.Now;

        // Set cache options.
        var cacheEntryOptions = new MemoryCacheEntryOptions()
            // Keep in cache for this time, reset time if accessed.
            .SetSlidingExpiration(TimeSpan.FromSeconds(3));

        // Save data in cache.
        _cache.Set(CacheKeys.Entry, cacheEntry, cacheEntryOptions);
    }

    return View("Cache", cacheEntry);
}
```

The current time and the cached time are displayed:

```
@model DateTime?

<div>
    <h2>Actions</h2>
    <ul>
        <li><a asp-controller="Home" asp-action="CacheTryGetValueSet">TryGetValue and Set</a></li>
        <li><a asp-controller="Home" asp-action="CacheGet">Get</a></li>
        <li><a asp-controller="Home" asp-action="CacheGetOrCreate">GetOrCreate</a></li>
        <li><a asp-controller="Home" asp-
action="CacheGetOrCreateAsynchronous">CacheGetOrCreateAsynchronous</a></li>
        <li><a asp-controller="Home" asp-action="CacheRemove">Remove</a></li>
        <li><a asp-controller="Home" asp-action="CacheGetOrCreateAbs">CacheGetOrCreateAbs</a></li>
        <li><a asp-controller="Home" asp-action="CacheGetOrCreateAbsSliding">CacheGetOrCreateAbsSliding</a>
</li>

    </ul>
</div>

<h3>Current Time: @DateTime.Now.TimeOfDay.ToString()</h3>
<h3>Cached Time: @(Model == null ? "No cached entry found" : Model.Value.TimeOfDay.ToString())</h3>
```

The cached `DateTime` value remains in the cache while there are requests within the timeout period.

The following code uses GetOrCreate and GetOrCreateAsync to cache data.

```
public IActionResult CacheGetOrCreate()
{
    var cacheEntry = _cache.GetOrCreate(CacheKeys.Entry, entry =>
    {
        entry.SlidingExpiration = TimeSpan.FromSeconds(3);
        return DateTime.Now;
    });

    return View("Cache", cacheEntry);
}

public async Task<IActionResult> CacheGetOrCreateAsynchronous()
{
    var cacheEntry = await
        _cache.GetOrCreateAsync(CacheKeys.Entry, entry =>
        {
            entry.SlidingExpiration = TimeSpan.FromSeconds(3);
            return Task.FromResult(DateTime.Now);
        });

    return View("Cache", cacheEntry);
}
```

The following code calls Get to fetch the cached time:

```
public IActionResult CacheGet()
{
    var cacheEntry = _cache.Get<DateTime?>(CacheKeys.Entry);
    return View("Cache", cacheEntry);
}
```

The following code gets or creates a cached item with absolute expiration:

```
public IActionResult CacheGetOrCreateAbs()
{
    var cacheEntry = _cache.GetOrCreate(CacheKeys.Entry, entry =>
    {
        entry.AbsoluteExpirationRelativeToNow = TimeSpan.FromSeconds(10);
        return DateTime.Now;
    });

    return View("Cache", cacheEntry);
}
```

A cached item set with a sliding expiration only is at risk of becoming stale. If it's accessed more frequently than the sliding expiration interval, the item will never expire. Combine a sliding expiration with an absolute expiration to guarantee that the item expires once its absolute expiration time passes. The absolute expiration sets an upper bound to how long the item can be cached while still allowing the item to expire earlier if it isn't requested within the sliding expiration interval. When both absolute and sliding expiration are specified, the expirations are logically ORed. If either the sliding expiration interval *or* the absolute expiration time pass, the item is evicted from the cache.

The following code gets or creates a cached item with both sliding *and* absolute expiration:

```
public IActionResult CacheGetOrCreateAbsSliding()
{
    var cacheEntry = _cache.GetOrCreate(CacheKeys.Entry, entry =>
    {
        entry.SetSlidingExpiration(TimeSpan.FromSeconds(3));
        entry.AbsoluteExpirationRelativeToNow = TimeSpan.FromSeconds(20);
        return DateTime.Now;
    });

    return View("Cache", cacheEntry);
}
```

The preceding code guarantees the data will not be cached longer than the absolute time.

GetOrCreate, GetOrCreateAsync, and Get are extension methods in the CacheExtensions class. These methods extend the capability of IMemoryCache.

MemoryCacheEntryOptions

The following sample:

- Sets a sliding expiration time. Requests that access this cached item will reset the sliding expiration clock.
- Sets the cache priority to CacheItemPriority.NeverRemove.
- Sets a PostEvictionDelegate that will be called after the entry is evicted from the cache. The callback is run on a different thread from the code that removes the item from the cache.

```
public IActionResult CreateCallbackEntry()
{
    var cacheEntryOptions = new MemoryCacheEntryOptions()
        // Pin to cache.
        .SetPriority(CacheItemPriority.NeverRemove)
        // Add eviction callback
        .RegisterPostEvictionCallback(callback: EvictionCallback, state: this);

    _cache.Set(CacheKeys.CallbackEntry, DateTime.Now, cacheEntryOptions);

    return RedirectToAction("GetCallbackEntry");
}

public IActionResult GetCallbackEntry()
{
    return View("Callback", new CallbackViewModel
    {
        CachedTime = _cache.Get<DateTime?>(CacheKeys.CallbackEntry),
        Message = _cache.Get<string>(CacheKeys.CallbackMessage)
    });
}

public IActionResult RemoveCallbackEntry()
{
    _cache.Remove(CacheKeys.CallbackEntry);
    return RedirectToAction("GetCallbackEntry");
}

private static void EvictionCallback(object key, object value,
    EvictionReason reason, object state)
{
    var message = $"Entry was evicted. Reason: {reason}.";
    ((HomeController)state)._cache.Set(CacheKeys.CallbackMessage, message);
}
```

Use SetSize, Size, and SizeLimit to limit cache size

A `MemoryCache` instance may optionally specify and enforce a size limit. The cache size limit does not have a defined unit of measure because the cache has no mechanism to measure the size of entries. If the cache size limit is set, all entries must specify size. The ASP.NET Core runtime does not limit cache size based on memory pressure. It's up to the developer to limit cache size. The size specified is in units the developer chooses.

For example:

- If the web app was primarily caching strings, each cache entry size could be the string length.
- The app could specify the size of all entries as 1, and the size limit is the count of entries.

If SizeLimit isn't set, the cache grows without bound. The ASP.NET Core runtime doesn't trim the cache when system memory is low. Apps must be architected to:

- Limit cache growth.
- Call Compact or Remove when available memory is limited:

The following code creates a unitless fixed size MemoryCache accessible by dependency injection:

```
// using Microsoft.Extensions.Caching.Memory;
public class MyMemoryCache
{
    public MemoryCache Cache { get; set; }
    public MyMemoryCache()
    {
        Cache = new MemoryCache(new MemoryCacheOptions
        {
            SizeLimit = 1024
        });
    }
}
```

`SizeLimit` does not have units. Cached entries must specify size in whatever units they deem most appropriate if the cache size limit has been set. All users of a cache instance should use the same unit system. An entry will not be cached if the sum of the cached entry sizes exceeds the value specified by `SizeLimit`. If no cache size limit is set, the cache size set on the entry will be ignored.

The following code registers `MyMemoryCache` with the dependency injection container.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();
    services.AddSingleton<MyMemoryCache>();
}
```

`MyMemoryCache` is created as an independent memory cache for components that are aware of this size limited cache and know how to set cache entry size appropriately.

The following code uses `MyMemoryCache`:

```
public class SetSize : PageModel
{
    private MemoryCache _cache;
    public static readonly string MyKey = "_MyKey";

    public SetSize(MyMemoryCache memoryCache)
    {
        _cache = memoryCache.Cache;
    }

    [TempData]
    public string DateTime_Now { get; set; }

    public IActionResult OnGet()
    {
        if (!_cache.TryGetValue(MyKey, out string cacheEntry))
        {
            // Key not in cache, so get data.
            cacheEntry = DateTime.Now.TimeOfDay.ToString();

            var cacheEntryOptions = new MemoryCacheEntryOptions()
                // Set cache entry size by extension method.
                .SetSize(1)
                // Keep in cache for this time, reset time if accessed.
                .SetSlidingExpiration(TimeSpan.FromSeconds(3));

            // Set cache entry size via property.
            // cacheEntryOptions.Size = 1;

            // Save data in cache.
            _cache.Set(MyKey, cacheEntry, cacheEntryOptions);
        }

        DateTime_Now = cacheEntry;

        return RedirectToPage("./Index");
    }
}
```

The size of the cache entry can be set by Size or the SetSize extension methods:

```
public IActionResult OnGet()
{
    if (!_cache.TryGetValue(MyKey, out string cacheEntry))
    {
        // Key not in cache, so get data.
        cacheEntry = DateTime.Now.TimeOfDay.ToString();

        var cacheEntryOptions = new MemoryCacheEntryOptions()
            // Set cache entry size by extension method.
            .SetSize(1)
            // Keep in cache for this time, reset time if accessed.
            .SetSlidingExpiration(TimeSpan.FromSeconds(3));

        // Set cache entry size via property.
        // cacheEntryOptions.Size = 1;

        // Save data in cache.
        _cache.Set(MyKey, cacheEntry, cacheEntryOptions);
    }

    DateTime_Now = cacheEntry;

    return RedirectToPage("./Index");
}
```

MemoryCache.Compact

`MemoryCache.Compact` attempts to remove the specified percentage of the cache in the following order:

- All expired items.
- Items by priority. Lowest priority items are removed first.
- Least recently used objects.
- Items with the earliest absolute expiration.
- Items with the earliest sliding expiration.

Pinned items with priority NeverRemove are never removed. The following code removes a cache item and calls `Compact`:

```
_cache.Remove(MyKey);

// Remove 33% of cached items.
_cache.Compact(.33);
cache_size = _cache.Count;
```

See Compact source on GitHub for more information.

Cache dependencies

The following sample shows how to expire a cache entry if a dependent entry expires. A CancellationChangeToken is added to the cached item. When `Cancel` is called on the `CancellationTokenSource`, both cache entries are evicted.

```
public IActionResult CreateDependentEntries()
{
    var cts = new CancellationTokenSource();
    _cache.Set(CacheKeys.DependentCTS, cts);

    using (var entry = _cache.CreateEntry(CacheKeys.Parent))
    {
        // expire this entry if the dependant entry expires.
        entry.Value = DateTime.Now;
        entry.RegisterPostEvictionCallback(DependentEvictionCallback, this);

        _cache.Set(CacheKeys.Child,
            DateTime.Now,
            new CancellationChangeToken(cts.Token));
    }

    return RedirectToAction("GetDependentEntries");
}

public IActionResult GetDependentEntries()
{
    return View("Dependent", new DependentViewModel
    {
        ParentCachedTime = _cache.Get<DateTime?>(CacheKeys.Parent),
        ChildCachedTime = _cache.Get<DateTime?>(CacheKeys.Child),
        Message = _cache.Get<string>(CacheKeys.DependentMessage)
    });
}

public IActionResult RemoveChildEntry()
{
    _cache.Get<CancellationTokenSource>(CacheKeys.DependentCTS).Cancel();
    return RedirectToAction("GetDependentEntries");
}

private static void DependentEvictionCallback(object key, object value,
    EvictionReason reason, object state)
{
    var message = $"Parent entry was evicted. Reason: {reason}.";
    ((HomeController)state)._cache.Set(CacheKeys.DependentMessage, message);
}
```

Using a CancellationTokenSource allows multiple cache entries to be evicted as a group. With the `using` pattern in the code above, cache entries created inside the `using` block will inherit triggers and expiration settings.

Additional notes

- Expiration doesn't happen in the background. There is no timer that actively scans the cache for expired items. Any activity on the cache (`Get` , `Set` , `Remove`) can trigger a background scan for expired items. A timer on the `CancellationTokenSource` (CancelAfter) also removes the entry and trigger a scan for expired items. The following example uses CancellationTokenSource(TimeSpan) for the registered token. When this token fires it removes the entry immediately and fires the eviction callbacks:

```
public IActionResult CacheAutoExpiringTryGetValueSet()
{
    DateTime cacheEntry;

    if (!_cache.TryGetValue(CacheKeys.Entry, out cacheEntry))
    {
        cacheEntry = DateTime.Now;

        var cts = new CancellationTokenSource(TimeSpan.FromSeconds(10));

        var cacheEntryOptions = new MemoryCacheEntryOptions()
            .AddExpirationToken(new CancellationChangeToken(cts.Token));

        _cache.Set(CacheKeys.Entry, cacheEntry, cacheEntryOptions);
    }

    return View("Cache", cacheEntry);
}
```

- When using a callback to repopulate a cache item:
  - Multiple requests can find the cached key value empty because the callback hasn't completed.
  - This can result in several threads repopulating the cached item.
- When one cache entry is used to create another, the child copies the parent entry's expiration tokens and time-based expiration settings. The child isn't expired by manual removal or updating of the parent entry.
- Use PostEvictionCallbacks to set the callbacks that will be fired after the cache entry is evicted from the cache.
- For most apps, `IMemoryCache` is enabled. For example, calling `AddMvc`, `AddControllersWithViews`, `AddRazorPages`, `AddMvcCore().AddRazorViewEngine`, and many other `Add{Service}` methods in `ConfigureServices`, enables `IMemoryCache`. For apps that are not calling one of the preceding `Add{Service}` methods, it may be necessary to call AddMemoryCache in `ConfigureServices`.

Background cache update

Use a background service such as IHostedService to update the cache. The background service can recompute the entries and then assign them to the cache only when they're ready.

Caching basics

Caching can significantly improve the performance and scalability of an app by reducing the work required to generate content. Caching works best with data that changes infrequently. Caching makes a copy of data that

can be returned much faster than from the original source. Code should be written and tested to **never** depend on cached data.

ASP.NET Core supports several different caches. The simplest cache is based on the IMemoryCache, which represents a cache stored in the memory of the web server. Apps that run on a server farm (multiple servers) should ensure that sessions are sticky when using the in-memory cache. Sticky sessions ensure that later requests from a client all go to the same server. For example, Azure Web apps use Application Request Routing (ARR) to route all requests from a user agent to the same server.

Non-sticky sessions in a web farm require a distributed cache to avoid cache consistency problems. For some apps, a distributed cache can support higher scale-out than an in-memory cache. Using a distributed cache offloads the cache memory to an external process.

The in-memory cache can store any object. The distributed cache interface is limited to `byte[]`. The in-memory and distributed cache store cache items as key-value pairs.

System.Runtime.Caching/MemoryCache

System.Runtime.Caching/MemoryCache (NuGet package) can be used with:

- .NET Standard 2.0 or later.
- Any .NET implementation that targets .NET Standard 2.0 or later. For example, ASP.NET Core 2.0 or later.
- .NET Framework 4.5 or later.

Microsoft.Extensions.Caching.Memory/ `IMemoryCache` (described in this article) is recommended over `System.Runtime.Caching` / `MemoryCache` because it's better integrated into ASP.NET Core. For example, `IMemoryCache` works natively with ASP.NET Core dependency injection.

Use `System.Runtime.Caching` / `MemoryCache` as a compatibility bridge when porting code from ASP.NET 4.x to ASP.NET Core.

Cache guidelines

- Code should always have a fallback option to fetch data and **not** depend on a cached value being available.
- The cache uses a scarce resource, memory. Limit cache growth:
  - Do **not** use external input as cache keys.
  - Use expirations to limit cache growth.
  - Use SetSize, Size, and SizeLimit to limit cache size. The ASP.NET Core runtime does not limit cache size based on memory pressure. It's up to the developer to limit cache size.

Using IMemoryCache

> **WARNING**
> Using a *shared* memory cache from Dependency Injection and calling `SetSize`, `Size`, or `SizeLimit` to limit cache size can cause the app to fail. When a size limit is set on a cache, all entries must specify a size when being added. This can lead to issues since developers may not have full control on what uses the shared cache. For example, Entity Framework Core uses the shared cache and does not specify a size. If an app sets a cache size limit and uses EF Core, the app throws an `InvalidOperationException`. When using `SetSize`, `Size`, or `SizeLimit` to limit cache, create a cache singleton for caching. For more information and an example, see Use SetSize, Size, and SizeLimit to limit cache size.

In-memory caching is a *service* that's referenced from your app using Dependency Injection. Call `AddMemoryCache` in `ConfigureServices`:

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.DependencyInjection;

public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddMemoryCache();

        services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
    }

    public void Configure(IApplicationBuilder app)
    {
        app.UseMvcWithDefaultRoute();
    }
}
```

Request the `IMemoryCache` instance in the constructor:

```
public class HomeController : Controller
{
    private IMemoryCache _cache;

    public HomeController(IMemoryCache memoryCache)
    {
        _cache = memoryCache;
    }
```

`IMemoryCache` requires NuGet package Microsoft.Extensions.Caching.Memory, which is available in the Microsoft.AspNetCore.App metapackage.

The following code uses TryGetValue to check if a time is in the cache. If a time isn't cached, a new entry is created and added to the cache with Set.

```
public static class CacheKeys
{
    public static string Entry { get { return "_Entry"; } }
    public static string CallbackEntry { get { return "_Callback"; } }
    public static string CallbackMessage { get { return "_CallbackMessage"; } }
    public static string Parent { get { return "_Parent"; } }
    public static string Child { get { return "_Child"; } }
    public static string DependentMessage { get { return "_DependentMessage"; } }
    public static string DependentCTS { get { return "_DependentCTS"; } }
    public static string Ticks { get { return "_Ticks"; } }
    public static string CancelMsg { get { return "_CancelMsg"; } }
    public static string CancelTokenSource { get { return "_CancelTokenSource"; } }
}
```

```
public IActionResult CacheTryGetValueSet()
{
    DateTime cacheEntry;

    // Look for cache key.
    if (!_cache.TryGetValue(CacheKeys.Entry, out cacheEntry))
    {
        // Key not in cache, so get data.
        cacheEntry = DateTime.Now;

        // Set cache options.
        var cacheEntryOptions = new MemoryCacheEntryOptions()
            // Keep in cache for this time, reset time if accessed.
            .SetSlidingExpiration(TimeSpan.FromSeconds(3));

        // Save data in cache.
        _cache.Set(CacheKeys.Entry, cacheEntry, cacheEntryOptions);
    }

    return View("Cache", cacheEntry);
}
```

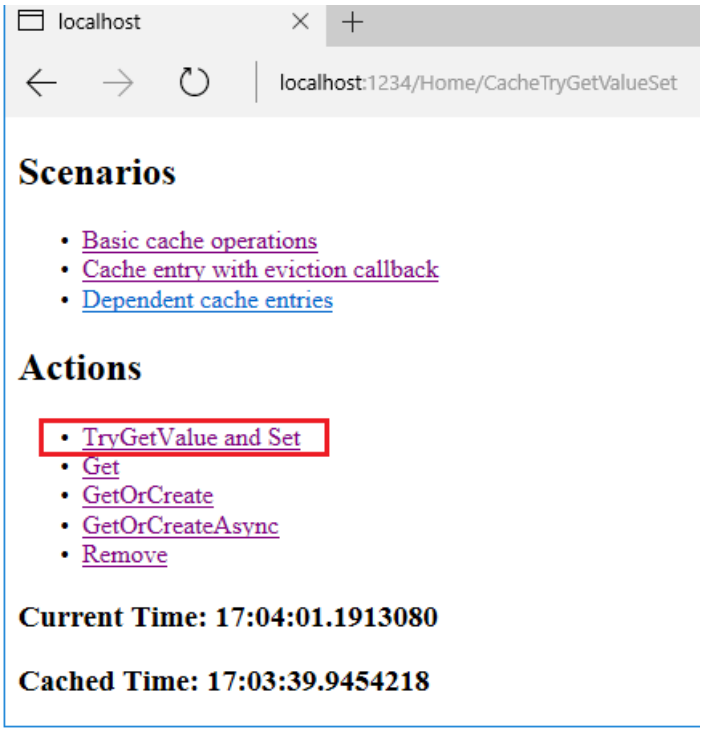
The current time and the cached time are displayed:

```
@model DateTime?

<div>
    <h2>Actions</h2>
    <ul>
        <li><a asp-controller="Home" asp-action="CacheTryGetValueSet">TryGetValue and Set</a></li>
        <li><a asp-controller="Home" asp-action="CacheGet">Get</a></li>
        <li><a asp-controller="Home" asp-action="CacheGetOrCreate">GetOrCreate</a></li>
        <li><a asp-controller="Home" asp-action="CacheGetOrCreateAsync">GetOrCreateAsync</a></li>
        <li><a asp-controller="Home" asp-action="CacheRemove">Remove</a></li>
    </ul>
</div>

<h3>Current Time: @DateTime.Now.TimeOfDay.ToString()</h3>
<h3>Cached Time: @(Model == null ? "No cached entry found" : Model.Value.TimeOfDay.ToString())</h3>
```

The cached `DateTime` value remains in the cache while there are requests within the timeout period. The following image shows the current time and an older time retrieved from the cache:



The following code uses GetOrCreate and GetOrCreateAsync to cache data.

```
public IActionResult CacheGetOrCreate()
{
    var cacheEntry = _cache.GetOrCreate(CacheKeys.Entry, entry =>
    {
        entry.SlidingExpiration = TimeSpan.FromSeconds(3);
        return DateTime.Now;
    });

    return View("Cache", cacheEntry);
}

public async Task<IActionResult> CacheGetOrCreateAsync()
{
    var cacheEntry = await
        _cache.GetOrCreateAsync(CacheKeys.Entry, entry =>
    {
        entry.SlidingExpiration = TimeSpan.FromSeconds(3);
        return Task.FromResult(DateTime.Now);
    });

    return View("Cache", cacheEntry);
}
```

The following code calls Get to fetch the cached time:

```
public IActionResult CacheGet()
{
    var cacheEntry = _cache.Get<DateTime?>(CacheKeys.Entry);
    return View("Cache", cacheEntry);
}
```

GetOrCreate , GetOrCreateAsync, and Get are extension methods part of the CacheExtensions class that extends the capability of IMemoryCache. See IMemoryCache methods and CacheExtensions methods for a description of other cache methods.

MemoryCacheEntryOptions

The following sample:

- Sets a sliding expiration time. Requests that access this cached item will reset the sliding expiration clock.
- Sets the cache priority to `CacheItemPriority.NeverRemove`.
- Sets a PostEvictionDelegate that will be called after the entry is evicted from the cache. The callback is run on a different thread from the code that removes the item from the cache.

```
public IActionResult CreateCallbackEntry()
{
    var cacheEntryOptions = new MemoryCacheEntryOptions()
        // Pin to cache.
        .SetPriority(CacheItemPriority.NeverRemove)
        // Add eviction callback
        .RegisterPostEvictionCallback(callback: EvictionCallback, state: this);

    _cache.Set(CacheKeys.CallbackEntry, DateTime.Now, cacheEntryOptions);

    return RedirectToAction("GetCallbackEntry");
}

public IActionResult GetCallbackEntry()
{
    return View("Callback", new CallbackViewModel
    {
        CachedTime = _cache.Get<DateTime?>(CacheKeys.CallbackEntry),
        Message = _cache.Get<string>(CacheKeys.CallbackMessage)
    });
}

public IActionResult RemoveCallbackEntry()
{
    _cache.Remove(CacheKeys.CallbackEntry);
    return RedirectToAction("GetCallbackEntry");
}

private static void EvictionCallback(object key, object value,
    EvictionReason reason, object state)
{
    var message = $"Entry was evicted. Reason: {reason}.";
    ((HomeController)state)._cache.Set(CacheKeys.CallbackMessage, message);
}
```

Use SetSize, Size, and SizeLimit to limit cache size

A `MemoryCache` instance may optionally specify and enforce a size limit. The cache size limit does not have a defined unit of measure because the cache has no mechanism to measure the size of entries. If the cache size limit is set, all entries must specify size. The ASP.NET Core runtime does not limit cache size based on memory pressure. It's up to the developer to limit cache size. The size specified is in units the developer chooses.

For example:

- If the web app was primarily caching strings, each cache entry size could be the string length.
- The app could specify the size of all entries as 1, and the size limit is the count of entries.

If SizeLimit is not set, the cache grows without bound. The ASP.NET Core runtime does not trim the cache when system memory is low. Apps much be architected to:

- Limit cache growth.
- Call Compact or Remove when available memory is limited:

The following code creates a unitless fixed size MemoryCache accessible by dependency injection:

```
// using Microsoft.Extensions.Caching.Memory;
public class MyMemoryCache
{
    public MemoryCache Cache { get; set; }
    public MyMemoryCache()
    {
        Cache = new MemoryCache(new MemoryCacheOptions
        {
            SizeLimit = 1024
        });
    }
}
```

`SizeLimit` does not have units. Cached entries must specify size in whatever units they deem most appropriate if the cache size limit has been set. All users of a cache instance should use the same unit system. An entry will not be cached if the sum of the cached entry sizes exceeds the value specified by `SizeLimit`. If no cache size limit is set, the cache size set on the entry will be ignored.

The following code registers `MyMemoryCache` with the dependency injection container.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);

    services.AddSingleton<MyMemoryCache>();
}
```

`MyMemoryCache` is created as an independent memory cache for components that are aware of this size limited cache and know how to set cache entry size appropriately.

The following code uses `MyMemoryCache`:

```
public class AboutModel : PageModel
{
    private MemoryCache _cache;
    public static readonly string MyKey = "_MyKey";

    public AboutModel(MyMemoryCache memoryCache)
    {
        _cache = memoryCache.Cache;
    }

    [TempData]
    public string DateTime_Now { get; set; }

    public IActionResult OnGet()
    {
        if (!_cache.TryGetValue(MyKey, out string cacheEntry))
        {
            // Key not in cache, so get data.
            cacheEntry = DateTime.Now.TimeOfDay.ToString();

            var cacheEntryOptions = new MemoryCacheEntryOptions()
                // Set cache entry size by extension method.
                .SetSize(1)
                // Keep in cache for this time, reset time if accessed.
                .SetSlidingExpiration(TimeSpan.FromSeconds(3));

            // Set cache entry size via property.
            // cacheEntryOptions.Size = 1;

            // Save data in cache.
            _cache.Set(MyKey, cacheEntry, cacheEntryOptions);
        }

        DateTime_Now = cacheEntry;

        return RedirectToPage("./Index");
    }
}
```

The size of the cache entry can be set by Size or the SetSize extension method:

```
public IActionResult OnGet()
{
    if (!_cache.TryGetValue(MyKey, out string cacheEntry))
    {
        // Key not in cache, so get data.
        cacheEntry = DateTime.Now.TimeOfDay.ToString();

        var cacheEntryOptions = new MemoryCacheEntryOptions()
            // Set cache entry size by extension method.
            .SetSize(1)
            // Keep in cache for this time, reset time if accessed.
            .SetSlidingExpiration(TimeSpan.FromSeconds(3));

        // Set cache entry size via property.
        // cacheEntryOptions.Size = 1;

        // Save data in cache.
        _cache.Set(MyKey, cacheEntry, cacheEntryOptions);
    }

    DateTime_Now = cacheEntry;

    return RedirectToPage("./Index");
}
```

MemoryCache.Compact

`MemoryCache.Compact` attempts to remove the specified percentage of the cache in the following order:

- All expired items.
- Items by priority. Lowest priority items are removed first.
- Least recently used objects.
- Items with the earliest absolute expiration.
- Items with the earliest sliding expiration.

Pinned items with priority NeverRemove are never removed.

```
_cache.Remove(MyKey);

// Remove 33% of cached items.
_cache.Compact(.33);
cache_size = _cache.Count;
```

See Compact source on GitHub for more information.

Cache dependencies

The following sample shows how to expire a cache entry if a dependent entry expires. A CancellationChangeToken is added to the cached item. When `Cancel` is called on the `CancellationTokenSource`, both cache entries are evicted.

```
public IActionResult CreateDependentEntries()
{
    var cts = new CancellationTokenSource();
    _cache.Set(CacheKeys.DependentCTS, cts);

    using (var entry = _cache.CreateEntry(CacheKeys.Parent))
    {
        // expire this entry if the dependant entry expires.
        entry.Value = DateTime.Now;
        entry.RegisterPostEvictionCallback(DependentEvictionCallback, this);

        _cache.Set(CacheKeys.Child,
            DateTime.Now,
            new CancellationChangeToken(cts.Token));
    }

    return RedirectToAction("GetDependentEntries");
}

public IActionResult GetDependentEntries()
{
    return View("Dependent", new DependentViewModel
    {
        ParentCachedTime = _cache.Get<DateTime?>(CacheKeys.Parent),
        ChildCachedTime = _cache.Get<DateTime?>(CacheKeys.Child),
        Message = _cache.Get<string>(CacheKeys.DependentMessage)
    });
}

public IActionResult RemoveChildEntry()
{
    _cache.Get<CancellationTokenSource>(CacheKeys.DependentCTS).Cancel();
    return RedirectToAction("GetDependentEntries");
}

private static void DependentEvictionCallback(object key, object value,
    EvictionReason reason, object state)
{
    var message = $"Parent entry was evicted. Reason: {reason}.";
    ((HomeController)state)._cache.Set(CacheKeys.DependentMessage, message);
}
```

Using a `CancellationTokenSource` allows multiple cache entries to be evicted as a group. With the `using` pattern in the code above, cache entries created inside the `using` block will inherit triggers and expiration settings.

Additional notes

- When using a callback to repopulate a cache item:
  - Multiple requests can find the cached key value empty because the callback hasn't completed.
  - This can result in several threads repopulating the cached item.
- When one cache entry is used to create another, the child copies the parent entry's expiration tokens and time-based expiration settings. The child isn't expired by manual removal or updating of the parent entry.
- Use PostEvictionCallbacks to set the callbacks that will be fired after the cache entry is evicted from the cache.

Background cache update

Use a background service such as IHostedService to update the cache. The background service can recompute

the entries and then assign them to the cache only when they're ready.

Distributed caching in ASP.NET Core

9/22/2020 • 20 minutes to read • Edit Online

By Mohsin Nasir and Steve Smith

A distributed cache is a cache shared by multiple app servers, typically maintained as an external service to the app servers that access it. A distributed cache can improve the performance and scalability of an ASP.NET Core app, especially when the app is hosted by a cloud service or a server farm.

A distributed cache has several advantages over other caching scenarios where cached data is stored on individual app servers.

When cached data is distributed, the data:

- Is *coherent* (consistent) across requests to multiple servers.
- Survives server restarts and app deployments.
- Doesn't use local memory.

Distributed cache configuration is implementation specific. This article describes how to configure SQL Server and Redis distributed caches. Third party implementations are also available, such as NCache (NCache on GitHub). Regardless of which implementation is selected, the app interacts with the cache using the IDistributedCache interface.

View or download sample code (how to download)

Prerequisites

To use a SQL Server distributed cache, add a package reference to the Microsoft.Extensions.Caching.SqlServer package.

To use a Redis distributed cache, add a package reference to the Microsoft.Extensions.Caching.StackExchangeRedis package.

To use NCache distributed cache, add a package reference to the NCache.Microsoft.Extensions.Caching.OpenSource package.

IDistributedCache interface

The IDistributedCache interface provides the following methods to manipulate items in the distributed cache implementation:

- Get, GetAsync: Accepts a string key and retrieves a cached item as a `byte[]` array if found in the cache.
- Set, SetAsync: Adds an item (as `byte[]` array) to the cache using a string key.
- Refresh, RefreshAsync: Refreshes an item in the cache based on its key, resetting its sliding expiration timeout (if any).
- Remove, RemoveAsync: Removes a cache item based on its string key.

Establish distributed caching services

Register an implementation of IDistributedCache in `Startup.ConfigureServices`. Framework-provided implementations described in this topic include:

- Distributed Memory Cache

- Distributed SQL Server cache
- Distributed Redis cache
- Distributed NCache cache

Distributed Memory Cache

The Distributed Memory Cache (AddDistributedMemoryCache) is a framework-provided implementation of IDistributedCache that stores items in memory. The Distributed Memory Cache isn't an actual distributed cache. Cached items are stored by the app instance on the server where the app is running.

The Distributed Memory Cache is a useful implementation:

- In development and testing scenarios.
- When a single server is used in production and memory consumption isn't an issue. Implementing the Distributed Memory Cache abstracts cached data storage. It allows for implementing a true distributed caching solution in the future if multiple nodes or fault tolerance become necessary.

The sample app makes use of the Distributed Memory Cache when the app is run in the Development environment in `Startup.ConfigureServices`:

```
services.AddDistributedMemoryCache();
```

Distributed SQL Server Cache

The Distributed SQL Server Cache implementation (AddDistributedSqlServerCache) allows the distributed cache to use a SQL Server database as its backing store. To create a SQL Server cached item table in a SQL Server instance, you can use the `sql-cache` tool. The tool creates a table with the name and schema that you specify.

Create a table in SQL Server by running the `sql-cache create` command. Provide the SQL Server instance (`Data Source`), database (`Initial Catalog`), schema (for example, `dbo`), and table name (for example, `TestCache`):

```
dotnet sql-cache create "Data Source=(localdb)\MSSQLLocalDB;Initial Catalog=DistCache;Integrated
Security=True;" dbo TestCache
```

A message is logged to indicate that the tool was successful:

```
Table and index were created successfully.
```

The table created by the `sql-cache` tool has the following schema:

	Name	Data Type	Allow Nulls
🔑	Id	nvarchar(449)	☐
	Value	varbinary(MAX)	☐
	ExpiresAtTime	datetimeoffset(7)	☐
	SlidingExpirationInSeconds	bigint	☑
	AbsoluteExpiration	datetimeoffset(7)	☑

> **NOTE**
>
> An app should manipulate cache values using an instance of IDistributedCache, not a SqlServerCache.

The sample app implements SqlServerCache in a non-Development environment in `Startup.ConfigureServices`:

```
services.AddDistributedSqlServerCache(options =>
{
    options.ConnectionString =
        _config["DistCache_ConnectionString"];
    options.SchemaName = "dbo";
    options.TableName = "TestCache";
});
```

> **NOTE**
>
> A ConnectionString (and optionally, SchemaName and TableName) are typically stored outside of source control (for example, stored by the Secret Manager or in *appsettings.json*/*appsettings.{ENVIRONMENT}.json* files). The connection string may contain credentials that should be kept out of source control systems.

Distributed Redis Cache

Redis is an open source in-memory data store, which is often used as a distributed cache. You can configure an Azure Redis Cache for an Azure-hosted ASP.NET Core app, and use an Azure Redis Cache for local development.

An app configures the cache implementation using a RedisCache instance (AddStackExchangeRedisCache).

For more information, see Azure Cache for Redis.

See this GitHub issue for a discussion on alternative approaches to a local Redis cache.

Distributed NCache Cache

NCache is an open source in-memory distributed cache developed natively in .NET and .NET Core. NCache works both locally and configured as a distributed cache cluster for an ASP.NET Core app running in Azure or on other hosting platforms.

To install and configure NCache on your local machine, see NCache Getting Started Guide for Windows.

To configure NCache:

1. Install NCache open source NuGet.
2. Configure the cache cluster in client.ncconf.
3. Add the following code to `Startup.ConfigureServices`:

```
services.AddNCacheDistributedCache(configuration =>
{
    configuration.CacheName = "demoClusteredCache";
    configuration.EnableLogs = true;
    configuration.ExceptionsEnabled = true;
});
```

Use the distributed cache

To use the IDistributedCache interface, request an instance of IDistributedCache from any constructor in the app. The instance is provided by dependency injection (DI).

When the sample app starts, IDistributedCache is injected into `Startup.Configure`. The current time is cached using IHostApplicationLifetime (for more information, see Generic Host: IHostApplicationLifetime):

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env,
    IHostApplicationLifetime lifetime, IDistributedCache cache)
{
    lifetime.ApplicationStarted.Register(() =>
    {
        var currentTimeUTC = DateTime.UtcNow.ToString();
        byte[] encodedCurrentTimeUTC = Encoding.UTF8.GetBytes(currentTimeUTC);
        var options = new DistributedCacheEntryOptions()
            .SetSlidingExpiration(TimeSpan.FromSeconds(20));
        cache.Set("cachedTimeUTC", encodedCurrentTimeUTC, options);
    });
```

The sample app injects IDistributedCache into the `IndexModel` for use by the Index page.

Each time the Index page is loaded, the cache is checked for the cached time in `OnGetAsync`. If the cached time hasn't expired, the time is displayed. If 20 seconds have elapsed since the last time the cached time was accessed (the last time this page was loaded), the page displays *Cached Time Expired*.

Immediately update the cached time to the current time by selecting the **Reset Cached Time** button. The button triggers the `OnPostResetCachedTime` handler method.

```
public class IndexModel : PageModel
{
    private readonly IDistributedCache _cache;

    public IndexModel(IDistributedCache cache)
    {
        _cache = cache;
    }

    public string CachedTimeUTC { get; set; }

    public async Task OnGetAsync()
    {
        CachedTimeUTC = "Cached Time Expired";
        var encodedCachedTimeUTC = await _cache.GetAsync("cachedTimeUTC");

        if (encodedCachedTimeUTC != null)
        {
            CachedTimeUTC = Encoding.UTF8.GetString(encodedCachedTimeUTC);
        }
    }

    public async Task<IActionResult> OnPostResetCachedTime()
    {
        var currentTimeUTC = DateTime.UtcNow.ToString();
        byte[] encodedCurrentTimeUTC = Encoding.UTF8.GetBytes(currentTimeUTC);
        var options = new DistributedCacheEntryOptions()
            .SetSlidingExpiration(TimeSpan.FromSeconds(20));
        await _cache.SetAsync("cachedTimeUTC", encodedCurrentTimeUTC, options);

        return RedirectToPage();
    }
}
```

> **NOTE**
>
> There's no need to use a Singleton or Scoped lifetime for IDistributedCache instances (at least for the built-in implementations).
>
> You can also create an IDistributedCache instance wherever you might need one instead of using DI, but creating an instance in code can make your code harder to test and violates the Explicit Dependencies Principle.

Recommendations

When deciding which implementation of IDistributedCache is best for your app, consider the following:

- Existing infrastructure
- Performance requirements
- Cost
- Team experience

Caching solutions usually rely on in-memory storage to provide fast retrieval of cached data, but memory is a limited resource and costly to expand. Only store commonly used data in a cache.

Generally, a Redis cache provides higher throughput and lower latency than a SQL Server cache. However, benchmarking is usually required to determine the performance characteristics of caching strategies.

When SQL Server is used as a distributed cache backing store, use of the same database for the cache and the app's ordinary data storage and retrieval can negatively impact the performance of both. We recommend using a dedicated SQL Server instance for the distributed cache backing store.

A distributed cache is a cache shared by multiple app servers, typically maintained as an external service to the app servers that access it. A distributed cache can improve the performance and scalability of an ASP.NET Core app, especially when the app is hosted by a cloud service or a server farm.

A distributed cache has several advantages over other caching scenarios where cached data is stored on individual app servers.

When cached data is distributed, the data:

- Is *coherent* (consistent) across requests to multiple servers.
- Survives server restarts and app deployments.
- Doesn't use local memory.

Distributed cache configuration is implementation specific. This article describes how to configure SQL Server

and Redis distributed caches. Third party implementations are also available, such as NCache (NCache on GitHub). Regardless of which implementation is selected, the app interacts with the cache using the IDistributedCache interface.

View or download sample code (how to download)

Prerequisites

To use a SQL Server distributed cache, reference the Microsoft.AspNetCore.App metapackage or add a package reference to the Microsoft.Extensions.Caching.SqlServer package.

To use a Redis distributed cache, reference the Microsoft.AspNetCore.App metapackage and add a package reference to the Microsoft.Extensions.Caching.StackExchangeRedis package. The Redis package isn't included in the `Microsoft.AspNetCore.App` package, so you must reference the Redis package separately in your project file.

To use NCache distributed cache, reference the Microsoft.AspNetCore.App metapackage and add a package reference to the NCache.Microsoft.Extensions.Caching.OpenSource package. The NCache package isn't included in the `Microsoft.AspNetCore.App` package, so you must reference the NCache package separately in your project file.

IDistributedCache interface

The IDistributedCache interface provides the following methods to manipulate items in the distributed cache implementation:

- Get, GetAsync: Accepts a string key and retrieves a cached item as a `byte[]` array if found in the cache.
- Set, SetAsync: Adds an item (as `byte[]` array) to the cache using a string key.
- Refresh, RefreshAsync: Refreshes an item in the cache based on its key, resetting its sliding expiration timeout (if any).
- Remove, RemoveAsync: Removes a cache item based on its string key.

Establish distributed caching services

Register an implementation of IDistributedCache in `Startup.ConfigureServices`. Framework-provided implementations described in this topic include:

- Distributed Memory Cache
- Distributed SQL Server cache
- Distributed Redis cache
- Distributed NCache cache

Distributed Memory Cache

The Distributed Memory Cache (AddDistributedMemoryCache) is a framework-provided implementation of IDistributedCache that stores items in memory. The Distributed Memory Cache isn't an actual distributed cache. Cached items are stored by the app instance on the server where the app is running.

The Distributed Memory Cache is a useful implementation:

- In development and testing scenarios.
- When a single server is used in production and memory consumption isn't an issue. Implementing the Distributed Memory Cache abstracts cached data storage. It allows for implementing a true distributed caching solution in the future if multiple nodes or fault tolerance become necessary.

The sample app makes use of the Distributed Memory Cache when the app is run in the Development

environment in `Startup.ConfigureServices`:

```
services.AddDistributedMemoryCache();
```

Distributed SQL Server Cache

The Distributed SQL Server Cache implementation (AddDistributedSqlServerCache) allows the distributed cache to use a SQL Server database as its backing store. To create a SQL Server cached item table in a SQL Server instance, you can use the `sql-cache` tool. The tool creates a table with the name and schema that you specify.

Create a table in SQL Server by running the `sql-cache create` command. Provide the SQL Server instance (`Data Source`), database (`Initial Catalog`), schema (for example, `dbo`), and table name (for example, `TestCache`):

```
dotnet sql-cache create "Data Source=(localdb)\MSSQLLocalDB;Initial Catalog=DistCache;Integrated
Security=True;" dbo TestCache
```

A message is logged to indicate that the tool was successful:

```
Table and index were created successfully.
```

The table created by the `sql-cache` tool has the following schema:

	Name	Data Type	Allow Nulls
🔑	Id	nvarchar(449)	☐
	Value	varbinary(MAX)	☐
	ExpiresAtTime	datetimeoffset(7)	☐
	SlidingExpirationInSeconds	bigint	☑
	AbsoluteExpiration	datetimeoffset(7)	☑

> **NOTE**
> An app should manipulate cache values using an instance of IDistributedCache, not a SqlServerCache.

The sample app implements SqlServerCache in a non-Development environment in `Startup.ConfigureServices`:

```
services.AddDistributedSqlServerCache(options =>
{
    options.ConnectionString =
        _config["DistCache_ConnectionString"];
    options.SchemaName = "dbo";
    options.TableName = "TestCache";
});
```

> **NOTE**
>
> A ConnectionString (and optionally, SchemaName and TableName) are typically stored outside of source control (for example, stored by the Secret Manager or in *appsettings.json*/*appsettings.{ENVIRONMENT}.json* files). The connection string may contain credentials that should be kept out of source control systems.

Distributed Redis Cache

Redis is an open source in-memory data store, which is often used as a distributed cache. You can use Redis locally, and you can configure an Azure Redis Cache for an Azure-hosted ASP.NET Core app.

An app configures the cache implementation using a RedisCache instance (AddStackExchangeRedisCache) in a non-Development environment in `Startup.ConfigureServices`:

```
services.AddStackExchangeRedisCache(options =>
{
    options.Configuration = "localhost";
    options.InstanceName = "SampleInstance";
});
```

To install Redis on your local machine:

1. Install the Chocolatey Redis package.
2. Run `redis-server` from a command prompt.

Distributed NCache Cache

NCache is an open source in-memory distributed cache developed natively in .NET and .NET Core. NCache works both locally and configured as a distributed cache cluster for an ASP.NET Core app running in Azure or on other hosting platforms.

To install and configure NCache on your local machine, see NCache Getting Started Guide for Windows.

To configure NCache:

1. Install NCache open source NuGet.
2. Configure the cache cluster in client.ncconf.
3. Add the following code to `Startup.ConfigureServices`:

```
services.AddNCacheDistributedCache(configuration =>
{
    configuration.CacheName = "demoClusteredCache";
    configuration.EnableLogs = true;
    configuration.ExceptionsEnabled = true;
});
```

Use the distributed cache

To use the IDistributedCache interface, request an instance of IDistributedCache from any constructor in the app. The instance is provided by dependency injection (DI).

When the sample app starts, IDistributedCache is injected into `Startup.Configure`. The current time is cached using IApplicationLifetime (for more information, see Web Host: IApplicationLifetime interface):

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env,
    IApplicationLifetime lifetime, IDistributedCache cache)
{
    lifetime.ApplicationStarted.Register(() =>
    {
        var currentTimeUTC = DateTime.UtcNow.ToString();
        byte[] encodedCurrentTimeUTC = Encoding.UTF8.GetBytes(currentTimeUTC);
        var options = new DistributedCacheEntryOptions()
            .SetSlidingExpiration(TimeSpan.FromSeconds(20));
        cache.Set("cachedTimeUTC", encodedCurrentTimeUTC, options);
    });
```

The sample app injects IDistributedCache into the `IndexModel` for use by the Index page.

Each time the Index page is loaded, the cache is checked for the cached time in `OnGetAsync`. If the cached time hasn't expired, the time is displayed. If 20 seconds have elapsed since the last time the cached time was accessed (the last time this page was loaded), the page displays *Cached Time Expired*.

Immediately update the cached time to the current time by selecting the **Reset Cached Time** button. The button triggers the `OnPostResetCachedTime` handler method.

```
public class IndexModel : PageModel
{
    private readonly IDistributedCache _cache;

    public IndexModel(IDistributedCache cache)
    {
        _cache = cache;
    }

    public string CachedTimeUTC { get; set; }

    public async Task OnGetAsync()
    {
        CachedTimeUTC = "Cached Time Expired";
        var encodedCachedTimeUTC = await _cache.GetAsync("cachedTimeUTC");

        if (encodedCachedTimeUTC != null)
        {
            CachedTimeUTC = Encoding.UTF8.GetString(encodedCachedTimeUTC);
        }
    }

    public async Task<IActionResult> OnPostResetCachedTime()
    {
        var currentTimeUTC = DateTime.UtcNow.ToString();
        byte[] encodedCurrentTimeUTC = Encoding.UTF8.GetBytes(currentTimeUTC);
        var options = new DistributedCacheEntryOptions()
            .SetSlidingExpiration(TimeSpan.FromSeconds(20));
        await _cache.SetAsync("cachedTimeUTC", encodedCurrentTimeUTC, options);

        return RedirectToPage();
    }
}
```

> **NOTE**
>
> There's no need to use a Singleton or Scoped lifetime for IDistributedCache instances (at least for the built-in implementations).
>
> You can also create an IDistributedCache instance wherever you might need one instead of using DI, but creating an instance in code can make your code harder to test and violates the Explicit Dependencies Principle.

Recommendations

When deciding which implementation of IDistributedCache is best for your app, consider the following:

- Existing infrastructure
- Performance requirements
- Cost
- Team experience

Caching solutions usually rely on in-memory storage to provide fast retrieval of cached data, but memory is a limited resource and costly to expand. Only store commonly used data in a cache.

Generally, a Redis cache provides higher throughput and lower latency than a SQL Server cache. However, benchmarking is usually required to determine the performance characteristics of caching strategies.

When SQL Server is used as a distributed cache backing store, use of the same database for the cache and the app's ordinary data storage and retrieval can negatively impact the performance of both. We recommend using a dedicated SQL Server instance for the distributed cache backing store.

- Distributed Cache Tag Helper in ASP.NET Core
- Host ASP.NET Core in a web farm

A distributed cache is a cache shared by multiple app servers, typically maintained as an external service to the app servers that access it. A distributed cache can improve the performance and scalability of an ASP.NET Core app, especially when the app is hosted by a cloud service or a server farm.

A distributed cache has several advantages over other caching scenarios where cached data is stored on individual app servers.

When cached data is distributed, the data:

- Is *coherent* (consistent) across requests to multiple servers.
- Survives server restarts and app deployments.
- Doesn't use local memory.

Distributed cache configuration is implementation specific. This article describes how to configure SQL Server

and Redis distributed caches. Third party implementations are also available, such as NCache (NCache on GitHub). Regardless of which implementation is selected, the app interacts with the cache using the IDistributedCache interface.

View or download sample code (how to download)

Prerequisites

To use a SQL Server distributed cache, reference the Microsoft.AspNetCore.App metapackage or add a package reference to the Microsoft.Extensions.Caching.SqlServer package.

To use a Redis distributed cache, reference the Microsoft.AspNetCore.App metapackage and add a package reference to the Microsoft.Extensions.Caching.Redis package. The Redis package isn't included in the `Microsoft.AspNetCore.App` package, so you must reference the Redis package separately in your project file.

To use NCache distributed cache, reference the Microsoft.AspNetCore.App metapackage and add a package reference to the NCache.Microsoft.Extensions.Caching.OpenSource package. The NCache package isn't included in the `Microsoft.AspNetCore.App` package, so you must reference the NCache package separately in your project file.

IDistributedCache interface

The IDistributedCache interface provides the following methods to manipulate items in the distributed cache implementation:

- Get, GetAsync: Accepts a string key and retrieves a cached item as a `byte[]` array if found in the cache.
- Set, SetAsync: Adds an item (as `byte[]` array) to the cache using a string key.
- Refresh, RefreshAsync: Refreshes an item in the cache based on its key, resetting its sliding expiration timeout (if any).
- Remove, RemoveAsync: Removes a cache item based on its string key.

Establish distributed caching services

Register an implementation of IDistributedCache in `Startup.ConfigureServices`. Framework-provided implementations described in this topic include:

- Distributed Memory Cache
- Distributed SQL Server cache
- Distributed Redis cache
- Distributed NCache cache

Distributed Memory Cache

The Distributed Memory Cache (AddDistributedMemoryCache) is a framework-provided implementation of IDistributedCache that stores items in memory. The Distributed Memory Cache isn't an actual distributed cache. Cached items are stored by the app instance on the server where the app is running.

The Distributed Memory Cache is a useful implementation:

- In development and testing scenarios.
- When a single server is used in production and memory consumption isn't an issue. Implementing the Distributed Memory Cache abstracts cached data storage. It allows for implementing a true distributed caching solution in the future if multiple nodes or fault tolerance become necessary.

The sample app makes use of the Distributed Memory Cache when the app is run in the Development environment in `Startup.ConfigureServices`:

```
services.AddDistributedMemoryCache();
```

Distributed SQL Server Cache

The Distributed SQL Server Cache implementation (AddDistributedSqlServerCache) allows the distributed cache to use a SQL Server database as its backing store. To create a SQL Server cached item table in a SQL Server instance, you can use the `sql-cache` tool. The tool creates a table with the name and schema that you specify.

Create a table in SQL Server by running the `sql-cache create` command. Provide the SQL Server instance (`Data Source`), database (`Initial Catalog`), schema (for example, `dbo`), and table name (for example, `TestCache`):

```
dotnet sql-cache create "Data Source=(localdb)\MSSQLLocalDB;Initial Catalog=DistCache;Integrated
Security=True;" dbo TestCache
```

A message is logged to indicate that the tool was successful:

```
Table and index were created successfully.
```

The table created by the `sql-cache` tool has the following schema:

	Name	Data Type	Allow Nulls
🔑	Id	nvarchar(449)	☐
	Value	varbinary(MAX)	☐
	ExpiresAtTime	datetimeoffset(7)	☐
	SlidingExpirationInSeconds	bigint	☑
	AbsoluteExpiration	datetimeoffset(7)	☑

> **NOTE**
> An app should manipulate cache values using an instance of IDistributedCache, not a SqlServerCache.

The sample app implements SqlServerCache in a non-Development environment in `Startup.ConfigureServices` :

```
services.AddDistributedSqlServerCache(options =>
{
    options.ConnectionString =
        _config["DistCache_ConnectionString"];
    options.SchemaName = "dbo";
    options.TableName = "TestCache";
});
```

> **NOTE**
> A ConnectionString (and optionally, SchemaName and TableName) are typically stored outside of source control (for example, stored by the Secret Manager or in *appsettings.json*/*appsettings.{ENVIRONMENT}.json* files). The connection string may contain credentials that should be kept out of source control systems.

Distributed Redis Cache

Redis is an open source in-memory data store, which is often used as a distributed cache. You can use Redis locally, and you can configure an Azure Redis Cache for an Azure-hosted ASP.NET Core app.

An app configures the cache implementation using a RedisCache instance (AddDistributedRedisCache):

```
services.AddDistributedRedisCache(options =>
{
    options.Configuration = "localhost";
    options.InstanceName = "SampleInstance";
});
```

To install Redis on your local machine:

1. Install the Chocolatey Redis package.
2. Run `redis-server` from a command prompt.

Distributed NCache Cache

NCache is an open source in-memory distributed cache developed natively in .NET and .NET Core. NCache works both locally and configured as a distributed cache cluster for an ASP.NET Core app running in Azure or on other hosting platforms.

To install and configure NCache on your local machine, see NCache Getting Started Guide for Windows.

To configure NCache:

1. Install NCache open source NuGet.
2. Configure the cache cluster in client.ncconf.
3. Add the following code to `Startup.ConfigureServices`:

```
services.AddNCacheDistributedCache(configuration =>
{
    configuration.CacheName = "demoClusteredCache";
    configuration.EnableLogs = true;
    configuration.ExceptionsEnabled = true;
});
```

Use the distributed cache

To use the IDistributedCache interface, request an instance of IDistributedCache from any constructor in the app. The instance is provided by dependency injection (DI).

When the sample app starts, IDistributedCache is injected into `Startup.Configure`. The current time is cached using IApplicationLifetime (for more information, see Web Host: IApplicationLifetime interface):

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env,
    IApplicationLifetime lifetime, IDistributedCache cache)
{
    lifetime.ApplicationStarted.Register(() =>
    {
        var currentTimeUTC = DateTime.UtcNow.ToString();
        byte[] encodedCurrentTimeUTC = Encoding.UTF8.GetBytes(currentTimeUTC);
        var options = new DistributedCacheEntryOptions()
            .SetSlidingExpiration(TimeSpan.FromSeconds(20));
        cache.Set("cachedTimeUTC", encodedCurrentTimeUTC, options);
    });
```

The sample app injects IDistributedCache into the `IndexModel` for use by the Index page.

Each time the Index page is loaded, the cache is checked for the cached time in `OnGetAsync`. If the cached time hasn't expired, the time is displayed. If 20 seconds have elapsed since the last time the cached time was accessed (the last time this page was loaded), the page displays *Cached Time Expired*.

Immediately update the cached time to the current time by selecting the **Reset Cached Time** button. The button triggers the `OnPostResetCachedTime` handler method.

```
public class IndexModel : PageModel
{
    private readonly IDistributedCache _cache;

    public IndexModel(IDistributedCache cache)
    {
        _cache = cache;
    }

    public string CachedTimeUTC { get; set; }

    public async Task OnGetAsync()
    {
        CachedTimeUTC = "Cached Time Expired";
        var encodedCachedTimeUTC = await _cache.GetAsync("cachedTimeUTC");

        if (encodedCachedTimeUTC != null)
        {
            CachedTimeUTC = Encoding.UTF8.GetString(encodedCachedTimeUTC);
        }
    }

    public async Task<IActionResult> OnPostResetCachedTime()
    {
        var currentTimeUTC = DateTime.UtcNow.ToString();
        byte[] encodedCurrentTimeUTC = Encoding.UTF8.GetBytes(currentTimeUTC);
        var options = new DistributedCacheEntryOptions()
            .SetSlidingExpiration(TimeSpan.FromSeconds(20));
        await _cache.SetAsync("cachedTimeUTC", encodedCurrentTimeUTC, options);

        return RedirectToPage();
    }
}
```

> **NOTE**
>
> There's no need to use a Singleton or Scoped lifetime for IDistributedCache instances (at least for the built-in implementations).
>
> You can also create an IDistributedCache instance wherever you might need one instead of using DI, but creating an instance in code can make your code harder to test and violates the Explicit Dependencies Principle.

Recommendations

When deciding which implementation of IDistributedCache is best for your app, consider the following:

- Existing infrastructure
- Performance requirements
- Cost
- Team experience

Caching solutions usually rely on in-memory storage to provide fast retrieval of cached data, but memory is a limited resource and costly to expand. Only store commonly used data in a cache.

Generally, a Redis cache provides higher throughput and lower latency than a SQL Server cache. However, benchmarking is usually required to determine the performance characteristics of caching strategies.

When SQL Server is used as a distributed cache backing store, use of the same database for the cache and the app's ordinary data storage and retrieval can negatively impact the performance of both. We recommend using a dedicated SQL Server instance for the distributed cache backing store.

Response Caching Middleware in ASP.NET Core

9/22/2020 • 14 minutes to read • Edit Online

By John Luo

This article explains how to configure Response Caching Middleware in an ASP.NET Core app. The middleware determines when responses are cacheable, stores responses, and serves responses from cache. For an introduction to HTTP caching and the `[ResponseCache]` attribute, see Response Caching.

View or download sample code (how to download)

Configuration

Response Caching Middleware is implicitly available for ASP.NET Core apps via the shared framework.

In `Startup.ConfigureServices`, add the Response Caching Middleware to the service collection:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCaching();
    services.AddRazorPages();
}
```

Configure the app to use the middleware with the UseResponseCaching extension method, which adds the middleware to the request processing pipeline in `Startup.Configure`:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
    }

    app.UseStaticFiles();
    app.UseRouting();
    // UseCors must be called before UseResponseCaching
    // app.UseCors("myAllowSpecificOrigins");

    app.UseResponseCaching();

    app.Use(async (context, next) =>
    {
        context.Response.GetTypedHeaders().CacheControl =
            new Microsoft.Net.Http.Headers.CacheControlHeaderValue()
            {
                Public = true,
                MaxAge = TimeSpan.FromSeconds(10)
            };
        context.Response.Headers[Microsoft.Net.Http.Headers.HeaderNames.Vary] =
            new string[] { "Accept-Encoding" };

        await next();
    });

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

WARNING

UseCors must be called before UseResponseCaching when using CORS middleware.

The sample app adds headers to control caching on subsequent requests:

- Cache-Control: Caches cacheable responses for up to 10 seconds.
- Vary: Configures the middleware to serve a cached response only if the Accept-Encoding header of subsequent requests matches that of the original request.

```
// using Microsoft.AspNetCore.Http;

app.Use(async (context, next) =>
{
    context.Response.GetTypedHeaders().CacheControl =
        new Microsoft.Net.Http.Headers.CacheControlHeaderValue()
        {
            Public = true,
            MaxAge = TimeSpan.FromSeconds(10)
        };
    context.Response.Headers[Microsoft.Net.Http.Headers.HeaderNames.Vary] =
        new string[] { "Accept-Encoding" };

    await next();
});
```

The preceding headers are not written to the response and are overridden when a controller, action, or Razor Page:

- Has a [ResponseCache] attribute. This applies even if a property isn't set. For example, omitting the VaryByHeader property will cause the corresponding header to be removed from the response.

Response Caching Middleware only caches server responses that result in a 200 (OK) status code. Any other responses, including error pages, are ignored by the middleware.

> **WARNING**
> Responses containing content for authenticated clients must be marked as not cacheable to prevent the middleware from storing and serving those responses. See Conditions for caching for details on how the middleware determines if a response is cacheable.

Options

Response caching options are shown in the following table.

OPTION	DESCRIPTION
MaximumBodySize	The largest cacheable size for the response body in bytes. The default value is `64 * 1024 * 1024` (64 MB).
SizeLimit	The size limit for the response cache middleware in bytes. The default value is `100 * 1024 * 1024` (100 MB).
UseCaseSensitivePaths	Determines if responses are cached on case-sensitive paths. The default value is `false`.

The following example configures the middleware to:

- Cache responses with a body size smaller than or equal to 1,024 bytes.
- Store the responses by case-sensitive paths. For example, `/page1` and `/Page1` are stored separately.

```
services.AddResponseCaching(options =>
{
    options.MaximumBodySize = 1024;
    options.UseCaseSensitivePaths = true;
});
```

VaryByQueryKeys

When using MVC / web API controllers or Razor Pages page models, the `[ResponseCache]` attribute specifies the parameters necessary for setting the appropriate headers for response caching. The only parameter of the `[ResponseCache]` attribute that strictly requires the middleware is VaryByQueryKeys, which doesn't correspond to an actual HTTP header. For more information, see Response caching in ASP.NET Core.

When not using the `[ResponseCache]` attribute, response caching can be varied with `VaryByQueryKeys`. Use the ResponseCachingFeature directly from the HttpContext.Features:

```
var responseCachingFeature = context.HttpContext.Features.Get<IResponseCachingFeature>();

if (responseCachingFeature != null)
{
    responseCachingFeature.VaryByQueryKeys = new[] { "MyKey" };
}
```

Using a single value equal to `*` in `VaryByQueryKeys` varies the cache by all request query parameters.

HTTP headers used by Response Caching Middleware

The following table provides information on HTTP headers that affect response caching.

HEADER	DETAILS
`Authorization`	The response isn't cached if the header exists.
`Cache-Control`	The middleware only considers caching responses marked with the `public` cache directive. Control caching with the following parameters: • max-age • max-stale† • min-fresh • must-revalidate • no-cache • no-store • only-if-cached • private • public • s-maxage • proxy-revalidate‡ †If no limit is specified to `max-stale`, the middleware takes no action. ‡ `proxy-revalidate` has the same effect as `must-revalidate`. For more information, see RFC 7231: Request Cache-Control Directives.
`Pragma`	A `Pragma: no-cache` header in the request produces the same effect as `Cache-Control: no-cache`. This header is overridden by the relevant directives in the `Cache-Control` header, if present. Considered for backward compatibility with HTTP/1.0.

HEADER	DETAILS
`Set-Cookie`	The response isn't cached if the header exists. Any middleware in the request processing pipeline that sets one or more cookies prevents the Response Caching Middleware from caching the response (for example, the cookie-based TempData provider).
`Vary`	The `Vary` header is used to vary the cached response by another header. For example, cache responses by encoding by including the `Vary: Accept-Encoding` header, which caches responses for requests with headers `Accept-Encoding: gzip` and `Accept-Encoding: text/plain` separately. A response with a header value of `*` is never stored.
`Expires`	A response deemed stale by this header isn't stored or retrieved unless overridden by other `Cache-Control` headers.
`If-None-Match`	The full response is served from cache if the value isn't `*` and the `ETag` of the response doesn't match any of the values provided. Otherwise, a 304 (Not Modified) response is served.
`If-Modified-Since`	If the `If-None-Match` header isn't present, a full response is served from cache if the cached response date is newer than the value provided. Otherwise, a *304 - Not Modified* response is served.
`Date`	When serving from cache, the `Date` header is set by the middleware if it wasn't provided on the original response.
`Content-Length`	When serving from cache, the `Content-Length` header is set by the middleware if it wasn't provided on the original response.
`Age`	The `Age` header sent in the original response is ignored. The middleware computes a new value when serving a cached response.

Caching respects request Cache-Control directives

The middleware respects the rules of the HTTP 1.1 Caching specification. The rules require a cache to honor a valid `Cache-Control` header sent by the client. Under the specification, a client can make requests with a `no-cache` header value and force the server to generate a new response for every request. Currently, there's no developer control over this caching behavior when using the middleware because the middleware adheres to the official caching specification.

For more control over caching behavior, explore other caching features of ASP.NET Core. See the following topics:

- Cache in-memory in ASP.NET Core
- Distributed caching in ASP.NET Core
- Cache Tag Helper in ASP.NET Core MVC
- Distributed Cache Tag Helper in ASP.NET Core

Troubleshooting

If caching behavior isn't as expected, confirm that responses are cacheable and capable of being served from the cache. Examine the request's incoming headers and the response's outgoing headers. Enable logging to help with debugging.

When testing and troubleshooting caching behavior, a browser may set request headers that affect caching in undesirable ways. For example, a browser may set the `Cache-Control` header to `no-cache` or `max-age=0` when refreshing a page. The following tools can explicitly set request headers and are preferred for testing caching:

- Fiddler
- Postman

Conditions for caching

- The request must result in a server response with a 200 (OK) status code.
- The request method must be GET or HEAD.
- In `Startup.Configure`, Response Caching Middleware must be placed before middleware that require caching. For more information, see ASP.NET Core Middleware.
- The `Authorization` header must not be present.
- `Cache-Control` header parameters must be valid, and the response must be marked `public` and not marked `private`.
- The `Pragma: no-cache` header must not be present if the `Cache-Control` header isn't present, as the `Cache-Control` header overrides the `Pragma` header when present.
- The `Set-Cookie` header must not be present.
- `Vary` header parameters must be valid and not equal to `*`.
- The `Content-Length` header value (if set) must match the size of the response body.
- The IHttpSendFileFeature isn't used.
- The response must not be stale as specified by the `Expires` header and the `max-age` and `s-maxage` cache directives.
- Response buffering must be successful. The size of the response must be smaller than the configured or default SizeLimit. The body size of the response must be smaller than the configured or default MaximumBodySize.
- The response must be cacheable according to the RFC 7234 specifications. For example, the `no-store` directive must not exist in request or response header fields. See *Section 3: Storing Responses in Caches* of RFC 7234 for details.

> **NOTE**
>
> The Antiforgery system for generating secure tokens to prevent Cross-Site Request Forgery (CSRF) attacks sets the `Cache-Control` and `Pragma` headers to `no-cache` so that responses aren't cached. For information on how to disable antiforgery tokens for HTML form elements, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

This article explains how to configure Response Caching Middleware in an ASP.NET Core app. The middleware determines when responses are cacheable, stores responses, and serves responses from cache. For an introduction to HTTP caching and the `[ResponseCache]` attribute, see Response Caching.

View or download sample code (how to download)

Configuration

Use the Microsoft.AspNetCore.App metapackage or add a package reference to the Microsoft.AspNetCore.ResponseCaching package.

In `Startup.ConfigureServices`, add the Response Caching Middleware to the service collection:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCaching();
    services.AddMvc()
        .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

Configure the app to use the middleware with the UseResponseCaching extension method, which adds the middleware to the request processing pipeline in `Startup.Configure`:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
    }

    app.UseStaticFiles();

    app.UseResponseCaching();

    app.Use(async (context, next) =>
    {
        context.Response.GetTypedHeaders().CacheControl =
            new Microsoft.Net.Http.Headers.CacheControlHeaderValue()
            {
                Public = true,
                MaxAge = TimeSpan.FromSeconds(10)
            };
        context.Response.Headers[Microsoft.Net.Http.Headers.HeaderNames.Vary] =
            new string[] { "Accept-Encoding" };

        await next();
    });

    app.UseMvc();
}
```

The sample app adds headers to control caching on subsequent requests:

- Cache-Control: Caches cacheable responses for up to 10 seconds.
- Vary: Configures the middleware to serve a cached response only if the Accept-Encoding header of subsequent requests matches that of the original request.

```
// using Microsoft.AspNetCore.Http;

app.Use(async (context, next) =>
{
    context.Response.GetTypedHeaders().CacheControl =
        new Microsoft.Net.Http.Headers.CacheControlHeaderValue()
        {
            Public = true,
            MaxAge = TimeSpan.FromSeconds(10)
        };
    context.Response.Headers[Microsoft.Net.Http.Headers.HeaderNames.Vary] =
        new string[] { "Accept-Encoding" };

    await next();
});
```

The preceding headers are not written to the response and are overridden when a controller, action, or Razor Page:

- Has a [ResponseCache] attribute. This applies even if a property isn't set. For example, omitting the VaryByHeader property will cause the corresponding header to be removed from the response.

Response Caching Middleware only caches server responses that result in a 200 (OK) status code. Any other responses, including error pages, are ignored by the middleware.

> **WARNING**
>
> Responses containing content for authenticated clients must be marked as not cacheable to prevent the middleware from storing and serving those responses. See Conditions for caching for details on how the middleware determines if a response is cacheable.

Options

Response caching options are shown in the following table.

OPTION	DESCRIPTION
MaximumBodySize	The largest cacheable size for the response body in bytes. The default value is `64 * 1024 * 1024` (64 MB).
SizeLimit	The size limit for the response cache middleware in bytes. The default value is `100 * 1024 * 1024` (100 MB).
UseCaseSensitivePaths	Determines if responses are cached on case-sensitive paths. The default value is `false`.

The following example configures the middleware to:

- Cache responses with a body size smaller than or equal to 1,024 bytes.
- Store the responses by case-sensitive paths. For example, `/page1` and `/Page1` are stored separately.

```
services.AddResponseCaching(options =>
{
    options.MaximumBodySize = 1024;
    options.UseCaseSensitivePaths = true;
});
```

VaryByQueryKeys

When using MVC / web API controllers or Razor Pages page models, the `[ResponseCache]` attribute specifies the parameters necessary for setting the appropriate headers for response caching. The only parameter of the `[ResponseCache]` attribute that strictly requires the middleware is VaryByQueryKeys, which doesn't correspond to an actual HTTP header. For more information, see Response caching in ASP.NET Core.

When not using the `[ResponseCache]` attribute, response caching can be varied with `VaryByQueryKeys`. Use the ResponseCachingFeature directly from the HttpContext.Features:

```
var responseCachingFeature = context.HttpContext.Features.Get<IResponseCachingFeature>();

if (responseCachingFeature != null)
{
    responseCachingFeature.VaryByQueryKeys = new[] { "MyKey" };
}
```

Using a single value equal to `*` in `VaryByQueryKeys` varies the cache by all request query parameters.

HTTP headers used by Response Caching Middleware

The following table provides information on HTTP headers that affect response caching.

HEADER	DETAILS
`Authorization`	The response isn't cached if the header exists.
`Cache-Control`	The middleware only considers caching responses marked with the `public` cache directive. Control caching with the following parameters: • max-age • max-stale† • min-fresh • must-revalidate • no-cache • no-store • only-if-cached • private • public • s-maxage • proxy-revalidate‡ †If no limit is specified to `max-stale`, the middleware takes no action. ‡ `proxy-revalidate` has the same effect as `must-revalidate`. For more information, see RFC 7231: Request Cache-Control Directives.

HEADER	DETAILS
`Pragma`	A `Pragma: no-cache` header in the request produces the same effect as `Cache-Control: no-cache`. This header is overridden by the relevant directives in the `Cache-Control` header, if present. Considered for backward compatibility with HTTP/1.0.
`Set-Cookie`	The response isn't cached if the header exists. Any middleware in the request processing pipeline that sets one or more cookies prevents the Response Caching Middleware from caching the response (for example, the cookie-based TempData provider).
`Vary`	The `Vary` header is used to vary the cached response by another header. For example, cache responses by encoding by including the `Vary: Accept-Encoding` header, which caches responses for requests with headers `Accept-Encoding: gzip` and `Accept-Encoding: text/plain` separately. A response with a header value of `*` is never stored.
`Expires`	A response deemed stale by this header isn't stored or retrieved unless overridden by other `Cache-Control` headers.
`If-None-Match`	The full response is served from cache if the value isn't `*` and the `ETag` of the response doesn't match any of the values provided. Otherwise, a 304 (Not Modified) response is served.
`If-Modified-Since`	If the `If-None-Match` header isn't present, a full response is served from cache if the cached response date is newer than the value provided. Otherwise, a *304 - Not Modified* response is served.
`Date`	When serving from cache, the `Date` header is set by the middleware if it wasn't provided on the original response.
`Content-Length`	When serving from cache, the `Content-Length` header is set by the middleware if it wasn't provided on the original response.
`Age`	The `Age` header sent in the original response is ignored. The middleware computes a new value when serving a cached response.

Caching respects request Cache-Control directives

The middleware respects the rules of the HTTP 1.1 Caching specification. The rules require a cache to honor a valid `Cache-Control` header sent by the client. Under the specification, a client can make requests with a `no-cache` header value and force the server to generate a new response for every request. Currently, there's no developer control over this caching behavior when using the middleware because the middleware adheres to the official caching specification.

For more control over caching behavior, explore other caching features of ASP.NET Core. See the following

topics:

- Cache in-memory in ASP.NET Core
- Distributed caching in ASP.NET Core
- Cache Tag Helper in ASP.NET Core MVC
- Distributed Cache Tag Helper in ASP.NET Core

Troubleshooting

If caching behavior isn't as expected, confirm that responses are cacheable and capable of being served from the cache. Examine the request's incoming headers and the response's outgoing headers. Enable logging to help with debugging.

When testing and troubleshooting caching behavior, a browser may set request headers that affect caching in undesirable ways. For example, a browser may set the `Cache-Control` header to `no-cache` or `max-age=0` when refreshing a page. The following tools can explicitly set request headers and are preferred for testing caching:

- Fiddler
- Postman

Conditions for caching

- The request must result in a server response with a 200 (OK) status code.
- The request method must be GET or HEAD.
- In `Startup.Configure`, Response Caching Middleware must be placed before middleware that require caching. For more information, see ASP.NET Core Middleware.
- The `Authorization` header must not be present.
- `Cache-Control` header parameters must be valid, and the response must be marked `public` and not marked `private`.
- The `Pragma: no-cache` header must not be present if the `Cache-Control` header isn't present, as the `Cache-Control` header overrides the `Pragma` header when present.
- The `Set-Cookie` header must not be present.
- `Vary` header parameters must be valid and not equal to `*`.
- The `Content-Length` header value (if set) must match the size of the response body.
- The IHttpSendFileFeature isn't used.
- The response must not be stale as specified by the `Expires` header and the `max-age` and `s-maxage` cache directives.
- Response buffering must be successful. The size of the response must be smaller than the configured or default SizeLimit. The body size of the response must be smaller than the configured or default MaximumBodySize.
- The response must be cacheable according to the RFC 7234 specifications. For example, the `no-store` directive must not exist in request or response header fields. See *Section 3: Storing Responses in Caches* of RFC 7234 for details.

> **NOTE**
>
> The Antiforgery system for generating secure tokens to prevent Cross-Site Request Forgery (CSRF) attacks sets the `Cache-Control` and `Pragma` headers to `no-cache` so that responses aren't cached. For information on how to disable antiforgery tokens for HTML form elements, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

Object reuse with ObjectPool in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

By Steve Gordon, Ryan Nowak, and Günther Foidl

Microsoft.Extensions.ObjectPool is part of the ASP.NET Core infrastructure that supports keeping a group of objects in memory for reuse rather than allowing the objects to be garbage collected.

You might want to use the object pool if the objects that are being managed are:

- Expensive to allocate/initialize.
- Represent some limited resource.
- Used predictably and frequently.

For example, the ASP.NET Core framework uses the object pool in some places to reuse StringBuilder instances. `StringBuilder` allocates and manages its own buffers to hold character data. ASP.NET Core regularly uses `StringBuilder` to implement features, and reusing them provides a performance benefit.

Object pooling doesn't always improve performance:

- Unless the initialization cost of an object is high, it's usually slower to get the object from the pool.
- Objects managed by the pool aren't de-allocated until the pool is de-allocated.

Use object pooling only after collecting performance data using realistic scenarios for your app or library.

WARNING: The `ObjectPool` doesn't implement `IDisposable`. We don't recommend using it with types that need disposal. `ObjectPool` in ASP.NET Core 3.0 and later supports `IDisposable`.

NOTE: The ObjectPool doesn't place a limit on the number of objects that it will allocate, it places a limit on the number of objects it will retain.

Concepts

ObjectPool<T> - the basic object pool abstraction. Used to get and return objects.

PooledObjectPolicy<T> - implement this to customize how an object is created and how it is *reset* when returned to the pool. This can be passed into an object pool that you construct directly.... OR

Create acts as a factory for creating object pools.

The ObjectPool can be used in an app in multiple ways:

- Instantiating a pool.
- Registering a pool in Dependency injection (DI) as an instance.
- Registering the `ObjectPoolProvider<>` in DI and using it as a factory.

How to use ObjectPool

Call Get to get an object and Return to return the object. There's no requirement that you return every object. If you don't return an object, it will be garbage collected.

When DefaultObjectPoolProvider is used and `T` implements `IDisposable`:

- Items that are ***not*** returned to the pool will be disposed.

- When the pool gets disposed by DI, all items in the pool are disposed.

NOTE: After the pool is disposed:

- Calling `Get` throws a `ObjectDisposedException`.
- `return` disposes the given item.

ObjectPool sample

The following code:

- Adds `ObjectPoolProvider` to the Dependency injection (DI) container.
- Adds and configures `ObjectPool<StringBuilder>` to the DI container.
- Adds the `BirthdayMiddleware`.

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.TryAddSingleton<ObjectPoolProvider, DefaultObjectPoolProvider>();

        services.TryAddSingleton<ObjectPool<StringBuilder>>(serviceProvider =>
        {
            var provider = serviceProvider.GetRequiredService<ObjectPoolProvider>();
            var policy = new StringBuilderPooledObjectPolicy();
            return provider.Create(policy);
        });

        services.AddWebEncoders();
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        // Test using /?firstname=Steve&lastName=Gordon&day=28&month=9
        app.UseMiddleware<BirthdayMiddleware>();
    }
}
```

The following code implements `BirthdayMiddleware`

```
public class BirthdayMiddleware
{
    private readonly RequestDelegate _next;

    public BirthdayMiddleware(RequestDelegate next)
    {
        _next = next;
    }

    public async Task InvokeAsync(HttpContext context,
                                  ObjectPool<StringBuilder> builderPool)
    {
        if (context.Request.Query.TryGetValue("firstName", out var firstName) &&
            context.Request.Query.TryGetValue("lastName", out var lastName) &&
            context.Request.Query.TryGetValue("month", out var month) &&
            context.Request.Query.TryGetValue("day", out var day) &&
            int.TryParse(month, out var monthOfYear) &&
            int.TryParse(day, out var dayOfMonth))
        {
            var now = DateTime.UtcNow; // Ignoring timezones.

            // Request a StringBuilder from the pool.
            var stringBuilder = builderPool.Get();

            try
            {
                stringBuilder.Append("Hi ")
                    .Append(firstName).Append(" ").Append(lastName).Append(". ");

                var encoder = context.RequestServices.GetRequiredService<HtmlEncoder>();

                if (now.Day == dayOfMonth && now.Month == monthOfYear)
                {
                    stringBuilder.Append("Happy birthday!!!");

                    var html = encoder.Encode(stringBuilder.ToString());
                    await context.Response.WriteAsync(html);
                }
                else
                {
                    var thisYearsBirthday = new DateTime(now.Year, monthOfYear,
                                                         dayOfMonth);

                    int daysUntilBirthday = thisYearsBirthday > now
                        ? (thisYearsBirthday - now).Days
                        : (thisYearsBirthday.AddYears(1) - now).Days;

                    stringBuilder.Append("There are ")
                        .Append(daysUntilBirthday).Append(" days until your birthday!");

                    var html = encoder.Encode(stringBuilder.ToString());
                    await context.Response.WriteAsync(html);
                }
            }
            finally // Ensure this runs even if the main code throws.
            {
                // Return the StringBuilder to the pool.
                builderPool.Return(stringBuilder);
            }

            return;
        }

        await _next(context);
    }
}
```

Response compression in ASP.NET Core

9/22/2020 • 27 minutes to read • Edit Online

Network bandwidth is a limited resource. Reducing the size of the response usually increases the responsiveness of an app, often dramatically. One way to reduce payload sizes is to compress an app's responses.

View or download sample code (how to download)

When to use Response Compression Middleware

Use server-based response compression technologies in IIS, Apache, or Nginx. The performance of the middleware probably won't match that of the server modules. HTTP.sys server server and Kestrel server don't currently offer built-in compression support.

Use Response Compression Middleware when you're:

- Unable to use the following server-based compression technologies:
  - IIS Dynamic Compression module
  - Apache mod_deflate module
  - Nginx Compression and Decompression
- Hosting directly on:
  - HTTP.sys server (formerly called WebListener)
  - Kestrel server

Response compression

Usually, any response not natively compressed can benefit from response compression. Responses not natively compressed typically include: CSS, JavaScript, HTML, XML, and JSON. You shouldn't compress natively compressed assets, such as PNG files. If you attempt to further compress a natively compressed response, any small additional reduction in size and transmission time will likely be overshadowed by the time it took to process the compression. Don't compress files smaller than about 150-1000 bytes (depending on the file's content and the efficiency of compression). The overhead of compressing small files may produce a compressed file larger than the uncompressed file.

When a client can process compressed content, the client must inform the server of its capabilities by sending the `Accept-Encoding` header with the request. When a server sends compressed content, it must include information in the `Content-Encoding` header on how the compressed response is encoded. Content encoding designations supported by the middleware are shown in the following table.

`ACCEPT-ENCODING` HEADER VALUES	MIDDLEWARE SUPPORTED	DESCRIPTION
`br`	Yes (default)	Brotli compressed data format
`deflate`	No	DEFLATE compressed data format
`exi`	No	W3C Efficient XML Interchange
`gzip`	Yes	Gzip file format

`Accept-Encoding` HEADER VALUES	MIDDLEWARE SUPPORTED	DESCRIPTION
`identity`	Yes	"No encoding" identifier: The response must not be encoded.
`pack200-gzip`	No	Network Transfer Format for Java Archives
`*`	Yes	Any available content encoding not explicitly requested

For more information, see the IANA Official Content Coding List.

The middleware allows you to add additional compression providers for custom `Accept-Encoding` header values. For more information, see Custom Providers below.

The middleware is capable of reacting to quality value (qvalue, `q`) weighting when sent by the client to prioritize compression schemes. For more information, see RFC 7231: Accept-Encoding.

Compression algorithms are subject to a tradeoff between compression speed and the effectiveness of the compression. *Effectiveness* in this context refers to the size of the output after compression. The smallest size is achieved by the most *optimal* compression.

The headers involved in requesting, sending, caching, and receiving compressed content are described in the table below.

HEADER	ROLE
`Accept-Encoding`	Sent from the client to the server to indicate the content encoding schemes acceptable to the client.
`Content-Encoding`	Sent from the server to the client to indicate the encoding of the content in the payload.
`Content-Length`	When compression occurs, the `Content-Length` header is removed, since the body content changes when the response is compressed.
`Content-MD5`	When compression occurs, the `Content-MD5` header is removed, since the body content has changed and the hash is no longer valid.
`Content-Type`	Specifies the MIME type of the content. Every response should specify its `Content-Type`. The middleware checks this value to determine if the response should be compressed. The middleware specifies a set of default MIME types that it can encode, but you can replace or add MIME types.
`Vary`	When sent by the server with a value of `Accept-Encoding` to clients and proxies, the `Vary` header indicates to the client or proxy that it should cache (vary) responses based on the value of the `Accept-Encoding` header of the request. The result of returning content with the `Vary: Accept-Encoding` header is that both compressed and uncompressed responses are cached separately.

Explore the features of the Response Compression Middleware with the sample app. The sample illustrates:

- The compression of app responses using Gzip and custom compression providers.
- How to add a MIME type to the default list of MIME types for compression.

Package

Response Compression Middleware is provided by the Microsoft.AspNetCore.ResponseCompression package, which is implicitly included in ASP.NET Core apps.

Configuration

The following code shows how to enable the Response Compression Middleware for default MIME types and compression providers (Brotli and Gzip):

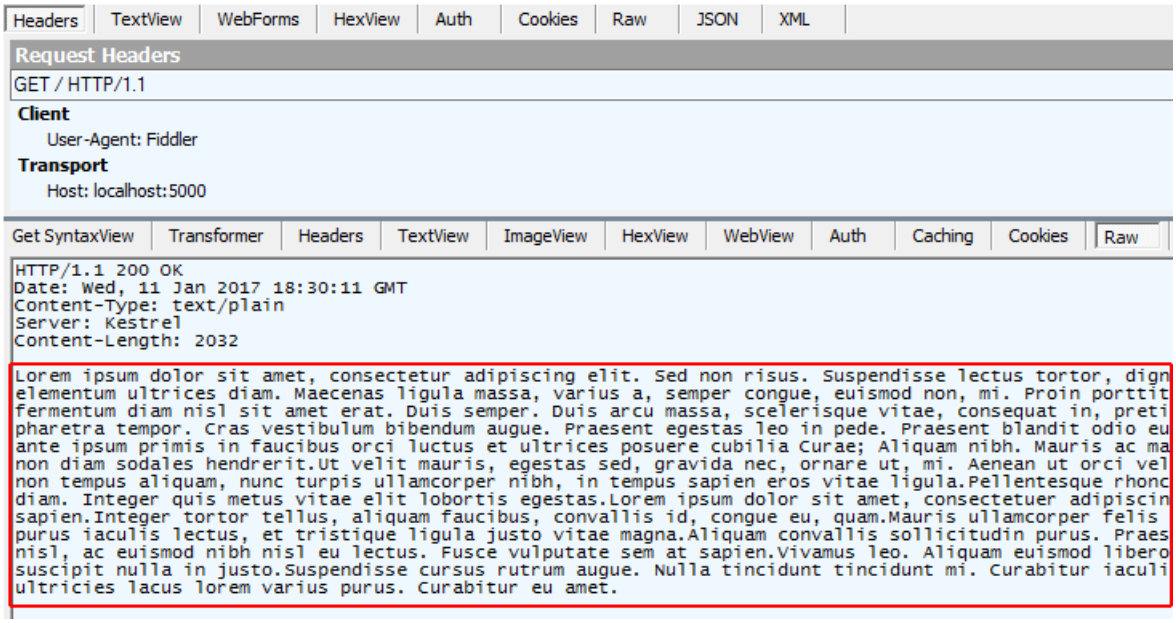
```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddResponseCompression();
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        app.UseResponseCompression();
    }
}
```

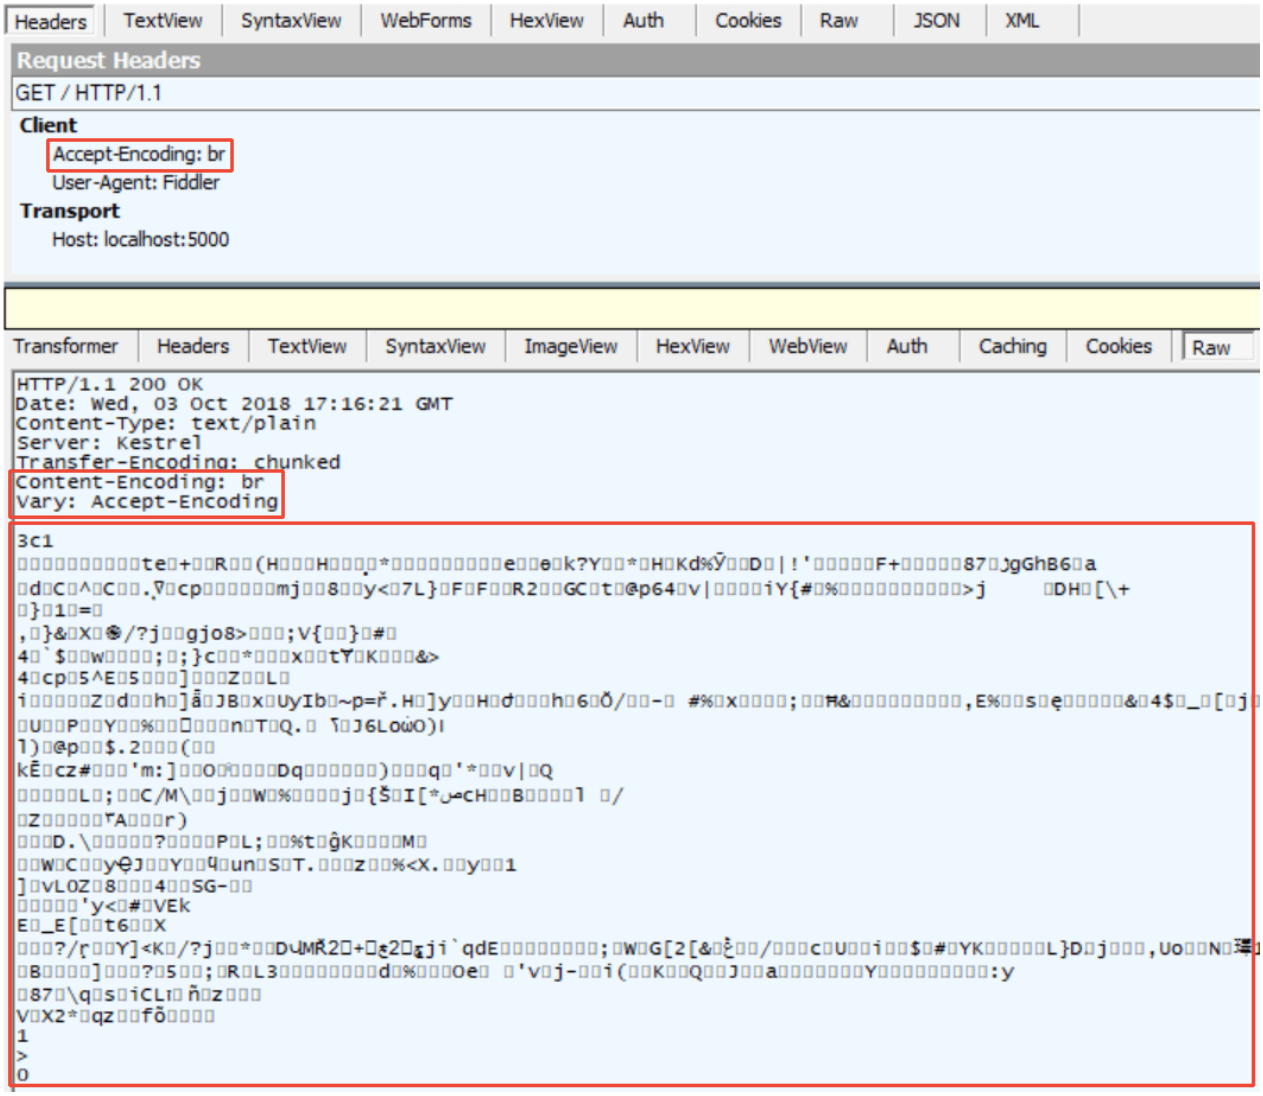
Notes:

- `app.UseResponseCompression` must be called before any middleware that compresses responses. For more information, see ASP.NET Core Middleware.
- Use a tool such as Fiddler, Firebug, or Postman to set the `Accept-Encoding` request header and study the response headers, size, and body.

Submit a request to the sample app without the `Accept-Encoding` header and observe that the response is uncompressed. The `Content-Encoding` and `Vary` headers aren't present on the response.



Submit a request to the sample app with the `Accept-Encoding: br` header (Brotli compression) and observe that the response is compressed. The `Content-Encoding` and `Vary` headers are present on the response.



Providers

Brotli Compression Provider

Use the BrotliCompressionProvider to compress responses with the Brotli compressed data format.

If no compression providers are explicitly added to the CompressionProviderCollection:

- The Brotli Compression Provider is added by default to the array of compression providers along with the Gzip compression provider.
- Compression defaults to Brotli compression when the Brotli compressed data format is supported by the client. If Brotli isn't supported by the client, compression defaults to Gzip when the client supports Gzip compression.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression();
}
```

The Brotli Compression Provider must be added when any compression providers are explicitly added:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression(options =>
    {
        options.Providers.Add<BrotliCompressionProvider>();
        options.Providers.Add<GzipCompressionProvider>();
        options.Providers.Add<CustomCompressionProvider>();
        options.MimeTypes =
            ResponseCompressionDefaults.MimeTypes.Concat(
                new[] { "image/svg+xml" });
    });
}
```

Set the compression level with BrotliCompressionProviderOptions. The Brotli Compression Provider defaults to the fastest compression level (CompressionLevel.Fastest), which might not produce the most efficient compression. If the most efficient compression is desired, configure the middleware for optimal compression.

COMPRESSION LEVEL	DESCRIPTION
CompressionLevel.Fastest	Compression should complete as quickly as possible, even if the resulting output isn't optimally compressed.
CompressionLevel.NoCompression	No compression should be performed.
CompressionLevel.Optimal	Responses should be optimally compressed, even if the compression takes more time to complete.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression();

    services.Configure<BrotliCompressionProviderOptions>(options =>
    {
        options.Level = CompressionLevel.Fastest;
    });
}
```

Gzip Compression Provider

Use the GzipCompressionProvider to compress responses with the Gzip file format.

If no compression providers are explicitly added to the CompressionProviderCollection:

- The Gzip Compression Provider is added by default to the array of compression providers along with the Brotli Compression Provider.
- Compression defaults to Brotli compression when the Brotli compressed data format is supported by the client. If Brotli isn't supported by the client, compression defaults to Gzip when the client supports Gzip compression.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression();
}
```

The Gzip Compression Provider must be added when any compression providers are explicitly added:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression(options =>
    {
        options.Providers.Add<BrotliCompressionProvider>();
        options.Providers.Add<GzipCompressionProvider>();
        options.Providers.Add<CustomCompressionProvider>();
        options.MimeTypes =
            ResponseCompressionDefaults.MimeTypes.Concat(
                new[] { "image/svg+xml" });
    });
}
```

Set the compression level with GzipCompressionProviderOptions. The Gzip Compression Provider defaults to the fastest compression level (CompressionLevel.Fastest), which might not produce the most efficient compression. If the most efficient compression is desired, configure the middleware for optimal compression.

COMPRESSION LEVEL	DESCRIPTION
CompressionLevel.Fastest	Compression should complete as quickly as possible, even if the resulting output isn't optimally compressed.
CompressionLevel.NoCompression	No compression should be performed.
CompressionLevel.Optimal	Responses should be optimally compressed, even if the compression takes more time to complete.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression();

    services.Configure<GzipCompressionProviderOptions>(options =>
    {
        options.Level = CompressionLevel.Fastest;
    });
}
```

Custom providers

Create custom compression implementations with ICompressionProvider. The EncodingName represents the content encoding that this `ICompressionProvider` produces. The middleware uses this information to choose the provider based on the list specified in the `Accept-Encoding` header of the request.

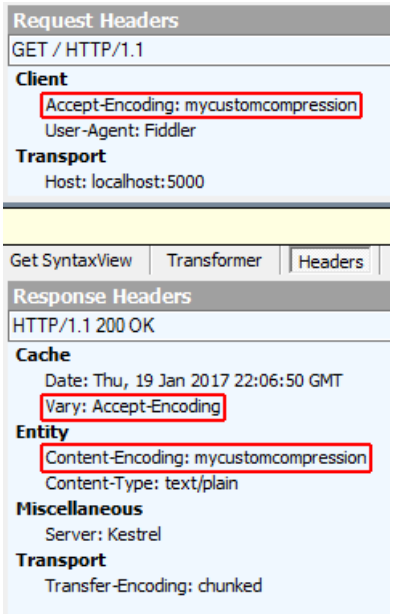
Using the sample app, the client submits a request with the `Accept-Encoding: mycustomcompression` header. The middleware uses the custom compression implementation and returns the response with a `Content-Encoding: mycustomcompression` header. The client must be able to decompress the custom encoding in order for a custom compression implementation to work.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression(options =>
    {
        options.Providers.Add<BrotliCompressionProvider>();
        options.Providers.Add<GzipCompressionProvider>();
        options.Providers.Add<CustomCompressionProvider>();
        options.MimeTypes =
            ResponseCompressionDefaults.MimeTypes.Concat(
                new[] { "image/svg+xml" });
    });
}
```

```
public class CustomCompressionProvider : ICompressionProvider
{
    public string EncodingName => "mycustomcompression";
    public bool SupportsFlush => true;

    public Stream CreateStream(Stream outputStream)
    {
        // Create a custom compression stream wrapper here
        return outputStream;
    }
}
```

Submit a request to the sample app with the `Accept-Encoding: mycustomcompression` header and observe the response headers. The `Vary` and `Content-Encoding` headers are present on the response. The response body (not shown) isn't compressed by the sample. There isn't a compression implementation in the `CustomCompressionProvider` class of the sample. However, the sample shows where you would implement such a compression algorithm.



MIME types

The middleware specifies a default set of MIME types for compression:

- `application/javascript`
- `application/json`
- `application/xml`
- `text/css`

- `text/html`
- `text/json`
- `text/plain`
- `text/xml`

Replace or append MIME types with the Response Compression Middleware options. Note that wildcard MIME types, such as `text/*` aren't supported. The sample app adds a MIME type for `image/svg+xml` and compresses and serves the ASP.NET Core banner image (*banner.svg*).

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression(options =>
    {
        options.Providers.Add<BrotliCompressionProvider>();
        options.Providers.Add<GzipCompressionProvider>();
        options.Providers.Add<CustomCompressionProvider>();
        options.MimeTypes =
            ResponseCompressionDefaults.MimeTypes.Concat(
                new[] { "image/svg+xml" });
    });
}
```

Compression with secure protocol

Compressed responses over secure connections can be controlled with the `EnableForHttps` option, which is disabled by default. Using compression with dynamically generated pages can lead to security problems such as the CRIME and BREACH attacks.

Adding the Vary header

When compressing responses based on the `Accept-Encoding` header, there are potentially multiple compressed versions of the response and an uncompressed version. In order to instruct client and proxy caches that multiple versions exist and should be stored, the `Vary` header is added with an `Accept-Encoding` value. In ASP.NET Core 2.0 or later, the middleware adds the `Vary` header automatically when the response is compressed.

Middleware issue when behind an Nginx reverse proxy

When a request is proxied by Nginx, the `Accept-Encoding` header is removed. Removal of the `Accept-Encoding` header prevents the middleware from compressing the response. For more information, see NGINX: Compression and Decompression. This issue is tracked by Figure out pass-through compression for Nginx (aspnet/BasicMiddleware #123).

Working with IIS dynamic compression

If you have an active IIS Dynamic Compression Module configured at the server level that you would like to disable for an app, disable the module with an addition to the *web.config* file. For more information, see Disabling IIS modules.

Troubleshooting

Use a tool like Fiddler, Firebug, or Postman, which allow you to set the `Accept-Encoding` request header and study the response headers, size, and body. By default, Response Compression Middleware compresses responses that meet the following conditions:

- The `Accept-Encoding` header is present with a value of `br`, `gzip`, `*`, or custom encoding that matches a

custom compression provider that you've established. The value must not be `identity` or have a quality value (qvalue, `q`) setting of 0 (zero).

- The MIME type (`Content-Type`) must be set and must match a MIME type configured on the ResponseCompressionOptions.
- The request must not include the `Content-Range` header.
- The request must use insecure protocol (http), unless secure protocol (https) is configured in the Response Compression Middleware options. *Note the danger described above when enabling secure content compression.*

Additional resources

When to use Response Compression Middleware

Use server-based response compression technologies in IIS, Apache, or Nginx. The performance of the middleware probably won't match that of the server modules. HTTP.sys server server and Kestrel server don't currently offer built-in compression support.

Use Response Compression Middleware when you're:

- Unable to use the following server-based compression technologies:
  - IIS Dynamic Compression module
  - Apache mod_deflate module
  - Nginx Compression and Decompression
- Hosting directly on:
  - HTTP.sys server (formerly called WebListener)
  - Kestrel server

Response compression

Usually, any response not natively compressed can benefit from response compression. Responses not natively compressed typically include: CSS, JavaScript, HTML, XML, and JSON. You shouldn't compress natively compressed assets, such as PNG files. If you attempt to further compress a natively compressed response, any small additional reduction in size and transmission time will likely be overshadowed by the time it took to process the compression. Don't compress files smaller than about 150-1000 bytes (depending on the file's content and the efficiency of compression). The overhead of compressing small files may produce a compressed file larger than the uncompressed file.

When a client can process compressed content, the client must inform the server of its capabilities by sending the `Accept-Encoding` header with the request. When a server sends compressed content, it must include information in the `Content-Encoding` header on how the compressed response is encoded. Content encoding designations supported by the middleware are shown in the following table.

`Accept-Encoding` header values	Middleware supported	Description
`br`	Yes (default)	Brotli compressed data format
`deflate`	No	DEFLATE compressed data format
`exi`	No	W3C Efficient XML Interchange
`gzip`	Yes	Gzip file format
`identity`	Yes	"No encoding" identifier: The response must not be encoded.
`pack200-gzip`	No	Network Transfer Format for Java Archives
`*`	Yes	Any available content encoding not explicitly requested

For more information, see the IANA Official Content Coding List.

The middleware allows you to add additional compression providers for custom `Accept-Encoding` header values. For more information, see Custom Providers below.

The middleware is capable of reacting to quality value (qvalue, `q`) weighting when sent by the client to prioritize compression schemes. For more information, see RFC 7231: Accept-Encoding.

Compression algorithms are subject to a tradeoff between compression speed and the effectiveness of the compression. *Effectiveness* in this context refers to the size of the output after compression. The smallest size is achieved by the most *optimal* compression.

The headers involved in requesting, sending, caching, and receiving compressed content are described in the table below.

Header	Role
`Accept-Encoding`	Sent from the client to the server to indicate the content encoding schemes acceptable to the client.
`Content-Encoding`	Sent from the server to the client to indicate the encoding of the content in the payload.
`Content-Length`	When compression occurs, the `Content-Length` header is removed, since the body content changes when the response is compressed.
`Content-MD5`	When compression occurs, the `Content-MD5` header is removed, since the body content has changed and the hash is no longer valid.
`Content-Type`	Specifies the MIME type of the content. Every response should specify its `Content-Type`. The middleware checks this value to determine if the response should be compressed. The middleware specifies a set of default MIME types that it can encode, but you can replace or add MIME types.

HEADER	ROLE
`Vary`	When sent by the server with a value of `Accept-Encoding` to clients and proxies, the `Vary` header indicates to the client or proxy that it should cache (vary) responses based on the value of the `Accept-Encoding` header of the request. The result of returning content with the `Vary: Accept-Encoding` header is that both compressed and uncompressed responses are cached separately.

Explore the features of the Response Compression Middleware with the sample app. The sample illustrates:

- The compression of app responses using Gzip and custom compression providers.
- How to add a MIME type to the default list of MIME types for compression.

Package

To include the middleware in a project, add a reference to the Microsoft.AspNetCore.App metapackage, which includes the Microsoft.AspNetCore.ResponseCompression package.

Configuration

The following code shows how to enable the Response Compression Middleware for default MIME types and compression providers (Brotli and Gzip):

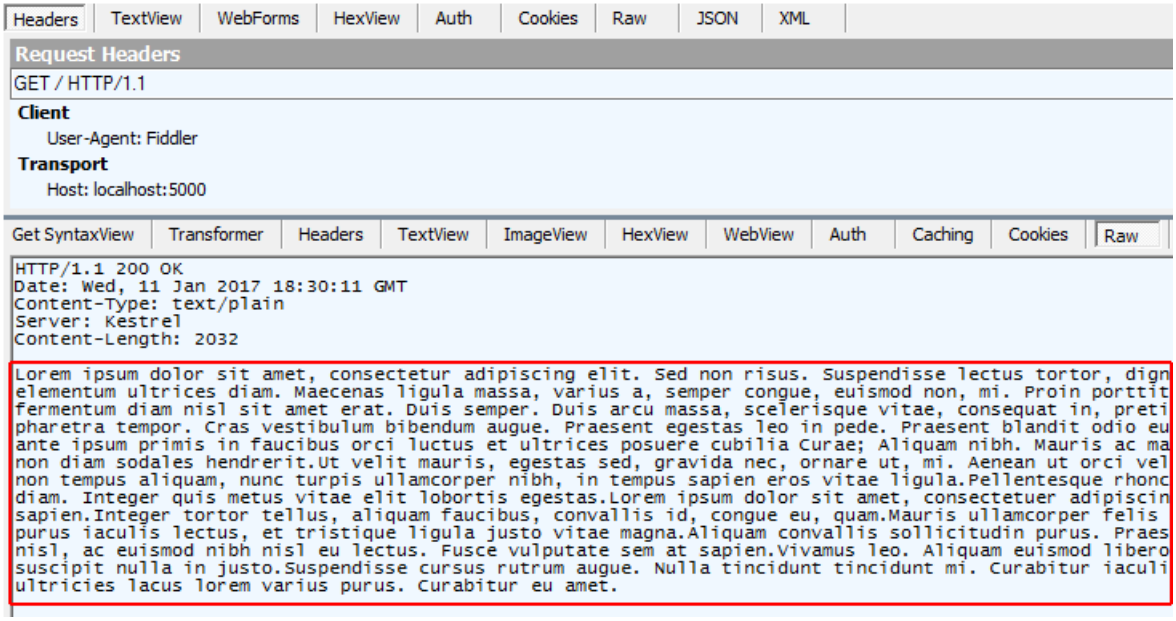
```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddResponseCompression();
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        app.UseResponseCompression();
    }
}
```

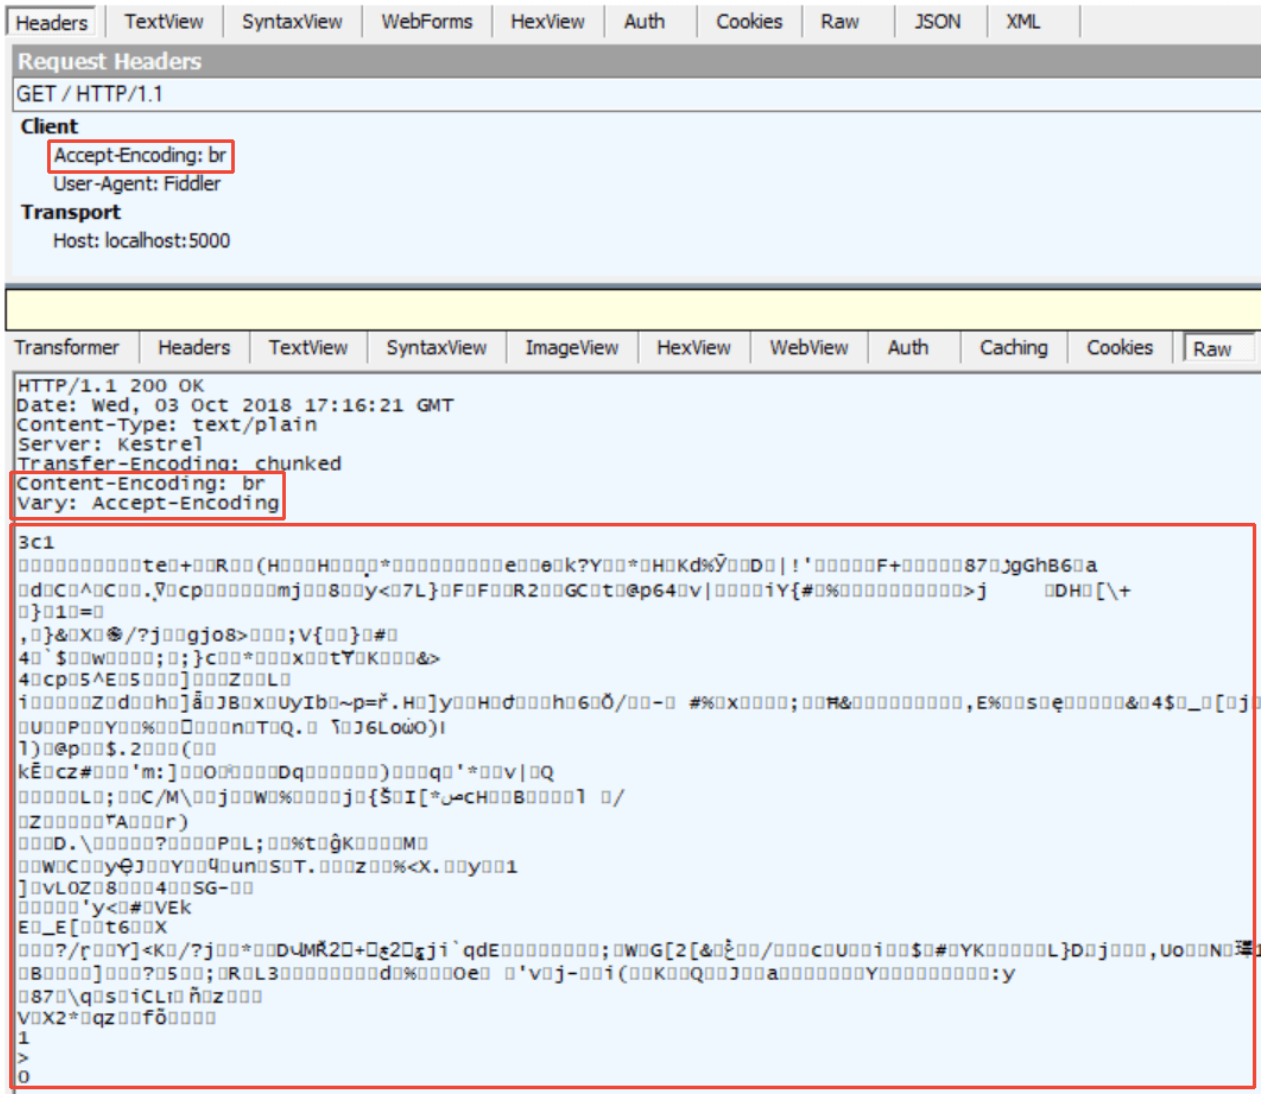
Notes:

- `app.UseResponseCompression` must be called before any middleware that compresses responses. For more information, see ASP.NET Core Middleware.
- Use a tool such as Fiddler, Firebug, or Postman to set the `Accept-Encoding` request header and study the response headers, size, and body.

Submit a request to the sample app without the `Accept-Encoding` header and observe that the response is uncompressed. The `Content-Encoding` and `Vary` headers aren't present on the response.



Submit a request to the sample app with the `Accept-Encoding: br` header (Brotli compression) and observe that the response is compressed. The `Content-Encoding` and `Vary` headers are present on the response.



Providers

Brotli Compression Provider

Use the BrotliCompressionProvider to compress responses with the Brotli compressed data format.

If no compression providers are explicitly added to the CompressionProviderCollection:

- The Brotli Compression Provider is added by default to the array of compression providers along with the Gzip compression provider.
- Compression defaults to Brotli compression when the Brotli compressed data format is supported by the client. If Brotli isn't supported by the client, compression defaults to Gzip when the client supports Gzip compression.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression();
}
```

The Brotli Compression Provider must be added when any compression providers are explicitly added:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression(options =>
    {
        options.Providers.Add<BrotliCompressionProvider>();
        options.Providers.Add<GzipCompressionProvider>();
        options.Providers.Add<CustomCompressionProvider>();
        options.MimeTypes =
            ResponseCompressionDefaults.MimeTypes.Concat(
                new[] { "image/svg+xml" });
    });
}
```

Set the compression level with BrotliCompressionProviderOptions. The Brotli Compression Provider defaults to the fastest compression level (CompressionLevel.Fastest), which might not produce the most efficient compression. If the most efficient compression is desired, configure the middleware for optimal compression.

COMPRESSION LEVEL	DESCRIPTION
CompressionLevel.Fastest	Compression should complete as quickly as possible, even if the resulting output isn't optimally compressed.
CompressionLevel.NoCompression	No compression should be performed.
CompressionLevel.Optimal	Responses should be optimally compressed, even if the compression takes more time to complete.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression();

    services.Configure<BrotliCompressionProviderOptions>(options =>
    {
        options.Level = CompressionLevel.Fastest;
    });
}
```

Gzip Compression Provider

Use the GzipCompressionProvider to compress responses with the Gzip file format.

If no compression providers are explicitly added to the CompressionProviderCollection:

- The Gzip Compression Provider is added by default to the array of compression providers along with the Brotli Compression Provider.
- Compression defaults to Brotli compression when the Brotli compressed data format is supported by the client. If Brotli isn't supported by the client, compression defaults to Gzip when the client supports Gzip compression.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression();
}
```

The Gzip Compression Provider must be added when any compression providers are explicitly added:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression(options =>
    {
        options.Providers.Add<BrotliCompressionProvider>();
        options.Providers.Add<GzipCompressionProvider>();
        options.Providers.Add<CustomCompressionProvider>();
        options.MimeTypes =
            ResponseCompressionDefaults.MimeTypes.Concat(
                new[] { "image/svg+xml" });
    });
}
```

Set the compression level with GzipCompressionProviderOptions. The Gzip Compression Provider defaults to the fastest compression level (CompressionLevel.Fastest), which might not produce the most efficient compression. If the most efficient compression is desired, configure the middleware for optimal compression.

COMPRESSION LEVEL	DESCRIPTION
CompressionLevel.Fastest	Compression should complete as quickly as possible, even if the resulting output isn't optimally compressed.
CompressionLevel.NoCompression	No compression should be performed.
CompressionLevel.Optimal	Responses should be optimally compressed, even if the compression takes more time to complete.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression();

    services.Configure<GzipCompressionProviderOptions>(options =>
    {
        options.Level = CompressionLevel.Fastest;
    });
}
```

Custom providers

Create custom compression implementations with ICompressionProvider. The EncodingName represents the content encoding that this `ICompressionProvider` produces. The middleware uses this information to choose the provider based on the list specified in the `Accept-Encoding` header of the request.

Using the sample app, the client submits a request with the `Accept-Encoding: mycustomcompression` header. The

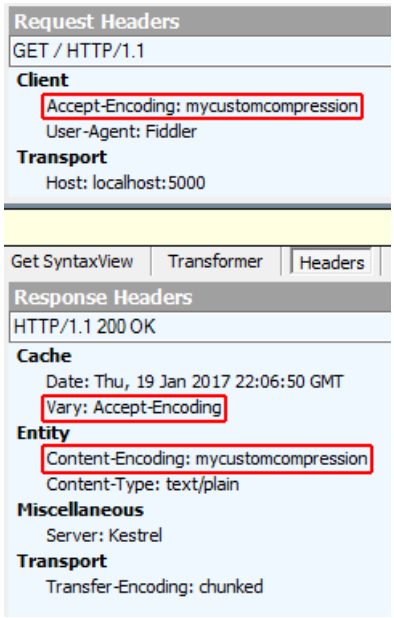
middleware uses the custom compression implementation and returns the response with a `Content-Encoding: mycustomcompression` header. The client must be able to decompress the custom encoding in order for a custom compression implementation to work.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression(options =>
    {
        options.Providers.Add<BrotliCompressionProvider>();
        options.Providers.Add<GzipCompressionProvider>();
        options.Providers.Add<CustomCompressionProvider>();
        options.MimeTypes =
            ResponseCompressionDefaults.MimeTypes.Concat(
                new[] { "image/svg+xml" });
    });
}
```

```
public class CustomCompressionProvider : ICompressionProvider
{
    public string EncodingName => "mycustomcompression";
    public bool SupportsFlush => true;

    public Stream CreateStream(Stream outputStream)
    {
        // Create a custom compression stream wrapper here
        return outputStream;
    }
}
```

Submit a request to the sample app with the `Accept-Encoding: mycustomcompression` header and observe the response headers. The `Vary` and `Content-Encoding` headers are present on the response. The response body (not shown) isn't compressed by the sample. There isn't a compression implementation in the `CustomCompressionProvider` class of the sample. However, the sample shows where you would implement such a compression algorithm.



MIME types

The middleware specifies a default set of MIME types for compression:

- `application/javascript`

- `application/json`
- `application/xml`
- `text/css`
- `text/html`
- `text/json`
- `text/plain`
- `text/xml`

Replace or append MIME types with the Response Compression Middleware options. Note that wildcard MIME types, such as `text/*` aren't supported. The sample app adds a MIME type for `image/svg+xml` and compresses and serves the ASP.NET Core banner image (*banner.svg*).

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression(options =>
    {
        options.Providers.Add<BrotliCompressionProvider>();
        options.Providers.Add<GzipCompressionProvider>();
        options.Providers.Add<CustomCompressionProvider>();
        options.MimeTypes =
            ResponseCompressionDefaults.MimeTypes.Concat(
                new[] { "image/svg+xml" });
    });
}
```

Compression with secure protocol

Compressed responses over secure connections can be controlled with the `EnableForHttps` option, which is disabled by default. Using compression with dynamically generated pages can lead to security problems such as the CRIME and BREACH attacks.

Adding the Vary header

When compressing responses based on the `Accept-Encoding` header, there are potentially multiple compressed versions of the response and an uncompressed version. In order to instruct client and proxy caches that multiple versions exist and should be stored, the `Vary` header is added with an `Accept-Encoding` value. In ASP.NET Core 2.0 or later, the middleware adds the `Vary` header automatically when the response is compressed.

Middleware issue when behind an Nginx reverse proxy

When a request is proxied by Nginx, the `Accept-Encoding` header is removed. Removal of the `Accept-Encoding` header prevents the middleware from compressing the response. For more information, see NGINX: Compression and Decompression. This issue is tracked by Figure out pass-through compression for Nginx (aspnet/BasicMiddleware #123).

Working with IIS dynamic compression

If you have an active IIS Dynamic Compression Module configured at the server level that you would like to disable for an app, disable the module with an addition to the *web.config* file. For more information, see Disabling IIS modules.

Troubleshooting

Use a tool like Fiddler, Firebug, or Postman, which allow you to set the `Accept-Encoding` request header and study

the response headers, size, and body. By default, Response Compression Middleware compresses responses that meet the following conditions:

- The `Accept-Encoding` header is present with a value of `br`, `gzip`, `*`, or custom encoding that matches a custom compression provider that you've established. The value must not be `identity` or have a quality value (qvalue, `q`) setting of 0 (zero).
- The MIME type (`Content-Type`) must be set and must match a MIME type configured on the ResponseCompressionOptions.
- The request must not include the `Content-Range` header.
- The request must use insecure protocol (http), unless secure protocol (https) is configured in the Response Compression Middleware options. *Note the danger described above when enabling secure content compression.*

Additional resources

- App startup in ASP.NET Core
- ASP.NET Core Middleware
- Mozilla Developer Network: Accept-Encoding
- RFC 7231 Section 3.1.2.1: Content Codings
- RFC 7230 Section 4.2.3: Gzip Coding
- GZIP file format specification version 4.3

Network bandwidth is a limited resource. Reducing the size of the response usually increases the responsiveness of an app, often dramatically. One way to reduce payload sizes is to compress an app's responses.

View or download sample code (how to download)

When to use Response Compression Middleware

Use server-based response compression technologies in IIS, Apache, or Nginx. The performance of the middleware probably won't match that of the server modules. HTTP.sys server server and Kestrel server don't currently offer built-in compression support.

Use Response Compression Middleware when you're:

- Unable to use the following server-based compression technologies:
  - IIS Dynamic Compression module
  - Apache mod_deflate module
  - Nginx Compression and Decompression
- Hosting directly on:
  - HTTP.sys server (formerly called WebListener)
  - Kestrel server

Response compression

Usually, any response not natively compressed can benefit from response compression. Responses not natively compressed typically include: CSS, JavaScript, HTML, XML, and JSON. You shouldn't compress natively compressed assets, such as PNG files. If you attempt to further compress a natively compressed response, any small additional reduction in size and transmission time will likely be overshadowed by the time it took to process the compression. Don't compress files smaller than about 150-1000 bytes (depending on the file's content and the efficiency of compression). The overhead of compressing small files may produce a compressed file larger than the uncompressed file.

When a client can process compressed content, the client must inform the server of its capabilities by sending the `Accept-Encoding` header with the request. When a server sends compressed content, it must include information in the `Content-Encoding` header on how the compressed response is encoded. Content encoding designations supported by the middleware are shown in the following table.

`ACCEPT-ENCODING` HEADER VALUES	MIDDLEWARE SUPPORTED	DESCRIPTION
`br`	No	Brotli compressed data format
`deflate`	No	DEFLATE compressed data format
`exi`	No	W3C Efficient XML Interchange
`gzip`	Yes (default)	Gzip file format
`identity`	Yes	"No encoding" identifier: The response must not be encoded.
`pack200-gzip`	No	Network Transfer Format for Java Archives
`*`	Yes	Any available content encoding not explicitly requested

For more information, see the IANA Official Content Coding List.

The middleware allows you to add additional compression providers for custom `Accept-Encoding` header values. For more information, see Custom Providers below.

The middleware is capable of reacting to quality value (qvalue, `q`) weighting when sent by the client to prioritize compression schemes. For more information, see RFC 7231: Accept-Encoding.

Compression algorithms are subject to a tradeoff between compression speed and the effectiveness of the compression. *Effectiveness* in this context refers to the size of the output after compression. The smallest size is achieved by the most *optimal* compression.

The headers involved in requesting, sending, caching, and receiving compressed content are described in the table below.

HEADER	ROLE
`Accept-Encoding`	Sent from the client to the server to indicate the content encoding schemes acceptable to the client.
`Content-Encoding`	Sent from the server to the client to indicate the encoding of the content in the payload.
`Content-Length`	When compression occurs, the `Content-Length` header is removed, since the body content changes when the response is compressed.
`Content-MD5`	When compression occurs, the `Content-MD5` header is removed, since the body content has changed and the hash is no longer valid.

HEADER	ROLE
`Content-Type`	Specifies the MIME type of the content. Every response should specify its `Content-Type`. The middleware checks this value to determine if the response should be compressed. The middleware specifies a set of default MIME types that it can encode, but you can replace or add MIME types.
`Vary`	When sent by the server with a value of `Accept-Encoding` to clients and proxies, the `Vary` header indicates to the client or proxy that it should cache (vary) responses based on the value of the `Accept-Encoding` header of the request. The result of returning content with the `Vary: Accept-Encoding` header is that both compressed and uncompressed responses are cached separately.

Explore the features of the Response Compression Middleware with the sample app. The sample illustrates:

- The compression of app responses using Gzip and custom compression providers.
- How to add a MIME type to the default list of MIME types for compression.

Package

To include the middleware in a project, add a reference to the Microsoft.AspNetCore.App metapackage, which includes the Microsoft.AspNetCore.ResponseCompression package.

Configuration

The following code shows how to enable the Response Compression Middleware for default MIME types and the Gzip Compression Provider:

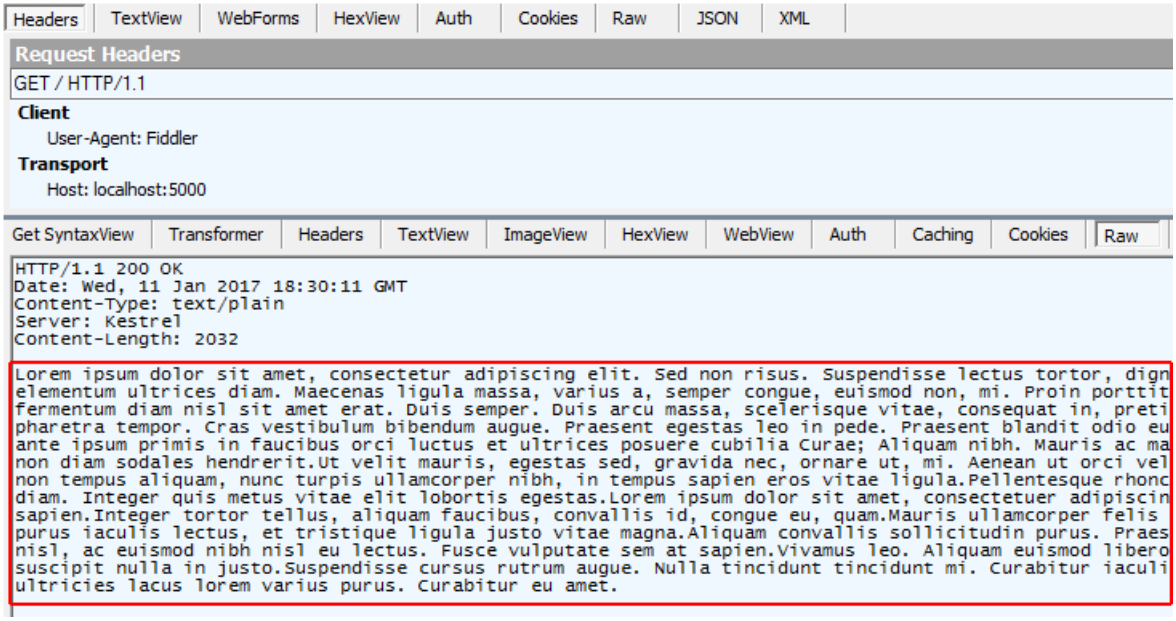
```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddResponseCompression();
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        app.UseResponseCompression();
    }
}
```

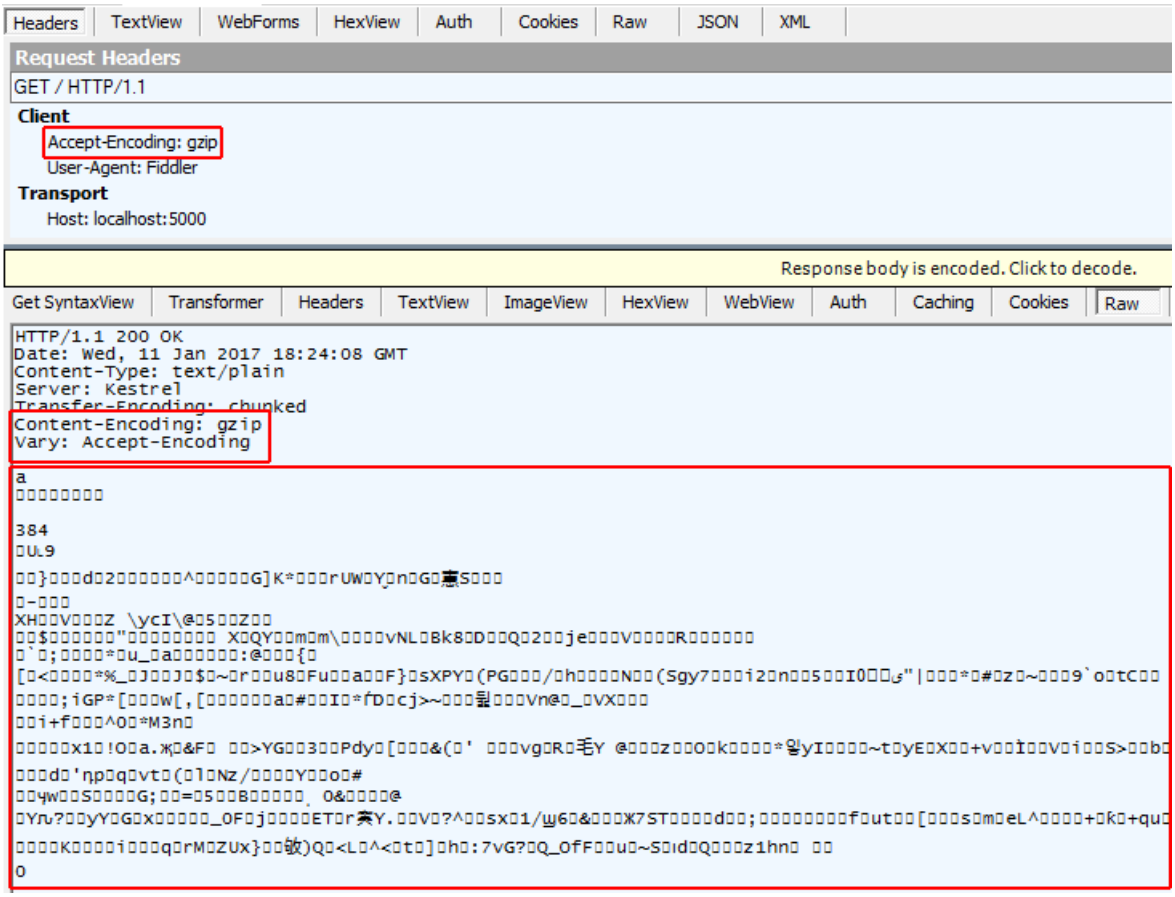
Notes:

- `app.UseResponseCompression` must be called before any middleware that compresses responses. For more information, see ASP.NET Core Middleware.
- Use a tool such as Fiddler, Firebug, or Postman to set the `Accept-Encoding` request header and study the response headers, size, and body.

Submit a request to the sample app without the `Accept-Encoding` header and observe that the response is uncompressed. The `Content-Encoding` and `Vary` headers aren't present on the response.



Submit a request to the sample app with the `Accept-Encoding: gzip` header and observe that the response is compressed. The `Content-Encoding` and `Vary` headers are present on the response.



Providers

Gzip Compression Provider

Use the GzipCompressionProvider to compress responses with the Gzip file format.

If no compression providers are explicitly added to the CompressionProviderCollection:

- The Gzip Compression Provider is added by default to the array of compression providers.
- Compression defaults to Gzip when the client supports Gzip compression.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression();
}
```

The Gzip Compression Provider must be added when any compression providers are explicitly added:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression(options =>
    {
        options.Providers.Add<BrotliCompressionProvider>();
        options.Providers.Add<GzipCompressionProvider>();
        options.Providers.Add<CustomCompressionProvider>();
        options.MimeTypes =
            ResponseCompressionDefaults.MimeTypes.Concat(
                new[] { "image/svg+xml" });
    });
}
```

Set the compression level with GzipCompressionProviderOptions. The Gzip Compression Provider defaults to the fastest compression level (CompressionLevel.Fastest), which might not produce the most efficient compression. If the most efficient compression is desired, configure the middleware for optimal compression.

COMPRESSION LEVEL	DESCRIPTION
CompressionLevel.Fastest	Compression should complete as quickly as possible, even if the resulting output isn't optimally compressed.
CompressionLevel.NoCompression	No compression should be performed.
CompressionLevel.Optimal	Responses should be optimally compressed, even if the compression takes more time to complete.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression();

    services.Configure<GzipCompressionProviderOptions>(options =>
    {
        options.Level = CompressionLevel.Fastest;
    });
}
```

Custom providers

Create custom compression implementations with ICompressionProvider. The EncodingName represents the content encoding that this `ICompressionProvider` produces. The middleware uses this information to choose the provider based on the list specified in the `Accept-Encoding` header of the request.

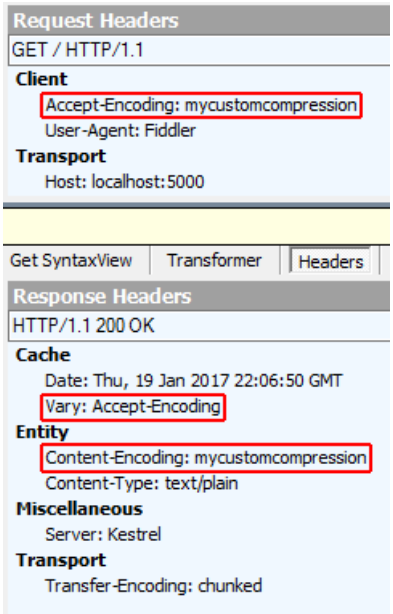
Using the sample app, the client submits a request with the `Accept-Encoding: mycustomcompression` header. The middleware uses the custom compression implementation and returns the response with a `Content-Encoding: mycustomcompression` header. The client must be able to decompress the custom encoding in order for a custom compression implementation to work.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression(options =>
    {
        options.Providers.Add<BrotliCompressionProvider>();
        options.Providers.Add<GzipCompressionProvider>();
        options.Providers.Add<CustomCompressionProvider>();
        options.MimeTypes =
            ResponseCompressionDefaults.MimeTypes.Concat(
                new[] { "image/svg+xml" });
    });
}
```

```
public class CustomCompressionProvider : ICompressionProvider
{
    public string EncodingName => "mycustomcompression";
    public bool SupportsFlush => true;

    public Stream CreateStream(Stream outputStream)
    {
        // Create a custom compression stream wrapper here
        return outputStream;
    }
}
```

Submit a request to the sample app with the `Accept-Encoding: mycustomcompression` header and observe the response headers. The `Vary` and `Content-Encoding` headers are present on the response. The response body (not shown) isn't compressed by the sample. There isn't a compression implementation in the `CustomCompressionProvider` class of the sample. However, the sample shows where you would implement such a compression algorithm.



MIME types

The middleware specifies a default set of MIME types for compression:

- `application/javascript`
- `application/json`
- `application/xml`
- `text/css`

- `text/html`
- `text/json`
- `text/plain`
- `text/xml`

Replace or append MIME types with the Response Compression Middleware options. Note that wildcard MIME types, such as `text/*` aren't supported. The sample app adds a MIME type for `image/svg+xml` and compresses and serves the ASP.NET Core banner image (*banner.svg*).

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddResponseCompression(options =>
    {
        options.Providers.Add<BrotliCompressionProvider>();
        options.Providers.Add<GzipCompressionProvider>();
        options.Providers.Add<CustomCompressionProvider>();
        options.MimeTypes =
            ResponseCompressionDefaults.MimeTypes.Concat(
                new[] { "image/svg+xml" });
    });
}
```

Compression with secure protocol

Compressed responses over secure connections can be controlled with the `EnableForHttps` option, which is disabled by default. Using compression with dynamically generated pages can lead to security problems such as the CRIME and BREACH attacks.

Adding the Vary header

When compressing responses based on the `Accept-Encoding` header, there are potentially multiple compressed versions of the response and an uncompressed version. In order to instruct client and proxy caches that multiple versions exist and should be stored, the `Vary` header is added with an `Accept-Encoding` value. In ASP.NET Core 2.0 or later, the middleware adds the `Vary` header automatically when the response is compressed.

Middleware issue when behind an Nginx reverse proxy

When a request is proxied by Nginx, the `Accept-Encoding` header is removed. Removal of the `Accept-Encoding` header prevents the middleware from compressing the response. For more information, see NGINX: Compression and Decompression. This issue is tracked by Figure out pass-through compression for Nginx (aspnet/BasicMiddleware #123).

Working with IIS dynamic compression

If you have an active IIS Dynamic Compression Module configured at the server level that you would like to disable for an app, disable the module with an addition to the *web.config* file. For more information, see Disabling IIS modules.

Troubleshooting

Use a tool like Fiddler, Firebug, or Postman, which allow you to set the `Accept-Encoding` request header and study the response headers, size, and body. By default, Response Compression Middleware compresses responses that meet the following conditions:

- The `Accept-Encoding` header is present with a value of `gzip`, `*`, or custom encoding that matches a custom

compression provider that you've established. The value must not be `identity` or have a quality value (qvalue, `q`) setting of 0 (zero).

- The MIME type (`Content-Type`) must be set and must match a MIME type configured on the ResponseCompressionOptions.
- The request must not include the `Content-Range` header.
- The request must use insecure protocol (http), unless secure protocol (https) is configured in the Response Compression Middleware options. *Note the danger described above when enabling secure content compression.*

Performance Diagnostic Tools

9/22/2020 • 2 minutes to read • Edit Online

By Mike Rousos

This article lists tools for diagnosing performance issues in ASP.NET Core.

Visual Studio Diagnostic Tools

The profiling and diagnostic tools built into Visual Studio are a good place to start investigating performance issues. These tools are powerful and convenient to use from the Visual Studio development environment. The tooling allows analysis of CPU usage, memory usage, and performance events in ASP.NET Core apps. Being built-in makes profiling easy at development time.

More information is available in Visual Studio documentation.

Application Insights

Application Insights provides in-depth performance data for your app. Application Insights automatically collects data on response rates, failure rates, dependency response times, and more. Application Insights supports logging custom events and metrics specific to your app.

Azure Application Insights provides multiple ways to give insights on monitored apps:

- Application Map – helps spot performance bottlenecks or failure hot-spots across all components of distributed apps.
- Azure Metrics Explorer is a component of the Microsoft Azure portal that allows plotting charts, visually correlating trends, and investigating spikes and dips in metrics' values.
- Performance blade in Application Insights portal:
  - Shows performance details for different operations in the monitored app.
  - Allows drilling into a single operation to check all parts/dependencies that contribute to a long duration.
  - Profiler can be invoked from here to collect performance traces on-demand.
- Azure Application Insights Profiler allows regular and on-demand profiling of .NET apps. Azure portal shows captured performance traces with call stacks and hot paths. The trace files can also be downloaded for deeper analysis using PerfView.

Application Insights can be used in a variety environments:

- Optimized to work in Azure.
- Works in production, development, and staging.
- Works locally from Visual Studio or in other hosting environments.

For more information, see Application Insights for ASP.NET Core.

PerfView

PerfView is a performance analysis tool created by the .NET team specifically for diagnosing .NET performance issues. PerfView allows analysis of CPU usage, memory and GC behavior, performance events, and wall clock time.

You can learn more about PerfView and how to get started with PerfView video tutorials or by reading the user's

guide available in the tool or on GitHub.

Windows Performance Toolkit

Windows Performance Toolkit (WPT) consists of two components: Windows Performance Recorder (WPR) and Windows Performance Analyzer (WPA). The tools produce in-depth performance profiles of Windows operating systems and apps. WPT has richer ways of visualizing data, but its data collecting is less powerful than PerfView's.

PerfCollect

While PerfView is a useful performance analysis tool for .NET scenarios, it only runs on Windows so you can't use it to collect traces from ASP.NET Core apps running in Linux environments.

PerfCollect is a bash script that uses native Linux profiling tools (Perf and LTTng) to collect traces on Linux that can be analyzed by PerfView. PerfCollect is useful when performance problems show up in Linux environments where PerfView can't be used directly. Instead, PerfCollect can collect traces from .NET Core apps that are then analyzed on a Windows computer using PerfView.

More information about how to install and get started with PerfCollect is available on GitHub.

Other Third-party Performance Tools

The following lists some third-party performance tools that are useful in performance investigation of .NET Core applications.

- MiniProfiler
- dotTrace and dotMemory from JetBrains
- VTune from Intel

ASP.NET Core load/stress testing

9/22/2020 • 2 minutes to read • Edit Online

Load testing and stress testing are important to ensure a web app is performant and scalable. Their goals are different even though they often share similar tests.

Load tests: Test whether the app can handle a specified load of users for a certain scenario while still satisfying the response goal. The app is run under normal conditions.

Stress tests: Test app stability when running under extreme conditions, often for a long period of time. The tests place high user load, either spikes or gradually increasing load, on the app, or they limit the app's computing resources.

Stress tests determine if an app under stress can recover from failure and gracefully return to expected behavior. Under stress, the app isn't run under normal conditions.

Visual Studio 2019 announced plans to deprecate the load testing. The corresponding Azure DevOps cloud-based load testing service has been closed.

Third-party tools

The following list contains third-party web performance tools with various feature sets:

- Apache JMeter
- ApacheBench (ab)
- Gatling
- k6
- Locust
- West Wind WebSurge
- Netling
- Vegeta

Globalization and localization in ASP.NET Core

9/22/2020 • 52 minutes to read • Edit Online

By Rick Anderson, Damien Bowden, Bart Calixto, Nadeem Afana, and Hisham Bin Ateya

A multilingual website allows the site to reach a wider audience. ASP.NET Core provides services and middleware for localizing into different languages and cultures.

Internationalization involves Globalization and Localization. Globalization is the process of designing apps that support different cultures. Globalization adds support for input, display, and output of a defined set of language scripts that relate to specific geographic areas.

Localization is the process of adapting a globalized app, which you have already processed for localizability, to a particular culture/locale. For more information see **Globalization and localization terms** near the end of this document.

App localization involves the following:

1. Make the app's content localizable
2. Provide localized resources for the languages and cultures you support
3. Implement a strategy to select the language/culture for each request

View or download sample code (how to download)

Make the app's content localizable

IStringLocalizer and IStringLocalizer<T> were architected to improve productivity when developing localized apps. `IStringLocalizer` uses the ResourceManager and ResourceReader to provide culture-specific resources at run time. The interface has an indexer and an `IEnumerable` for returning localized strings. `IStringLocalizer` doesn't require storing the default language strings in a resource file. You can develop an app targeted for localization and not need to create resource files early in development. The code below shows how to wrap the string "About Title" for localization.

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Localization;

namespace Localization.Controllers
{
    [Route("api/[controller]")]
    public class AboutController : Controller
    {
        private readonly IStringLocalizer<AboutController> _localizer;

        public AboutController(IStringLocalizer<AboutController> localizer)
        {
            _localizer = localizer;
        }

        [HttpGet]
        public string Get()
        {
            return _localizer["About Title"];
        }
    }
}
```

In the preceding code, the `IStringLocalizer<T>` implementation comes from Dependency Injection. If the localized value of "About Title" isn't found, then the indexer key is returned, that is, the string "About Title". You can leave the default language literal strings in the app and wrap them in the localizer, so that you can focus on developing the app. You develop your app with your default language and prepare it for the localization step without first creating a default resource file. Alternatively, you can use the traditional approach and provide a key to retrieve the default language string. For many developers the new workflow of not having a default language *.resx* file and simply wrapping the string literals can reduce the overhead of localizing an app. Other developers will prefer the traditional work flow as it can make it easier to work with longer string literals and make it easier to update localized strings.

Use the `IHtmlLocalizer<T>` implementation for resources that contain HTML. `IHtmlLocalizer` HTML encodes arguments that are formatted in the resource string, but doesn't HTML encode the resource string itself. In the sample highlighted below, only the value of `name` parameter is HTML encoded.

```
using System;
using Microsoft.AspNetCore.Http;
using Microsoft.AspNetCore.Localization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.Localization;

namespace Localization.Controllers
{
    public class BookController : Controller
    {
        private readonly IHtmlLocalizer<BookController> _localizer;

        public BookController(IHtmlLocalizer<BookController> localizer)
        {
            _localizer = localizer;
        }

        public IActionResult Hello(string name)
        {
            ViewData["Message"] = _localizer["<b>Hello</b><i> {0}</i>", name];

            return View();
        }
```

NOTE

Generally, only localize text, not HTML.

At the lowest level, you can get `IStringLocalizerFactory` out of Dependency Injection:

```
{
    public class TestController : Controller
    {
        private readonly IStringLocalizer _localizer;
        private readonly IStringLocalizer _localizer2;

        public TestController(IStringLocalizerFactory factory)
        {
            var type = typeof(SharedResource);
            var assemblyName = new AssemblyName(type.GetTypeInfo().Assembly.FullName);
            _localizer = factory.Create(type);
            _localizer2 = factory.Create("SharedResource", assemblyName.Name);
        }

        public IActionResult About()
        {
            ViewData["Message"] = _localizer["Your application description page."]
                + " loc 2: " + _localizer2["Your application description page."];
```

The code above demonstrates each of the two factory create methods.

You can partition your localized strings by controller, area, or have just one container. In the sample app, a dummy class named `SharedResource` is used for shared resources.

```
// Dummy class to group shared resources

namespace Localization
{
    public class SharedResource
    {
    }
}
```

Some developers use the `Startup` class to contain global or shared strings. In the sample below, the `InfoController` and the `SharedResource` localizers are used:

```
public class InfoController : Controller
{
    private readonly IStringLocalizer<InfoController> _localizer;
    private readonly IStringLocalizer<SharedResource> _sharedLocalizer;

    public InfoController(IStringLocalizer<InfoController> localizer,
                          IStringLocalizer<SharedResource> sharedLocalizer)
    {
        _localizer = localizer;
        _sharedLocalizer = sharedLocalizer;
    }

    public string TestLoc()
    {
        string msg = "Shared resx: " + _sharedLocalizer["Hello!"] +
                     " Info resx " + _localizer["Hello!"];
        return msg;
    }
```

View localization

The `IViewLocalizer` service provides localized strings for a view. The `ViewLocalizer` class implements this interface and finds the resource location from the view file path. The following code shows how to use the default implementation of `IViewLocalizer`:

```
@using Microsoft.AspNetCore.Mvc.Localization

@inject IViewLocalizer Localizer

@{
    ViewData["Title"] = Localizer["About"];
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<p>@Localizer["Use this area to provide additional information."]</p>
```

The default implementation of `IViewLocalizer` finds the resource file based on the view's file name. There's no option to use a global shared resource file. `ViewLocalizer` implements the localizer using `IHtmlLocalizer`, so Razor doesn't HTML encode the localized string. You can parameterize resource strings and `IViewLocalizer` will HTML encode the parameters, but not the resource string. Consider the following Razor markup:

```
@Localizer["<i>Hello</i> <b>{0}!</b>", UserManager.GetUserName(User)]
```

A French resource file could contain the following:

KEY	VALUE
`<i>Hello</i> <b>{0}!</b>`	`<i>Bonjour</i> <b>{0} !</b>`

The rendered view would contain the HTML markup from the resource file.

> **NOTE**
> Generally, only localize text, not HTML.

To use a shared resource file in a view, inject `IHtmlLocalizer<T>`:

```
@using Microsoft.AspNetCore.Mvc.Localization
@using Localization.Services

@inject IViewLocalizer Localizer
@inject IHtmlLocalizer<SharedResource> SharedLocalizer

@{
    ViewData["Title"] = Localizer["About"];
}
<h2>@ViewData["Title"].</h2>

<h1>@SharedLocalizer["Hello!"]</h1>
```

DataAnnotations localization

DataAnnotations error messages are localized with `IStringLocalizer<T>`. Using the option `ResourcesPath = "Resources"`, the error messages in `RegisterViewModel` can be stored in either of the following paths:

- *Resources/ViewModels.Account.RegisterViewModel.fr.resx*
- *Resources/ViewModels/Account/RegisterViewModel.fr.resx*

```
public class RegisterViewModel
{
    [Required(ErrorMessage = "The Email field is required.")]
    [EmailAddress(ErrorMessage = "The Email field is not a valid email address.")]
    [Display(Name = "Email")]
    public string Email { get; set; }

    [Required(ErrorMessage = "The Password field is required.")]
    [StringLength(8, ErrorMessage = "The {0} must be at least {2} characters long.", MinimumLength = 6)]
    [DataType(DataType.Password)]
    [Display(Name = "Password")]
    public string Password { get; set; }

    [DataType(DataType.Password)]
    [Display(Name = "Confirm password")]
    [Compare("Password", ErrorMessage = "The password and confirmation password do not match.")]
    public string ConfirmPassword { get; set; }
}
```

In ASP.NET Core MVC 1.1.0 and higher, non-validation attributes are localized. ASP.NET Core MVC 1.0 does **not** look up localized strings for non-validation attributes.

Using one resource string for multiple classes

The following code shows how to use one resource string for validation attributes with multiple classes:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
        .AddDataAnnotationsLocalization(options => {
            options.DataAnnotationLocalizerProvider = (type, factory) =>
                factory.Create(typeof(SharedResource));
        });
}
```

In the preceding code, `SharedResource` is the class corresponding to the resx where your validation messages are stored. With this approach, DataAnnotations will only use `SharedResource`, rather than the resource for each class.

Provide localized resources for the languages and cultures you support

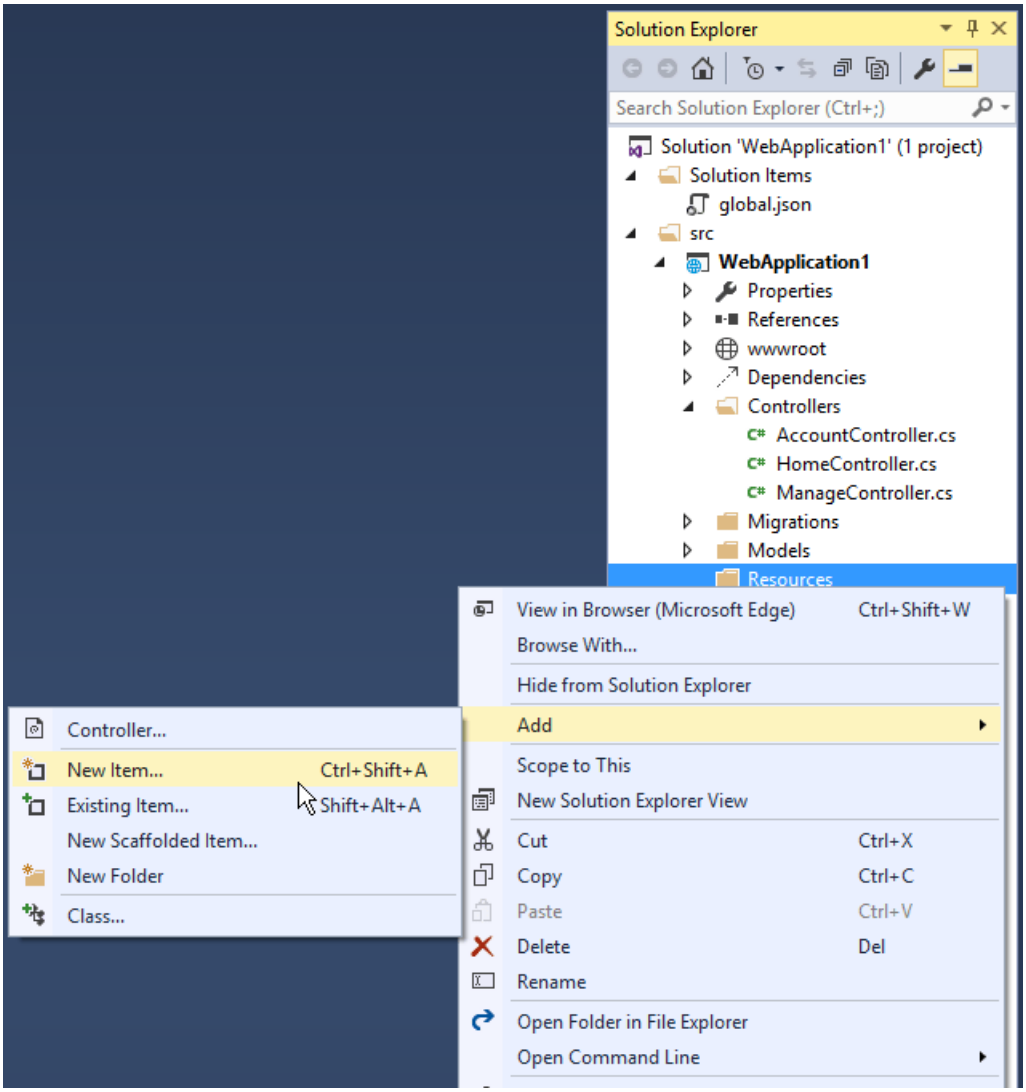
SupportedCultures and SupportedUICultures

ASP.NET Core allows you to specify two culture values, `SupportedCultures` and `SupportedUICultures`. The CultureInfo object for `SupportedCultures` determines the results of culture-dependent functions, such as date, time, number, and currency formatting. `SupportedCultures` also determines the sorting order of text, casing conventions, and string comparisons. See CultureInfo.CurrentCulture for more info on how the server gets the Culture. The `SupportedUICultures` determines which translated strings (from *.resx* files) are looked up by the ResourceManager. The `ResourceManager` simply looks up culture-specific strings that's determined by `CurrentUICulture`. Every thread in .NET has `CurrentCulture` and `CurrentUICulture` objects. ASP.NET Core inspects these values when rendering culture-dependent functions. For example, if the current thread's culture is set to "en-US" (English, United States), `DateTime.Now.ToLongDateString()` displays "Thursday, February 18, 2016", but if `CurrentCulture` is set to "es-ES" (Spanish, Spain) the output will be "jueves, 18 de febrero de 2016".

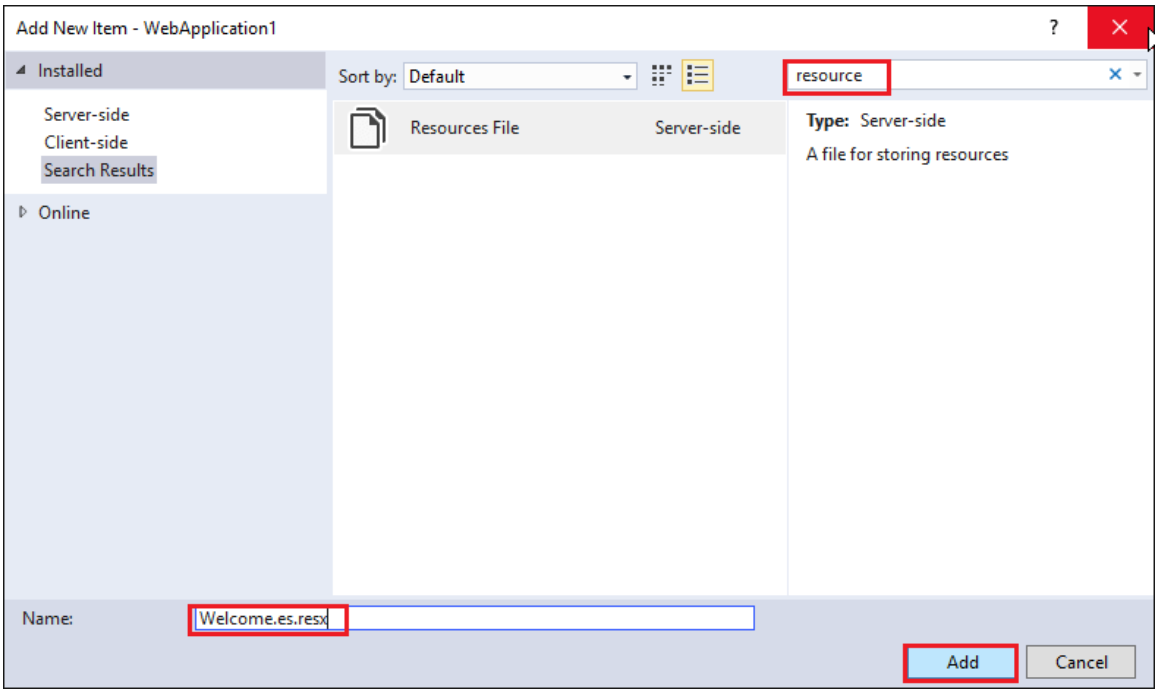
Resource files

A resource file is a useful mechanism for separating localizable strings from code. Translated strings for the non-default language are isolated in *.resx* resource files. For example, you might want to create Spanish resource file named *Welcome.es.resx* containing translated strings. "es" is the language code for Spanish. To create this resource file in Visual Studio:

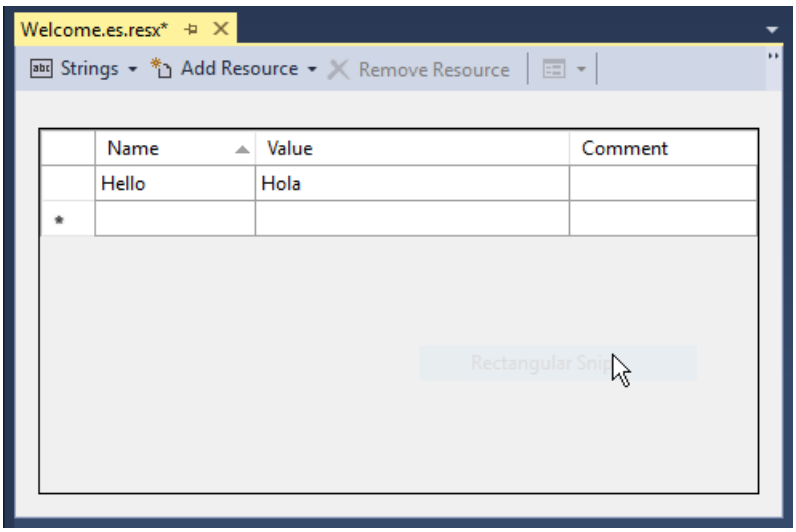
1. In **Solution Explorer**, right click on the folder which will contain the resource file > **Add** > **New Item**.



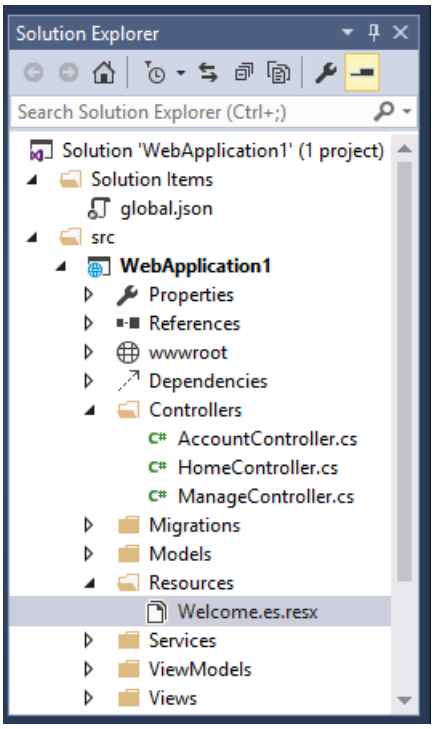
2. In the **Search installed templates** box, enter "resource" and name the file.



3. Enter the key value (native string) in the **Name** column and the translated string in the **Value** column.



Visual Studio shows the *Welcome.es.resx* file.



Resource file naming

Resources are named for the full type name of their class minus the assembly name. For example, a French resource in a project whose main assembly is `LocalizationWebsite.Web.dll` for the class `LocalizationWebsite.Web.Startup` would be named *Startup.fr.resx*. A resource for the class `LocalizationWebsite.Web.Controllers.HomeController` would be named *Controllers.HomeController.fr.resx*. If your targeted class's namespace isn't the same as the assembly name you will need the full type name. For example, in the sample project a resource for the type `ExtraNamespace.Tools` would be named *ExtraNamespace.Tools.fr.resx*.

In the sample project, the `ConfigureServices` method sets the `ResourcesPath` to "Resources", so the project relative path for the home controller's French resource file is *Resources/Controllers.HomeController.fr.resx*. Alternatively, you can use folders to organize resource files. For the home controller, the path would be *Resources/Controllers/HomeController.fr.resx*. If you don't use the `ResourcesPath` option, the *.resx* file would go in the project base directory. The resource file for `HomeController` would be named *Controllers.HomeController.fr.resx*. The choice of using the dot or path naming convention depends on how you want to organize your resource files.

RESOURCE NAME	DOT OR PATH NAMING
Resources/Controllers.HomeController.fr.resx	Dot
Resources/Controllers/HomeController.fr.resx	Path

Resource files using `@inject IViewLocalizer` in Razor views follow a similar pattern. The resource file for a view can be named using either dot naming or path naming. Razor view resource files mimic the path of their associated view file. Assuming we set the `ResourcesPath` to "Resources", the French resource file associated with the *Views/Home/About.cshtml* view could be either of the following:

- Resources/Views/Home/About.fr.resx
- Resources/Views.Home.About.fr.resx

If you don't use the `ResourcesPath` option, the *.resx* file for a view would be located in the same folder as the

view.

RootNamespaceAttribute

The RootNamespace attribute provides the root namespace of an assembly when the root namespace of an assembly is different than the assembly name.

> **WARNING**
> This can occur when a project's name is not a valid .NET identifier. For instance `my-project-name.csproj` will use the root namespace `my_project_name` and the assembly name `my-project-name` leading to this error.

If the root namespace of an assembly is different than the assembly name:

- Localization does not work by default.
- Localization fails due to the way resources are searched for within the assembly. `RootNamespace` is a build-time value which is not available to the executing process.

If the `RootNamespace` is different from the `AssemblyName`, include the following in *AssemblyInfo.cs* (with parameter values replaced with the actual values):

```
using System.Reflection;
using Microsoft.Extensions.Localization;

[assembly: ResourceLocation("Resource Folder Name")]
[assembly: RootNamespace("App Root Namespace")]
```

The preceding code enables the successful resolution of resx files.

Culture fallback behavior

When searching for a resource, localization engages in "culture fallback". Starting from the requested culture, if not found, it reverts to the parent culture of that culture. As an aside, the CultureInfo.Parent property represents the parent culture. This usually (but not always) means removing the national signifier from the ISO. For example, the dialect of Spanish spoken in Mexico is "es-MX". It has the parent "es"—Spanish non-specific to any country.

Imagine your site receives a request for a "Welcome" resource using culture "fr-CA". The localization system looks for the following resources, in order, and selects the first match:

- *Welcome.fr-CA.resx*
- *Welcome.fr.resx*
- *Welcome.resx* (if the `NeutralResourcesLanguage` is "fr-CA")

As an example, if you remove the ".fr" culture designator and you have the culture set to French, the default resource file is read and strings are localized. The Resource manager designates a default or fallback resource for when nothing meets your requested culture. If you want to just return the key when missing a resource for the requested culture you must not have a default resource file.

Generate resource files with Visual Studio

If you create a resource file in Visual Studio without a culture in the file name (for example, *Welcome.resx*), Visual Studio will create a C# class with a property for each string. That's usually not what you want with ASP.NET Core. You typically don't have a default *.resx* resource file (a *.resx* file without the culture name). We suggest you create the *.resx* file with a culture name (for example *Welcome.fr.resx*). When you create a *.resx* file with a culture name, Visual Studio won't generate the class file.

Add other cultures

Each language and culture combination (other than the default language) requires a unique resource file. You create resource files for different cultures and locales by creating new resource files in which the ISO language codes are part of the file name (for example, **en-us**, **fr-ca**, and **en-gb**). These ISO codes are placed between the file name and the *.resx* file extension, as in *Welcome.es-MX.resx* (Spanish/Mexico).

Implement a strategy to select the language/culture for each request

Configure localization

Localization is configured in the `Startup.ConfigureServices` method:

```
services.AddLocalization(options => options.ResourcesPath = "Resources");

services.AddMvc()
    .AddViewLocalization(LanguageViewLocationExpanderFormat.Suffix)
    .AddDataAnnotationsLocalization();
```

- `AddLocalization` adds the localization services to the services container. The code above also sets the resources path to "Resources".
- `AddViewLocalization` adds support for localized view files. In this sample view localization is based on the view file suffix. For example "fr" in the *Index.fr.cshtml* file.
- `AddDataAnnotationsLocalization` adds support for localized `DataAnnotations` validation messages through `IStringLocalizer` abstractions.

Localization middleware

The current culture on a request is set in the localization Middleware. The localization middleware is enabled in the `Startup.Configure` method. The localization middleware must be configured before any middleware which might check the request culture (for example, `app.UseMvcWithDefaultRoute()`).

```
var supportedCultures = new[] { "en-US", "fr" };
var localizationOptions = new RequestLocalizationOptions().SetDefaultCulture(supportedCultures[0])
    .AddSupportedCultures(supportedCultures)
    .AddSupportedUICultures(supportedCultures);

app.UseRequestLocalization(localizationOptions);

app.UseRouting();
app.UseStaticFiles();

app.UseAuthentication();

app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(name: "default", pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

`UseRequestLocalization` initializes a `RequestLocalizationOptions` object. On every request the list of `RequestCultureProvider` in the `RequestLocalizationOptions` is enumerated and the first provider that can successfully determine the request culture is used. The default providers come from the `RequestLocalizationOptions` class:

1. `QueryStringRequestCultureProvider`

2. `CookieRequestCultureProvider`
3. `AcceptLanguageHeaderRequestCultureProvider`

The default list goes from most specific to least specific. Later in the article we'll see how you can change the order and even add a custom culture provider. If none of the providers can determine the request culture, the `DefaultRequestCulture` is used.

QueryStringRequestCultureProvider

Some apps will use a query string to set the /dotnet/api/system.globalization.cultureinfo?view=netcore-3.1. For apps that use the cookie or Accept-Language header approach, adding a query string to the URL is useful for debugging and testing code. By default, the `QueryStringRequestCultureProvider` is registered as the first localization provider in the `RequestCultureProvider` list. You pass the query string parameters `culture` and `ui-culture`. The following example sets the specific culture (language and region) to Spanish/Mexico:

`http://localhost:5000/?culture=es-MX&ui-culture=es-MX`

If you only pass in one of the two (`culture` or `ui-culture`), the query string provider will set both values using the one you passed in. For example, setting just the culture will set both the `Culture` and the `UICulture`:

```
http://localhost:5000/?culture=es-MX
```

CookieRequestCultureProvider

Production apps will often provide a mechanism to set the culture with the ASP.NET Core culture cookie. Use the `MakeCookieValue` method to create a cookie.

The `CookieRequestCultureProvider` `DefaultCookieName` returns the default cookie name used to track the user's preferred culture information. The default cookie name is `.AspNetCore.Culture`.

The cookie format is `c=%LANGCODE%|uic=%LANGCODE%`, where `c` is `Culture` and `uic` is `UICulture`, for example:

```
c=en-UK|uic=en-US
```

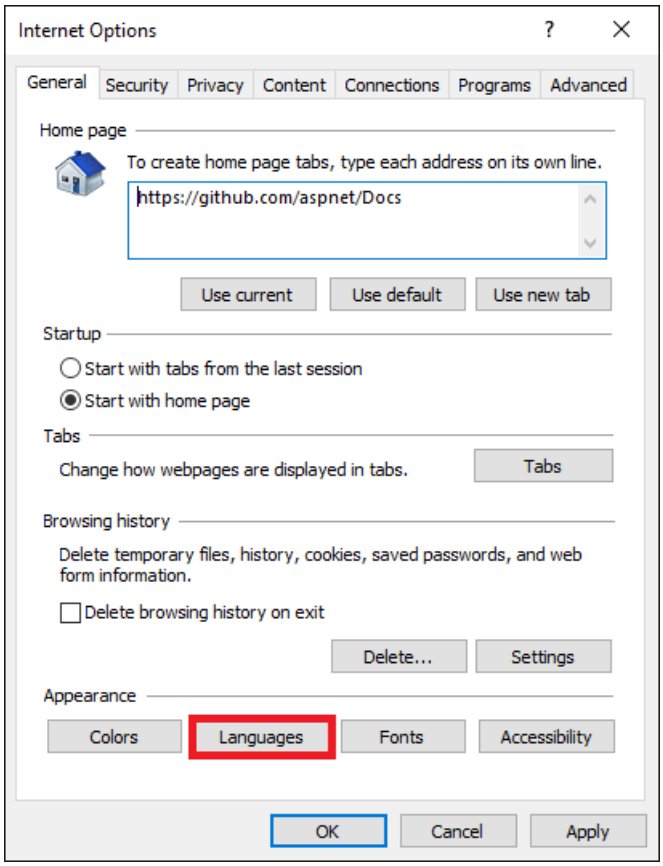
If you only specify one of culture info and UI culture, the specified culture will be used for both culture info and UI culture.

The Accept-Language HTTP header

The Accept-Language header is settable in most browsers and was originally intended to specify the user's language. This setting indicates what the browser has been set to send or has inherited from the underlying operating system. The Accept-Language HTTP header from a browser request isn't an infallible way to detect the user's preferred language (see Setting language preferences in a browser). A production app should include a way for a user to customize their choice of culture.

Set the Accept-Language HTTP header in IE

1. From the gear icon, tap **Internet Options**.
2. Tap **Languages**.



3. Tap **Set Language Preferences**.
4. Tap **Add a language**.
5. Add the language.
6. Tap the language, then tap **Move Up**.

Use a custom provider

Suppose you want to let your customers store their language and culture in your databases. You could write a provider to look up these values for the user. The following code shows how to add a custom provider:

```
private const string enUSCulture = "en-US";

services.Configure<RequestLocalizationOptions>(options =>
{
    var supportedCultures = new[]
    {
        new CultureInfo(enUSCulture),
        new CultureInfo("fr")
    };

    options.DefaultRequestCulture = new RequestCulture(culture: enUSCulture, uiCulture: enUSCulture);
    options.SupportedCultures = supportedCultures;
    options.SupportedUICultures = supportedCultures;

    options.AddInitialRequestCultureProvider(new CustomRequestCultureProvider(async context =>
    {
        // My custom request culture logic
        return new ProviderCultureResult("en");
    }));
});
```

Use `RequestLocalizationOptions` to add or remove localization providers.

Set the culture programmatically

This sample **Localization.StarterWeb** project on GitHub contains UI to set the `Culture`. The *Views/Shared/_SelectLanguagePartial.cshtml* file allows you to select the culture from the list of supported cultures:

```
@using Microsoft.AspNetCore.Builder
@using Microsoft.AspNetCore.Http.Features
@using Microsoft.AspNetCore.Localization
@using Microsoft.AspNetCore.Mvc.Localization
@using Microsoft.Extensions.Options

@inject IViewLocalizer Localizer
@inject IOptions<RequestLocalizationOptions> LocOptions

@{
    var requestCulture = Context.Features.Get<IRequestCultureFeature>();
    var cultureItems = LocOptions.Value.SupportedUICultures
        .Select(c => new SelectListItem { Value = c.Name, Text = c.DisplayName })
        .ToList();
    var returnUrl = string.IsNullOrEmpty(Context.Request.Path) ? "~/" : $"~{Context.Request.Path.Value}";
}

<div title="@Localizer["Request culture provider:"] @requestCulture?.Provider?.GetType().Name">
    <form id="selectLanguage" asp-controller="Home"
          asp-action="SetLanguage" asp-route-returnUrl="@returnUrl"
          method="post" class="form-horizontal" role="form">
        <label asp-for="@requestCulture.RequestCulture.UICulture.Name">@Localizer["Language:"]</label>
<select name="culture"
          onchange="this.form.submit();"
          asp-for="@requestCulture.RequestCulture.UICulture.Name" asp-items="cultureItems">
        </select>
    </form>
</div>
```

The *Views/Shared/_SelectLanguagePartial.cshtml* file is added to the `footer` section of the layout file so it will be available to all views:

```
<div class="container body-content" style="margin-top:60px">
    @RenderBody()
    <hr>
    <footer>
        <div class="row">
            <div class="col-md-6">
                <p>&copy; @System.DateTime.Now.Year - Localization</p>
            </div>
            <div class="col-md-6 text-right">
                @await Html.PartialAsync("_SelectLanguagePartial")
            </div>
        </div>
    </footer>
</div>
```

The `SetLanguage` method sets the culture cookie.

```
[HttpPost]
public IActionResult SetLanguage(string culture, string returnUrl)
{
    Response.Cookies.Append(
        CookieRequestCultureProvider.DefaultCookieName,
        CookieRequestCultureProvider.MakeCookieValue(new RequestCulture(culture)),
        new CookieOptions { Expires = DateTimeOffset.UtcNow.AddYears(1) }
    );

    return LocalRedirect(returnUrl);
}
```

You can't plug in the *_SelectLanguagePartial.cshtml* to sample code for this project. The **Localization.StarterWeb** project on GitHub has code to flow the `RequestLocalizationOptions` to a Razor partial through the Dependency Injection container.

Model binding route data and query strings

See Globalization behavior of model binding route data and query strings.

Globalization and localization terms

The process of localizing your app also requires a basic understanding of relevant character sets commonly used in modern software development and an understanding of the issues associated with them. Although all computers store text as numbers (codes), different systems store the same text using different numbers. The localization process refers to translating the app user interface (UI) for a specific culture/locale.

Localizability is an intermediate process for verifying that a globalized app is ready for localization.

The RFC 4646 format for the culture name is `<languagecode2>-<country/regioncode2>`, where `<languagecode2>` is the language code and `<country/regioncode2>` is the subculture code. For example, `es-CL` for Spanish (Chile), `en-US` for English (United States), and `en-AU` for English (Australia). RFC 4646 is a combination of an ISO 639 two-letter lowercase culture code associated with a language and an ISO 3166 two-letter uppercase subculture code associated with a country or region. See /previous-versions/commerce-server/ee825488(v=cs.20).

Internationalization is often abbreviated to "I18N". The abbreviation takes the first and last letters and the number of letters between them, so 18 stands for the number of letters between the first "I" and the last "N". The same applies to Globalization (G11N), and Localization (L10N).

Terms:

- Globalization (G11N): The process of making an app support different languages and regions.
- Localization (L10N): The process of customizing an app for a given language and region.
- Internationalization (I18N): Describes both globalization and localization.
- Culture: It's a language and, optionally, a region.
- Neutral culture: A culture that has a specified language, but not a region. (for example "en", "es")
- Specific culture: A culture that has a specified language and region. (for example "en-US", "en-GB", "es-CL")
- Parent culture: The neutral culture that contains a specific culture. (for example, "en" is the parent culture of "en-US" and "en-GB")
- Locale: A locale is the same as a culture.

NOTE

You may not be able to enter decimal commas in decimal fields. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. See this GitHub issue 4076 for instructions on adding decimal comma.

NOTE

Prior to ASP.NET Core 3.0 web apps write one log of type `LogLevel.Warning` per request if the requested culture is unsupported. Logging one `LogLevel.Warning` per request is can make large log files with redundant information. This behavior has been changed in ASP.NET 3.0. The `RequestLocalizationMiddleware` writes a log of type `LogLevel.Debug`, which reduces the size of production logs.

By Rick Anderson, Damien Bowden, Bart Calixto, Nadeem Afana, and Hisham Bin Ateya

A multilingual website allows the site to reach a wider audience. ASP.NET Core provides services and middleware for localizing into different languages and cultures.

Internationalization involves Globalization and Localization. Globalization is the process of designing apps that support different cultures. Globalization adds support for input, display, and output of a defined set of language scripts that relate to specific geographic areas.

Localization is the process of adapting a globalized app, which you have already processed for localizability, to a particular culture/locale. For more information see **Globalization and localization terms** near the end of this document.

App localization involves the following:

1. Make the app's content localizable
2. Provide localized resources for the languages and cultures you support
3. Implement a strategy to select the language/culture for each request

View or download sample code (how to download)

Make the app's content localizable

IStringLocalizer and IStringLocalizer<T> were architected to improve productivity when developing localized apps. `IStringLocalizer` uses the ResourceManager and ResourceReader to provide culture-specific resources at run time. The interface has an indexer and an `IEnumerable` for returning localized strings. `IStringLocalizer` doesn't require storing the default language strings in a resource file. You can develop an app targeted for localization and not need to create resource files early in development. The code below shows how to wrap the string "About Title" for localization.

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Localization;

namespace Localization.Controllers
{
    [Route("api/[controller]")]
    public class AboutController : Controller
    {
        private readonly IStringLocalizer<AboutController> _localizer;

        public AboutController(IStringLocalizer<AboutController> localizer)
        {
            _localizer = localizer;
        }

        [HttpGet]
        public string Get()
        {
            return _localizer["About Title"];
        }
    }
}
```

In the preceding code, the `IStringLocalizer<T>` implementation comes from Dependency Injection. If the localized value of "About Title" isn't found, then the indexer key is returned, that is, the string "About Title". You can leave the default language literal strings in the app and wrap them in the localizer, so that you can focus on developing the app. You develop your app with your default language and prepare it for the localization step without first creating a default resource file. Alternatively, you can use the traditional approach and provide a key to retrieve the default language string. For many developers the new workflow of not having a default language *.resx* file and simply wrapping the string literals can reduce the overhead of localizing an app. Other developers will prefer the traditional work flow as it can make it easier to work with longer string literals and make it easier to update localized strings.

Use the `IHtmlLocalizer<T>` implementation for resources that contain HTML. `IHtmlLocalizer` HTML encodes arguments that are formatted in the resource string, but doesn't HTML encode the resource string itself. In the sample highlighted below, only the value of `name` parameter is HTML encoded.

```
using System;
using Microsoft.AspNetCore.Http;
using Microsoft.AspNetCore.Localization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.Localization;

namespace Localization.Controllers
{
    public class BookController : Controller
    {
        private readonly IHtmlLocalizer<BookController> _localizer;

        public BookController(IHtmlLocalizer<BookController> localizer)
        {
            _localizer = localizer;
        }

        public IActionResult Hello(string name)
        {
            ViewData["Message"] = _localizer["<b>Hello</b><i> {0}</i>", name];

            return View();
        }
```

> **NOTE**
> Generally, only localize text, not HTML.

At the lowest level, you can get `IStringLocalizerFactory` out of Dependency Injection:

```
{
    public class TestController : Controller
    {
        private readonly IStringLocalizer _localizer;
        private readonly IStringLocalizer _localizer2;

        public TestController(IStringLocalizerFactory factory)
        {
            var type = typeof(SharedResource);
            var assemblyName = new AssemblyName(type.GetTypeInfo().Assembly.FullName);
            _localizer = factory.Create(type);
            _localizer2 = factory.Create("SharedResource", assemblyName.Name);
        }

        public IActionResult About()
        {
            ViewData["Message"] = _localizer["Your application description page."]
                + " loc 2: " + _localizer2["Your application description page."];
```

The code above demonstrates each of the two factory create methods.

You can partition your localized strings by controller, area, or have just one container. In the sample app, a dummy class named `SharedResource` is used for shared resources.

```
// Dummy class to group shared resources

namespace Localization
{
    public class SharedResource
    {
    }
}
```

Some developers use the `Startup` class to contain global or shared strings. In the sample below, the `InfoController` and the `SharedResource` localizers are used:

```
public class InfoController : Controller
{
    private readonly IStringLocalizer<InfoController> _localizer;
    private readonly IStringLocalizer<SharedResource> _sharedLocalizer;

    public InfoController(IStringLocalizer<InfoController> localizer,
                          IStringLocalizer<SharedResource> sharedLocalizer)
    {
        _localizer = localizer;
        _sharedLocalizer = sharedLocalizer;
    }

    public string TestLoc()
    {
        string msg = "Shared resx: " + _sharedLocalizer["Hello!"] +
                     " Info resx " + _localizer["Hello!"];
        return msg;
    }
```

View localization

The `IViewLocalizer` service provides localized strings for a view. The `ViewLocalizer` class implements this interface and finds the resource location from the view file path. The following code shows how to use the default implementation of `IViewLocalizer`:

```
@using Microsoft.AspNetCore.Mvc.Localization

@inject IViewLocalizer Localizer

@{
    ViewData["Title"] = Localizer["About"];
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<p>@Localizer["Use this area to provide additional information."]</p>
```

The default implementation of `IViewLocalizer` finds the resource file based on the view's file name. There's no option to use a global shared resource file. `ViewLocalizer` implements the localizer using `IHtmlLocalizer`, so Razor doesn't HTML encode the localized string. You can parameterize resource strings and `IViewLocalizer` will HTML encode the parameters, but not the resource string. Consider the following Razor markup:

```
@Localizer["<i>Hello</i> <b>{0}!</b>", UserManager.GetUserName(User)]
```

A French resource file could contain the following:

KEY	VALUE
`<i>Hello</i> <b>{0}!</b>`	`<i>Bonjour</i> <b>{0} !</b>`

The rendered view would contain the HTML markup from the resource file.

> **NOTE**
> Generally, only localize text, not HTML.

To use a shared resource file in a view, inject `IHtmlLocalizer<T>`:

```
@using Microsoft.AspNetCore.Mvc.Localization
@using Localization.Services

@inject IViewLocalizer Localizer
@inject IHtmlLocalizer<SharedResource> SharedLocalizer

@{
    ViewData["Title"] = Localizer["About"];
}
<h2>@ViewData["Title"].</h2>

<h1>@SharedLocalizer["Hello!"]</h1>
```

DataAnnotations localization

DataAnnotations error messages are localized with `IStringLocalizer<T>`. Using the option

`ResourcesPath = "Resources"`, the error messages in `RegisterViewModel` can be stored in either of the following paths:

- *Resources/ViewModels.Account.RegisterViewModel.fr.resx*
- *Resources/ViewModels/Account/RegisterViewModel.fr.resx*

```
public class RegisterViewModel
{
    [Required(ErrorMessage = "The Email field is required.")]
    [EmailAddress(ErrorMessage = "The Email field is not a valid email address.")]
    [Display(Name = "Email")]
    public string Email { get; set; }

    [Required(ErrorMessage = "The Password field is required.")]
    [StringLength(8, ErrorMessage = "The {0} must be at least {2} characters long.", MinimumLength = 6)]
    [DataType(DataType.Password)]
    [Display(Name = "Password")]
    public string Password { get; set; }

    [DataType(DataType.Password)]
    [Display(Name = "Confirm password")]
    [Compare("Password", ErrorMessage = "The password and confirmation password do not match.")]
    public string ConfirmPassword { get; set; }
}
```

In ASP.NET Core MVC 1.1.0 and higher, non-validation attributes are localized. ASP.NET Core MVC 1.0 does **not** look up localized strings for non-validation attributes.

Using one resource string for multiple classes

The following code shows how to use one resource string for validation attributes with multiple classes:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
        .AddDataAnnotationsLocalization(options => {
            options.DataAnnotationLocalizerProvider = (type, factory) =>
                factory.Create(typeof(SharedResource));
        });
}
```

In the preceding code, `SharedResource` is the class corresponding to the resx where your validation messages are stored. With this approach, DataAnnotations will only use `SharedResource`, rather than the resource for each class.

Provide localized resources for the languages and cultures you support

SupportedCultures and SupportedUICultures

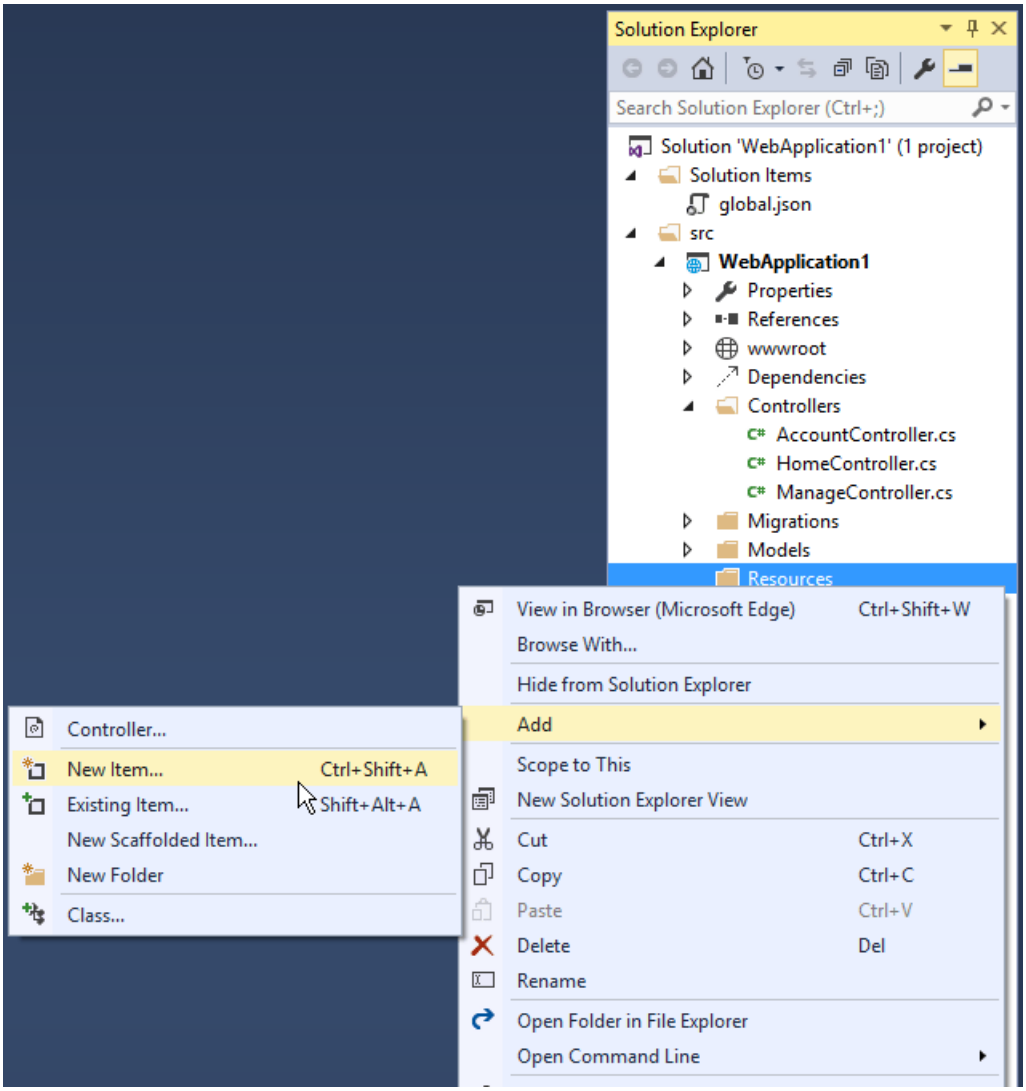
ASP.NET Core allows you to specify two culture values, `SupportedCultures` and `SupportedUICultures`. The CultureInfo object for `SupportedCultures` determines the results of culture-dependent functions, such as date, time, number, and currency formatting. `SupportedCultures` also determines the sorting order of text, casing conventions, and string comparisons. See CultureInfo.CurrentCulture for more info on how the server gets the Culture. The `SupportedUICultures` determines which translated strings (from *.resx* files) are looked up by the ResourceManager. The `ResourceManager` simply looks up culture-specific strings that's determined by `CurrentUICulture`. Every thread in .NET has `CurrentCulture` and `CurrentUICulture` objects. ASP.NET Core inspects these values when rendering culture-dependent functions. For example, if the current thread's culture is set to "en-US" (English, United States), `DateTime.Now.ToLongDateString()` displays "Thursday, February 18,

2016", but if `CurrentCulture` is set to "es-ES" (Spanish, Spain) the output will be "jueves, 18 de febrero de 2016".

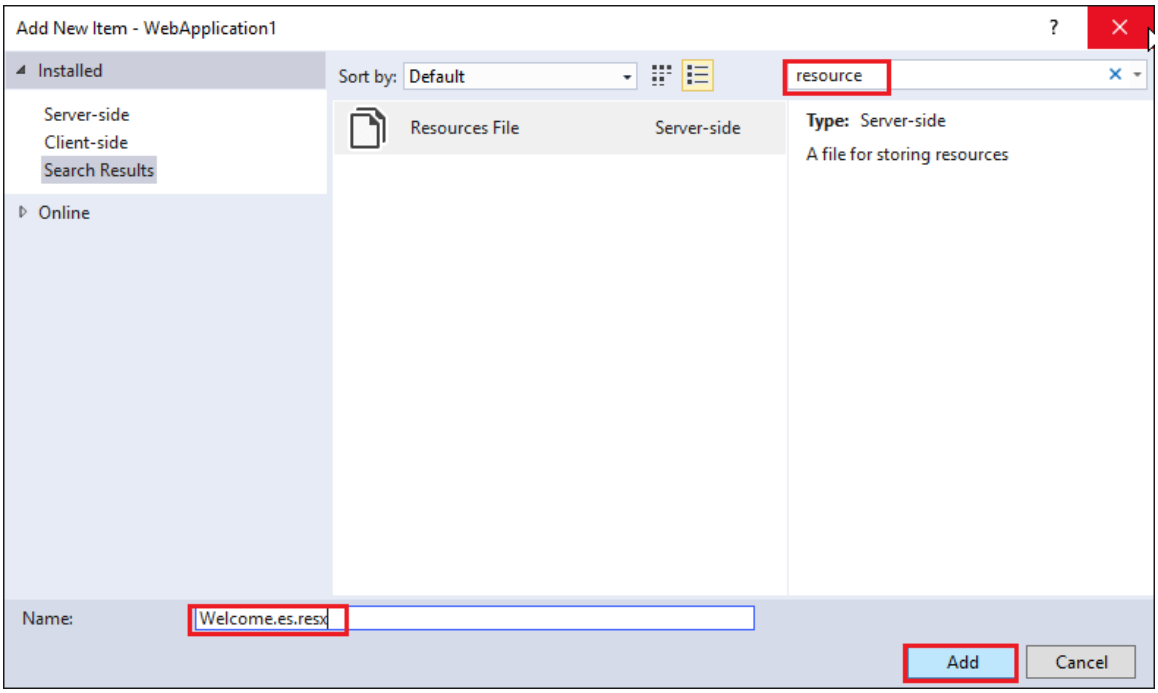
Resource files

A resource file is a useful mechanism for separating localizable strings from code. Translated strings for the non-default language are isolated in *.resx* resource files. For example, you might want to create Spanish resource file named *Welcome.es.resx* containing translated strings. "es" is the language code for Spanish. To create this resource file in Visual Studio:

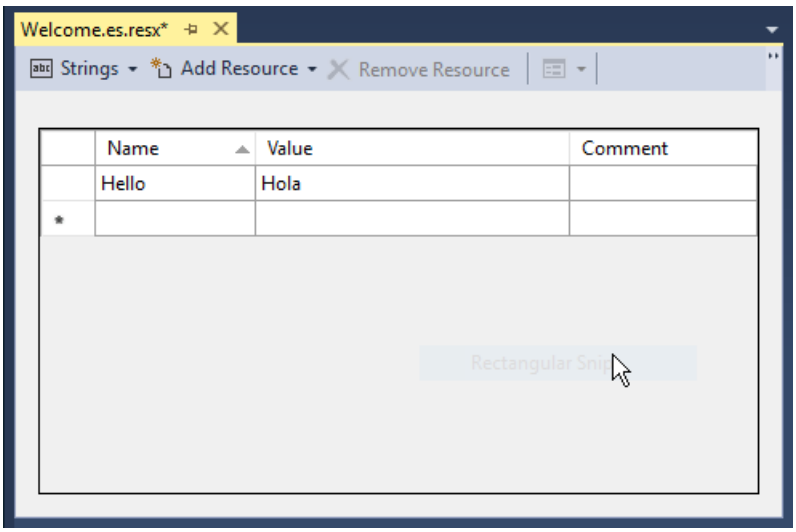
1. In **Solution Explorer**, right click on the folder which will contain the resource file > **Add** > **New Item**.



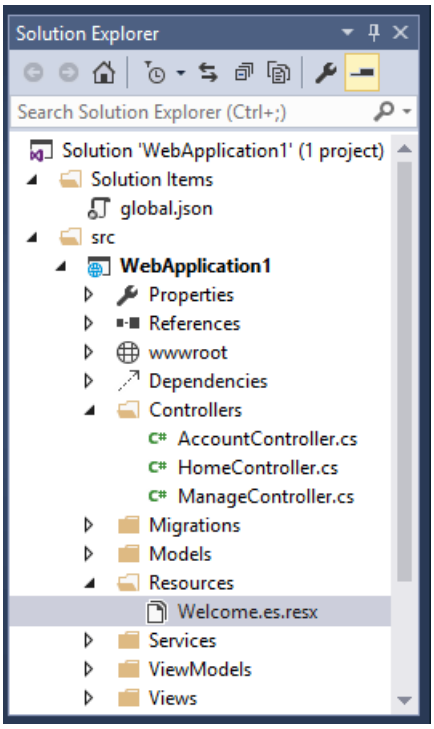
2. In the **Search installed templates** box, enter "resource" and name the file.



3. Enter the key value (native string) in the **Name** column and the translated string in the **Value** column.



Visual Studio shows the *Welcome.es.resx* file.



Resource file naming

Resources are named for the full type name of their class minus the assembly name. For example, a French resource in a project whose main assembly is `LocalizationWebsite.Web.dll` for the class `LocalizationWebsite.Web.Startup` would be named *Startup.fr.resx*. A resource for the class `LocalizationWebsite.Web.Controllers.HomeController` would be named *Controllers.HomeController.fr.resx*. If your targeted class's namespace isn't the same as the assembly name you will need the full type name. For example, in the sample project a resource for the type `ExtraNamespace.Tools` would be named *ExtraNamespace.Tools.fr.resx*.

In the sample project, the `ConfigureServices` method sets the `ResourcesPath` to "Resources", so the project relative path for the home controller's French resource file is *Resources/Controllers.HomeController.fr.resx*. Alternatively, you can use folders to organize resource files. For the home controller, the path would be *Resources/Controllers/HomeController.fr.resx*. If you don't use the `ResourcesPath` option, the *.resx* file would go in the project base directory. The resource file for `HomeController` would be named *Controllers.HomeController.fr.resx*. The choice of using the dot or path naming convention depends on how you want to organize your resource files.

RESOURCE NAME	DOT OR PATH NAMING
Resources/Controllers.HomeController.fr.resx	Dot
Resources/Controllers/HomeController.fr.resx	Path

Resource files using `@inject IViewLocalizer` in Razor views follow a similar pattern. The resource file for a view can be named using either dot naming or path naming. Razor view resource files mimic the path of their associated view file. Assuming we set the `ResourcesPath` to "Resources", the French resource file associated with the *Views/Home/About.cshtml* view could be either of the following:

- Resources/Views/Home/About.fr.resx
- Resources/Views.Home.About.fr.resx

If you don't use the `ResourcesPath` option, the *.resx* file for a view would be located in the same folder as the

view.

RootNamespaceAttribute

The RootNamespace attribute provides the root namespace of an assembly when the root namespace of an assembly is different than the assembly name.

> **WARNING**
> This can occur when a project's name is not a valid .NET identifier. For instance `my-project-name.csproj` will use the root namespace `my_project_name` and the assembly name `my-project-name` leading to this error.

If the root namespace of an assembly is different than the assembly name:

- Localization does not work by default.
- Localization fails due to the way resources are searched for within the assembly. `RootNamespace` is a build-time value which is not available to the executing process.

If the `RootNamespace` is different from the `AssemblyName`, include the following in *AssemblyInfo.cs* (with parameter values replaced with the actual values):

```
using System.Reflection;
using Microsoft.Extensions.Localization;

[assembly: ResourceLocation("Resource Folder Name")]
[assembly: RootNamespace("App Root Namespace")]
```

The preceding code enables the successful resolution of resx files.

Culture fallback behavior

When searching for a resource, localization engages in "culture fallback". Starting from the requested culture, if not found, it reverts to the parent culture of that culture. As an aside, the CultureInfo.Parent property represents the parent culture. This usually (but not always) means removing the national signifier from the ISO. For example, the dialect of Spanish spoken in Mexico is "es-MX". It has the parent "es"—Spanish non-specific to any country.

Imagine your site receives a request for a "Welcome" resource using culture "fr-CA". The localization system looks for the following resources, in order, and selects the first match:

- *Welcome.fr-CA.resx*
- *Welcome.fr.resx*
- *Welcome.resx* (if the `NeutralResourcesLanguage` is "fr-CA")

As an example, if you remove the ".fr" culture designator and you have the culture set to French, the default resource file is read and strings are localized. The Resource manager designates a default or fallback resource for when nothing meets your requested culture. If you want to just return the key when missing a resource for the requested culture you must not have a default resource file.

Generate resource files with Visual Studio

If you create a resource file in Visual Studio without a culture in the file name (for example, *Welcome.resx*), Visual Studio will create a C# class with a property for each string. That's usually not what you want with ASP.NET Core. You typically don't have a default *.resx* resource file (a *.resx* file without the culture name). We suggest you create the *.resx* file with a culture name (for example *Welcome.fr.resx*). When you create a *.resx* file with a culture name, Visual Studio won't generate the class file.

Add other cultures

Each language and culture combination (other than the default language) requires a unique resource file. You create resource files for different cultures and locales by creating new resource files in which the ISO language codes are part of the file name (for example, **en-us**, **fr-ca**, and **en-gb**). These ISO codes are placed between the file name and the *.resx* file extension, as in *Welcome.es-MX.resx* (Spanish/Mexico).

Implement a strategy to select the language/culture for each request

Configure localization

Localization is configured in the `Startup.ConfigureServices` method:

```
services.AddLocalization(options => options.ResourcesPath = "Resources");

services.AddMvc()
    .AddViewLocalization(LanguageViewLocationExpanderFormat.Suffix)
    .AddDataAnnotationsLocalization();
```

- `AddLocalization` adds the localization services to the services container. The code above also sets the resources path to "Resources".
- `AddViewLocalization` adds support for localized view files. In this sample view localization is based on the view file suffix. For example "fr" in the *Index.fr.cshtml* file.
- `AddDataAnnotationsLocalization` adds support for localized `DataAnnotations` validation messages through `IStringLocalizer` abstractions.

Localization middleware

The current culture on a request is set in the localization Middleware. The localization middleware is enabled in the `Startup.Configure` method. The localization middleware must be configured before any middleware which might check the request culture (for example, `app.UseMvcWithDefaultRoute()`).

```
var supportedCultures = new[] { "en-US", "fr" };
var localizationOptions = new RequestLocalizationOptions().SetDefaultCulture(supportedCultures[0])
    .AddSupportedCultures(supportedCultures)
    .AddSupportedUICultures(supportedCultures);

app.UseRequestLocalization(localizationOptions);

app.UseRouting();
app.UseStaticFiles();

app.UseAuthentication();

app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(name: "default", pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

`UseRequestLocalization` initializes a `RequestLocalizationOptions` object. On every request the list of `RequestCultureProvider` in the `RequestLocalizationOptions` is enumerated and the first provider that can successfully determine the request culture is used. The default providers come from the `RequestLocalizationOptions` class:

1. `QueryStringRequestCultureProvider`

2. `CookieRequestCultureProvider`
3. `AcceptLanguageHeaderRequestCultureProvider`

The default list goes from most specific to least specific. Later in the article we'll see how you can change the order and even add a custom culture provider. If none of the providers can determine the request culture, the `DefaultRequestCulture` is used.

QueryStringRequestCultureProvider

Some apps will use a query string to set the /dotnet/api/system.globalization.cultureinfo?view=netcore-3.1. For apps that use the cookie or Accept-Language header approach, adding a query string to the URL is useful for debugging and testing code. By default, the `QueryStringRequestCultureProvider` is registered as the first localization provider in the `RequestCultureProvider` list. You pass the query string parameters `culture` and `ui-culture`. The following example sets the specific culture (language and region) to Spanish/Mexico:

```
http://localhost:5000/?culture=es-MX&ui-culture=es-MX
```

If you only pass in one of the two (`culture` or `ui-culture`), the query string provider will set both values using the one you passed in. For example, setting just the culture will set both the `Culture` and the `UICulture`:

```
http://localhost:5000/?culture=es-MX
```

CookieRequestCultureProvider

Production apps will often provide a mechanism to set the culture with the ASP.NET Core culture cookie. Use the `MakeCookieValue` method to create a cookie.

The `CookieRequestCultureProvider` `DefaultCookieName` returns the default cookie name used to track the user's preferred culture information. The default cookie name is `.AspNetCore.Culture`.

The cookie format is `c=%LANGCODE%|uic=%LANGCODE%`, where `c` is `Culture` and `uic` is `UICulture`, for example:

```
c=en-UK|uic=en-US
```

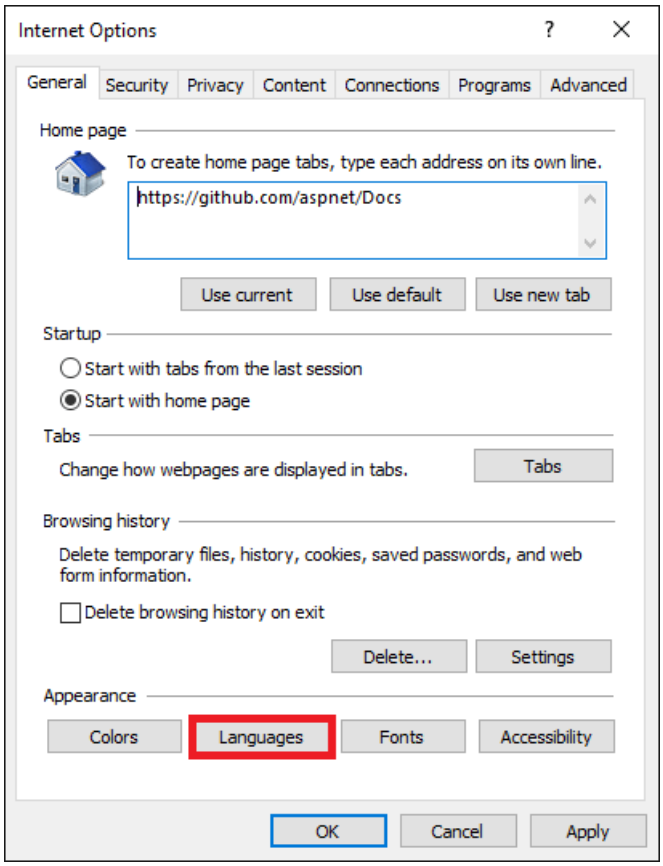
If you only specify one of culture info and UI culture, the specified culture will be used for both culture info and UI culture.

The Accept-Language HTTP header

The Accept-Language header is settable in most browsers and was originally intended to specify the user's language. This setting indicates what the browser has been set to send or has inherited from the underlying operating system. The Accept-Language HTTP header from a browser request isn't an infallible way to detect the user's preferred language (see Setting language preferences in a browser). A production app should include a way for a user to customize their choice of culture.

Set the Accept-Language HTTP header in IE

1. From the gear icon, tap **Internet Options**.
2. Tap **Languages**.



3. Tap **Set Language Preferences**.
4. Tap **Add a language**.
5. Add the language.
6. Tap the language, then tap **Move Up**.

Use a custom provider

Suppose you want to let your customers store their language and culture in your databases. You could write a provider to look up these values for the user. The following code shows how to add a custom provider:

```
private const string enUSCulture = "en-US";

services.Configure<RequestLocalizationOptions>(options =>
{
    var supportedCultures = new[]
    {
        new CultureInfo(enUSCulture),
        new CultureInfo("fr")
    };

    options.DefaultRequestCulture = new RequestCulture(culture: enUSCulture, uiCulture: enUSCulture);
    options.SupportedCultures = supportedCultures;
    options.SupportedUICultures = supportedCultures;

    options.RequestCultureProviders.Insert(0, new CustomRequestCultureProvider(async context =>
    {
        // My custom request culture logic
        return new ProviderCultureResult("en");
    }));
});
```

Use `RequestLocalizationOptions` to add or remove localization providers.

Set the culture programmatically

This sample **Localization.StarterWeb** project on GitHub contains UI to set the `Culture`. The *Views/Shared/_SelectLanguagePartial.cshtml* file allows you to select the culture from the list of supported cultures:

```
@using Microsoft.AspNetCore.Builder
@using Microsoft.AspNetCore.Http.Features
@using Microsoft.AspNetCore.Localization
@using Microsoft.AspNetCore.Mvc.Localization
@using Microsoft.Extensions.Options

@inject IViewLocalizer Localizer
@inject IOptions<RequestLocalizationOptions> LocOptions

@{
    var requestCulture = Context.Features.Get<IRequestCultureFeature>();
    var cultureItems = LocOptions.Value.SupportedUICultures
        .Select(c => new SelectListItem { Value = c.Name, Text = c.DisplayName })
        .ToList();
    var returnUrl = string.IsNullOrEmpty(Context.Request.Path) ? "~/" : $"~{Context.Request.Path.Value}";
}

<div title="@Localizer["Request culture provider:"] @requestCulture?.Provider?.GetType().Name">
    <form id="selectLanguage" asp-controller="Home"
          asp-action="SetLanguage" asp-route-returnUrl="@returnUrl"
          method="post" class="form-horizontal" role="form">
        <label asp-for="@requestCulture.RequestCulture.UICulture.Name">@Localizer["Language:"]</label>
<select name="culture"
          onchange="this.form.submit();"
          asp-for="@requestCulture.RequestCulture.UICulture.Name" asp-items="cultureItems">
        </select>
    </form>
</div>
```

The *Views/Shared/_SelectLanguagePartial.cshtml* file is added to the `footer` section of the layout file so it will be available to all views:

```
<div class="container body-content" style="margin-top:60px">
    @RenderBody()
    <hr>
    <footer>
        <div class="row">
            <div class="col-md-6">
                <p>&copy; @System.DateTime.Now.Year - Localization</p>
            </div>
            <div class="col-md-6 text-right">
                @await Html.PartialAsync("_SelectLanguagePartial")
            </div>
        </div>
    </footer>
</div>
```

The `SetLanguage` method sets the culture cookie.

```
[HttpPost]
public IActionResult SetLanguage(string culture, string returnUrl)
{
    Response.Cookies.Append(
        CookieRequestCultureProvider.DefaultCookieName,
        CookieRequestCultureProvider.MakeCookieValue(new RequestCulture(culture)),
        new CookieOptions { Expires = DateTimeOffset.UtcNow.AddYears(1) }
    );

    return LocalRedirect(returnUrl);
}
```

You can't plug in the *_SelectLanguagePartial.cshtml* to sample code for this project. The **Localization.StarterWeb** project on GitHub has code to flow the `RequestLocalizationOptions` to a Razor partial through the Dependency Injection container.

Model binding route data and query strings

See Globalization behavior of model binding route data and query strings.

Globalization and localization terms

The process of localizing your app also requires a basic understanding of relevant character sets commonly used in modern software development and an understanding of the issues associated with them. Although all computers store text as numbers (codes), different systems store the same text using different numbers. The localization process refers to translating the app user interface (UI) for a specific culture/locale.

Localizability is an intermediate process for verifying that a globalized app is ready for localization.

The RFC 4646 format for the culture name is `<languagecode2>-<country/regioncode2>`, where `<languagecode2>` is the language code and `<country/regioncode2>` is the subculture code. For example, `es-CL` for Spanish (Chile), `en-US` for English (United States), and `en-AU` for English (Australia). RFC 4646 is a combination of an ISO 639 two-letter lowercase culture code associated with a language and an ISO 3166 two-letter uppercase subculture code associated with a country or region. See /previous-versions/commerce-server/ee825488(v=cs.20).

Internationalization is often abbreviated to "I18N". The abbreviation takes the first and last letters and the number of letters between them, so 18 stands for the number of letters between the first "I" and the last "N". The same applies to Globalization (G11N), and Localization (L10N).

Terms:

- Globalization (G11N): The process of making an app support different languages and regions.
- Localization (L10N): The process of customizing an app for a given language and region.
- Internationalization (I18N): Describes both globalization and localization.
- Culture: It's a language and, optionally, a region.
- Neutral culture: A culture that has a specified language, but not a region. (for example "en", "es")
- Specific culture: A culture that has a specified language and region. (for example "en-US", "en-GB", "es-CL")
- Parent culture: The neutral culture that contains a specific culture. (for example, "en" is the parent culture of "en-US" and "en-GB")
- Locale: A locale is the same as a culture.

NOTE

You may not be able to enter decimal commas in decimal fields. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. See this GitHub issue 4076 for instructions on adding decimal comma.

By Rick Anderson, Damien Bowden, Bart Calixto, Nadeem Afana, and Hisham Bin Ateya

A multilingual website allows the site to reach a wider audience. ASP.NET Core provides services and middleware for localizing into different languages and cultures.

Internationalization involves Globalization and Localization. Globalization is the process of designing apps that support different cultures. Globalization adds support for input, display, and output of a defined set of language scripts that relate to specific geographic areas.

Localization is the process of adapting a globalized app, which you have already processed for localizability, to a particular culture/locale. For more information see **Globalization and localization terms** near the end of this document.

App localization involves the following:

1. Make the app's content localizable
2. Provide localized resources for the languages and cultures you support
3. Implement a strategy to select the language/culture for each request

View or download sample code (how to download)

Make the app's content localizable

IStringLocalizer and IStringLocalizer<T> were architected to improve productivity when developing localized apps. `IStringLocalizer` uses the ResourceManager and ResourceReader to provide culture-specific resources at run time. The interface has an indexer and an `IEnumerable` for returning localized strings. `IStringLocalizer` doesn't require storing the default language strings in a resource file. You can develop an app targeted for localization and not need to create resource files early in development. The code below shows how to wrap the string "About Title" for localization.

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Localization;

namespace Localization.Controllers
{
    [Route("api/[controller]")]
    public class AboutController : Controller
    {
        private readonly IStringLocalizer<AboutController> _localizer;

        public AboutController(IStringLocalizer<AboutController> localizer)
        {
            _localizer = localizer;
        }

        [HttpGet]
        public string Get()
        {
            return _localizer["About Title"];
        }
    }
}
```

In the preceding code, the `IStringLocalizer<T>` implementation comes from Dependency Injection. If the localized value of "About Title" isn't found, then the indexer key is returned, that is, the string "About Title". You can leave the default language literal strings in the app and wrap them in the localizer, so that you can focus on developing the app. You develop your app with your default language and prepare it for the localization step without first creating a default resource file. Alternatively, you can use the traditional approach and provide a key to retrieve the default language string. For many developers the new workflow of not having a default language *.resx* file and simply wrapping the string literals can reduce the overhead of localizing an app. Other developers will prefer the traditional work flow as it can make it easier to work with longer string literals and make it easier to update localized strings.

Use the `IHtmlLocalizer<T>` implementation for resources that contain HTML. `IHtmlLocalizer` HTML encodes arguments that are formatted in the resource string, but doesn't HTML encode the resource string itself. In the sample highlighted below, only the value of `name` parameter is HTML encoded.

```
using System;
using Microsoft.AspNetCore.Http;
using Microsoft.AspNetCore.Localization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.Localization;

namespace Localization.Controllers
{
    public class BookController : Controller
    {
        private readonly IHtmlLocalizer<BookController> _localizer;

        public BookController(IHtmlLocalizer<BookController> localizer)
        {
            _localizer = localizer;
        }

        public IActionResult Hello(string name)
        {
            ViewData["Message"] = _localizer["<b>Hello</b><i> {0}</i>", name];

            return View();
        }
```

> **NOTE**
> Generally, only localize text, not HTML.

At the lowest level, you can get `IStringLocalizerFactory` out of Dependency Injection:

```
{
    public class TestController : Controller
    {
        private readonly IStringLocalizer _localizer;
        private readonly IStringLocalizer _localizer2;

        public TestController(IStringLocalizerFactory factory)
        {
            var type = typeof(SharedResource);
            var assemblyName = new AssemblyName(type.GetTypeInfo().Assembly.FullName);
            _localizer = factory.Create(type);
            _localizer2 = factory.Create("SharedResource", assemblyName.Name);
        }

        public IActionResult About()
        {
            ViewData["Message"] = _localizer["Your application description page."]
                + " loc 2: " + _localizer2["Your application description page."];
```

The code above demonstrates each of the two factory create methods.

You can partition your localized strings by controller, area, or have just one container. In the sample app, a dummy class named `SharedResource` is used for shared resources.

```
// Dummy class to group shared resources

namespace Localization
{
    public class SharedResource
    {
    }
}
```

Some developers use the `Startup` class to contain global or shared strings. In the sample below, the `InfoController` and the `SharedResource` localizers are used:

```
public class InfoController : Controller
{
    private readonly IStringLocalizer<InfoController> _localizer;
    private readonly IStringLocalizer<SharedResource> _sharedLocalizer;

    public InfoController(IStringLocalizer<InfoController> localizer,
                          IStringLocalizer<SharedResource> sharedLocalizer)
    {
        _localizer = localizer;
        _sharedLocalizer = sharedLocalizer;
    }

    public string TestLoc()
    {
        string msg = "Shared resx: " + _sharedLocalizer["Hello!"] +
                     " Info resx " + _localizer["Hello!"];
        return msg;
    }
```

View localization

The `IViewLocalizer` service provides localized strings for a view. The `ViewLocalizer` class implements this interface and finds the resource location from the view file path. The following code shows how to use the default implementation of `IViewLocalizer`:

```
@using Microsoft.AspNetCore.Mvc.Localization

@inject IViewLocalizer Localizer

@{
    ViewData["Title"] = Localizer["About"];
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<p>@Localizer["Use this area to provide additional information."]</p>
```

The default implementation of `IViewLocalizer` finds the resource file based on the view's file name. There's no option to use a global shared resource file. `ViewLocalizer` implements the localizer using `IHtmlLocalizer`, so Razor doesn't HTML encode the localized string. You can parameterize resource strings and `IViewLocalizer` will HTML encode the parameters, but not the resource string. Consider the following Razor markup:

```
@Localizer["<i>Hello</i> <b>{0}!</b>", UserManager.GetUserName(User)]
```

A French resource file could contain the following:

KEY	VALUE
`<i>Hello</i> <b>{0}!</b>`	`<i>Bonjour</i> <b>{0} !</b>`

The rendered view would contain the HTML markup from the resource file.

> **NOTE**
> Generally, only localize text, not HTML.

To use a shared resource file in a view, inject `IHtmlLocalizer<T>`:

```
@using Microsoft.AspNetCore.Mvc.Localization
@using Localization.Services

@inject IViewLocalizer Localizer
@inject IHtmlLocalizer<SharedResource> SharedLocalizer

@{
    ViewData["Title"] = Localizer["About"];
}
<h2>@ViewData["Title"].</h2>

<h1>@SharedLocalizer["Hello!"]</h1>
```

DataAnnotations localization

DataAnnotations error messages are localized with `IStringLocalizer<T>`. Using the option

`ResourcesPath = "Resources"`, the error messages in `RegisterViewModel` can be stored in either of the following paths:

- *Resources/ViewModels.Account.RegisterViewModel.fr.resx*
- *Resources/ViewModels/Account/RegisterViewModel.fr.resx*

```
public class RegisterViewModel
{
    [Required(ErrorMessage = "The Email field is required.")]
    [EmailAddress(ErrorMessage = "The Email field is not a valid email address.")]
    [Display(Name = "Email")]
    public string Email { get; set; }

    [Required(ErrorMessage = "The Password field is required.")]
    [StringLength(8, ErrorMessage = "The {0} must be at least {2} characters long.", MinimumLength = 6)]
    [DataType(DataType.Password)]
    [Display(Name = "Password")]
    public string Password { get; set; }

    [DataType(DataType.Password)]
    [Display(Name = "Confirm password")]
    [Compare("Password", ErrorMessage = "The password and confirmation password do not match.")]
    public string ConfirmPassword { get; set; }
}
```

In ASP.NET Core MVC 1.1.0 and higher, non-validation attributes are localized. ASP.NET Core MVC 1.0 does **not** look up localized strings for non-validation attributes.

Using one resource string for multiple classes

The following code shows how to use one resource string for validation attributes with multiple classes:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
        .AddDataAnnotationsLocalization(options => {
            options.DataAnnotationLocalizerProvider = (type, factory) =>
                factory.Create(typeof(SharedResource));
        });
}
```

In the preceding code, `SharedResource` is the class corresponding to the resx where your validation messages are stored. With this approach, DataAnnotations will only use `SharedResource`, rather than the resource for each class.

Provide localized resources for the languages and cultures you support

SupportedCultures and SupportedUICultures

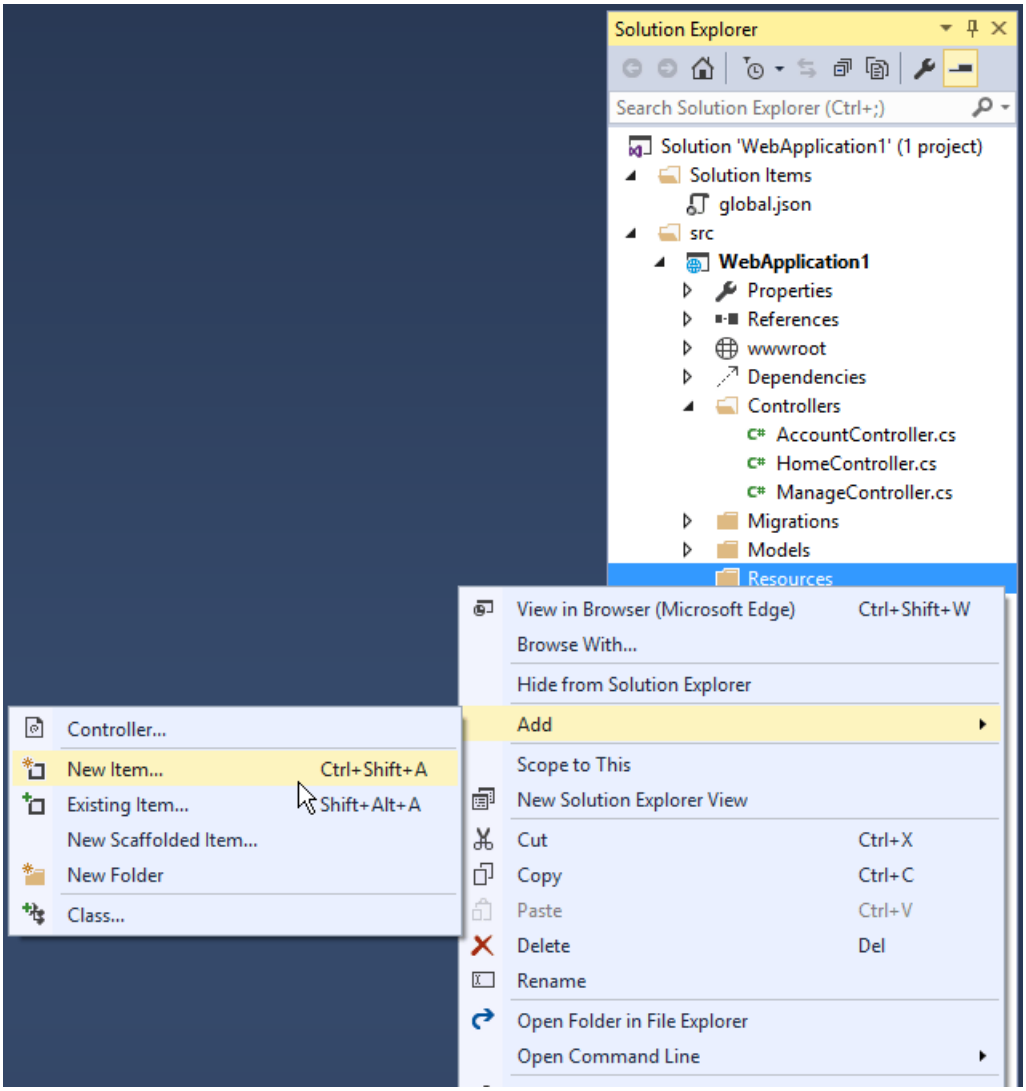
ASP.NET Core allows you to specify two culture values, `SupportedCultures` and `SupportedUICultures`. The CultureInfo object for `SupportedCultures` determines the results of culture-dependent functions, such as date, time, number, and currency formatting. `SupportedCultures` also determines the sorting order of text, casing conventions, and string comparisons. See CultureInfo.CurrentCulture for more info on how the server gets the Culture. The `SupportedUICultures` determines which translated strings (from *.resx* files) are looked up by the ResourceManager. The `ResourceManager` simply looks up culture-specific strings that's determined by `CurrentUICulture`. Every thread in .NET has `CurrentCulture` and `CurrentUICulture` objects. ASP.NET Core inspects these values when rendering culture-dependent functions. For example, if the current thread's culture is set to "en-US" (English, United States), `DateTime.Now.ToLongDateString()` displays "Thursday, February 18,

2016", but if `CurrentCulture` is set to "es-ES" (Spanish, Spain) the output will be "jueves, 18 de febrero de 2016".

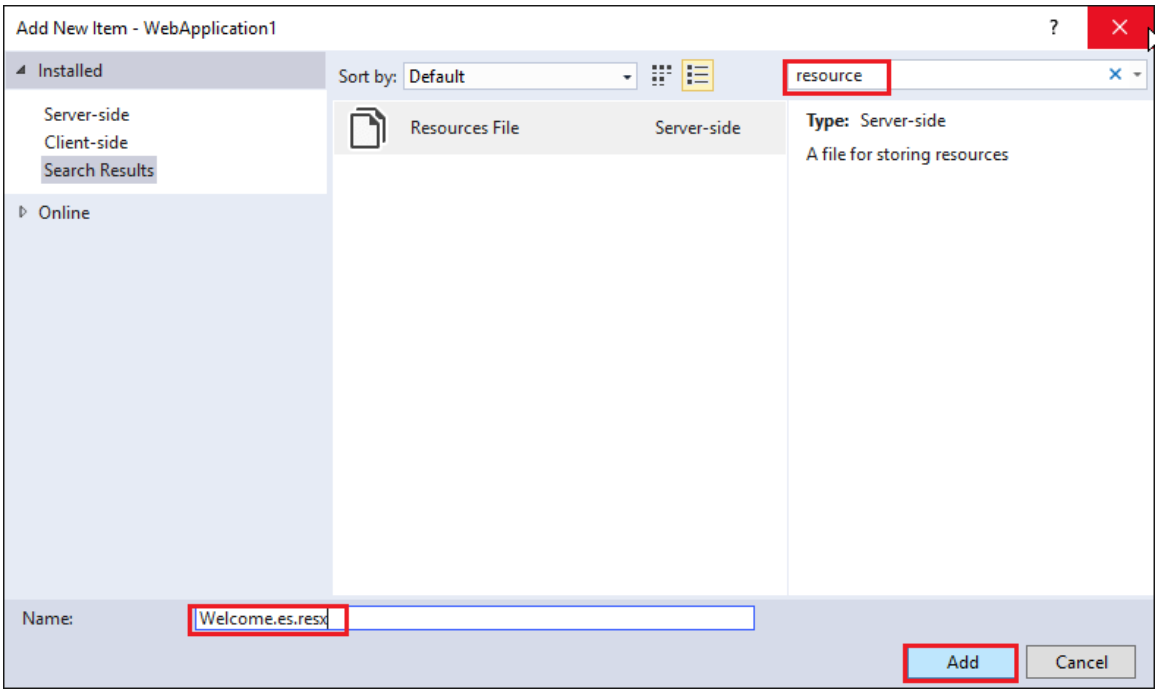
Resource files

A resource file is a useful mechanism for separating localizable strings from code. Translated strings for the non-default language are isolated in *.resx* resource files. For example, you might want to create Spanish resource file named *Welcome.es.resx* containing translated strings. "es" is the language code for Spanish. To create this resource file in Visual Studio:

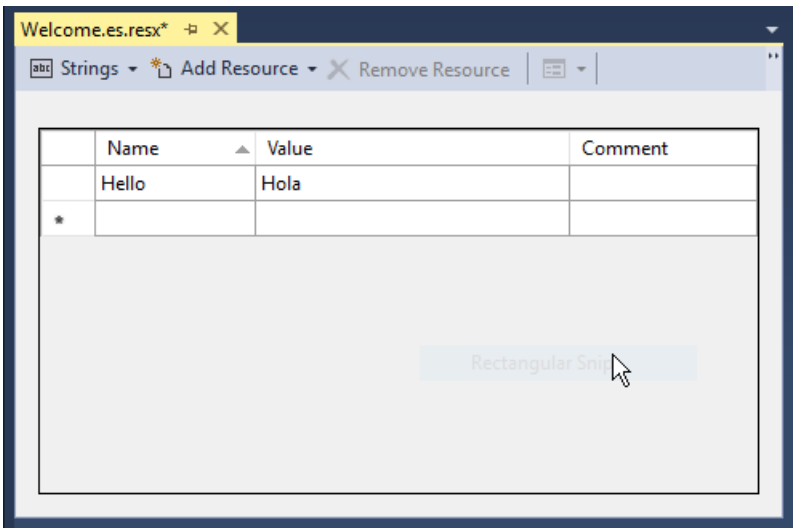
1. In **Solution Explorer**, right click on the folder which will contain the resource file > **Add** > **New Item**.



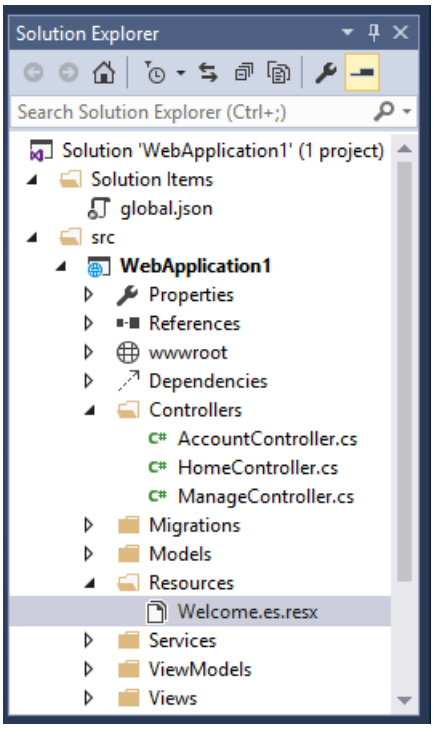
2. In the **Search installed templates** box, enter "resource" and name the file.



3. Enter the key value (native string) in the **Name** column and the translated string in the **Value** column.



Visual Studio shows the *Welcome.es.resx* file.



Resource file naming

Resources are named for the full type name of their class minus the assembly name. For example, a French resource in a project whose main assembly is `LocalizationWebsite.Web.dll` for the class `LocalizationWebsite.Web.Startup` would be named *Startup.fr.resx*. A resource for the class `LocalizationWebsite.Web.Controllers.HomeController` would be named *Controllers.HomeController.fr.resx*. If your targeted class's namespace isn't the same as the assembly name you will need the full type name. For example, in the sample project a resource for the type `ExtraNamespace.Tools` would be named *ExtraNamespace.Tools.fr.resx*.

In the sample project, the `ConfigureServices` method sets the `ResourcesPath` to "Resources", so the project relative path for the home controller's French resource file is *Resources/Controllers.HomeController.fr.resx*. Alternatively, you can use folders to organize resource files. For the home controller, the path would be *Resources/Controllers/HomeController.fr.resx*. If you don't use the `ResourcesPath` option, the *.resx* file would go in the project base directory. The resource file for `HomeController` would be named *Controllers.HomeController.fr.resx*. The choice of using the dot or path naming convention depends on how you want to organize your resource files.

RESOURCE NAME	DOT OR PATH NAMING
Resources/Controllers.HomeController.fr.resx	Dot
Resources/Controllers/HomeController.fr.resx	Path

Resource files using `@inject IViewLocalizer` in Razor views follow a similar pattern. The resource file for a view can be named using either dot naming or path naming. Razor view resource files mimic the path of their associated view file. Assuming we set the `ResourcesPath` to "Resources", the French resource file associated with the *Views/Home/About.cshtml* view could be either of the following:

- Resources/Views/Home/About.fr.resx
- Resources/Views.Home.About.fr.resx

If you don't use the `ResourcesPath` option, the *.resx* file for a view would be located in the same folder as the

view.

RootNamespaceAttribute

The RootNamespace attribute provides the root namespace of an assembly when the root namespace of an assembly is different than the assembly name.

> **WARNING**
> This can occur when a project's name is not a valid .NET identifier. For instance `my-project-name.csproj` will use the root namespace `my_project_name` and the assembly name `my-project-name` leading to this error.

If the root namespace of an assembly is different than the assembly name:

- Localization does not work by default.
- Localization fails due to the way resources are searched for within the assembly. `RootNamespace` is a build-time value which is not available to the executing process.

If the `RootNamespace` is different from the `AssemblyName`, include the following in *AssemblyInfo.cs* (with parameter values replaced with the actual values):

```
using System.Reflection;
using Microsoft.Extensions.Localization;

[assembly: ResourceLocation("Resource Folder Name")]
[assembly: RootNamespace("App Root Namespace")]
```

The preceding code enables the successful resolution of resx files.

Culture fallback behavior

When searching for a resource, localization engages in "culture fallback". Starting from the requested culture, if not found, it reverts to the parent culture of that culture. As an aside, the CultureInfo.Parent property represents the parent culture. This usually (but not always) means removing the national signifier from the ISO. For example, the dialect of Spanish spoken in Mexico is "es-MX". It has the parent "es"—Spanish non-specific to any country.

Imagine your site receives a request for a "Welcome" resource using culture "fr-CA". The localization system looks for the following resources, in order, and selects the first match:

- *Welcome.fr-CA.resx*
- *Welcome.fr.resx*
- *Welcome.resx* (if the `NeutralResourcesLanguage` is "fr-CA")

As an example, if you remove the ".fr" culture designator and you have the culture set to French, the default resource file is read and strings are localized. The Resource manager designates a default or fallback resource for when nothing meets your requested culture. If you want to just return the key when missing a resource for the requested culture you must not have a default resource file.

Generate resource files with Visual Studio

If you create a resource file in Visual Studio without a culture in the file name (for example, *Welcome.resx*), Visual Studio will create a C# class with a property for each string. That's usually not what you want with ASP.NET Core. You typically don't have a default *.resx* resource file (a *.resx* file without the culture name). We suggest you create the *.resx* file with a culture name (for example *Welcome.fr.resx*). When you create a *.resx* file with a culture name, Visual Studio won't generate the class file.

Add other cultures

Each language and culture combination (other than the default language) requires a unique resource file. You create resource files for different cultures and locales by creating new resource files in which the ISO language codes are part of the file name (for example, **en-us**, **fr-ca**, and **en-gb**). These ISO codes are placed between the file name and the *.resx* file extension, as in *Welcome.es-MX.resx* (Spanish/Mexico).

Implement a strategy to select the language/culture for each request

Configure localization

Localization is configured in the `Startup.ConfigureServices` method:

```
services.AddLocalization(options => options.ResourcesPath = "Resources");

services.AddMvc()
    .AddViewLocalization(LanguageViewLocationExpanderFormat.Suffix)
    .AddDataAnnotationsLocalization();
```

- `AddLocalization` adds the localization services to the services container. The code above also sets the resources path to "Resources".
- `AddViewLocalization` adds support for localized view files. In this sample view localization is based on the view file suffix. For example "fr" in the *Index.fr.cshtml* file.
- `AddDataAnnotationsLocalization` adds support for localized `DataAnnotations` validation messages through `IStringLocalizer` abstractions.

Localization middleware

The current culture on a request is set in the localization Middleware. The localization middleware is enabled in the `Startup.Configure` method. The localization middleware must be configured before any middleware which might check the request culture (for example, `app.UseMvcWithDefaultRoute()`).

```
var supportedCultures = new[] { "en-US", "fr" };
var localizationOptions = new RequestLocalizationOptions().SetDefaultCulture(supportedCultures[0])
    .AddSupportedCultures(supportedCultures)
    .AddSupportedUICultures(supportedCultures);

app.UseRequestLocalization(localizationOptions);

app.UseRouting();
app.UseStaticFiles();

app.UseAuthentication();

app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(name: "default", pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

`UseRequestLocalization` initializes a `RequestLocalizationOptions` object. On every request the list of `RequestCultureProvider` in the `RequestLocalizationOptions` is enumerated and the first provider that can successfully determine the request culture is used. The default providers come from the `RequestLocalizationOptions` class:

1. `QueryStringRequestCultureProvider`

2. `CookieRequestCultureProvider`
3. `AcceptLanguageHeaderRequestCultureProvider`

The default list goes from most specific to least specific. Later in the article we'll see how you can change the order and even add a custom culture provider. If none of the providers can determine the request culture, the `DefaultRequestCulture` is used.

QueryStringRequestCultureProvider

Some apps will use a query string to set the /dotnet/api/system.globalization.cultureinfo?view=netcore-3.1. For apps that use the cookie or Accept-Language header approach, adding a query string to the URL is useful for debugging and testing code. By default, the `QueryStringRequestCultureProvider` is registered as the first localization provider in the `RequestCultureProvider` list. You pass the query string parameters `culture` and `ui-culture`. The following example sets the specific culture (language and region) to Spanish/Mexico:

```
http://localhost:5000/?culture=es-MX&ui-culture=es-MX
```

If you only pass in one of the two (`culture` or `ui-culture`), the query string provider will set both values using the one you passed in. For example, setting just the culture will set both the `Culture` and the `UICulture`:

```
http://localhost:5000/?culture=es-MX
```

CookieRequestCultureProvider

Production apps will often provide a mechanism to set the culture with the ASP.NET Core culture cookie. Use the `MakeCookieValue` method to create a cookie.

The `CookieRequestCultureProvider` `DefaultCookieName` returns the default cookie name used to track the user's preferred culture information. The default cookie name is `.AspNetCore.Culture`.

The cookie format is `c=%LANGCODE%|uic=%LANGCODE%`, where `c` is `Culture` and `uic` is `UICulture`, for example:

```
c=en-UK|uic=en-US
```

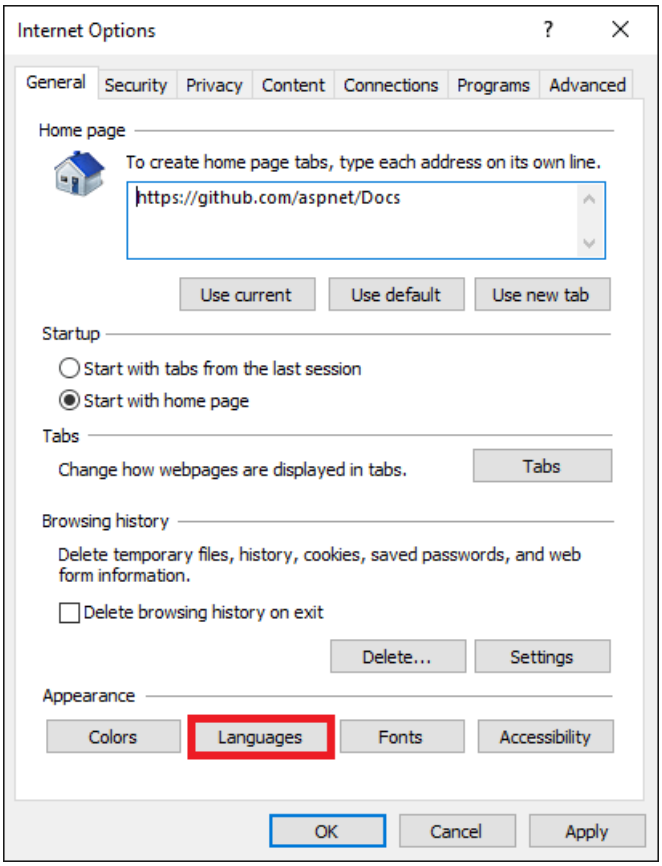
If you only specify one of culture info and UI culture, the specified culture will be used for both culture info and UI culture.

The Accept-Language HTTP header

The Accept-Language header is settable in most browsers and was originally intended to specify the user's language. This setting indicates what the browser has been set to send or has inherited from the underlying operating system. The Accept-Language HTTP header from a browser request isn't an infallible way to detect the user's preferred language (see Setting language preferences in a browser). A production app should include a way for a user to customize their choice of culture.

Set the Accept-Language HTTP header in IE

1. From the gear icon, tap **Internet Options**.
2. Tap **Languages**.



3. Tap **Set Language Preferences**.
4. Tap **Add a language**.
5. Add the language.
6. Tap the language, then tap **Move Up**.

The Content-Language HTTP header

The Content-Language entity header:

- Is used to describe the language(s) intended for the audience.
- Allows a user to differentiate according to the users' own preferred language.

Entity headers are used in both HTTP requests and responses.

The `Content-Language` header can be added by setting the property `ApplyCurrentCultureToResponseHeaders`.

Adding the `Content-Language` header:

- Allows the RequestLocalizationMiddleware to set the `Content-Language` header with the `CurrentUICulture`.
- Eliminates the need to set the response header `Content-Language` explicitly.

```
app.UseRequestLocalization(new RequestLocalizationOptions
{
    ApplyCurrentCultureToResponseHeaders = true
});
```

Use a custom provider

Suppose you want to let your customers store their language and culture in your databases. You could write a provider to look up these values for the user. The following code shows how to add a custom provider:

```
private const string enUSCulture = "en-US";

services.Configure<RequestLocalizationOptions>(options =>
{
    var supportedCultures = new[]
    {
        new CultureInfo(enUSCulture),
        new CultureInfo("fr")
    };

    options.DefaultRequestCulture = new RequestCulture(culture: enUSCulture, uiCulture: enUSCulture);
    options.SupportedCultures = supportedCultures;
    options.SupportedUICultures = supportedCultures;

    options.AddInitialRequestCultureProvider(new CustomRequestCultureProvider(async context =>
    {
        // My custom request culture logic
        return new ProviderCultureResult("en");
    }));
});
```

Use `RequestLocalizationOptions` to add or remove localization providers.

Set the culture programmatically

This sample **Localization.StarterWeb** project on GitHub contains UI to set the `Culture`. The *Views/Shared/_SelectLanguagePartial.cshtml* file allows you to select the culture from the list of supported cultures:

```
@using Microsoft.AspNetCore.Builder
@using Microsoft.AspNetCore.Http.Features
@using Microsoft.AspNetCore.Localization
@using Microsoft.AspNetCore.Mvc.Localization
@using Microsoft.Extensions.Options

@inject IViewLocalizer Localizer
@inject IOptions<RequestLocalizationOptions> LocOptions

@{
    var requestCulture = Context.Features.Get<IRequestCultureFeature>();
    var cultureItems = LocOptions.Value.SupportedUICultures
        .Select(c => new SelectListItem { Value = c.Name, Text = c.DisplayName })
        .ToList();
    var returnUrl = string.IsNullOrEmpty(Context.Request.Path) ? "~/" : $"~{Context.Request.Path.Value}";
}

<div title="@Localizer["Request culture provider:"] @requestCulture?.Provider?.GetType().Name">
    <form id="selectLanguage" asp-controller="Home"
          asp-action="SetLanguage" asp-route-returnUrl="@returnUrl"
          method="post" class="form-horizontal" role="form">
        <label asp-for="@requestCulture.RequestCulture.UICulture.Name">@Localizer["Language:"]</label>
<select name="culture"
          onchange="this.form.submit();"
          asp-for="@requestCulture.RequestCulture.UICulture.Name" asp-items="cultureItems">
        </select>
    </form>
</div>
```

The *Views/Shared/_SelectLanguagePartial.cshtml* file is added to the `footer` section of the layout file so it will be available to all views:

```
<div class="container body-content" style="margin-top:60px">
    @RenderBody()
    <hr>
    <footer>
        <div class="row">
            <div class="col-md-6">
                <p>&copy; @System.DateTime.Now.Year - Localization</p>
            </div>
            <div class="col-md-6 text-right">
                @await Html.PartialAsync("_SelectLanguagePartial")
            </div>
        </div>
    </footer>
</div>
```

The `SetLanguage` method sets the culture cookie.

```
[HttpPost]
public IActionResult SetLanguage(string culture, string returnUrl)
{
    Response.Cookies.Append(
        CookieRequestCultureProvider.DefaultCookieName,
        CookieRequestCultureProvider.MakeCookieValue(new RequestCulture(culture)),
        new CookieOptions { Expires = DateTimeOffset.UtcNow.AddYears(1) }
    );

    return LocalRedirect(returnUrl);
}
```

You can't plug in the *_SelectLanguagePartial.cshtml* to sample code for this project. The **Localization.StarterWeb** project on GitHub has code to flow the `RequestLocalizationOptions` to a Razor partial through the Dependency Injection container.

Model binding route data and query strings

See Globalization behavior of model binding route data and query strings.

Globalization and localization terms

The process of localizing your app also requires a basic understanding of relevant character sets commonly used in modern software development and an understanding of the issues associated with them. Although all computers store text as numbers (codes), different systems store the same text using different numbers. The localization process refers to translating the app user interface (UI) for a specific culture/locale.

Localizability is an intermediate process for verifying that a globalized app is ready for localization.

The RFC 4646 format for the culture name is `<languagecode2>-<country/regioncode2>`, where `<languagecode2>` is the language code and `<country/regioncode2>` is the subculture code. For example, `es-CL` for Spanish (Chile), `en-US` for English (United States), and `en-AU` for English (Australia). RFC 4646 is a combination of an ISO 639 two-letter lowercase culture code associated with a language and an ISO 3166 two-letter uppercase subculture code associated with a country or region. See /previous-versions/commerce-server/ee825488(v=cs.20).

Internationalization is often abbreviated to "I18N". The abbreviation takes the first and last letters and the number of letters between them, so 18 stands for the number of letters between the first "I" and the last "N". The same applies to Globalization (G11N), and Localization (L10N).

Terms:

- Globalization (G11N): The process of making an app support different languages and regions.
- Localization (L10N): The process of customizing an app for a given language and region.
- Internationalization (I18N): Describes both globalization and localization.
- Culture: It's a language and, optionally, a region.
- Neutral culture: A culture that has a specified language, but not a region. (for example "en", "es")
- Specific culture: A culture that has a specified language and region. (for example "en-US", "en-GB", "es-CL")
- Parent culture: The neutral culture that contains a specific culture. (for example, "en" is the parent culture of "en-US" and "en-GB")
- Locale: A locale is the same as a culture.

> **NOTE**
>
> You may not be able to enter decimal commas in decimal fields. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. See this GitHub issue 4076 for instructions on adding decimal comma.

> **NOTE**
>
> Prior to ASP.NET Core 3.0 web apps write one log of type `LogLevel.Warning` per request if the requested culture is unsupported. Logging one `LogLevel.Warning` per request is can make large log files with redundant information. This behavior has been changed in ASP.NET 3.0. The `RequestLocalizationMiddleware` writes a log of type `LogLevel.Debug`, which reduces the size of production logs.

Configure portable object localization in ASP.NET Core

9/22/2020 • 13 minutes to read • Edit Online

By Sébastien Ros, Scott Addie and Hisham Bin Ateya

This article walks through the steps for using Portable Object (PO) files in an ASP.NET Core application with the Orchard Core framework.

Note: Orchard Core isn't a Microsoft product. Consequently, Microsoft provides no support for this feature.

View or download sample code (how to download)

What is a PO file?

PO files are distributed as text files containing the translated strings for a given language. Some advantages of using PO files instead *.resx* files include:

- PO files support pluralization; *.resx* files don't support pluralization.
- PO files aren't compiled like *.resx* files. As such, specialized tooling and build steps aren't required.
- PO files work well with collaborative online editing tools.

Example

Here is a sample PO file containing the translation for two strings in French, including one with its plural form:

fr.po

```
#: Services/EmailService.cs:29
msgid "Enter a comma separated list of email addresses."
msgstr "Entrez une liste d'emails séparés par une virgule."

#: Views/Email.cshtml:112
msgid "The email address is \"{0}\"."
msgid_plural "The email addresses are \"{0}\"."
msgstr[0] "L'adresse email est \"{0}\"."
msgstr[1] "Les adresses email sont \"{0}\""
```

This example uses the following syntax:

- `#:` : A comment indicating the context of the string to be translated. The same string might be translated differently depending on where it's being used.
- `msgid` : The untranslated string.
- `msgstr` : The translated string.

In the case of pluralization support, more entries can be defined.

- `msgid_plural` : The untranslated plural string.
- `msgstr[0]` : The translated string for the case 0.
- `msgstr[N]` : The translated string for the case N.

The PO file specification can be found here.

Configuring PO file support in ASP.NET Core

This example is based on an ASP.NET Core MVC application generated from a Visual Studio 2017 project template.

Referencing the package

Add a reference to the `OrchardCore.Localization.Core` NuGet package. It's available on MyGet at the following package source: https://www.myget.org/F/orchardcore-preview/api/v3/index.json

The *.csproj* file now contains a line similar to the following (version number may vary):

```
<PackageReference Include="OrchardCore.Localization.Core" Version="1.0.0-rc2-13450" />
```

Registering the service

Add the required services to the `ConfigureServices` method of *Startup.cs*:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
        .AddViewLocalization(LanguageViewLocationExpanderFormat.Suffix);

    services.AddPortableObjectLocalization();

    services.Configure<RequestLocalizationOptions>(options =>
        {
            var supportedCultures = new List<CultureInfo>
            {
                new CultureInfo("en-US"),
                new CultureInfo("en"),
                new CultureInfo("fr-FR"),
                new CultureInfo("fr")
            };

            options.DefaultRequestCulture = new RequestCulture("en-US");
            options.SupportedCultures = supportedCultures;
            options.SupportedUICultures = supportedCultures;
        });
}
```

Add the required middleware to the `Configure` method of *Startup.cs*:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
    }

    app.UseRouting();
    app.UseStaticFiles();

    app.UseRequestLocalization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllerRoute(name: "default", pattern: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

Add the following code to your Razor view of choice. *About.cshtml* is used in this example.

```
@using Microsoft.AspNetCore.Mvc.Localization
@inject IViewLocalizer Localizer

<p>@Localizer["Hello world!"]</p>
```

An `IViewLocalizer` instance is injected and used to translate the text "Hello world!".

Creating a PO file

Create a file named *<culture code>.po* in your application root folder. In this example, the file name is *fr.po* because the French language is used:

```
msgid "Hello world!"
msgstr "Bonjour le monde!"
```

This file stores both the string to translate and the French-translated string. Translations revert to their parent culture, if necessary. In this example, the *fr.po* file is used if the requested culture is `fr-FR` or `fr-CA`.

Testing the application

Run your application, and navigate to the URL `/Home/About`. The text **Hello world!** is displayed.

Navigate to the URL `/Home/About?culture=fr-FR`. The text **Bonjour le monde!** is displayed.

Pluralization

PO files support pluralization forms, which is useful when the same string needs to be translated differently based on a cardinality. This task is made complicated by the fact that each language defines custom rules to select which string to use based on the cardinality.

The Orchard Localization package provides an API to invoke these different plural forms automatically.

Creating pluralization PO files

Add the following content to the previously mentioned *fr.po* file:

```
msgid "There is one item."
msgid_plural "There are {0} items."
msgstr[0] "Il y a un élément."
msgstr[1] "Il y a {0} éléments."
```

See What is a PO file? for an explanation of what each entry in this example represents.

Adding a language using different pluralization forms

English and French strings were used in the previous example. English and French have only two pluralization forms and share the same form rules, which is that a cardinality of one is mapped to the first plural form. Any other cardinality is mapped to the second plural form.

Not all languages share the same rules. This is illustrated with the Czech language, which has three plural forms.

Create the `cs.po` file as follows, and note how the pluralization needs three different translations:

```
msgid "Hello world!"
msgstr "Ahoj světe!!"

msgid "There is one item."
msgid_plural "There are {0} items."
msgstr[0] "Existuje jedna položka."
msgstr[1] "Existují {0} položky."
msgstr[2] "Existuje {0} položek."
```

To accept Czech localizations, add `"cs"` to the list of supported cultures in the `ConfigureServices` method:

```
var supportedCultures = new List<CultureInfo>
{
    new CultureInfo("en-US"),
    new CultureInfo("en"),
    new CultureInfo("fr-FR"),
    new CultureInfo("fr"),
    new CultureInfo("cs")
};
```

Edit the *Views/Home/About.cshtml* file to render localized, plural strings for several cardinalities:

```
<p>@Localizer.Plural(1, "There is one item.", "There are {0} items.")</p>
<p>@Localizer.Plural(2, "There is one item.", "There are {0} items.")</p>
<p>@Localizer.Plural(5, "There is one item.", "There are {0} items.")</p>
```

Note: In a real world scenario, a variable would be used to represent the count. Here, we repeat the same code with three different values to expose a very specific case.

Upon switching cultures, you see the following:

For `/Home/About`:

```
There is one item.
There are 2 items.
There are 5 items.
```

For `/Home/About?culture=fr`:

```
Il y a un élément.
Il y a 2 éléments.
Il y a 5 éléments.
```

For `/Home/About?culture=cs`:

```
Existuje jedna položka.
Existují 2 položky.
Existuje 5 položek.
```

Note that for the Czech culture, the three translations are different. The French and English cultures share the same construction for the two last translated strings.

Advanced tasks

Contextualizing strings

Applications often contain the strings to be translated in several places. The same string may have a different translation in certain locations within an app (Razor views or class files). A PO file supports the notion of a file context, which can be used to categorize the string being represented. Using a file context, a string can be translated differently, depending on the file context (or lack of a file context).

The PO localization services use the name of the full class or the view that's used when translating a string. This is accomplished by setting the value on the `msgctxt` entry.

Consider a minor addition to the previous *fr.po* example. A Razor view located at *Views/Home/About.cshtml* can be defined as the file context by setting the reserved `msgctxt` entry's value:

```
msgctxt "Views.Home.About"
msgid "Hello world!"
msgstr "Bonjour le monde!"
```

With the `msgctxt` set as such, text translation occurs when navigating to `/Home/About?culture=fr-FR`. The translation won't occur when navigating to `/Home/Contact?culture=fr-FR`.

When no specific entry is matched with a given file context, Orchard Core's fallback mechanism looks for an appropriate PO file without a context. Assuming there's no specific file context defined for *Views/Home/Contact.cshtml*, navigating to `/Home/Contact?culture=fr-FR` loads a PO file such as:

```
msgid "Hello world!"
msgstr "Bonjour le monde!"
```

Changing the location of PO files

The default location of PO files can be changed in `ConfigureServices`:

```
services.AddPortableObjectLocalization(options => options.ResourcesPath = "Localization");
```

In this example, the PO files are loaded from the *Localization* folder.

Implementing a custom logic for finding localization files

When more complex logic is needed to locate PO files, the `OrchardCore.Localization.PortableObject.ILocalizationFileLocationProvider` interface can be implemented and registered as a service. This is useful when PO files can be stored in varying locations or when the files have to be

found within a hierarchy of folders.

Using a different default pluralized language

The package includes a `Plural` extension method that's specific to two plural forms. For languages requiring more plural forms, create an extension method. With an extension method, you won't need to provide any localization file for the default language — the original strings are already available directly in the code.

You can use the more generic `Plural(int count, string[] pluralForms, params object[] arguments)` overload which accepts a string array of translations.

By Sébastien Ros and Scott Addie

This article walks through the steps for using Portable Object (PO) files in an ASP.NET Core application with the Orchard Core framework.

Note: Orchard Core isn't a Microsoft product. Consequently, Microsoft provides no support for this feature.

View or download sample code (how to download)

What is a PO file?

PO files are distributed as text files containing the translated strings for a given language. Some advantages of using PO files instead *.resx* files include:

- PO files support pluralization; *.resx* files don't support pluralization.
- PO files aren't compiled like *.resx* files. As such, specialized tooling and build steps aren't required.
- PO files work well with collaborative online editing tools.

Example

Here is a sample PO file containing the translation for two strings in French, including one with its plural form:

fr.po

```
#: Services/EmailService.cs:29
msgid "Enter a comma separated list of email addresses."
msgstr "Entrez une liste d'emails séparés par une virgule."

#: Views/Email.cshtml:112
msgid "The email address is \"{0}\"."
msgid_plural "The email addresses are \"{0}\"."
msgstr[0] "L'adresse email est \"{0}\"."
msgstr[1] "Les adresses email sont \"{0}\""
```

This example uses the following syntax:

- `#:` : A comment indicating the context of the string to be translated. The same string might be translated differently depending on where it's being used.
- `msgid` : The untranslated string.
- `msgstr` : The translated string.

In the case of pluralization support, more entries can be defined.

- `msgid_plural` : The untranslated plural string.
- `msgstr[0]` : The translated string for the case 0.
- `msgstr[N]` : The translated string for the case N.

The PO file specification can be found here.

Configuring PO file support in ASP.NET Core

This example is based on an ASP.NET Core MVC application generated from a Visual Studio 2017 project template.

Referencing the package

Add a reference to the `OrchardCore.Localization.Core` NuGet package. It's available on MyGet at the following package source: https://www.myget.org/F/orchardcore-preview/api/v3/index.json

The *.csproj* file now contains a line similar to the following (version number may vary):

```
<PackageReference Include="OrchardCore.Localization.Core" Version="1.0.0-beta1-3187" />
```

Registering the service

Add the required services to the `ConfigureServices` method of *Startup.cs*:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
        .AddViewLocalization(LanguageViewLocationExpanderFormat.Suffix);

    services.AddPortableObjectLocalization();

    services.Configure<RequestLocalizationOptions>(options =>
        {
            var supportedCultures = new List<CultureInfo>
            {
                new CultureInfo("en-US"),
                new CultureInfo("en"),
                new CultureInfo("fr-FR"),
                new CultureInfo("fr")
            };

            options.DefaultRequestCulture = new RequestCulture("en-US");
            options.SupportedCultures = supportedCultures;
            options.SupportedUICultures = supportedCultures;
        });
}
```

Add the required middleware to the `Configure` method of *Startup.cs*:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseBrowserLink();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
    }

    app.UseStaticFiles();

    app.UseRequestLocalization();

    app.UseMvcWithDefaultRoute();
}
```

Add the following code to your Razor view of choice. *About.cshtml* is used in this example.

```
@using Microsoft.AspNetCore.Mvc.Localization
@inject IViewLocalizer Localizer

<p>@Localizer["Hello world!"]</p>
```

An `IViewLocalizer` instance is injected and used to translate the text "Hello world!".

Creating a PO file

Create a file named *<culture code>.po* in your application root folder. In this example, the file name is *fr.po* because the French language is used:

```
msgid "Hello world!"
msgstr "Bonjour le monde!"
```

This file stores both the string to translate and the French-translated string. Translations revert to their parent culture, if necessary. In this example, the *fr.po* file is used if the requested culture is `fr-FR` or `fr-CA`.

Testing the application

Run your application, and navigate to the URL `/Home/About`. The text **Hello world!** is displayed.

Navigate to the URL `/Home/About?culture=fr-FR`. The text **Bonjour le monde!** is displayed.

Pluralization

PO files support pluralization forms, which is useful when the same string needs to be translated differently based on a cardinality. This task is made complicated by the fact that each language defines custom rules to select which string to use based on the cardinality.

The Orchard Localization package provides an API to invoke these different plural forms automatically.

Creating pluralization PO files

Add the following content to the previously mentioned *fr.po* file:

```
msgid "There is one item."
msgid_plural "There are {0} items."
msgstr[0] "Il y a un élément."
msgstr[1] "Il y a {0} éléments."
```

See What is a PO file? for an explanation of what each entry in this example represents.

Adding a language using different pluralization forms

English and French strings were used in the previous example. English and French have only two pluralization forms and share the same form rules, which is that a cardinality of one is mapped to the first plural form. Any other cardinality is mapped to the second plural form.

Not all languages share the same rules. This is illustrated with the Czech language, which has three plural forms.

Create the `cs.po` file as follows, and note how the pluralization needs three different translations:

```
msgid "Hello world!"
msgstr "Ahoj světe!!"

msgid "There is one item."
msgid_plural "There are {0} items."
msgstr[0] "Existuje jedna položka."
msgstr[1] "Existují {0} položky."
msgstr[2] "Existuje {0} položek."
```

To accept Czech localizations, add `"cs"` to the list of supported cultures in the `ConfigureServices` method:

```
var supportedCultures = new List<CultureInfo>
{
    new CultureInfo("en-US"),
    new CultureInfo("en"),
    new CultureInfo("fr-FR"),
    new CultureInfo("fr"),
    new CultureInfo("cs")
};
```

Edit the *Views/Home/About.cshtml* file to render localized, plural strings for several cardinalities:

```
<p>@Localizer.Plural(1, "There is one item.", "There are {0} items.")</p>
<p>@Localizer.Plural(2, "There is one item.", "There are {0} items.")</p>
<p>@Localizer.Plural(5, "There is one item.", "There are {0} items.")</p>
```

Note: In a real world scenario, a variable would be used to represent the count. Here, we repeat the same code with three different values to expose a very specific case.

Upon switching cultures, you see the following:

For `/Home/About`:

```
There is one item.
There are 2 items.
There are 5 items.
```

For `/Home/About?culture=fr`:

```
Il y a un élément.
Il y a 2 éléments.
Il y a 5 éléments.
```

For `/Home/About?culture=cs`:

```
Existuje jedna položka.
Existují 2 položky.
Existuje 5 položek.
```

Note that for the Czech culture, the three translations are different. The French and English cultures share the same construction for the two last translated strings.

Advanced tasks

Contextualizing strings

Applications often contain the strings to be translated in several places. The same string may have a different translation in certain locations within an app (Razor views or class files). A PO file supports the notion of a file context, which can be used to categorize the string being represented. Using a file context, a string can be translated differently, depending on the file context (or lack of a file context).

The PO localization services use the name of the full class or the view that's used when translating a string. This is accomplished by setting the value on the `msgctxt` entry.

Consider a minor addition to the previous *fr.po* example. A Razor view located at *Views/Home/About.cshtml* can be defined as the file context by setting the reserved `msgctxt` entry's value:

```
msgctxt "Views.Home.About"
msgid "Hello world!"
msgstr "Bonjour le monde!"
```

With the `msgctxt` set as such, text translation occurs when navigating to `/Home/About?culture=fr-FR`. The translation won't occur when navigating to `/Home/Contact?culture=fr-FR`.

When no specific entry is matched with a given file context, Orchard Core's fallback mechanism looks for an appropriate PO file without a context. Assuming there's no specific file context defined for *Views/Home/Contact.cshtml*, navigating to `/Home/Contact?culture=fr-FR` loads a PO file such as:

```
msgid "Hello world!"
msgstr "Bonjour le monde!"
```

Changing the location of PO files

The default location of PO files can be changed in `ConfigureServices`:

```
services.AddPortableObjectLocalization(options => options.ResourcesPath = "Localization");
```

In this example, the PO files are loaded from the *Localization* folder.

Implementing a custom logic for finding localization files

When more complex logic is needed to locate PO files, the `OrchardCore.Localization.PortableObject.ILocalizationFileLocationProvider` interface can be implemented and registered as a service. This is useful when PO files can be stored in varying locations or when the files have to be found within a hierarchy of folders.

Using a different default pluralized language

The package includes a `Plural` extension method that's specific to two plural forms. For languages requiring more plural forms, create an extension method. With an extension method, you won't need to provide any localization file for the default language — the original strings are already available directly in the code.

You can use the more generic `Plural(int count, string[] pluralForms, params object[] arguments)` overload which accepts a string array of translations.

Localization Extensibility

9/22/2020 • 2 minutes to read • Edit Online

By Hisham Bin Ateya

This article:

- Lists the extensibility points on the localization APIs.
- Provides instructions on how to extend ASP.NET Core app localization.

Extensible Points in Localization APIs

ASP.NET Core localization APIs are built to be extensible. Extensibility allows developers to customize the localization according to their needs. For instance, OrchardCore has a `POStringLocalizer`. `POStringLocalizer` describes in detail using Portable Object localization to use `PO` files to store localization resources.

This article lists the two main extensibility points that localization APIs provide:

- RequestCultureProvider
- IStringLocalizer

Localization Culture Providers

ASP.NET Core localization APIs have four default providers that can determine the current culture of an executing request:

- QueryStringRequestCultureProvider
- CookieRequestCultureProvider
- AcceptLanguageHeaderRequestCultureProvider
- CustomRequestCultureProvider

The preceding providers are described in detail in the Localization Middleware documentation. If the default providers don't meet your needs, build a custom provider using one of the following approaches:

Use CustomRequestCultureProvider

CustomRequestCultureProvider provides a custom RequestCultureProvider that uses a simple delegate to determine the current localization culture:

```
options.RequestCultureProviders.Insert(0, new CustomRequestCultureProvider(async context =>
{
    var currentCulture = "en";
    var segments = context.Request.Path.Value.Split(new char[] { '/' },
        StringSplitOptions.RemoveEmptyEntries);

    if (segments.Length > 1 && segments[0].Length == 2)
    {
        currentCulture = segments[0];
    }

    var requestCulture = new ProviderCultureResult(currentCulture);

    return Task.FromResult(requestCulture);
}));
```

```
options.AddInitialRequestCultureProvider(new CustomRequestCultureProvider(async context =>
{
    var currentCulture = "en";
    var segments = context.Request.Path.Value.Split(new char[] { '/' },
        StringSplitOptions.RemoveEmptyEntries);

    if (segments.Length > 1 && segments[0].Length == 2)
    {
        currentCulture = segments[0];
    }

    var requestCulture = new ProviderCultureResult(currentCulture);

    return Task.FromResult(requestCulture);
}));
```

Use a new implemetation of RequestCultureProvider

A new implementation of RequestCultureProvider can be created that determines the request culture information from a custom source. For example, the custom source can be a configuration file or database.

The following example shows `AppSettingsRequestCultureProvider`, which extends the RequestCultureProvider to determine the request culture information from *appsettings.json*:

```
public class AppSettingsRequestCultureProvider : RequestCultureProvider
{
    public string CultureKey { get; set; } = "culture";

    public string UICultureKey { get; set; } = "ui-culture";

    public override Task<ProviderCultureResult> DetermineProviderCultureResult(HttpContext httpContext)
    {
        if (httpContext == null)
        {
            throw new ArgumentNullException();
        }

        var configuration = httpContext.RequestServices.GetService<IConfigurationRoot>();
        var culture = configuration[CultureKey];
        var uiCulture = configuration[UICultureKey];

        if (culture == null && uiCulture == null)
        {
            return Task.FromResult((ProviderCultureResult)null);
        }

        if (culture != null && uiCulture == null)
        {
            uiCulture = culture;
        }

        if (culture == null && uiCulture != null)
        {
            culture = uiCulture;
        }

        var providerResultCulture = new ProviderCultureResult(culture, uiCulture);

        return Task.FromResult(providerResultCulture);
    }
}
```

Localization resources

ASP.NET Core localization provides ResourceManagerStringLocalizer. ResourceManagerStringLocalizer is an implementation of IStringLocalizer that is uses `resx` to store localization resources.

You aren't limited to using `resx` files. By implementing `IStringLocalized`, any data source can be used.

The following example projects implement IStringLocalizer:

- EFStringLocalizer
- JsonStringLocalizer
- SqlLocalizer

Troubleshoot ASP.NET Core Localization

9/22/2020 • 2 minutes to read • Edit Online

By Hisham Bin Ateya

This article provides instructions on how to diagnose ASP.NET Core app localization issues.

Localization configuration issues

Localization middleware order

The app may not localize because the localization middleware isn't ordered as expected.

To resolve this issue, ensure that localization middleware is registered before MVC middleware. Otherwise, the localization middleware isn't applied.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddLocalization(options => options.ResourcesPath = "Resources");

    services.AddMvc();
}
```

Localization resources path not found

Supported Cultures in RequestCultureProvider don't match with registered once

Resource file naming issues

ASP.NET Core has predefined rules and guidelines for localization resources file naming, which are described in detail here.

Missing resources

Common causes of resources not being found include:

- Resource names are misspelled in either the `resx` file or the localizer request.
- The resource is missing from the `resx` for some languages, but exists in others.
- If you're still having trouble, check the localization log messages (which are at `Debug` log level) for more details about the missing resources.

Hint: *When using* `CookieRequestCultureProvider`*, verify single quotes are not used with the cultures inside the localization cookie value. For example,* `c='en-UK'|uic='en-US'` *is an invalid cookie value, while* `c=en-UK|uic=en-US` *is a valid.*

Resources & Class Libraries issues

ASP.NET Core by default provides a way to allow the class libraries to find their resource files via ResourceLocationAttribute.

Common issues with class libraries include:

- Missing the `ResourceLocationAttribute` in a class library will prevent `ResourceManagerStringLocalizerFactory` from discovering the resources.

- Resource file naming. For more information, see Resource file naming issues section.
- Changing the root namespace of the class library. For more information, see Root Namespace issues section.

CustomRequestCultureProvider doesn't work as expected

The `RequestLocalizationOptions` class has three default providers:

1. `QueryStringRequestCultureProvider`
2. `CookieRequestCultureProvider`
3. `AcceptLanguageHeaderRequestCultureProvider`

The CustomRequestCultureProvider allows you to customize how the localization culture is provided in your app. The `CustomRequestCultureProvider` is used when the default providers don't meet your requirements.

- A common reason custom provider don't work properly is that it isn't the first provider in the `RequestCultureProviders` list. To resolve this issue:
- Insert the custom provider at the position 0 in the `RequestCultureProviders` list as the following:

```
options.RequestCultureProviders.Insert(0, new CustomRequestCultureProvider(async context =>
    {
        // My custom request culture logic
        return new ProviderCultureResult("en");
    }));
```

```
options.AddInitialRequestCultureProvider(new CustomRequestCultureProvider(async context =>
    {
        // My custom request culture logic
        return new ProviderCultureResult("en");
    }));
```

- Use `AddInitialRequestCultureProvider` extension method to set the custom provider as initial provider.

Root Namespace issues

When the root namespace of an assembly is different than the assembly name, localization doesn't work by default. To avoid this issue use RootNamespace, which is described in detail here

> **WARNING**
> This can occur when a project's name is not a valid .NET identifier. For instance `my-project-name.csproj` will use the root namespace `my_project_name` and the assembly name `my-project-name` leading to this error.

Resources & Build Action

If you use resource files for localization, it's important that they have an appropriate build action. They should be **Embedded Resource**, otherwise the `ResourceStringLocalizer` is not able to find these resources.

Model Binding in ASP.NET Core

9/22/2020 • 31 minutes to read • Edit Online

This article explains what model binding is, how it works, and how to customize its behavior.

View or download sample code (how to download).

What is Model binding

Controllers and Razor pages work with data that comes from HTTP requests. For example, route data may provide a record key, and posted form fields may provide values for the properties of the model. Writing code to retrieve each of these values and convert them from strings to .NET types would be tedious and error-prone. Model binding automates this process. The model binding system:

- Retrieves data from various sources such as route data, form fields, and query strings.
- Provides the data to controllers and Razor pages in method parameters and public properties.
- Converts string data to .NET types.
- Updates properties of complex types.

Example

Suppose you have the following action method:

```
[HttpGet("{id}")]
public ActionResult<Pet> GetById(int id, bool dogsOnly)
```

And the app receives a request with this URL:

```
http://contoso.com/api/pets/2?DogsOnly=true
```

Model binding goes through the following steps after the routing system selects the action method:

- Finds the first parameter of `GetByID`, an integer named `id`.
- Looks through the available sources in the HTTP request and finds `id` = "2" in route data.
- Converts the string "2" into integer 2.
- Finds the next parameter of `GetByID`, a boolean named `dogsOnly`.
- Looks through the sources and finds "DogsOnly=true" in the query string. Name matching is not case-sensitive.
- Converts the string "true" into boolean `true`.

The framework then calls the `GetById` method, passing in 2 for the `id` parameter, and `true` for the `dogsOnly` parameter.

In the preceding example, the model binding targets are method parameters that are simple types. Targets may also be the properties of a complex type. After each property is successfully bound, model validation occurs for that property. The record of what data is bound to the

model, and any binding or validation errors, is stored in ControllerBase.ModelState or PageModel.ModelState. To find out if this process was successful, the app checks the ModelState.IsValid flag.

Targets

Model binding tries to find values for the following kinds of targets:

- Parameters of the controller action method that a request is routed to.
- Parameters of the Razor Pages handler method that a request is routed to.
- Public properties of a controller or `PageModel` class, if specified by attributes.

[BindProperty] attribute

Can be applied to a public property of a controller or `PageModel` class to cause model binding to target that property:

```
public class EditModel : InstructorsPageModel
{
    [BindProperty]
    public Instructor Instructor { get; set; }
```

[BindProperties] attribute

Available in ASP.NET Core 2.1 and later. Can be applied to a controller or `PageModel` class to tell model binding to target all public properties of the class:

```
[BindProperties(SupportsGet = true)]
public class CreateModel : InstructorsPageModel
{
    public Instructor Instructor { get; set; }
```

Model binding for HTTP GET requests

By default, properties are not bound for HTTP GET requests. Typically, all you need for a GET request is a record ID parameter. The record ID is used to look up the item in the database. Therefore, there is no need to bind a property that holds an instance of the model. In scenarios where you do want properties bound to data from GET requests, set the `SupportsGet` property to `true`:

```
[BindProperty(Name = "ai_user", SupportsGet = true)]
public string ApplicationInsightsCookie { get; set; }
```

Sources

By default, model binding gets data in the form of key-value pairs from the following sources in an HTTP request:

1. Form fields
2. The request body (For controllers that have the [ApiController] attribute.)
3. Route data
4. Query string parameters
5. Uploaded files

For each target parameter or property, the sources are scanned in the order indicated in the

preceding list. There are a few exceptions:

- Route data and query string values are used only for simple types.
- Uploaded files are bound only to target types that implement `IFormFile` or `IEnumerable<IFormFile>`.

If the default source is not correct, use one of the following attributes to specify the source:

- `[FromQuery]` - Gets values from the query string.
- `[FromRoute]` - Gets values from route data.
- `[FromForm]` - Gets values from posted form fields.
- `[FromBody]` - Gets values from the request body.
- `[FromHeader]` - Gets values from HTTP headers.

These attributes:

- Are added to model properties individually (not to the model class), as in the following example:

```
public class Instructor
{
    public int ID { get; set; }

    [FromQuery(Name = "Note")]
    public string NoteFromQueryString { get; set; }
```

- Optionally accept a model name value in the constructor. This option is provided in case the property name doesn't match the value in the request. For instance, the value in the request might be a header with a hyphen in its name, as in the following example:

```
public void OnGet([FromHeader(Name = "Accept-Language")] string language)
```

[FromBody] attribute

Apply the `[FromBody]` attribute to a parameter to populate its properties from the body of an HTTP request. The ASP.NET Core runtime delegates the responsibility of reading the body to an input formatter. Input formatters are explained later in this article.

When `[FromBody]` is applied to a complex type parameter, any binding source attributes applied to its properties are ignored. For example, the following `Create` action specifies that its `pet` parameter is populated from the body:

```
public ActionResult<Pet> Create([FromBody] Pet pet)
```

The `Pet` class specifies that its `Breed` property is populated from a query string parameter:

```
public class Pet
{
    public string Name { get; set; }

    [FromQuery] // Attribute is ignored.
    public string Breed { get; set; }
}
```

In the preceding example:

- The `[FromQuery]` attribute is ignored.
- The `Breed` property is not populated from a query string parameter.

Input formatters read only the body and don't understand binding source attributes. If a suitable value is found in the body, that value is used to populate the `Breed` property.

Don't apply `[FromBody]` to more than one parameter per action method. Once the request stream is read by an input formatter, it's no longer available to be read again for binding other `[FromBody]` parameters.

Additional sources

Source data is provided to the model binding system by *value providers*. You can write and register custom value providers that get data for model binding from other sources. For example, you might want data from cookies or session state. To get data from a new source:

- Create a class that implements `IValueProvider`.
- Create a class that implements `IValueProviderFactory`.
- Register the factory class in `Startup.ConfigureServices`.

The sample app includes a value provider and factory example that gets values from cookies. Here's the registration code in `Startup.ConfigureServices`:

```
services.AddRazorPages()
    .AddMvcOptions(options =>
{
    options.ValueProviderFactories.Add(new CookieValueProviderFactory());
    options.ModelMetadataDetailsProviders.Add(
        new ExcludeBindingMetadataProvider(typeof(System.Version)));
    options.ModelMetadataDetailsProviders.Add(
        new SuppressChildValidationMetadataProvider(typeof(System.Guid)));
})
.AddXmlSerializerFormatters();
```

The code shown puts the custom value provider after all the built-in value providers. To make it the first in the list, call `Insert(0, new CookieValueProviderFactory())` instead of `Add`.

No source for a model property

By default, a model state error isn't created if no value is found for a model property. The property is set to null or a default value:

- Nullable simple types are set to `null`.
- Non-nullable value types are set to `default(T)`. For example, a parameter `int id` is set to 0.
- For complex Types, model binding creates an instance by using the default constructor, without setting properties.
- Arrays are set to `Array.Empty<T>()`, except that `byte[]` arrays are set to `null`.

If model state should be invalidated when nothing is found in form fields for a model property, use the `[BindRequired]` attribute.

Note that this `[BindRequired]` behavior applies to model binding from posted form data, not to JSON or XML data in a request body. Request body data is handled by input formatters.

Type conversion errors

If a source is found but can't be converted into the target type, model state is flagged as invalid. The target parameter or property is set to null or a default value, as noted in the previous section.

In an API controller that has the `[ApiController]` attribute, invalid model state results in an automatic HTTP 400 response.

In a Razor page, redisplay the page with an error message:

```
public IActionResult OnPost()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _instructorsInMemoryStore.Add(Instructor);
    return RedirectToPage("./Index");
}
```

Client-side validation catches most bad data that would otherwise be submitted to a Razor Pages form. This validation makes it hard to trigger the preceding highlighted code. The sample app includes a **Submit with Invalid Date** button that puts bad data in the **Hire Date** field and submits the form. This button shows how the code for redisplaying the page works when data conversion errors occur.

When the page is redisplayed by the preceding code, the invalid input is not shown in the form field. This is because the model property has been set to null or a default value. The invalid input does appear in an error message. But if you want to redisplay the bad data in the form field, consider making the model property a string and doing the data conversion manually.

The same strategy is recommended if you don't want type conversion errors to result in model state errors. In that case, make the model property a string.

Simple types

The simple types that the model binder can convert source strings into include the following:

- Boolean
- Byte, SByte
- Char
- DateTime
- DateTimeOffset
- Decimal
- Double
- Enum
- Guid
- Int16, Int32, Int64
- Single
- TimeSpan
- UInt16, UInt32, UInt64
- Uri
- Version

Complex types

A complex type must have a public default constructor and public writable properties to bind. When model binding occurs, the class is instantiated using the public default constructor.

For each property of the complex type, model binding looks through the sources for the name pattern *prefix.property_name*. If nothing is found, it looks for just *property_name* without the prefix.

For binding to a parameter, the prefix is the parameter name. For binding to a `PageModel` public property, the prefix is the public property name. Some attributes have a `Prefix` property that lets you override the default usage of parameter or property name.

For example, suppose the complex type is the following `Instructor` class:

```
public class Instructor
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstName { get; set; }
}
```

Prefix = parameter name

If the model to be bound is a parameter named `instructorToUpdate`:

```
public IActionResult OnPost(int? id, Instructor instructorToUpdate)
```

Model binding starts by looking through the sources for the key `instructorToUpdate.ID`. If that isn't found, it looks for `ID` without a prefix.

Prefix = property name

If the model to be bound is a property named `Instructor` of the controller or `PageModel` class:

```
[BindProperty]
public Instructor Instructor { get; set; }
```

Model binding starts by looking through the sources for the key `Instructor.ID`. If that isn't found, it looks for `ID` without a prefix.

Custom prefix

If the model to be bound is a parameter named `instructorToUpdate` and a `Bind` attribute specifies `Instructor` as the prefix:

```
public IActionResult OnPost(
    int? id, [Bind(Prefix = "Instructor")] Instructor instructorToUpdate)
```

Model binding starts by looking through the sources for the key `Instructor.ID`. If that isn't found, it looks for `ID` without a prefix.

Attributes for complex type targets

Several built-in attributes are available for controlling model binding of complex types:

- `[Bind]`
- `[BindRequired]`

- `[BindNever]`

> **WARNING**
> These attributes affect model binding when posted form data is the source of values. They do ***not*** affect input formatters, which process posted JSON and XML request bodies. Input formatters are explained later in this article.

[Bind] attribute

Can be applied to a class or a method parameter. Specifies which properties of a model should be included in model binding. `[Bind]` does ***not*** affect input formatters.

In the following example, only the specified properties of the `Instructor` model are bound when any handler or action method is called:

```
[Bind("LastName,FirstMidName,HireDate")]
public class Instructor
```

In the following example, only the specified properties of the `Instructor` model are bound when the `OnPost` method is called:

```
[HttpPost]
public IActionResult OnPost([Bind("LastName,FirstMidName,HireDate")] Instructor instructor)
```

The `[Bind]` attribute can be used to protect against overposting in *create* scenarios. It doesn't work well in edit scenarios because excluded properties are set to null or a default value instead of being left unchanged. For defense against overposting, view models are recommended rather than the `[Bind]` attribute. For more information, see Security note about overposting.

[BindRequired] attribute

Can only be applied to model properties, not to method parameters. Causes model binding to add a model state error if binding cannot occur for a model's property. Here's an example:

```
public class InstructorWithCollection
{
    public int ID { get; set; }

    [DataType(DataType.Date)]
    [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
    [Display(Name = "Hire Date")]
    [BindRequired]
    public DateTime HireDate { get; set; }
```

See also the discussion of the `[Required]` attribute in Model validation.

[BindNever] attribute

Can only be applied to model properties, not to method parameters. Prevents model binding from setting a model's property. Here's an example:

```
public class InstructorWithDictionary
{
    [BindNever]
    public int ID { get; set; }
```

Collections

For targets that are collections of simple types, model binding looks for matches to *parameter_name* or *property_name*. If no match is found, it looks for one of the supported formats without the prefix. For example:

- Suppose the parameter to be bound is an array named `selectedCourses`:

  ```
  public IActionResult OnPost(int? id, int[] selectedCourses)
  ```

- Form or query string data can be in one of the following formats:

  ```
  selectedCourses=1050&selectedCourses=2000
  ```

  ```
  selectedCourses[0]=1050&selectedCourses[1]=2000
  ```

  ```
  [0]=1050&[1]=2000
  ```

  ```
  selectedCourses[a]=1050&selectedCourses[b]=2000&selectedCourses.index=a&selectedCour
  ses.index=b
  ```

  ```
  [a]=1050&[b]=2000&index=a&index=b
  ```

- The following format is supported only in form data:

  ```
  selectedCourses[]=1050&selectedCourses[]=2000
  ```

- For all of the preceding example formats, model binding passes an array of two items to the `selectedCourses` parameter:

  - selectedCourses[0]=1050
  - selectedCourses[1]=2000

  Data formats that use subscript numbers (... [0] ... [1] ...) must ensure that they are numbered sequentially starting at zero. If there are any gaps in subscript numbering, all items after the gap are ignored. For example, if the subscripts are 0 and 2 instead of 0 and 1, the second item is ignored.

Dictionaries

For `Dictionary` targets, model binding looks for matches to *parameter_name* or *property_name*. If no match is found, it looks for one of the supported formats without the prefix. For example:

- Suppose the target parameter is a `Dictionary<int, string>` named `selectedCourses`:

```
public IActionResult OnPost(int? id, Dictionary<int, string> selectedCourses)
```

- The posted form or query string data can look like one of the following examples:

```
selectedCourses[1050]=Chemistry&selectedCourses[2000]=Economics
```

```
[1050]=Chemistry&selectedCourses[2000]=Economics
```

```
selectedCourses[0].Key=1050&selectedCourses[0].Value=Chemistry&
selectedCourses[1].Key=2000&selectedCourses[1].Value=Economics
```

```
[0].Key=1050&[0].Value=Chemistry&[1].Key=2000&[1].Value=Economics
```

- For all of the preceding example formats, model binding passes a dictionary of two items to the `selectedCourses` parameter:
  - selectedCourses["1050"]="Chemistry"
  - selectedCourses["2000"]="Economics"

Globalization behavior of model binding route data and query strings

The ASP.NET Core route value provider and query string value provider:

- Treat values as invariant culture.
- Expect that URLs are culture-invariant.

In contrast, values coming from form data undergo a culture-sensitive conversion. This is by design so that URLs are shareable across locales.

To make the ASP.NET Core route value provider and query string value provider undergo a culture-sensitive conversion:

- Inherit from IValueProviderFactory
- Copy the code from QueryStringValueProviderFactory or RouteValueValueProviderFactory
- Replace the culture value passed to the value provider constructor with CultureInfo.CurrentCulture
- Replace the default value provider factory in MVC options with your new one:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews(options =>
    {
        var index = options.ValueProviderFactories.IndexOf(
            options.ValueProviderFactories.OfType<QueryStringValueProviderFactory>
().Single());
        options.ValueProviderFactories[index] = new
CulturedQueryStringValueProviderFactory();
    });
}
```

```
public class CulturedQueryStringValueProviderFactory : IValueProviderFactory
{
    public Task CreateValueProviderAsync(ValueProviderFactoryContext context)
    {
        if (context == null)
        {
            throw new ArgumentNullException(nameof(context));
        }

        var query = context.ActionContext.HttpContext.Request.Query;
        if (query != null && query.Count > 0)
        {
            var valueProvider = new QueryStringValueProvider(
                BindingSource.Query,
                query,
                CultureInfo.CurrentCulture);

            context.ValueProviders.Add(valueProvider);
        }

        return Task.CompletedTask;
    }
}
```

Special data types

There are some special data types that model binding can handle.

IFormFile and IFormFileCollection

An uploaded file included in the HTTP request. Also supported is `IEnumerable<IFormFile>` for multiple files.

CancellationToken

Used to cancel activity in asynchronous controllers.

FormCollection

Used to retrieve all the values from posted form data.

Input formatters

Data in the request body can be in JSON, XML, or some other format. To parse this data, model binding uses an *input formatter* that is configured to handle a particular content type. By default, ASP.NET Core includes JSON based input formatters for handling JSON data. You can add other formatters for other content types.

ASP.NET Core selects input formatters based on the Consumes attribute. If no attribute is present, it uses the Content-Type header.

To use the built-in XML input formatters:

- Install the `Microsoft.AspNetCore.Mvc.Formatters.Xml` NuGet package.
- In `Startup.ConfigureServices`, call AddXmlSerializerFormatters or AddXmlDataContractSerializerFormatters.

```
services.AddRazorPages()
    .AddMvcOptions(options =>
{
    options.ValueProviderFactories.Add(new CookieValueProviderFactory());
    options.ModelMetadataDetailsProviders.Add(
        new ExcludeBindingMetadataProvider(typeof(System.Version)));
    options.ModelMetadataDetailsProviders.Add(
        new SuppressChildValidationMetadataProvider(typeof(System.Guid)));
})
.AddXmlSerializerFormatters();
```

- Apply the `Consumes` attribute to controller classes or action methods that should expect XML in the request body.

```
[HttpPost]
[Consumes("application/xml")]
public ActionResult<Pet> Create(Pet pet)
```

For more information, see Introducing XML Serialization.

Customize model binding with input formatters

An input formatter takes full responsibility for reading data from the request body. To customize this process, configure the APIs used by the input formatter. This section describes how to customize the `System.Text.Json`-based input formatter to understand a custom type named `ObjectId`.

Consider the following model, which contains a custom `ObjectId` property named `Id`:

```
public class ModelWithObjectId
{
    public ObjectId Id { get; set; }
}
```

To customize the model binding process when using `System.Text.Json`, create a class derived from JsonConverter<T>:

```
internal class ObjectIdConverter : JsonConverter<ObjectId>
{
    public override ObjectId Read(
        ref Utf8JsonReader reader, Type typeToConvert, JsonSerializerOptions options)
    {
        return new ObjectId(JsonSerializer.Deserialize<int>(ref reader, options));
    }

    public override void Write(
        Utf8JsonWriter writer, ObjectId value, JsonSerializerOptions options)
    {
        writer.WriteNumberValue(value.Id);
    }
}
```

To use a custom converter, apply the JsonConverterAttribute attribute to the type. In the following example, the `ObjectId` type is configured with `ObjectIdConverter` as its custom converter:

```
[JsonConverter(typeof(ObjectIdConverter))]
public struct ObjectId
{
    public ObjectId(int id) =>
        Id = id;

    public int Id { get; }
}
```

For more information, see How to write custom converters.

Exclude specified types from model binding

The model binding and validation systems' behavior is driven by ModelMetadata. You can customize `ModelMetadata` by adding a details provider to MvcOptions.ModelMetadataDetailsProviders. Built-in details providers are available for disabling model binding or validation for specified types.

To disable model binding on all models of a specified type, add an ExcludeBindingMetadataProvider in `Startup.ConfigureServices`. For example, to disable model binding on all models of type `System.Version`:

```
services.AddRazorPages()
    .AddMvcOptions(options =>
{
    options.ValueProviderFactories.Add(new CookieValueProviderFactory());
    options.ModelMetadataDetailsProviders.Add(
        new ExcludeBindingMetadataProvider(typeof(System.Version)));
    options.ModelMetadataDetailsProviders.Add(
        new SuppressChildValidationMetadataProvider(typeof(System.Guid)));
})
.AddXmlSerializerFormatters();
```

To disable validation on properties of a specified type, add a SuppressChildValidationMetadataProvider in `Startup.ConfigureServices`. For example, to disable validation on properties of type `System.Guid`:

```
services.AddRazorPages()
    .AddMvcOptions(options =>
{
    options.ValueProviderFactories.Add(new CookieValueProviderFactory());
    options.ModelMetadataDetailsProviders.Add(
        new ExcludeBindingMetadataProvider(typeof(System.Version)));
    options.ModelMetadataDetailsProviders.Add(
        new SuppressChildValidationMetadataProvider(typeof(System.Guid)));
})
.AddXmlSerializerFormatters();
```

Custom model binders

You can extend model binding by writing a custom model binder and using the `[ModelBinder]` attribute to select it for a given target. Learn more about custom model binding.

Manual model binding

Model binding can be invoked manually by using the TryUpdateModelAsync method. The method is defined on both `ControllerBase` and `PageModel` classes. Method overloads let you specify the prefix and value provider to use. The method returns `false` if model binding fails. Here's an example:

```
if (await TryUpdateModelAsync<InstructorWithCollection>(
    newInstructor,
    "Instructor",
    i => i.FirstMidName, i => i.LastName, i => i.HireDate))
{
    _instructorsInMemoryStore.Add(newInstructor);
    return RedirectToPage("./Index");
}
PopulateAssignedCourseData(newInstructor);
return Page();
```

TryUpdateModelAsync uses value providers to get data from the form body, query string, and route data. `TryUpdateModelAsync` is typically:

- Used with Razor Pages and MVC apps using controllers and views to prevent over-posting.
- Not used with a web API unless consumed from form data, query strings, and route data. Web API endpoints that consume JSON use Input formatters to deserialize the request body into an object.

For more information, see TryUpdateModelAsync.

[FromServices] attribute

This attribute's name follows the pattern of model binding attributes that specify a data source. But it's not about binding data from a value provider. It gets an instance of a type from the dependency injection container. Its purpose is to provide an alternative to constructor injection for when you need a service only if a particular method is called.

Additional resources

- Model validation in ASP.NET Core MVC
- Custom Model Binding in ASP.NET Core

This article explains what model binding is, how it works, and how to customize its behavior.

View or download sample code (how to download).

What is Model binding

Controllers and Razor pages work with data that comes from HTTP requests. For example, route data may provide a record key, and posted form fields may provide values for the properties of the model. Writing code to retrieve each of these values and convert them from strings to .NET types would be tedious and error-prone. Model binding automates this process. The model binding system:

- Retrieves data from various sources such as route data, form fields, and query strings.
- Provides the data to controllers and Razor pages in method parameters and public properties.
- Converts string data to .NET types.

- Updates properties of complex types.

Example

Suppose you have the following action method:

```
[HttpGet("{id}")]
public ActionResult<Pet> GetById(int id, bool dogsOnly)
```

And the app receives a request with this URL:

```
http://contoso.com/api/pets/2?DogsOnly=true
```

Model binding goes through the following steps after the routing system selects the action method:

- Finds the first parameter of `GetByID`, an integer named `id`.
- Looks through the available sources in the HTTP request and finds `id` = "2" in route data.
- Converts the string "2" into integer 2.
- Finds the next parameter of `GetByID`, a boolean named `dogsOnly`.
- Looks through the sources and finds "DogsOnly=true" in the query string. Name matching is not case-sensitive.
- Converts the string "true" into boolean `true`.

The framework then calls the `GetById` method, passing in 2 for the `id` parameter, and `true` for the `dogsOnly` parameter.

In the preceding example, the model binding targets are method parameters that are simple types. Targets may also be the properties of a complex type. After each property is successfully bound, model validation occurs for that property. The record of what data is bound to the model, and any binding or validation errors, is stored in ControllerBase.ModelState or PageModel.ModelState. To find out if this process was successful, the app checks the ModelState.IsValid flag.

Targets

Model binding tries to find values for the following kinds of targets:

- Parameters of the controller action method that a request is routed to.
- Parameters of the Razor Pages handler method that a request is routed to.
- Public properties of a controller or `PageModel` class, if specified by attributes.

[BindProperty] attribute

Can be applied to a public property of a controller or `PageModel` class to cause model binding to target that property:

```
public class EditModel : InstructorsPageModel
{
    [BindProperty]
    public Instructor Instructor { get; set; }
```

[BindProperties] attribute

Available in ASP.NET Core 2.1 and later. Can be applied to a controller or `PageModel` class to tell model binding to target all public properties of the class:

```
[BindProperties(SupportsGet = true)]
public class CreateModel : InstructorsPageModel
{
    public Instructor Instructor { get; set; }
```

Model binding for HTTP GET requests

By default, properties are not bound for HTTP GET requests. Typically, all you need for a GET request is a record ID parameter. The record ID is used to look up the item in the database. Therefore, there is no need to bind a property that holds an instance of the model. In scenarios where you do want properties bound to data from GET requests, set the `SupportsGet` property to `true`:

```
[BindProperty(Name = "ai_user", SupportsGet = true)]
public string ApplicationInsightsCookie { get; set; }
```

Sources

By default, model binding gets data in the form of key-value pairs from the following sources in an HTTP request:

1. Form fields
2. The request body (For controllers that have the [ApiController] attribute.)
3. Route data
4. Query string parameters
5. Uploaded files

For each target parameter or property, the sources are scanned in the order indicated in the preceding list. There are a few exceptions:

- Route data and query string values are used only for simple types.
- Uploaded files are bound only to target types that implement `IFormFile` or `IEnumerable<IFormFile>`.

If the default source is not correct, use one of the following attributes to specify the source:

- `[FromQuery]` - Gets values from the query string.
- `[FromRoute]` - Gets values from route data.
- `[FromForm]` - Gets values from posted form fields.
- `[FromBody]` - Gets values from the request body.
- `[FromHeader]` - Gets values from HTTP headers.

These attributes:

- Are added to model properties individually (not to the model class), as in the following example:

```
public class Instructor
{
    public int ID { get; set; }

    [FromQuery(Name = "Note")]
    public string NoteFromQueryString { get; set; }
```

- Optionally accept a model name value in the constructor. This option is provided in case the property name doesn't match the value in the request. For instance, the value in the request might be a header with a hyphen in its name, as in the following example:

```
public void OnGet([FromHeader(Name = "Accept-Language")] string language)
```

[FromBody] attribute

Apply the `[FromBody]` attribute to a parameter to populate its properties from the body of an HTTP request. The ASP.NET Core runtime delegates the responsibility of reading the body to an input formatter. Input formatters are explained later in this article.

When `[FromBody]` is applied to a complex type parameter, any binding source attributes applied to its properties are ignored. For example, the following `Create` action specifies that its `pet` parameter is populated from the body:

```
public ActionResult<Pet> Create([FromBody] Pet pet)
```

The `Pet` class specifies that its `Breed` property is populated from a query string parameter:

```
public class Pet
{
    public string Name { get; set; }

    [FromQuery] // Attribute is ignored.
    public string Breed { get; set; }
}
```

In the preceding example:

- The `[FromQuery]` attribute is ignored.
- The `Breed` property is not populated from a query string parameter.

Input formatters read only the body and don't understand binding source attributes. If a suitable value is found in the body, that value is used to populate the `Breed` property.

Don't apply `[FromBody]` to more than one parameter per action method. Once the request stream is read by an input formatter, it's no longer available to be read again for binding other `[FromBody]` parameters.

Additional sources

Source data is provided to the model binding system by *value providers*. You can write and register custom value providers that get data for model binding from other sources. For example, you might want data from cookies or session state. To get data from a new source:

- Create a class that implements `IValueProvider`.
- Create a class that implements `IValueProviderFactory`.
- Register the factory class in `Startup.ConfigureServices`.

The sample app includes a value provider and factory example that gets values from cookies. Here's the registration code in `Startup.ConfigureServices`:

```
services.AddMvc(options =>
{
    options.ValueProviderFactories.Add(new CookieValueProviderFactory());
    options.ModelMetadataDetailsProviders.Add(
        new ExcludeBindingMetadataProvider(typeof(System.Version)));
    options.ModelMetadataDetailsProviders.Add(
        new SuppressChildValidationMetadataProvider(typeof(System.Guid)));
})
.AddXmlSerializerFormatters()
.SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

The code shown puts the custom value provider after all the built-in value providers. To make it the first in the list, call `Insert(0, new CookieValueProviderFactory())` instead of `Add`.

No source for a model property

By default, a model state error isn't created if no value is found for a model property. The property is set to null or a default value:

- Nullable simple types are set to `null`.
- Non-nullable value types are set to `default(T)`. For example, a parameter `int id` is set to 0.
- For complex Types, model binding creates an instance by using the default constructor, without setting properties.
- Arrays are set to `Array.Empty<T>()`, except that `byte[]` arrays are set to `null`.

If model state should be invalidated when nothing is found in form fields for a model property, use the `[BindRequired]` attribute.

Note that this `[BindRequired]` behavior applies to model binding from posted form data, not to JSON or XML data in a request body. Request body data is handled by input formatters.

Type conversion errors

If a source is found but can't be converted into the target type, model state is flagged as invalid. The target parameter or property is set to null or a default value, as noted in the previous section.

In an API controller that has the `[ApiController]` attribute, invalid model state results in an automatic HTTP 400 response.

In a Razor page, redisplay the page with an error message:

```
public IActionResult OnPost()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _instructorsInMemoryStore.Add(Instructor);
    return RedirectToPage("./Index");
}
```

Client-side validation catches most bad data that would otherwise be submitted to a Razor Pages form. This validation makes it hard to trigger the preceding highlighted code. The sample app includes a **Submit with Invalid Date** button that puts bad data in the **Hire Date** field and submits the form. This button shows how the code for redisplaying the page works when data conversion errors occur.

When the page is redisplayed by the preceding code, the invalid input is not shown in the form field. This is because the model property has been set to null or a default value. The invalid input does appear in an error message. But if you want to redisplay the bad data in the form field, consider making the model property a string and doing the data conversion manually.

The same strategy is recommended if you don't want type conversion errors to result in model state errors. In that case, make the model property a string.

Simple types

The simple types that the model binder can convert source strings into include the following:

- Boolean
- Byte, SByte
- Char
- DateTime
- DateTimeOffset
- Decimal
- Double
- Enum
- Guid
- Int16, Int32, Int64
- Single
- TimeSpan
- UInt16, UInt32, UInt64
- Uri
- Version

Complex types

A complex type must have a public default constructor and public writable properties to bind. When model binding occurs, the class is instantiated using the public default constructor.

For each property of the complex type, model binding looks through the sources for the name pattern *prefix.property_name*. If nothing is found, it looks for just *property_name* without the prefix.

For binding to a parameter, the prefix is the parameter name. For binding to a `PageModel` public property, the prefix is the public property name. Some attributes have a `Prefix` property that lets you override the default usage of parameter or property name.

For example, suppose the complex type is the following `Instructor` class:

```
public class Instructor
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstName { get; set; }
}
```

Prefix = parameter name

If the model to be bound is a parameter named `instructorToUpdate`:

```
public IActionResult OnPost(int? id, Instructor instructorToUpdate)
```

Model binding starts by looking through the sources for the key `instructorToUpdate.ID`. If that isn't found, it looks for `ID` without a prefix.

Prefix = property name

If the model to be bound is a property named `Instructor` of the controller or `PageModel` class:

```
[BindProperty]
public Instructor Instructor { get; set; }
```

Model binding starts by looking through the sources for the key `Instructor.ID`. If that isn't found, it looks for `ID` without a prefix.

Custom prefix

If the model to be bound is a parameter named `instructorToUpdate` and a `Bind` attribute specifies `Instructor` as the prefix:

```
public IActionResult OnPost(
    int? id, [Bind(Prefix = "Instructor")] Instructor instructorToUpdate)
```

Model binding starts by looking through the sources for the key `Instructor.ID`. If that isn't found, it looks for `ID` without a prefix.

Attributes for complex type targets

Several built-in attributes are available for controlling model binding of complex types:

- `[BindRequired]`
- `[BindNever]`
- `[Bind]`

> **NOTE**
>
> These attributes affect model binding when posted form data is the source of values. They do not affect input formatters, which process posted JSON and XML request bodies. Input formatters are explained later in this article.
>
> See also the discussion of the `[Required]` attribute in Model validation.

[BindRequired] attribute

Can only be applied to model properties, not to method parameters. Causes model binding to add a model state error if binding cannot occur for a model's property. Here's an example:

```
public class InstructorWithCollection
{
    public int ID { get; set; }

    [DataType(DataType.Date)]
    [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
    [Display(Name = "Hire Date")]
    [BindRequired]
    public DateTime HireDate { get; set; }
```

[BindNever] attribute

Can only be applied to model properties, not to method parameters. Prevents model binding from setting a model's property. Here's an example:

```
public class InstructorWithDictionary
{
    [BindNever]
    public int ID { get; set; }
```

[Bind] attribute

Can be applied to a class or a method parameter. Specifies which properties of a model should be included in model binding.

In the following example, only the specified properties of the `Instructor` model are bound when any handler or action method is called:

```
[Bind("LastName,FirstMidName,HireDate")]
public class Instructor
```

In the following example, only the specified properties of the `Instructor` model are bound when the `OnPost` method is called:

```
[HttpPost]
public IActionResult OnPost([Bind("LastName,FirstMidName,HireDate")] Instructor instructor)
```

The `[Bind]` attribute can be used to protect against overposting in *create* scenarios. It doesn't work well in edit scenarios because excluded properties are set to null or a default value instead of being left unchanged. For defense against overposting, view models are recommended rather than the `[Bind]` attribute. For more information, see Security note about overposting.

Collections

For targets that are collections of simple types, model binding looks for matches to *parameter_name* or *property_name*. If no match is found, it looks for one of the supported formats without the prefix. For example:

- Suppose the parameter to be bound is an array named `selectedCourses`:

  ```
  public IActionResult OnPost(int? id, int[] selectedCourses)
  ```

- Form or query string data can be in one of the following formats:

```
selectedCourses=1050&selectedCourses=2000
```

```
selectedCourses[0]=1050&selectedCourses[1]=2000
```

```
[0]=1050&[1]=2000
```

```
selectedCourses[a]=1050&selectedCourses[b]=2000&selectedCourses.index=a&selectedCour
ses.index=b
```

```
[a]=1050&[b]=2000&index=a&index=b
```

- The following format is supported only in form data:

```
selectedCourses[]=1050&selectedCourses[]=2000
```

- For all of the preceding example formats, model binding passes an array of two items to the `selectedCourses` parameter:
  - selectedCourses[0]=1050
  - selectedCourses[1]=2000

  Data formats that use subscript numbers (... [0] ... [1] ...) must ensure that they are numbered sequentially starting at zero. If there are any gaps in subscript numbering, all items after the gap are ignored. For example, if the subscripts are 0 and 2 instead of 0 and 1, the second item is ignored.

Dictionaries

For `Dictionary` targets, model binding looks for matches to *parameter_name* or *property_name*. If no match is found, it looks for one of the supported formats without the prefix. For example:

- Suppose the target parameter is a `Dictionary<int, string>` named `selectedCourses`:

```
public IActionResult OnPost(int? id, Dictionary<int, string> selectedCourses)
```

- The posted form or query string data can look like one of the following examples:

```
selectedCourses[1050]=Chemistry&selectedCourses[2000]=Economics
```

```
[1050]=Chemistry&selectedCourses[2000]=Economics
```

```
selectedCourses[0].Key=1050&selectedCourses[0].Value=Chemistry&
selectedCourses[1].Key=2000&selectedCourses[1].Value=Economics
```

```
[0].Key=1050&[0].Value=Chemistry&[1].Key=2000&[1].Value=Economics
```

- For all of the preceding example formats, model binding passes a dictionary of two items to the `selectedCourses` parameter:
  - selectedCourses["1050"]="Chemistry"
  - selectedCourses["2000"]="Economics"

Globalization behavior of model binding route data and query strings

The ASP.NET Core route value provider and query string value provider:

- Treat values as invariant culture.
- Expect that URLs are culture-invariant.

In contrast, values coming from form data undergo a culture-sensitive conversion. This is by design so that URLs are shareable across locales.

To make the ASP.NET Core route value provider and query string value provider undergo a culture-sensitive conversion:

- Inherit from IValueProviderFactory
- Copy the code from QueryStringValueProviderFactory or RouteValueValueProviderFactory
- Replace the culture value passed to the value provider constructor with CultureInfo.CurrentCulture
- Replace the default value provider factory in MVC options with your new one:

```
services.AddMvc(options =>
{
    var index = options.ValueProviderFactories.IndexOf(
        options.ValueProviderFactories.OfType<QueryStringValueProviderFactory>().Single());
    options.ValueProviderFactories[index] = new CulturedQueryStringValueProviderFactory();
});
```

```
public class CulturedQueryStringValueProviderFactory : IValueProviderFactory
{
    public Task CreateValueProviderAsync(ValueProviderFactoryContext context)
    {
        if (context == null)
        {
            throw new ArgumentNullException(nameof(context));
        }

        var query = context.ActionContext.HttpContext.Request.Query;
        if (query != null && query.Count > 0)
        {
            var valueProvider = new QueryStringValueProvider(
                BindingSource.Query,
                query,
                CultureInfo.CurrentCulture);

            context.ValueProviders.Add(valueProvider);
        }

        return Task.CompletedTask;
    }
}
```

Special data types

There are some special data types that model binding can handle.

IFormFile and IFormFileCollection

An uploaded file included in the HTTP request. Also supported is `IEnumerable<IFormFile>` for multiple files.

CancellationToken

Used to cancel activity in asynchronous controllers.

FormCollection

Used to retrieve all the values from posted form data.

Input formatters

Data in the request body can be in JSON, XML, or some other format. To parse this data, model binding uses an *input formatter* that is configured to handle a particular content type. By default, ASP.NET Core includes JSON based input formatters for handling JSON data. You can add other formatters for other content types.

ASP.NET Core selects input formatters based on the Consumes attribute. If no attribute is present, it uses the Content-Type header.

To use the built-in XML input formatters:

- Install the `Microsoft.AspNetCore.Mvc.Formatters.Xml` NuGet package.
- In `Startup.ConfigureServices`, call AddXmlSerializerFormatters or AddXmlDataContractSerializerFormatters.

  ```
  services.AddMvc(options =>
  {
      options.ValueProviderFactories.Add(new CookieValueProviderFactory());
      options.ModelMetadataDetailsProviders.Add(
          new ExcludeBindingMetadataProvider(typeof(System.Version)));
      options.ModelMetadataDetailsProviders.Add(
          new SuppressChildValidationMetadataProvider(typeof(System.Guid)));
  })
  .AddXmlSerializerFormatters()
  .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
  ```

- Apply the `Consumes` attribute to controller classes or action methods that should expect XML in the request body.

  ```
  [HttpPost]
  [Consumes("application/xml")]
  public ActionResult<Pet> Create(Pet pet)
  ```

  For more information, see Introducing XML Serialization.

Exclude specified types from model binding

The model binding and validation systems' behavior is driven by ModelMetadata. You can customize `ModelMetadata` by adding a details provider to MvcOptions.ModelMetadataDetailsProviders. Built-in details providers are available for disabling model binding or validation for specified types.

To disable model binding on all models of a specified type, add an ExcludeBindingMetadataProvider in `Startup.ConfigureServices`. For example, to disable model binding on all models of type `System.Version`:

```
services.AddMvc(options =>
{
    options.ValueProviderFactories.Add(new CookieValueProviderFactory());
    options.ModelMetadataDetailsProviders.Add(
        new ExcludeBindingMetadataProvider(typeof(System.Version)));
    options.ModelMetadataDetailsProviders.Add(
        new SuppressChildValidationMetadataProvider(typeof(System.Guid)));
})
.AddXmlSerializerFormatters()
.SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

To disable validation on properties of a specified type, add a SuppressChildValidationMetadataProvider in `Startup.ConfigureServices`. For example, to disable validation on properties of type `System.Guid`:

```
services.AddMvc(options =>
{
    options.ValueProviderFactories.Add(new CookieValueProviderFactory());
    options.ModelMetadataDetailsProviders.Add(
        new ExcludeBindingMetadataProvider(typeof(System.Version)));
    options.ModelMetadataDetailsProviders.Add(
        new SuppressChildValidationMetadataProvider(typeof(System.Guid)));
})
.AddXmlSerializerFormatters()
.SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

Custom model binders

You can extend model binding by writing a custom model binder and using the `[ModelBinder]` attribute to select it for a given target. Learn more about custom model binding.

Manual model binding

Model binding can be invoked manually by using the TryUpdateModelAsync method. The method is defined on both `ControllerBase` and `PageModel` classes. Method overloads let you specify the prefix and value provider to use. The method returns `false` if model binding fails. Here's an example:

```
if (await TryUpdateModelAsync<InstructorWithCollection>(
    newInstructor,
    "Instructor",
    i => i.FirstMidName, i => i.LastName, i => i.HireDate))
{
    _instructorsInMemoryStore.Add(newInstructor);
    return RedirectToPage("./Index");
}
PopulateAssignedCourseData(newInstructor);
return Page();
```

[FromServices] attribute

This attribute's name follows the pattern of model binding attributes that specify a data source.

But it's not about binding data from a value provider. It gets an instance of a type from the dependency injection container. Its purpose is to provide an alternative to constructor injection for when you need a service only if a particular method is called.

Custom Model Binding in ASP.NET Core

9/22/2020 • 16 minutes to read • Edit Online

By Steve Smith and Kirk Larkin

Model binding allows controller actions to work directly with model types (passed in as method arguments), rather than HTTP requests. Mapping between incoming request data and application models is handled by model binders. Developers can extend the built-in model binding functionality by implementing custom model binders (though typically, you don't need to write your own provider).

View or download sample code (how to download)

Default model binder limitations

The default model binders support most of the common .NET Core data types and should meet most developers' needs. They expect to bind text-based input from the request directly to model types. You might need to transform the input prior to binding it. For example, when you have a key that can be used to look up model data. You can use a custom model binder to fetch data based on the key.

Model binding review

Model binding uses specific definitions for the types it operates on. A *simple type* is converted from a single string in the input. A *complex type* is converted from multiple input values. The framework determines the difference based on the existence of a `TypeConverter`. We recommended you create a type converter if you have a simple `string` -> `SomeType` mapping that doesn't require external resources.

Before creating your own custom model binder, it's worth reviewing how existing model binders are implemented. Consider the ByteArrayModelBinder which can be used to convert base64-encoded strings into byte arrays. The byte arrays are often stored as files or database BLOB fields.

Working with the ByteArrayModelBinder

Base64-encoded strings can be used to represent binary data. For example, an image can be encoded as a string. The sample includes an image as a base64-encoded string in Base64String.txt.

ASP.NET Core MVC can take a base64-encoded string and use a `ByteArrayModelBinder` to convert it into a byte array. The ByteArrayModelBinderProvider maps `byte[]` arguments to `ByteArrayModelBinder`:

```
public IModelBinder GetBinder(ModelBinderProviderContext context)
{
    if (context == null)
    {
        throw new ArgumentNullException(nameof(context));
    }

    if (context.Metadata.ModelType == typeof(byte[]))
    {
        var loggerFactory = context.Services.GetRequiredService<ILoggerFactory>();
        return new ByteArrayModelBinder(loggerFactory);
    }

    return null;
}
```

When creating your own custom model binder, you can implement your own `IModelBinderProvider` type, or use the ModelBinderAttribute.

The following example shows how to use `ByteArrayModelBinder` to convert a base64-encoded string to a `byte[]` and save the result to a file:

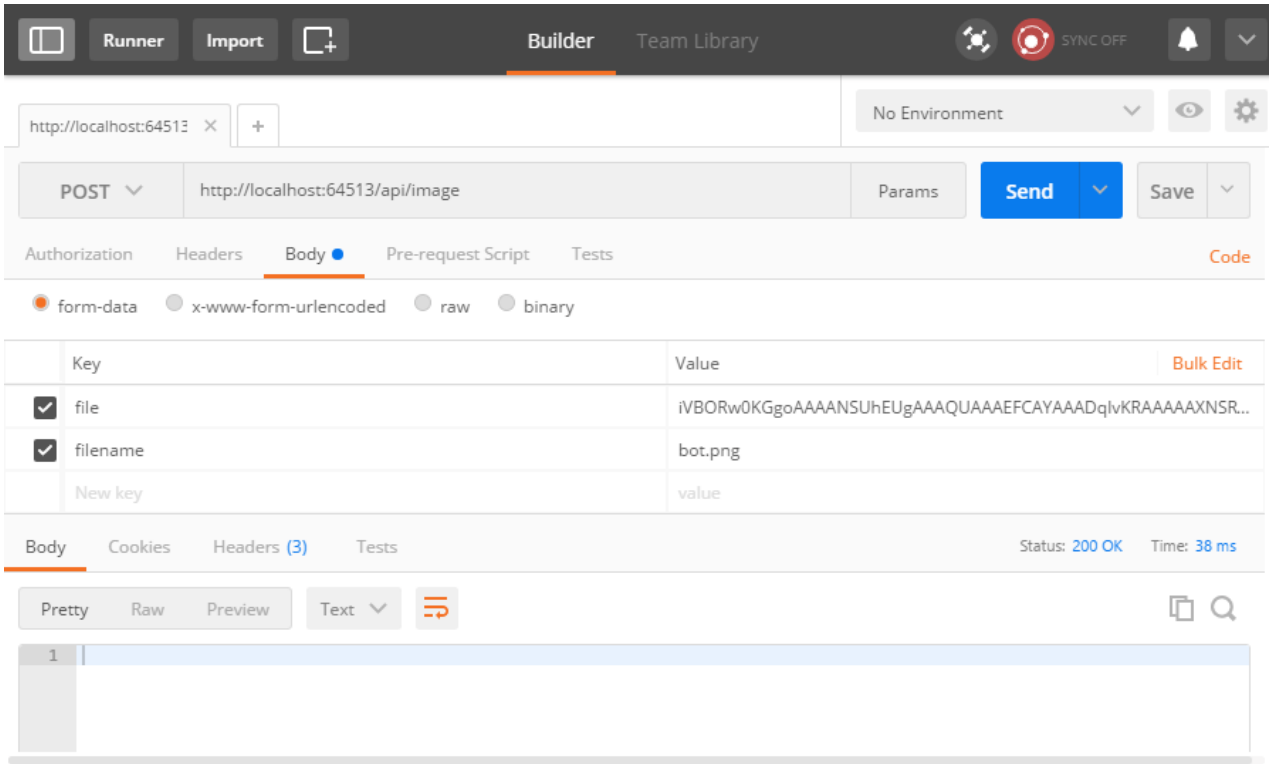
```
[HttpPost]
public void Post([FromForm] byte[] file, string filename)
{
    // Don't trust the file name sent by the client. Use
    // Path.GetRandomFileName to generate a safe random
    // file name. _targetFilePath receives a value
    // from configuration (the appsettings.json file in
    // the sample app).
    var trustedFileName = Path.GetRandomFileName();
    var filePath = Path.Combine(_targetFilePath, trustedFileName);

    if (System.IO.File.Exists(filePath))
    {
        return;
    }

    System.IO.File.WriteAllBytes(filePath, file);
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

You can POST a base64-encoded string to this api method using a tool like Postman:



As long as the binder can bind request data to appropriately named properties or arguments, model binding will succeed. The following example shows how to use `ByteArrayModelBinder` with a view model:

```
[HttpPost("Profile")]
public void SaveProfile([FromForm] ProfileViewModel model)
{
    // Don't trust the file name sent by the client. Use
    // Path.GetRandomFileName to generate a safe random
    // file name. _targetFilePath receives a value
    // from configuration (the appsettings.json file in
    // the sample app).
    var trustedFileName = Path.GetRandomFileName();
    var filePath = Path.Combine(_targetFilePath, trustedFileName);

    if (System.IO.File.Exists(filePath))
    {
        return;
    }

    System.IO.File.WriteAllBytes(filePath, model.File);
}

public class ProfileViewModel
{
    public byte[] File { get; set; }
    public string FileName { get; set; }
}
```

Custom model binder sample

In this section we'll implement a custom model binder that:

- Converts incoming request data into strongly typed key arguments.
- Uses Entity Framework Core to fetch the associated entity.
- Passes the associated entity as an argument to the action method.

The following sample uses the `ModelBinder` attribute on the `Author` model:

```
using CustomModelBindingSample.Binders;
using Microsoft.AspNetCore.Mvc;

namespace CustomModelBindingSample.Data
{
    [ModelBinder(BinderType = typeof(AuthorEntityBinder))]
    public class Author
    {
        public int Id { get; set; }
        public string Name { get; set; }
        public string GitHub { get; set; }
        public string Twitter { get; set; }
        public string BlogUrl { get; set; }
    }
}
```

In the preceding code, the `ModelBinder` attribute specifies the type of `IModelBinder` that should be used to bind `Author` action parameters.

The following `AuthorEntityBinder` class binds an `Author` parameter by fetching the entity from a data source using Entity Framework Core and an `authorId`:

```
public class AuthorEntityBinder : IModelBinder
{
    private readonly AuthorContext _context;

    public AuthorEntityBinder(AuthorContext context)
    {
        _context = context;
    }

    public Task BindModelAsync(ModelBindingContext bindingContext)
    {
        if (bindingContext == null)
        {
            throw new ArgumentNullException(nameof(bindingContext));
        }

        var modelName = bindingContext.ModelName;

        // Try to fetch the value of the argument by name
        var valueProviderResult = bindingContext.ValueProvider.GetValue(modelName);

        if (valueProviderResult == ValueProviderResult.None)
        {
            return Task.CompletedTask;
        }

        bindingContext.ModelState.SetModelValue(modelName, valueProviderResult);

        var value = valueProviderResult.FirstValue;

        // Check if the argument value is null or empty
        if (string.IsNullOrEmpty(value))
        {
            return Task.CompletedTask;
        }

        if (!int.TryParse(value, out var id))
        {
            // Non-integer arguments result in model state errors
            bindingContext.ModelState.TryAddModelError(
                modelName, "Author Id must be an integer.");

            return Task.CompletedTask;
        }

        // Model will be null if not found, including for
        // out of range id values (0, -3, etc.)
        var model = _context.Authors.Find(id);
        bindingContext.Result = ModelBindingResult.Success(model);
        return Task.CompletedTask;
    }
}
```

NOTE

The preceding `AuthorEntityBinder` class is intended to illustrate a custom model binder. The class isn't intended to illustrate best practices for a lookup scenario. For lookup, bind the `authorId` and query the database in an action method. This approach separates model binding failures from `NotFound` cases.

The following code shows how to use the `AuthorEntityBinder` in an action method:

```
[HttpGet("get/{authorId}")]
public IActionResult Get(Author author)
{
    if (author == null)
    {
        return NotFound();
    }

    return Ok(author);
}
```

The `ModelBinder` attribute can be used to apply the `AuthorEntityBinder` to parameters that don't use default conventions:

```
[HttpGet("{id}")]
public IActionResult GetById([ModelBinder(Name = "id")] Author author)
{
    if (author == null)
    {
        return NotFound();
    }

    return Ok(author);
}
```

In this example, since the name of the argument isn't the default `authorId`, it's specified on the parameter using the `ModelBinder` attribute. Both the controller and action method are simplified compared to looking up the entity in the action method. The logic to fetch the author using Entity Framework Core is moved to the model binder. This can be a considerable simplification when you have several methods that bind to the `Author` model.

You can apply the `ModelBinder` attribute to individual model properties (such as on a viewmodel) or to action method parameters to specify a certain model binder or model name for just that type or action.

Implementing a ModelBinderProvider

Instead of applying an attribute, you can implement `IModelBinderProvider`. This is how the built-in framework binders are implemented. When you specify the type your binder operates on, you specify the type of argument it produces, **not** the input your binder accepts. The following binder provider works with the `AuthorEntityBinder`. When it's added to MVC's collection of providers, you don't need to use the `ModelBinder` attribute on `Author` or `Author`-typed parameters.

```
using CustomModelBindingSample.Data;
using Microsoft.AspNetCore.Mvc.ModelBinding;
using Microsoft.AspNetCore.Mvc.ModelBinding.Binders;
using System;

namespace CustomModelBindingSample.Binders
{
    public class AuthorEntityBinderProvider : IModelBinderProvider
    {
        public IModelBinder GetBinder(ModelBinderProviderContext context)
        {
            if (context == null)
            {
                throw new ArgumentNullException(nameof(context));
            }

            if (context.Metadata.ModelType == typeof(Author))
            {
                return new BinderTypeModelBinder(typeof(AuthorEntityBinder));
            }

            return null;
        }
    }
}
```

> Note: The preceding code returns a `BinderTypeModelBinder`. `BinderTypeModelBinder` acts as a factory for model binders and provides dependency injection (DI). The `AuthorEntityBinder` requires DI to access EF Core. Use `BinderTypeModelBinder` if your model binder requires services from DI.

To use a custom model binder provider, add it in `ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<AuthorContext>(options => options.UseInMemoryDatabase("Authors"));

    services.AddControllers(options =>
    {
        options.ModelBinderProviders.Insert(0, new AuthorEntityBinderProvider());
    });
}
```

When evaluating model binders, the collection of providers is examined in order. The first provider that returns a binder that matches the input model is used. Adding your provider to the end of the collection may thus result in a built-in model binder being called before your custom binder has a chance. In this example, the custom provider is added to the beginning of the collection to ensure it's always used for `Author` action arguments.

Polymorphic model binding

Binding to different models of derived types is known as polymorphic model binding. Polymorphic custom model binding is required when the request value must be bound to the specific derived model type. Polymorphic model binding:

- Isn't typical for a REST API that's designed to interoperate with all languages.
- Makes it difficult to reason about the bound models.

However, if an app requires polymorphic model binding, an implementation might look like the following code:

```
public abstract class Device
{
```

```
    public string Kind { get; set; }
}

public class Laptop : Device
{
    public string CPUIndex { get; set; }
}

public class SmartPhone : Device
{
    public string ScreenSize { get; set; }
}

public class DeviceModelBinderProvider : IModelBinderProvider
{
    public IModelBinder GetBinder(ModelBinderProviderContext context)
    {
        if (context.Metadata.ModelType != typeof(Device))
        {
            return null;
        }

        var subclasses = new[] { typeof(Laptop), typeof(SmartPhone), };

        var binders = new Dictionary<Type, (ModelMetadata, IModelBinder)>();
        foreach (var type in subclasses)
        {
            var modelMetadata = context.MetadataProvider.GetMetadataForType(type);
            binders[type] = (modelMetadata, context.CreateBinder(modelMetadata));
        }

        return new DeviceModelBinder(binders);
    }
}

public class DeviceModelBinder : IModelBinder
{
    private Dictionary<Type, (ModelMetadata, IModelBinder)> binders;

    public DeviceModelBinder(Dictionary<Type, (ModelMetadata, IModelBinder)> binders)
    {
        this.binders = binders;
    }

    public async Task BindModelAsync(ModelBindingContext bindingContext)
    {
        var modelKindName = ModelNames.CreatePropertyModelName(bindingContext.ModelName, nameof(Device.Kind));
        var modelTypeValue = bindingContext.ValueProvider.GetValue(modelKindName).FirstValue;

        IModelBinder modelBinder;
        ModelMetadata modelMetadata;
        if (modelTypeValue == "Laptop")
        {
            (modelMetadata, modelBinder) = binders[typeof(Laptop)];
        }
        else if (modelTypeValue == "SmartPhone")
        {
            (modelMetadata, modelBinder) = binders[typeof(SmartPhone)];
        }
        else
        {
            bindingContext.Result = ModelBindingResult.Failed();
            return;
        }

        var newBindingContext = DefaultModelBindingContext.CreateBindingContext(
            bindingContext.ActionContext,
            bindingContext.ValueProvider,
            modelMetadata,
```

```
            bindingInfo: null,
            bindingContext.ModelName);

        await modelBinder.BindModelAsync(newBindingContext);
        bindingContext.Result = newBindingContext.Result;

        if (newBindingContext.Result.IsModelSet)
        {
            // Setting the ValidationState ensures properties on derived types are correctly
            bindingContext.ValidationState[newBindingContext.Result] = new ValidationStateEntry
            {
                Metadata = modelMetadata,
            };
        }
    }
}
```

Recommendations and best practices

Custom model binders:

- Shouldn't attempt to set status codes or return results (for example, 404 Not Found). If model binding fails, an action filter or logic within the action method itself should handle the failure.
- Are most useful for eliminating repetitive code and cross-cutting concerns from action methods.
- Typically shouldn't be used to convert a string into a custom type, a TypeConverter is usually a better option.

By Steve Smith

Model binding allows controller actions to work directly with model types (passed in as method arguments), rather than HTTP requests. Mapping between incoming request data and application models is handled by model binders. Developers can extend the built-in model binding functionality by implementing custom model binders (though typically, you don't need to write your own provider).

View or download sample code (how to download)

Default model binder limitations

The default model binders support most of the common .NET Core data types and should meet most developers' needs. They expect to bind text-based input from the request directly to model types. You might need to transform the input prior to binding it. For example, when you have a key that can be used to look up model data. You can use a custom model binder to fetch data based on the key.

Model binding review

Model binding uses specific definitions for the types it operates on. A *simple type* is converted from a single string in the input. A *complex type* is converted from multiple input values. The framework determines the difference based on the existence of a `TypeConverter`. We recommended you create a type converter if you have a simple `string` -> `SomeType` mapping that doesn't require external resources.

Before creating your own custom model binder, it's worth reviewing how existing model binders are implemented. Consider the ByteArrayModelBinder which can be used to convert base64-encoded strings into byte arrays. The byte arrays are often stored as files or database BLOB fields.

Working with the ByteArrayModelBinder

Base64-encoded strings can be used to represent binary data. For example, an image can be encoded as a string. The sample includes an image as a base64-encoded string in Base64String.txt.

ASP.NET Core MVC can take a base64-encoded string and use a `ByteArrayModelBinder` to convert it into a byte

array. The ByteArrayModelBinderProvider maps `byte[]` arguments to `ByteArrayModelBinder`:

```
public IModelBinder GetBinder(ModelBinderProviderContext context)
{
    if (context == null)
    {
        throw new ArgumentNullException(nameof(context));
    }

    if (context.Metadata.ModelType == typeof(byte[]))
    {
        return new ByteArrayModelBinder();
    }

    return null;
}
```

When creating your own custom model binder, you can implement your own `IModelBinderProvider` type, or use the ModelBinderAttribute.

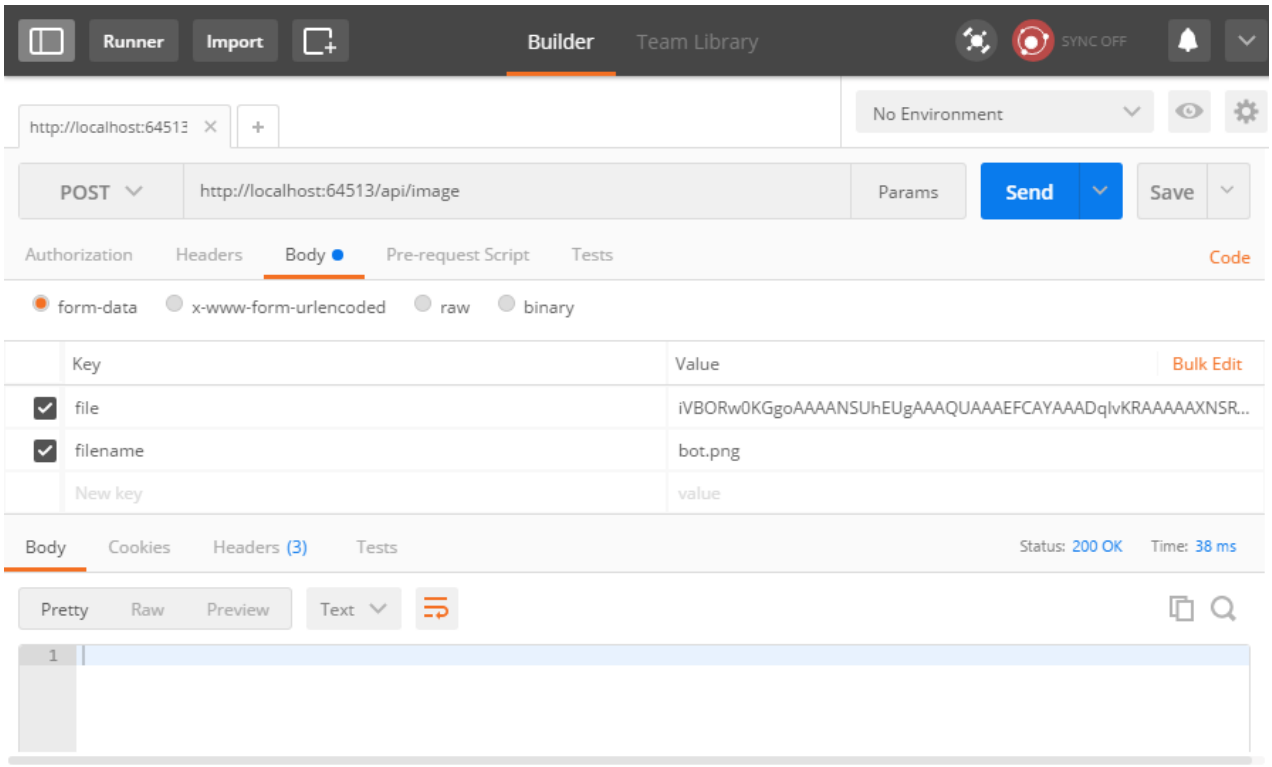
The following example shows how to use `ByteArrayModelBinder` to convert a base64-encoded string to a `byte[]` and save the result to a file:

```
[HttpPost]
public void Post([FromForm] byte[] file, string filename)
{
    // Don't trust the file name sent by the client. Use
    // Path.GetRandomFileName to generate a safe random
    // file name. _targetFilePath receives a value
    // from configuration (the appsettings.json file in
    // the sample app).
    var trustedFileName = Path.GetRandomFileName();
    var filePath = Path.Combine(_targetFilePath, trustedFileName);

    if (System.IO.File.Exists(filePath))
    {
        return;
    }

    System.IO.File.WriteAllBytes(filePath, file);
}
```

You can POST a base64-encoded string to this api method using a tool like Postman:



As long as the binder can bind request data to appropriately named properties or arguments, model binding will succeed. The following example shows how to use `ByteArrayModelBinder` with a view model:

```
[HttpPost("Profile")]
public void SaveProfile([FromForm] ProfileViewModel model)
{
    // Don't trust the file name sent by the client. Use
    // Path.GetRandomFileName to generate a safe random
    // file name. _targetFilePath receives a value
    // from configuration (the appsettings.json file in
    // the sample app).
    var trustedFileName = Path.GetRandomFileName();
    var filePath = Path.Combine(_targetFilePath, trustedFileName);

    if (System.IO.File.Exists(filePath))
    {
        return;
    }

    System.IO.File.WriteAllBytes(filePath, model.File);
}

public class ProfileViewModel
{
    public byte[] File { get; set; }
    public string FileName { get; set; }
}
```

Custom model binder sample

In this section we'll implement a custom model binder that:

- Converts incoming request data into strongly typed key arguments.
- Uses Entity Framework Core to fetch the associated entity.
- Passes the associated entity as an argument to the action method.

The following sample uses the `ModelBinder` attribute on the `Author` model:

```
using CustomModelBindingSample.Binders;
using Microsoft.AspNetCore.Mvc;

namespace CustomModelBindingSample.Data
{
    [ModelBinder(BinderType = typeof(AuthorEntityBinder))]
    public class Author
    {
        public int Id { get; set; }
        public string Name { get; set; }
        public string GitHub { get; set; }
        public string Twitter { get; set; }
        public string BlogUrl { get; set; }
    }
}
```

In the preceding code, the `ModelBinder` attribute specifies the type of `IModelBinder` that should be used to bind `Author` action parameters.

The following `AuthorEntityBinder` class binds an `Author` parameter by fetching the entity from a data source using Entity Framework Core and an `authorId`:

```
public class AuthorEntityBinder : IModelBinder
{
    private readonly AppDbContext _db;

    public AuthorEntityBinder(AppDbContext db)
    {
        _db = db;
    }

    public Task BindModelAsync(ModelBindingContext bindingContext)
    {
        if (bindingContext == null)
        {
            throw new ArgumentNullException(nameof(bindingContext));
        }

        var modelName = bindingContext.ModelName;

        // Try to fetch the value of the argument by name
        var valueProviderResult = bindingContext.ValueProvider.GetValue(modelName);

        if (valueProviderResult == ValueProviderResult.None)
        {
            return Task.CompletedTask;
        }

        bindingContext.ModelState.SetModelValue(modelName, valueProviderResult);

        var value = valueProviderResult.FirstValue;

        // Check if the argument value is null or empty
        if (string.IsNullOrEmpty(value))
        {
            return Task.CompletedTask;
        }

        if (!int.TryParse(value, out var id))
        {
            // Non-integer arguments result in model state errors
            bindingContext.ModelState.TryAddModelError(
                modelName, "Author Id must be an integer.");

            return Task.CompletedTask;
        }

        // Model will be null if not found, including for
        // out of range id values (0, -3, etc.)
        var model = _db.Authors.Find(id);
        bindingContext.Result = ModelBindingResult.Success(model);
        return Task.CompletedTask;
    }
}
```

NOTE

The preceding `AuthorEntityBinder` class is intended to illustrate a custom model binder. The class isn't intended to illustrate best practices for a lookup scenario. For lookup, bind the `authorId` and query the database in an action method. This approach separates model binding failures from `NotFound` cases.

The following code shows how to use the `AuthorEntityBinder` in an action method:

```
[HttpGet("get/{authorId}")]
public IActionResult Get(Author author)
{
    if (author == null)
    {
        return NotFound();
    }

    return Ok(author);
}
```

The `ModelBinder` attribute can be used to apply the `AuthorEntityBinder` to parameters that don't use default conventions:

```
[HttpGet("{id}")]
public IActionResult GetById([ModelBinder(Name = "id")] Author author)
{
    if (author == null)
    {
        return NotFound();
    }

    return Ok(author);
}
```

In this example, since the name of the argument isn't the default `authorId`, it's specified on the parameter using the `ModelBinder` attribute. Both the controller and action method are simplified compared to looking up the entity in the action method. The logic to fetch the author using Entity Framework Core is moved to the model binder. This can be a considerable simplification when you have several methods that bind to the `Author` model.

You can apply the `ModelBinder` attribute to individual model properties (such as on a viewmodel) or to action method parameters to specify a certain model binder or model name for just that type or action.

Implementing a ModelBinderProvider

Instead of applying an attribute, you can implement `IModelBinderProvider`. This is how the built-in framework binders are implemented. When you specify the type your binder operates on, you specify the type of argument it produces, **not** the input your binder accepts. The following binder provider works with the `AuthorEntityBinder`. When it's added to MVC's collection of providers, you don't need to use the `ModelBinder` attribute on `Author` or `Author`-typed parameters.

```
using CustomModelBindingSample.Data;
using Microsoft.AspNetCore.Mvc.ModelBinding;
using Microsoft.AspNetCore.Mvc.ModelBinding.Binders;
using System;

namespace CustomModelBindingSample.Binders
{
    public class AuthorEntityBinderProvider : IModelBinderProvider
    {
        public IModelBinder GetBinder(ModelBinderProviderContext context)
        {
            if (context == null)
            {
                throw new ArgumentNullException(nameof(context));
            }

            if (context.Metadata.ModelType == typeof(Author))
            {
                return new BinderTypeModelBinder(typeof(AuthorEntityBinder));
            }

            return null;
        }
    }
}
```

> Note: The preceding code returns a `BinderTypeModelBinder`. `BinderTypeModelBinder` acts as a factory for model binders and provides dependency injection (DI). The `AuthorEntityBinder` requires DI to access EF Core. Use `BinderTypeModelBinder` if your model binder requires services from DI.

To use a custom model binder provider, add it in `ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<AppDbContext>(options => options.UseInMemoryDatabase("App"));

    services.AddMvc(options =>
        {
            // add custom binder to beginning of collection
            options.ModelBinderProviders.Insert(0, new AuthorEntityBinderProvider());
        })
        .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
}
```

When evaluating model binders, the collection of providers is examined in order. The first provider that returns a binder is used. Adding your provider to the end of the collection may result in a built-in model binder being called before your custom binder has a chance. In this example, the custom provider is added to the beginning of the collection to ensure it's used for `Author` action arguments.

Polymorphic model binding

Binding to different models of derived types is known as polymorphic model binding. Polymorphic custom model binding is required when the request value must be bound to the specific derived model type. Polymorphic model binding:

- Isn't typical for a REST API that's designed to interoperate with all languages.
- Makes it difficult to reason about the bound models.

However, if an app requires polymorphic model binding, an implementation might look like the following code:

```
public abstract class Device
{
    public string Kind { get; set; }
}

public class Laptop : Device
{
    public string CPUIndex { get; set; }
}

public class SmartPhone : Device
{
    public string ScreenSize { get; set; }
}

public class DeviceModelBinderProvider : IModelBinderProvider
{
    public IModelBinder GetBinder(ModelBinderProviderContext context)
    {
        if (context.Metadata.ModelType != typeof(Device))
        {
            return null;
        }

        var subclasses = new[] { typeof(Laptop), typeof(SmartPhone), };

        var binders = new Dictionary<Type, (ModelMetadata, IModelBinder)>();
        foreach (var type in subclasses)
        {
            var modelMetadata = context.MetadataProvider.GetMetadataForType(type);
            binders[type] = (modelMetadata, context.CreateBinder(modelMetadata));
        }

        return new DeviceModelBinder(binders);
    }
}

public class DeviceModelBinder : IModelBinder
{
    private Dictionary<Type, (ModelMetadata, IModelBinder)> binders;

    public DeviceModelBinder(Dictionary<Type, (ModelMetadata, IModelBinder)> binders)
    {
        this.binders = binders;
    }

    public async Task BindModelAsync(ModelBindingContext bindingContext)
    {
        var modelKindName = ModelNames.CreatePropertyModelName(bindingContext.ModelName, nameof(Device.Kind));
        var modelTypeValue = bindingContext.ValueProvider.GetValue(modelKindName).FirstValue;

        IModelBinder modelBinder;
        ModelMetadata modelMetadata;
        if (modelTypeValue == "Laptop")
        {
            (modelMetadata, modelBinder) = binders[typeof(Laptop)];
        }
        else if (modelTypeValue == "SmartPhone")
        {
            (modelMetadata, modelBinder) = binders[typeof(SmartPhone)];
        }
        else
        {
            bindingContext.Result = ModelBindingResult.Failed();
            return;
        }

        var newBindingContext = DefaultModelBindingContext.CreateBindingContext(
            bindingContext.ActionContext,
```

```
            bindingContext.ValueProvider,
            modelMetadata,
            bindingInfo: null,
            bindingContext.ModelName);

        await modelBinder.BindModelAsync(newBindingContext);
        bindingContext.Result = newBindingContext.Result;

        if (newBindingContext.Result.IsModelSet)
        {
            // Setting the ValidationState ensures properties on derived types are correctly
            bindingContext.ValidationState[newBindingContext.Result] = new ValidationStateEntry
            {
                Metadata = modelMetadata,
            };
        }
    }
}
```

Recommendations and best practices

Custom model binders:

- Shouldn't attempt to set status codes or return results (for example, 404 Not Found). If model binding fails, an action filter or logic within the action method itself should handle the failure.
- Are most useful for eliminating repetitive code and cross-cutting concerns from action methods.
- Typically shouldn't be used to convert a string into a custom type, a TypeConverter is usually a better option.

Model validation in ASP.NET Core MVC and Razor Pages

9/22/2020 • 35 minutes to read • Edit Online

By Kirk Larkin

This article explains how to validate user input in an ASP.NET Core MVC or Razor Pages app.

View or download sample code (how to download).

Model state

Model state represents errors that come from two subsystems: model binding and model validation. Errors that originate from model binding are generally data conversion errors. For example, an "x" is entered in an integer field. Model validation occurs after model binding and reports errors where data doesn't conform to business rules. For example, a 0 is entered in a field that expects a rating between 1 and 5.

Both model binding and model validation occur before the execution of a controller action or a Razor Pages handler method. For web apps, it's the app's responsibility to inspect `ModelState.IsValid` and react appropriately. Web apps typically redisplay the page with an error message:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Movies.Add(Movie);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

Web API controllers don't have to check `ModelState.IsValid` if they have the `[ApiController]` attribute. In that case, an automatic HTTP 400 response containing error details is returned when model state is invalid. For more information, see Automatic HTTP 400 responses.

Rerun validation

Validation is automatic, but you might want to repeat it manually. For example, you might compute a value for a property and want to rerun validation after setting the property to the computed value. To rerun validation, call the `TryValidateModel` method, as shown here:

```
Movie.ReleaseDate = modifiedReleaseDate;

if (!TryValidateModel(Movie, nameof(Movie)))
{
    return Page();
}

_context.Movies.Add(Movie);
await _context.SaveChangesAsync();

return RedirectToPage("./Index");
```

Validation attributes

Validation attributes let you specify validation rules for model properties. The following example from the sample app shows a model class that is annotated with validation attributes. The `[ClassicMovie]` attribute is a custom validation attribute and the others are built-in. Not shown is `[ClassicMovieWithClientValidator]`. `[ClassicMovieWithClientValidator]` shows an alternative way to implement a custom attribute.

```
public class Movie
{
    public int Id { get; set; }

    [Required]
    [StringLength(100)]
    public string Title { get; set; }

    [ClassicMovie(1960)]
    [DataType(DataType.Date)]
    [Display(Name = "Release Date")]
    public DateTime ReleaseDate { get; set; }

    [Required]
    [StringLength(1000)]
    public string Description { get; set; }

    [Range(0, 999.99)]
    public decimal Price { get; set; }

    public Genre Genre { get; set; }

    public bool Preorder { get; set; }
}
```

Built-in attributes

Here are some of the built-in validation attributes:

- `[CreditCard]`: Validates that the property has a credit card format. Requires jQuery Validation Additional Methods.
- `[Compare]`: Validates that two properties in a model match.
- `[EmailAddress]`: Validates that the property has an email format.
- `[Phone]`: Validates that the property has a telephone number format.
- `[Range]`: Validates that the property value falls within a specified range.
- `[RegularExpression]`: Validates that the property value matches a specified regular expression.
- `[Required]`: Validates that the field is not null. See `[Required]` attribute for details about this

attribute's behavior.

- `[StringLength]`: Validates that a string property value doesn't exceed a specified length limit.
- `[Url]`: Validates that the property has a URL format.
- `[Remote]`: Validates input on the client by calling an action method on the server. See `[Remote]` attribute for details about this attribute's behavior.

A complete list of validation attributes can be found in the System.ComponentModel.DataAnnotations namespace.

Error messages

Validation attributes let you specify the error message to be displayed for invalid input. For example:

```
[StringLength(8, ErrorMessage = "Name length can't be more than 8.")]
```

Internally, the attributes call `String.Format` with a placeholder for the field name and sometimes additional placeholders. For example:

```
[StringLength(8, ErrorMessage = "{0} length must be between {2} and {1}.", MinimumLength = 6)]
```

When applied to a `Name` property, the error message created by the preceding code would be "Name length must be between 6 and 8.".

To find out which parameters are passed to `String.Format` for a particular attribute's error message, see the DataAnnotations source code.

[Required] attribute

The validation system in .NET Core 3.0 and later treats non-nullable parameters or bound properties as if they had a `[Required]` attribute. Value types such as `decimal` and `int` are non-nullable. This behavior can be disabled by configuring SuppressImplicitRequiredAttributeForNonNullableReferenceTypes in `Startup.ConfigureServices`:

```
services.AddControllers(options =>
options.SuppressImplicitRequiredAttributeForNonNullableReferenceTypes = true);
```

[Required] validation on the server

On the server, a required value is considered missing if the property is null. A non-nullable field is always valid, and the `[Required]` attribute's error message is never displayed.

However, model binding for a non-nullable property may fail, resulting in an error message such as `The value '' is invalid`. To specify a custom error message for server-side validation of non-nullable types, you have the following options:

- Make the field nullable (for example, `decimal?` instead of `decimal`). Nullable<T> value types are treated like standard nullable types.
- Specify the default error message to be used by model binding, as shown in the following example:

```
services.AddRazorPages()
    .AddMvcOptions(options =>
    {
        options.MaxModelValidationErrors = 50;
        options.ModelBindingMessageProvider.SetValueMustNotBeNullAccessor(
            _ => "The field is required.");
    });

services.AddSingleton<IValidationAttributeAdapterProvider,
    CustomValidationAttributeAdapterProvider>();
```

For more information about model binding errors that you can set default messages for, see DefaultModelBindingMessageProvider.

[Required] validation on the client

Non-nullable types and strings are handled differently on the client compared to the server. On the client:

- A value is considered present only if input is entered for it. Therefore, client-side validation handles non-nullable types the same as nullable types.
- Whitespace in a string field is considered valid input by the jQuery Validation required method. Server-side validation considers a required string field invalid if only whitespace is entered.

As noted earlier, non-nullable types are treated as though they had a `[Required]` attribute. That means you get client-side validation even if you don't apply the `[Required]` attribute. But if you don't use the attribute, you get a default error message. To specify a custom error message, use the attribute.

[Remote] attribute

The `[Remote]` attribute implements client-side validation that requires calling a method on the server to determine whether field input is valid. For example, the app may need to verify whether a user name is already in use.

To implement remote validation:

1. Create an action method for JavaScript to call. The jQuery Validation remote method expects a JSON response:

   - `true` means the input data is valid.
   - `false`, `undefined`, or `null` means the input is invalid. Display the default error message.
   - Any other string means the input is invalid. Display the string as a custom error message.

   Here's an example of an action method that returns a custom error message:

   ```
   [AcceptVerbs("GET", "POST")]
   public IActionResult VerifyEmail(string email)
   {
       if (!_userService.VerifyEmail(email))
       {
           return Json($"Email {email} is already in use.");
       }

       return Json(true);
   }
   ```

2. In the model class, annotate the property with a `[Remote]` attribute that points to the

validation action method, as shown in the following example:

```
[Remote(action: "VerifyEmail", controller: "Users")]
public string Email { get; set; }
```

The `[Remote]` attribute is in the `Microsoft.AspNetCore.Mvc` namespace.

Additional fields

The `AdditionalFields` property of the `[Remote]` attribute lets you validate combinations of fields against data on the server. For example, if the `User` model had `FirstName` and `LastName` properties, you might want to verify that no existing users already have that pair of names. The following example shows how to use `AdditionalFields`:

```
[Remote(action: "VerifyName", controller: "Users", AdditionalFields = nameof(LastName))]
[Display(Name = "First Name")]
public string FirstName { get; set; }

[Remote(action: "VerifyName", controller: "Users", AdditionalFields = nameof(FirstName))]
[Display(Name = "Last Name")]
public string LastName { get; set; }
```

`AdditionalFields` could be set explicitly to the strings "FirstName" and "LastName", but using the nameof operator simplifies later refactoring. The action method for this validation must accept both `firstName` and `lastName` arguments:

```
[AcceptVerbs("GET", "POST")]
public IActionResult VerifyName(string firstName, string lastName)
{
    if (!_userService.VerifyName(firstName, lastName))
    {
        return Json($"A user named {firstName} {lastName} already exists.");
    }

    return Json(true);
}
```

When the user enters a first or last name, JavaScript makes a remote call to see if that pair of names has been taken.

To validate two or more additional fields, provide them as a comma-delimited list. For example, to add a `MiddleName` property to the model, set the `[Remote]` attribute as shown in the following example:

```
[Remote(action: "VerifyName", controller: "Users", AdditionalFields = nameof(FirstName) + "," +
nameof(LastName))]
public string MiddleName { get; set; }
```

`AdditionalFields`, like all attribute arguments, must be a constant expression. Therefore, don't use an interpolated string or call Join to initialize `AdditionalFields`.

Alternatives to built-in attributes

If you need validation not provided by built-in attributes, you can:

- Create custom attributes.
- Implement IValidatableObject.

Custom attributes

For scenarios that the built-in validation attributes don't handle, you can create custom validation attributes. Create a class that inherits from ValidationAttribute, and override the IsValid method.

The `IsValid` method accepts an object named *value*, which is the input to be validated. An overload also accepts a `ValidationContext` object, which provides additional information, such as the model instance created by model binding.

The following example validates that the release date for a movie in the *Classic* genre isn't later than a specified year. The `[ClassicMovie]` attribute:

- Is only run on the server.
- For Classic movies, validates the release date:

```
public class ClassicMovieAttribute : ValidationAttribute
{
    public ClassicMovieAttribute(int year)
    {
        Year = year;
    }

    public int Year { get; }

    public string GetErrorMessage() =>
        $"Classic movies must have a release year no later than {Year}.";

    protected override ValidationResult IsValid(object value,
        ValidationContext validationContext)
    {
        var movie = (Movie)validationContext.ObjectInstance;
        var releaseYear = ((DateTime)value).Year;

        if (movie.Genre == Genre.Classic && releaseYear > Year)
        {
            return new ValidationResult(GetErrorMessage());
        }

        return ValidationResult.Success;
    }
}
```

The `movie` variable in the preceding example represents a `Movie` object that contains the data from the form submission. When validation fails, a `ValidationResult` with an error message is returned.

IValidatableObject

The preceding example works only with `Movie` types. Another option for class-level validation is to implement `IValidatableObject` in the model class, as shown in the following example:

```
public class ValidatableMovie : IValidatableObject
{
    private const int _classicYear = 1960;

    public int Id { get; set; }

    [Required]
    [StringLength(100)]
    public string Title { get; set; }

    [DataType(DataType.Date)]
    [Display(Name = "Release Date")]
    public DateTime ReleaseDate { get; set; }

    [Required]
    [StringLength(1000)]
    public string Description { get; set; }

    [Range(0, 999.99)]
    public decimal Price { get; set; }

    public Genre Genre { get; set; }

    public bool Preorder { get; set; }

    public IEnumerable<ValidationResult> Validate(ValidationContext validationContext)
    {
        if (Genre == Genre.Classic && ReleaseDate.Year > _classicYear)
        {
            yield return new ValidationResult(
                $"Classic movies must have a release year no later than {_classicYear}.",
                new[] { nameof(ReleaseDate) });
        }
    }
}
```

Top-level node validation

Top-level nodes include:

- Action parameters
- Controller properties
- Page handler parameters
- Page model properties

Model-bound top-level nodes are validated in addition to validating model properties. In the following example from the sample app, the `VerifyPhone` method uses the RegularExpressionAttribute to validate the `phone` action parameter:

```
[AcceptVerbs("GET", "POST")]
public IActionResult VerifyPhone(
    [RegularExpression(@"^\d{3}-\d{3}-\d{4}$")] string phone)
{
    if (!ModelState.IsValid)
    {
        return Json($"Phone {phone} has an invalid format. Format: ###-###-####");
    }

    return Json(true);
}
```

Top-level nodes can use BindRequiredAttribute with validation attributes. In the following example from the sample app, the `CheckAge` method specifies that the `age` parameter must be bound from the query string when the form is submitted:

```
[HttpPost]
public IActionResult CheckAge([BindRequired, FromQuery] int age)
{
```

In the Check Age page (*CheckAge.cshtml*), there are two forms. The first form submits an `Age` value of `99` as a query string parameter: `https://localhost:5001/Users/CheckAge?Age=99`.

When a properly formatted `age` parameter from the query string is submitted, the form validates.

The second form on the Check Age page submits the `Age` value in the body of the request, and validation fails. Binding fails because the `age` parameter must come from a query string.

Maximum errors

Validation stops when the maximum number of errors is reached (200 by default). You can configure this number with the following code in `Startup.ConfigureServices`:

```
services.AddRazorPages()
    .AddMvcOptions(options =>
    {
        options.MaxModelValidationErrors = 50;
        options.ModelBindingMessageProvider.SetValueMustNotBeNullAccessor(
            _ => "The field is required.");
    });

services.AddSingleton<IValidationAttributeAdapterProvider,
    CustomValidationAttributeAdapterProvider>();
```

Maximum recursion

ValidationVisitor traverses the object graph of the model being validated. For models that are deep or are infinitely recursive, validation may result in stack overflow. MvcOptions.MaxValidationDepth provides a way to stop validation early if the visitor recursion exceeds a configured depth. The default value of `MvcOptions.MaxValidationDepth` is 32.

Automatic short-circuit

Validation is automatically short-circuited (skipped) if the model graph doesn't require validation. Objects that the runtime skips validation for include collections of primitives (such as `byte[]`, `string[]`, `Dictionary<string, string>`) and complex object graphs that don't have any validators.

Disable validation

To disable validation:

1. Create an implementation of `IObjectModelValidator` that doesn't mark any fields as invalid.

```
public class NullObjectModelValidator : IObjectModelValidator
{
    public void Validate(ActionContext actionContext,
        ValidationStateDictionary validationState, string prefix, object model)
    {

    }
}
```

2. Add the following code to `Startup.ConfigureServices` to replace the default `IObjectModelValidator` implementation in the dependency injection container.

```
services.AddSingleton<IObjectModelValidator, NullObjectModelValidator>();
```

You might still see model state errors that originate from model binding.

Client-side validation

Client-side validation prevents submission until the form is valid. The Submit button runs JavaScript that either submits the form or displays error messages.

Client-side validation avoids an unnecessary round trip to the server when there are input errors on a form. The following script references in *_Layout.cshtml* and *_ValidationScriptsPartial.cshtml* support client-side validation:

```
<script src="https://cdnjs.cloudflare.com/ajax/libs/jquery/3.4.1/jquery.min.js"></script>
```

```
<script src="https://cdnjs.cloudflare.com/ajax/libs/jquery-
validate/1.19.1/jquery.validate.min.js"></script>
<script src="https://cdnjs.cloudflare.com/ajax/libs/jquery-validation-
unobtrusive/3.2.11/jquery.validate.unobtrusive.min.js"></script>
```

The jQuery Unobtrusive Validation script is a custom Microsoft front-end library that builds on the popular jQuery Validation plugin. Without jQuery Unobtrusive Validation, you would have to code the same validation logic in two places: once in the server-side validation attributes on model properties, and then again in client-side scripts. Instead, Tag Helpers and HTML helpers use the validation attributes and type metadata from model properties to render HTML 5 `data-` attributes for the form elements that need validation. jQuery Unobtrusive Validation parses the `data-` attributes and passes the logic to jQuery Validation, effectively "copying" the server-side validation logic to the client. You can display validation errors on the client using tag helpers as shown here:

```
<div class="form-group">
    <label asp-for="Movie.ReleaseDate" class="control-label"></label>
    <input asp-for="Movie.ReleaseDate" class="form-control" />
    <span asp-validation-for="Movie.ReleaseDate" class="text-danger"></span>
</div>
```

The preceding tag helpers render the following HTML:

```
<div class="form-group">
    <label class="control-label" for="Movie_ReleaseDate">Release Date</label>
    <input class="form-control" type="date" data-val="true"
        data-val-required="The Release Date field is required."
        id="Movie_ReleaseDate" name="Movie.ReleaseDate" value="">
    <span class="text-danger field-validation-valid"
        data-valmsg-for="Movie.ReleaseDate" data-valmsg-replace="true"></span>
</div>
```

Notice that the `data-` attributes in the HTML output correspond to the validation attributes for the `Movie.ReleaseDate` property. The `data-val-required` attribute contains an error message to display if the user doesn't fill in the release date field. jQuery Unobtrusive Validation passes this value to the jQuery Validation required() method, which then displays that message in the accompanying `<span>` element.

Data type validation is based on the .NET type of a property, unless that is overridden by a `[DataType]` attribute. Browsers have their own default error messages, but the jQuery Validation Unobtrusive Validation package can override those messages. `[DataType]` attributes and subclasses such as `[EmailAddress]` let you specify the error message.

Unobtrusive validation

For information on unobtrusive validation, see this GitHub issue.

Add Validation to Dynamic Forms

jQuery Unobtrusive Validation passes validation logic and parameters to jQuery Validation when the page first loads. Therefore, validation doesn't work automatically on dynamically generated forms. To enable validation, tell jQuery Unobtrusive Validation to parse the dynamic form immediately after you create it. For example, the following code sets up client-side validation on a form added via AJAX.

```
$.get({
    url: "https://url/that/returns/a/form",
    dataType: "html",
    error: function(jqXHR, textStatus, errorThrown) {
        alert(textStatus + ": Couldn't add form. " + errorThrown);
    },
    success: function(newFormHTML) {
        var container = document.getElementById("form-container");
        container.insertAdjacentHTML("beforeend", newFormHTML);
        var forms = container.getElementsByTagName("form");
        var newForm = forms[forms.length - 1];
        $.validator.unobtrusive.parse(newForm);
    }
})
```

The `$.validator.unobtrusive.parse()` method accepts a jQuery selector for its one argument. This method tells jQuery Unobtrusive Validation to parse the `data-` attributes of forms within that selector. The values of those attributes are then passed to the jQuery Validation plugin.

Add Validation to Dynamic Controls

The `$.validator.unobtrusive.parse()` method works on an entire form, not on individual dynamically generated controls, such as `<input>` and `<select/>`. To reparse the form, remove the validation data that was added when the form was parsed earlier, as shown in the following example:

```
$.get({
    url: "https://url/that/returns/a/control",
    dataType: "html",
    error: function(jqXHR, textStatus, errorThrown) {
        alert(textStatus + ": Couldn't add control. " + errorThrown);
    },
    success: function(newInputHTML) {
        var form = document.getElementById("my-form");
        form.insertAdjacentHTML("beforeend", newInputHTML);
        $(form).removeData("validator")    // Added by jQuery Validation
               .removeData("unobtrusiveValidation");   // Added by jQuery Unobtrusive
Validation
        $.validator.unobtrusive.parse(form);
    }
})
```

Custom client-side validation

Custom client-side validation is done by generating `data-` HTML attributes that work with a custom jQuery Validation adapter. The following sample adapter code was written for the `[ClassicMovie]` and `[ClassicMovieWithClientValidator]` attributes that were introduced earlier in this article:

```
$.validator.addMethod('classicmovie', function (value, element, params) {
    var genre = $(params[0]).val(), year = params[1], date = new Date(value);

    // The Classic genre has a value of '0'.
    if (genre && genre.length > 0 && genre[0] === '0') {
        // The release date for a Classic is valid if it's no greater than the given year.
        return date.getUTCFullYear() <= year;
    }

    return true;
});

$.validator.unobtrusive.adapters.add('classicmovie', ['year'], function (options) {
    var element = $(options.form).find('select#Movie_Genre')[0];

    options.rules['classicmovie'] = [element, parseInt(options.params['year'])];
    options.messages['classicmovie'] = options.message;
});
```

For information about how to write adapters, see the jQuery Validation documentation.

The use of an adapter for a given field is triggered by `data-` attributes that:

- Flag the field as being subject to validation (`data-val="true"`).
- Identify a validation rule name and error message text (for example, `data-val-rulename="Error message."`).
- Provide any additional parameters the validator needs (for example, `data-val-rulename-param1="value"`).

The following example shows the `data-` attributes for the sample app's `ClassicMovie` attribute:

```
<input class="form-control" type="date"
    data-val="true"
    data-val-classicmovie="Classic movies must have a release year no later than 1960."
    data-val-classicmovie-year="1960"
    data-val-required="The Release Date field is required."
    id="Movie_ReleaseDate" name="Movie.ReleaseDate" value="">
```

As noted earlier, Tag Helpers and HTML helpers use information from validation attributes to render `data-` attributes. There are two options for writing code that results in the creation of custom `data-` HTML attributes:

- Create a class that derives from `AttributeAdapterBase<TAttribute>` and a class that implements `IValidationAttributeAdapterProvider`, and register your attribute and its adapter in DI. This method follows the single responsibility principal in that server-related and client-related validation code is in separate classes. The adapter also has the advantage that since it is registered in DI, other services in DI are available to it if needed.
- Implement `IClientModelValidator` in your `ValidationAttribute` class. This method might be appropriate if the attribute doesn't do any server-side validation and doesn't need any services from DI.

AttributeAdapter for client-side validation

This method of rendering `data-` attributes in HTML is used by the `ClassicMovie` attribute in the sample app. To add client validation by using this method:

1. Create an attribute adapter class for the custom validation attribute. Derive the class from AttributeAdapterBase<T>. Create an `AddValidation` method that adds `data-` attributes to the rendered output, as shown in this example:

   ```
   public class ClassicMovieAttributeAdapter : AttributeAdapterBase<ClassicMovieAttribute>
   {
       public ClassicMovieAttributeAdapter(ClassicMovieAttribute attribute,
           IStringLocalizer stringLocalizer)
           : base(attribute, stringLocalizer)
       {

       }

       public override void AddValidation(ClientModelValidationContext context)
       {
           MergeAttribute(context.Attributes, "data-val", "true");
           MergeAttribute(context.Attributes, "data-val-classicmovie",
   GetErrorMessage(context));

           var year = Attribute.Year.ToString(CultureInfo.InvariantCulture);
           MergeAttribute(context.Attributes, "data-val-classicmovie-year", year);
       }

       public override string GetErrorMessage(ModelValidationContextBase validationContext)
   =>
           Attribute.GetErrorMessage();
   }
   ```

2. Create an adapter provider class that implements IValidationAttributeAdapterProvider. In the `GetAttributeAdapter` method pass in the custom attribute to the adapter's constructor, as shown in this example:

```
public class CustomValidationAttributeAdapterProvider :
IValidationAttributeAdapterProvider
{
    private readonly IValidationAttributeAdapterProvider baseProvider =
        new ValidationAttributeAdapterProvider();

    public IAttributeAdapter GetAttributeAdapter(ValidationAttribute attribute,
        IStringLocalizer stringLocalizer)
    {
        if (attribute is ClassicMovieAttribute classicMovieAttribute)
        {
            return new ClassicMovieAttributeAdapter(classicMovieAttribute,
stringLocalizer);
        }

        return baseProvider.GetAttributeAdapter(attribute, stringLocalizer);
    }
}
```

3. Register the adapter provider for DI in `Startup.ConfigureServices`:

```
services.AddRazorPages()
    .AddMvcOptions(options =>
    {
        options.MaxModelValidationErrors = 50;
        options.ModelBindingMessageProvider.SetValueMustNotBeNullAccessor(
            _ => "The field is required.");
    });

services.AddSingleton<IValidationAttributeAdapterProvider,
    CustomValidationAttributeAdapterProvider>();
```

IClientModelValidator for client-side validation

This method of rendering `data-` attributes in HTML is used by the `ClassicMovieWithClientValidator` attribute in the sample app. To add client validation by using this method:

- In the custom validation attribute, implement the `IClientModelValidator` interface and create an `AddValidation` method. In the `AddValidation` method, add `data-` attributes for validation, as shown in the following example:

```
public class ClassicMovieWithClientValidatorAttribute :
    ValidationAttribute, IClientModelValidator
{
    public ClassicMovieWithClientValidatorAttribute(int year)
    {
        Year = year;
    }

    public int Year { get; }

    public void AddValidation(ClientModelValidationContext context)
    {
        MergeAttribute(context.Attributes, "data-val", "true");
        MergeAttribute(context.Attributes, "data-val-classicmovie", GetErrorMessage());

        var year = Year.ToString(CultureInfo.InvariantCulture);
        MergeAttribute(context.Attributes, "data-val-classicmovie-year", year);
    }

    public string GetErrorMessage() =>
        $"Classic movies must have a release year no later than {Year}.";

    protected override ValidationResult IsValid(object value,
        ValidationContext validationContext)
    {
        var movie = (Movie)validationContext.ObjectInstance;
        var releaseYear = ((DateTime)value).Year;

        if (movie.Genre == Genre.Classic && releaseYear > Year)
        {
            return new ValidationResult(GetErrorMessage());
        }

        return ValidationResult.Success;
    }

    private bool MergeAttribute(IDictionary<string, string> attributes, string key,
string value)
    {
        if (attributes.ContainsKey(key))
        {
            return false;
        }

        attributes.Add(key, value);
        return true;
    }
}
```

Disable client-side validation

The following code disables client validation in Razor Pages:

```
services.AddRazorPages()
    .AddViewOptions(options =>
    {
        options.HtmlHelperOptions.ClientValidationEnabled = false;
    });
```

Other options to disable client-side validation:

- Comment out the reference to `_ValidationScriptsPartial` in all the *.cshtml* files.
- Remove the contents of the *Pages\Shared_ValidationScriptsPartial.cshtml* file.

The preceding approach won't prevent client side validation of ASP.NET Core Identity Razor Class Library. For more information, see Scaffold Identity in ASP.NET Core projects.

Additional resources

- System.ComponentModel.DataAnnotations namespace
- Model Binding

This article explains how to validate user input in an ASP.NET Core MVC or Razor Pages app.

View or download sample code (how to download).

Model state

Model state represents errors that come from two subsystems: model binding and model validation. Errors that originate from model binding are generally data conversion errors (for example, an "x" is entered in a field that expects an integer). Model validation occurs after model binding and reports errors where the data doesn't conform to business rules (for example, a 0 is entered in a field that expects a rating between 1 and 5).

Both model binding and validation occur before the execution of a controller action or a Razor Pages handler method. For web apps, it's the app's responsibility to inspect `ModelState.IsValid` and react appropriately. Web apps typically redisplay the page with an error message:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Movie.Add(Movie);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

Web API controllers don't have to check `ModelState.IsValid` if they have the `[ApiController]` attribute. In that case, an automatic HTTP 400 response containing error details is returned when model state is invalid. For more information, see Automatic HTTP 400 responses.

Rerun validation

Validation is automatic, but you might want to repeat it manually. For example, you might compute a value for a property and want to rerun validation after setting the property to the computed value. To rerun validation, call the `TryValidateModel` method, as shown here:

```
var movie = new Movie
{
    Title = title,
    Genre = genre,
    ReleaseDate = modifiedReleaseDate,
    Description = description,
    Price = price,
    Preorder = preorder,
};

TryValidateModel(movie);

if (ModelState.IsValid)
{
    _context.AddMovie(movie);
    _context.SaveChanges();

    return RedirectToAction(actionName: nameof(Index));
}

return View(movie);
```

Validation attributes

Validation attributes let you specify validation rules for model properties. The following example from the sample app shows a model class that is annotated with validation attributes. The `[ClassicMovie]` attribute is a custom validation attribute and the others are built-in. Not shown is `[ClassicMovie2]`, which shows an alternative way to implement a custom attribute.

```
public class Movie
{
    public int Id { get; set; }

    [Required]
    [StringLength(100)]
    public string Title { get; set; }

    [ClassicMovie(1960)]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [Required]
    [StringLength(1000)]
    public string Description { get; set; }

    [Range(0, 999.99)]
    public decimal Price { get; set; }

    [Required]
    public Genre Genre { get; set; }

    public bool Preorder { get; set; }
}
```

Built-in attributes

Built-in validation attributes include:

- `[CreditCard]`: Validates that the property has a credit card format.
- `[Compare]`: Validates that two properties in a model match. For example, the *Register.cshtml.cs*

file uses `[Compare]` to validate the two entered passwords match. Scaffold Identity to see the Register code.

- `[EmailAddress]`: Validates that the property has an email format.
- `[Phone]`: Validates that the property has a telephone number format.
- `[Range]`: Validates that the property value falls within a specified range.
- `[RegularExpression]`: Validates that the property value matches a specified regular expression.
- `[Required]`: Validates that the field is not null. See `[Required]` attribute for details about this attribute's behavior.
- `[StringLength]`: Validates that a string property value doesn't exceed a specified length limit.
- `[Url]`: Validates that the property has a URL format.
- `[Remote]`: Validates input on the client by calling an action method on the server. See `[Remote]` attribute for details about this attribute's behavior.

When using the `[RegularExpression]` attribute with client-side validation, the regex is executed in JavaScript on the client. This means ECMAScript matching behavior will be used. For more information, see this GitHub issue.

A complete list of validation attributes can be found in the System.ComponentModel.DataAnnotations namespace.

Error messages

Validation attributes let you specify the error message to be displayed for invalid input. For example:

```
[StringLength(8, ErrorMessage = "Name length can't be more than 8.")]
```

Internally, the attributes call `String.Format` with a placeholder for the field name and sometimes additional placeholders. For example:

```
[StringLength(8, ErrorMessage = "{0} length must be between {2} and {1}.", MinimumLength = 6)]
```

When applied to a `Name` property, the error message created by the preceding code would be "Name length must be between 6 and 8.".

To find out which parameters are passed to `String.Format` for a particular attribute's error message, see the DataAnnotations source code.

[Required] attribute

By default, the validation system treats non-nullable parameters or properties as if they had a `[Required]` attribute. Value types such as `decimal` and `int` are non-nullable.

[Required] validation on the server

On the server, a required value is considered missing if the property is null. A non-nullable field is always valid, and the [Required] attribute's error message is never displayed.

However, model binding for a non-nullable property may fail, resulting in an error message such as `The value '' is invalid`. To specify a custom error message for server-side validation of non-nullable types, you have the following options:

- Make the field nullable (for example, `decimal?` instead of `decimal`). Nullable<T> value types are treated like standard nullable types.

- Specify the default error message to be used by model binding, as shown in the following example:

```
services.AddMvc(options =>
    {
        options.MaxModelValidationErrors = 50;
        options.ModelBindingMessageProvider.SetValueMustNotBeNullAccessor(
            (_) => "The field is required.");
    })
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
services.AddSingleton
    <IValidationAttributeAdapterProvider,
     CustomValidationAttributeAdapterProvider>();
```

  For more information about model binding errors that you can set default messages for, see DefaultModelBindingMessageProvider.

[Required] validation on the client

Non-nullable types and strings are handled differently on the client compared to the server. On the client:

- A value is considered present only if input is entered for it. Therefore, client-side validation handles non-nullable types the same as nullable types.
- Whitespace in a string field is considered valid input by the jQuery Validation required method. Server-side validation considers a required string field invalid if only whitespace is entered.

As noted earlier, non-nullable types are treated as though they had a `[Required]` attribute. That means you get client-side validation even if you don't apply the `[Required]` attribute. But if you don't use the attribute, you get a default error message. To specify a custom error message, use the attribute.

[Remote] attribute

The `[Remote]` attribute implements client-side validation that requires calling a method on the server to determine whether field input is valid. For example, the app may need to verify whether a user name is already in use.

To implement remote validation:

1. Create an action method for JavaScript to call. The jQuery Validate remote method expects a JSON response:
   - `"true"` means the input data is valid.
   - `"false"`, `undefined`, or `null` means the input is invalid. Display the default error message.
   - Any other string means the input is invalid. Display the string as a custom error message.

   Here's an example of an action method that returns a custom error message:

```
[AcceptVerbs("Get", "Post")]
public IActionResult VerifyEmail(string email)
{
    if (!_userRepository.VerifyEmail(email))
    {
        return Json($"Email {email} is already in use.");
    }

    return Json(true);
}
```

2. In the model class, annotate the property with a `[Remote]` attribute that points to the validation action method, as shown in the following example:

```
[Remote(action: "VerifyEmail", controller: "Users")]
public string Email { get; set; }
```

The `[Remote]` attribute is in the `Microsoft.AspNetCore.Mvc` namespace. Install the Microsoft.AspNetCore.Mvc.ViewFeatures NuGet package if you're not using the `Microsoft.AspNetCore.App` or `Microsoft.AspNetCore.All` metapackage.

Additional fields

The `AdditionalFields` property of the `[Remote]` attribute lets you validate combinations of fields against data on the server. For example, if the `User` model had `FirstName` and `LastName` properties, you might want to verify that no existing users already have that pair of names. The following example shows how to use `AdditionalFields`:

```
[Remote(action: "VerifyName", controller: "Users", AdditionalFields = nameof(LastName))]
public string FirstName { get; set; }
[Remote(action: "VerifyName", controller: "Users", AdditionalFields = nameof(FirstName))]
public string LastName { get; set; }
```

`AdditionalFields` could be set explicitly to the strings `"FirstName"` and `"LastName"`, but using the nameof operator simplifies later refactoring. The action method for this validation must accept both first name and last name arguments:

```
[AcceptVerbs("Get", "Post")]
public IActionResult VerifyName(string firstName, string lastName)
{
    if (!_userRepository.VerifyName(firstName, lastName))
    {
        return Json($"A user named {firstName} {lastName} already exists.");
    }

    return Json(true);
}
```

When the user enters a first or last name, JavaScript makes a remote call to see if that pair of names has been taken.

To validate two or more additional fields, provide them as a comma-delimited list. For example, to add a `MiddleName` property to the model, set the `[Remote]` attribute as shown in the following example:

```
[Remote(action: "VerifyName", controller: "Users", AdditionalFields = nameof(FirstName) + "," +
nameof(LastName))]
public string MiddleName { get; set; }
```

`AdditionalFields`, like all attribute arguments, must be a constant expression. Therefore, don't use an interpolated string or call Join to initialize `AdditionalFields`.

Alternatives to built-in attributes

If you need validation not provided by built-in attributes, you can:

- Create custom attributes.
- Implement IValidatableObject.

Custom attributes

For scenarios that the built-in validation attributes don't handle, you can create custom validation attributes. Create a class that inherits from ValidationAttribute, and override the IsValid method.

The `IsValid` method accepts an object named *value*, which is the input to be validated. An overload also accepts a `ValidationContext` object, which provides additional information, such as the model instance created by model binding.

The following example validates that the release date for a movie in the *Classic* genre isn't later than a specified year. The `[ClassicMovie2]` attribute checks the genre first and continues only if it's *Classic*. For movies identified as classics, it checks the release date to make sure it's not later than the limit passed to the attribute constructor.)

```
public class ClassicMovieAttribute : ValidationAttribute
{
    private int _year;

    public ClassicMovieAttribute(int year)
    {
        _year = year;
    }

    protected override ValidationResult IsValid(
        object value, ValidationContext validationContext)
    {
        var movie = (Movie)validationContext.ObjectInstance;
        var releaseYear = ((DateTime)value).Year;

        if (movie.Genre == Genre.Classic && releaseYear > _year)
        {
            return new ValidationResult(GetErrorMessage());
        }

        return ValidationResult.Success;
    }

    public int Year => _year;

    public string GetErrorMessage()
    {
        return $"Classic movies must have a release year no later than {_year}.";
    }
}
```

The `movie` variable in the preceding example represents a `Movie` object that contains the data from the form submission. The `IsValid` method checks the date and genre. Upon successful validation, `IsValid` returns a `ValidationResult.Success` code. When validation fails, a `ValidationResult` with an error message is returned.

IValidatableObject

The preceding example works only with `Movie` types. Another option for class-level validation is to implement `IValidatableObject` in the model class, as shown in the following example:

```
public class MovieIValidatable : IValidatableObject
{
    private const int _classicYear = 1960;

    public int Id { get; set; }

    [Required]
    [StringLength(100)]
    public string Title { get; set; }

    [Required]
    public DateTime ReleaseDate { get; set; }

    [Required]
    [StringLength(1000)]
    public string Description { get; set; }

    [Range(0, 999.99)]
    public decimal Price { get; set; }

    [Required]
    public Genre Genre { get; set; }

    public bool Preorder { get; set; }

    public IEnumerable<ValidationResult> Validate(ValidationContext validationContext)
    {
        if (Genre == Genre.Classic && ReleaseDate.Year > _classicYear)
        {
            yield return new ValidationResult(
                $"Classic movies must have a release year earlier than {_classicYear}.",
                new[] { "ReleaseDate" });
        }
    }
}
```

Top-level node validation

Top-level nodes include:

- Action parameters
- Controller properties
- Page handler parameters
- Page model properties

Model-bound top-level nodes are validated in addition to validating model properties. In the following example from the sample app, the `VerifyPhone` method uses the RegularExpressionAttribute to validate the `phone` action parameter:

```
[AcceptVerbs("Get", "Post")]
public IActionResult VerifyPhone(
    [RegularExpression(@"^\d{3}-\d{3}-\d{4}$")] string phone)
{
    if (!ModelState.IsValid)
    {
        return Json($"Phone {phone} has an invalid format. Format: ###-###-####");
    }

    return Json(true);
}
```

Top-level nodes can use BindRequiredAttribute with validation attributes. In the following example from the sample app, the `CheckAge` method specifies that the `age` parameter must be bound from the query string when the form is submitted:

```
[HttpPost]
public IActionResult CheckAge(
    [BindRequired, FromQuery] int age)
{
```

In the Check Age page (*CheckAge.cshtml*), there are two forms. The first form submits an `Age` value of `99` as a query string: `https://localhost:5001/Users/CheckAge?Age=99`.

When a properly formatted `age` parameter from the query string is submitted, the form validates.

The second form on the Check Age page submits the `Age` value in the body of the request, and validation fails. Binding fails because the `age` parameter must come from a query string.

When running with `CompatibilityVersion.Version_2_1` or later, top-level node validation is enabled by default. Otherwise, top-level node validation is disabled. The default option can be overridden by setting the AllowValidatingTopLevelNodes property in (`Startup.ConfigureServices`), as shown here:

```
services.AddMvc(options =>
    {
        options.MaxModelValidationErrors = 50;
        options.AllowValidatingTopLevelNodes = false;
    })
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

Maximum errors

Validation stops when the maximum number of errors is reached (200 by default). You can configure this number with the following code in `Startup.ConfigureServices`:

```
services.AddMvc(options =>
    {
        options.MaxModelValidationErrors = 50;
        options.ModelBindingMessageProvider.SetValueMustNotBeNullAccessor(
            (_) => "The field is required.");
    })
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
services.AddSingleton
    <IValidationAttributeAdapterProvider,
     CustomValidationAttributeAdapterProvider>();
```

Maximum recursion

ValidationVisitor traverses the object graph of the model being validated. For models that are very deep or are infinitely recursive, validation may result in stack overflow. MvcOptions.MaxValidationDepth provides a way to stop validation early if the visitor recursion exceeds a configured depth. The default value of `MvcOptions.MaxValidationDepth` is 32 when running with `CompatibilityVersion.Version_2_2` or later. For earlier versions, the value is null, which means no depth constraint.

Automatic short-circuit

Validation is automatically short-circuited (skipped) if the model graph doesn't require validation. Objects that the runtime skips validation for include collections of primitives (such as `byte[]`, `string[]`, `Dictionary<string, string>`) and complex object graphs that don't have any validators.

Disable validation

To disable validation:

1. Create an implementation of `IObjectModelValidator` that doesn't mark any fields as invalid.

   ```
   public class NullObjectModelValidator : IObjectModelValidator
   {
       public void Validate(
           ActionContext actionContext,
           ValidationStateDictionary validationState,
           string prefix,
           object model)
       {
       }
   }
   ```

2. Add the following code to `Startup.ConfigureServices` to replace the default `IObjectModelValidator` implementation in the dependency injection container.

   ```
   // There is only one `IObjectModelValidator` object,
   // so AddSingleton replaces the default one.
   services.AddSingleton<IObjectModelValidator>(new NullObjectModelValidator());
   ```

You might still see model state errors that originate from model binding.

Client-side validation

Client-side validation prevents submission until the form is valid. The Submit button runs JavaScript that either submits the form or displays error messages.

Client-side validation avoids an unnecessary round trip to the server when there are input errors on a form. The following script references in *_Layout.cshtml* and *_ValidationScriptsPartial.cshtml* support client-side validation:

```
<script src="https://cdnjs.cloudflare.com/ajax/libs/jquery/3.3.1/jquery.min.js"></script>
```

```
<script src="https://cdnjs.cloudflare.com/ajax/libs/jquery-
validate/1.17.0/jquery.validate.min.js"></script>
<script src="https://cdnjs.cloudflare.com/ajax/libs/jquery-validation-
unobtrusive/3.2.11/jquery.validate.unobtrusive.min.js"></script>
```

The jQuery Unobtrusive Validation script is a custom Microsoft front-end library that builds on the popular jQuery Validate plugin. Without jQuery Unobtrusive Validation, you would have to code the same validation logic in two places: once in the server-side validation attributes on model properties, and then again in client-side scripts. Instead, Tag Helpers and HTML helpers use the validation attributes and type metadata from model properties to render HTML 5 `data-` attributes for the form elements that need validation. jQuery Unobtrusive Validation parses the `data-` attributes and passes the logic to jQuery Validate, effectively "copying" the server-side validation logic to the client. You can display validation errors on the client using tag helpers as shown here:

```
<div class="form-group">
    <label asp-for="ReleaseDate" class="col-md-2 control-label"></label>
    <div class="col-md-10">
        <input asp-for="ReleaseDate" class="form-control" />
        <span asp-validation-for="ReleaseDate" class="text-danger"></span>
    </div>
</div>
```

The preceding tag helpers render the following HTML.

```
<form action="/Movies/Create" method="post">
    <div class="form-horizontal">
        <h4>Movie</h4>
        <div class="text-danger"></div>
        <div class="form-group">
            <label class="col-md-2 control-label" for="ReleaseDate">ReleaseDate</label>
            <div class="col-md-10">
                <input class="form-control" type="datetime"
                data-val="true" data-val-required="The ReleaseDate field is required."
                id="ReleaseDate" name="ReleaseDate" value="">
                <span class="text-danger field-validation-valid"
                data-valmsg-for="ReleaseDate" data-valmsg-replace="true"></span>
            </div>
        </div>
    </div>
</form>
```

Notice that the `data-` attributes in the HTML output correspond to the validation attributes for the `ReleaseDate` property. The `data-val-required` attribute contains an error message to display if the user doesn't fill in the release date field. jQuery Unobtrusive Validation passes this value to the jQuery Validate required() method, which then displays that message in the accompanying `<span>` element.

Data type validation is based on the .NET type of a property, unless that is overridden by a `[DataType]` attribute. Browsers have their own default error messages, but the jQuery Validation Unobtrusive Validation package can override those messages. `[DataType]` attributes and subclasses such as `[EmailAddress]` let you specify the error message.

Add Validation to Dynamic Forms

jQuery Unobtrusive Validation passes validation logic and parameters to jQuery Validate when the page first loads. Therefore, validation doesn't work automatically on dynamically generated forms. To enable validation, tell jQuery Unobtrusive Validation to parse the dynamic form immediately

after you create it. For example, the following code sets up client-side validation on a form added via AJAX.

```
$.get({
    url: "https://url/that/returns/a/form",
    dataType: "html",
    error: function(jqXHR, textStatus, errorThrown) {
        alert(textStatus + ": Couldn't add form. " + errorThrown);
    },
    success: function(newFormHTML) {
        var container = document.getElementById("form-container");
        container.insertAdjacentHTML("beforeend", newFormHTML);
        var forms = container.getElementsByTagName("form");
        var newForm = forms[forms.length - 1];
        $.validator.unobtrusive.parse(newForm);
    }
})
```

The `$.validator.unobtrusive.parse()` method accepts a jQuery selector for its one argument. This method tells jQuery Unobtrusive Validation to parse the `data-` attributes of forms within that selector. The values of those attributes are then passed to the jQuery Validate plugin.

Add Validation to Dynamic Controls

The `$.validator.unobtrusive.parse()` method works on an entire form, not on individual dynamically generated controls, such as `<input>` and `<select/>`. To reparse the form, remove the validation data that was added when the form was parsed earlier, as shown in the following example:

```
$.get({
    url: "https://url/that/returns/a/control",
    dataType: "html",
    error: function(jqXHR, textStatus, errorThrown) {
        alert(textStatus + ": Couldn't add control. " + errorThrown);
    },
    success: function(newInputHTML) {
        var form = document.getElementById("my-form");
        form.insertAdjacentHTML("beforeend", newInputHTML);
        $(form).removeData("validator")    // Added by jQuery Validate
               .removeData("unobtrusiveValidation");   // Added by jQuery Unobtrusive
Validation
        $.validator.unobtrusive.parse(form);
    }
})
```

Custom client-side validation

Custom client-side validation is done by generating `data-` HTML attributes that work with a custom jQuery Validate adapter. The following sample adapter code was written for the `ClassicMovie` and `ClassicMovie2` attributes that were introduced earlier in this article:

```
$.validator.addMethod('classicmovie',
    function (value, element, params) {
        // Get element value. Classic genre has value '0'.
        var genre = $(params[0]).val(),
            year = params[1],
            date = new Date(value);
        if (genre && genre.length > 0 && genre[0] === '0') {
            // Since this is a classic movie, invalid if release date is after given year.
            return date.getUTCFullYear() <= year;
        }

        return true;
    });

$.validator.unobtrusive.adapters.add('classicmovie',
    ['year'],
    function (options) {
        var element = $(options.form).find('select#Genre')[0];
        options.rules['classicmovie'] = [element, parseInt(options.params['year'])];
        options.messages['classicmovie'] = options.message;
    });
```

For information about how to write adapters, see the jQuery Validate documentation.

The use of an adapter for a given field is triggered by `data-` attributes that:

- Flag the field as being subject to validation (`data-val="true"`).
- Identify a validation rule name and error message text (for example, `data-val-rulename="Error message."`).
- Provide any additional parameters the validator needs (for example, `data-val-rulename-parm1="value"`).

The following example shows the `data-` attributes for the sample app's `ClassicMovie` attribute:

```
<input class="form-control" type="datetime"
    data-val="true"
    data-val-classicmovie1="Classic movies must have a release year earlier than 1960."
    data-val-classicmovie1-year="1960"
    data-val-required="The ReleaseDate field is required."
    id="ReleaseDate" name="ReleaseDate" value="">
```

As noted earlier, Tag Helpers and HTML helpers use information from validation attributes to render `data-` attributes. There are two options for writing code that results in the creation of custom `data-` HTML attributes:

- Create a class that derives from `AttributeAdapterBase<TAttribute>` and a class that implements `IValidationAttributeAdapterProvider` , and register your attribute and its adapter in DI. This method follows the single responsibility principal in that server-related and client-related validation code is in separate classes. The adapter also has the advantage that since it is registered in DI, other services in DI are available to it if needed.
- Implement `IClientModelValidator` in your `ValidationAttribute` class. This method might be appropriate if the attribute doesn't do any server-side validation and doesn't need any services from DI.

AttributeAdapter for client-side validation

This method of rendering `data-` attributes in HTML is used by the `ClassicMovie` attribute in the sample app. To add client validation by using this method:

1. Create an attribute adapter class for the custom validation attribute. Derive the class from AttributeAdapterBase<T>. Create an `AddValidation` method that adds `data-` attributes to the rendered output, as shown in this example:

```
public class ClassicMovieAttributeAdapter : AttributeAdapterBase<ClassicMovieAttribute>
{
    private int _year;

    public ClassicMovieAttributeAdapter(ClassicMovieAttribute attribute,
IStringLocalizer stringLocalizer) : base (attribute, stringLocalizer)
    {
        _year = attribute.Year;
    }
    public override void AddValidation(ClientModelValidationContext context)
    {
        if (context == null)
        {
            throw new ArgumentNullException(nameof(context));
        }

        MergeAttribute(context.Attributes, "data-val", "true");
        MergeAttribute(context.Attributes, "data-val-classicmovie",
GetErrorMessage(context));

        var year = Attribute.Year.ToString(CultureInfo.InvariantCulture);
        MergeAttribute(context.Attributes, "data-val-classicmovie-year", year);
    }
    public override string GetErrorMessage(ModelValidationContextBase validationContext)
    {
        return Attribute.GetErrorMessage();
    }
}
```

2. Create an adapter provider class that implements IValidationAttributeAdapterProvider. In the `GetAttributeAdapter` method pass in the custom attribute to the adapter's constructor, as shown in this example:

```
public class CustomValidationAttributeAdapterProvider :
    IValidationAttributeAdapterProvider
{
    IValidationAttributeAdapterProvider baseProvider =
        new ValidationAttributeAdapterProvider();
    public IAttributeAdapter GetAttributeAdapter(ValidationAttribute attribute,
        IStringLocalizer stringLocalizer)
    {
        if (attribute is ClassicMovieAttribute classicMovieAttribute)
        {
            return new ClassicMovieAttributeAdapter(classicMovieAttribute,
stringLocalizer);
        }
        else
        {
            return baseProvider.GetAttributeAdapter(attribute, stringLocalizer);
        }
    }
}
```

3. Register the adapter provider for DI in `Startup.ConfigureServices`:

```
services.AddMvc(options =>
    {
        options.MaxModelValidationErrors = 50;
        options.ModelBindingMessageProvider.SetValueMustNotBeNullAccessor(
            (_) => "The field is required.");
    })
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
services.AddSingleton
    <IValidationAttributeAdapterProvider,
     CustomValidationAttributeAdapterProvider>();
```

IClientModelValidator for client-side validation

This method of rendering `data-` attributes in HTML is used by the `ClassicMovie2` attribute in the sample app. To add client validation by using this method:

- In the custom validation attribute, implement the `IClientModelValidator` interface and create an `AddValidation` method. In the `AddValidation` method, add `data-` attributes for validation, as shown in the following example:

```
public class ClassicMovie2Attribute : ValidationAttribute, IClientModelValidator
{
    private int _year;

    public ClassicMovie2Attribute(int year)
    {
        _year = year;
    }

    protected override ValidationResult IsValid(
        object value, ValidationContext validationContext)
    {
        var movie = (Movie)validationContext.ObjectInstance;
        var releaseYear = ((DateTime)value).Year;

        if (movie.Genre == Genre.Classic && releaseYear > _year)
        {
            return new ValidationResult(GetErrorMessage());
        }

        return ValidationResult.Success;
    }

    public void AddValidation(ClientModelValidationContext context)
    {
        if (context == null)
        {
            throw new ArgumentNullException(nameof(context));
        }

        MergeAttribute(context.Attributes, "data-val", "true");
        MergeAttribute(context.Attributes, "data-val-classicmovie", GetErrorMessage());

        var year = _year.ToString(CultureInfo.InvariantCulture);
        MergeAttribute(context.Attributes, "data-val-classicmovie-year", year);
    }
    private bool MergeAttribute(IDictionary<string, string> attributes, string key,
string value)
    {
        if (attributes.ContainsKey(key))
        {
            return false;
        }

        attributes.Add(key, value);
        return true;
    }
    protected string GetErrorMessage()
    {
        return $"Classic movies must have a release year no later than {_year} [from
attribute 2].";
    }
}
```

Disable client-side validation

The following code disables client validation in MVC views:

```
services.AddMvc().AddViewOptions(options =>
{
    if (_env.IsDevelopment())
    {
        options.HtmlHelperOptions.ClientValidationEnabled = false;
    }
});
```

And in Razor Pages:

```
services.Configure<HtmlHelperOptions>(o => o.ClientValidationEnabled = false);
```

Another option for disabling client validation is to comment out the reference to `_ValidationScriptsPartial` in your *.cshtml* file.

Compatibility version for ASP.NET Core MVC

9/22/2020 • 2 minutes to read • Edit Online

By Rick Anderson

The SetCompatibilityVersion method is a no-op for ASP.NET Core 3.0 apps. That is, calling `SetCompatibilityVersion` with any value of CompatibilityVersion has no impact on the application.

- The next minor version of ASP.NET Core may provide a new `CompatibilityVersion` value.
- `CompatibilityVersion` values `Version_2_0` through `Version_2_2` are marked `[Obsolete(...)]`.
- See Breaking API changes in Antiforgery, CORS, Diagnostics, Mvc, and Routing. This list includes breaking changes for compatibility switches.

To see how `SetCompatibilityVersion` works with ASP.NET Core 2.x apps, select the .

The SetCompatibilityVersion method allows an ASP.NET Core 2.x app to opt-in or opt-out of potentially breaking behavior changes introduced in ASP.NET Core MVC 2.1 or 2.2. These potentially breaking behavior changes are generally in how the MVC subsystem behaves and how **your code** is called by the runtime. By opting in, you get the latest behavior, and the long-term behavior of ASP.NET Core.

The following code sets the compatibility mode to ASP.NET Core 2.2:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
        .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

We recommend you test your app using the latest version (`CompatibilityVersion.Latest`). We anticipate that most apps won't have breaking behavior changes using the latest version.

Apps that call `SetCompatibilityVersion(CompatibilityVersion.Version_2_0)` are protected from potentially breaking behavior changes introduced in the ASP.NET Core 2.1/2.2 MVC versions. This protection:

- Does not apply to all 2.1 and later changes, it's targeted to potentially breaking ASP.NET Core runtime behavior changes in the MVC subsystem.
- Does not extend to ASP.NET Core 3.0.

The default compatibility for ASP.NET Core 2.1 and 2.2 apps that do **not** call `SetCompatibilityVersion` is 2.0 compatibility. That is, not calling `SetCompatibilityVersion` is the same as calling `SetCompatibilityVersion(CompatibilityVersion.Version_2_0)`.

The following code sets the compatibility mode to ASP.NET Core 2.2, except for the following behaviors:

- AllowCombiningAuthorizeFilters
- InputFormatterExceptionPolicy

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
        // Include the 2.2 behaviors
        .SetCompatibilityVersion(CompatibilityVersion.Version_2_2)
        // Except for the following.
        .AddMvcOptions(options =>
        {
            // Don't combine authorize filters (keep 2.0 behavior).
            options.AllowCombiningAuthorizeFilters = false;
            // All exceptions thrown by an IInputFormatter are treated
            // as model state errors (keep 2.0 behavior).
            options.InputFormatterExceptionPolicy =
                InputFormatterExceptionPolicy.AllExceptions;
        });
}
```

For apps that encounter breaking behavior changes, using the appropriate compatibility switches:

- Allows you to use the latest release and opt out of specific breaking behavior changes.
- Gives you time to update your app so it works with the latest changes.

The MvcOptions documentation has a good explanation of what changed and why the changes are an improvement for most users.

With ASP.NET Core 3.0, old behaviors supported by compatibility switches have been removed. We feel these are positive changes benefitting nearly all users. By introducing these changes in 2.1 and 2.2, most apps can benefit, while others have time to update.

Write custom ASP.NET Core middleware

9/22/2020 • 3 minutes to read • Edit Online

By Rick Anderson and Steve Smith

Middleware is software that's assembled into an app pipeline to handle requests and responses. ASP.NET Core provides a rich set of built-in middleware components, but in some scenarios you might want to write a custom middleware.

> **NOTE**
> This topic describes how to write *convention-based* middleware. For an approach that uses strong typing and per-request activation, see Factory-based middleware activation in ASP.NET Core.

Middleware class

Middleware is generally encapsulated in a class and exposed with an extension method. Consider the following middleware, which sets the culture for the current request from a query string:

```
public class Startup
{
    public void Configure(IApplicationBuilder app)
    {
        app.Use(async (context, next) =>
        {
            var cultureQuery = context.Request.Query["culture"];
            if (!string.IsNullOrWhiteSpace(cultureQuery))
            {
                var culture = new CultureInfo(cultureQuery);

                CultureInfo.CurrentCulture = culture;
                CultureInfo.CurrentUICulture = culture;
            }

            // Call the next delegate/middleware in the pipeline
            await next();
        });

        app.Run(async (context) =>
        {
            await context.Response.WriteAsync(
                $"Hello {CultureInfo.CurrentCulture.DisplayName}");
        });

    }
}
```

The preceding sample code is used to demonstrate creating a middleware component. For ASP.NET Core's built-in localization support, see Globalization and localization in ASP.NET Core.

Test the middleware by passing in the culture. For example, request `https://localhost:5001/?culture=no`.

The following code moves the middleware delegate to a class:

```
using Microsoft.AspNetCore.Http;
using System.Globalization;
using System.Threading.Tasks;

namespace Culture
{
    public class RequestCultureMiddleware
    {
        private readonly RequestDelegate _next;

        public RequestCultureMiddleware(RequestDelegate next)
        {
            _next = next;
        }

        public async Task InvokeAsync(HttpContext context)
        {
            var cultureQuery = context.Request.Query["culture"];
            if (!string.IsNullOrWhiteSpace(cultureQuery))
            {
                var culture = new CultureInfo(cultureQuery);

                CultureInfo.CurrentCulture = culture;
                CultureInfo.CurrentUICulture = culture;

            }

            // Call the next delegate/middleware in the pipeline
            await _next(context);
        }
    }
}
```

The middleware class must include:

- A public constructor with a parameter of type RequestDelegate.
- A public method named `Invoke` or `InvokeAsync`. This method must:
  - Return a `Task`.
  - Accept a first parameter of type HttpContext.

Additional parameters for the constructor and `Invoke` / `InvokeAsync` are populated by dependency injection (DI).

Middleware dependencies

Middleware should follow the Explicit Dependencies Principle by exposing its dependencies in its constructor. Middleware is constructed once per *application lifetime*. See the Per-request middleware dependencies section if you need to share services with middleware within a request.

Middleware components can resolve their dependencies from dependency injection (DI) through constructor parameters. UseMiddleware<T> can also accept additional parameters directly.

Per-request middleware dependencies

Because middleware is constructed at app startup, not per-request, *scoped* lifetime services used by middleware constructors aren't shared with other dependency-injected types during each request. If you must share a *scoped* service between your middleware and other types, add these services to the `Invoke` method's signature. The `Invoke` method can accept additional parameters that are populated by DI:

```
public class CustomMiddleware
{
    private readonly RequestDelegate _next;

    public CustomMiddleware(RequestDelegate next)
    {
        _next = next;
    }

    // IMyScopedService is injected into Invoke
    public async Task Invoke(HttpContext httpContext, IMyScopedService svc)
    {
        svc.MyProperty = 1000;
        await _next(httpContext);
    }
}
```

Lifetime and registration options contains a complete sample of middleware with *scoped* lifetime services.

Middleware extension method

The following extension method exposes the middleware through IApplicationBuilder:

```
using Microsoft.AspNetCore.Builder;

namespace Culture
{
    public static class RequestCultureMiddlewareExtensions
    {
        public static IApplicationBuilder UseRequestCulture(
            this IApplicationBuilder builder)
        {
            return builder.UseMiddleware<RequestCultureMiddleware>();
        }
    }
}
```

The following code calls the middleware from `Startup.Configure`:

```
public class Startup
{
    public void Configure(IApplicationBuilder app)
    {
        app.UseRequestCulture();

        app.Run(async (context) =>
        {
            await context.Response.WriteAsync(
                $"Hello {CultureInfo.CurrentCulture.DisplayName}");
        });
    }
}
```

Request and response operations in ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

By Justin Kotalik

This article explains how to read from the request body and write to the response body. Code for these operations might be required when writing middleware. Outside of writing middleware, custom code isn't generally required because the operations are handled by MVC and Razor Pages.

There are two abstractions for the request and response bodies: Stream and Pipe. For request reading, HttpRequest.Body is a Stream, and `HttpRequest.BodyReader` is a PipeReader. For response writing, HttpResponse.Body is a Stream, and `HttpResponse.BodyWriter` is a PipeWriter.

Pipelines are recommended over streams. Streams can be easier to use for some simple operations, but pipelines have a performance advantage and are easier to use in most scenarios. ASP.NET Core is starting to use pipelines instead of streams internally. Examples include:

- `FormReader`
- `TextReader`
- `TextWriter`
- `HttpResponse.WriteAsync`

Streams aren't being removed from the framework. Streams continue to be used throughout .NET, and many stream types don't have pipe equivalents, such as `FileStreams` and `ResponseCompression`.

Stream examples

Suppose the goal is to create a middleware that reads the entire request body as a list of strings, splitting on new lines. A simple stream implementation might look like the following example:

> **WARNING**
>
> The following code:
>
> - Is used to demonstrate the problems with not using a pipe to read the request body.
> - Is not intended to be used in production apps.

```
private async Task<List<string>> GetListOfStringsFromStream(Stream requestBody)
{
    // Build up the request body in a string builder.
    StringBuilder builder = new StringBuilder();

    // Rent a shared buffer to write the request body into.
    byte[] buffer = ArrayPool<byte>.Shared.Rent(4096);

    while (true)
    {
        var bytesRemaining = await requestBody.ReadAsync(buffer, offset: 0, buffer.Length);
        if (bytesRemaining == 0)
        {
            break;
        }

        // Append the encoded string into the string builder.
        var encodedString = Encoding.UTF8.GetString(buffer, 0, bytesRemaining);
        builder.Append(encodedString);
    }

    ArrayPool<byte>.Shared.Return(buffer);

    var entireRequestBody = builder.ToString();

    // Split on \n in the string.
    return new List<string>(entireRequestBody.Split("\n"));
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

This code works, but there are some issues:

- Before appending to the `StringBuilder`, the example creates another string (`encodedString`) that is thrown away immediately. This process occurs for all bytes in the stream, so the result is extra memory allocation the size of the entire request body.
- The example reads the entire string before splitting on new lines. It's more efficient to check for new lines in the byte array.

Here's an example that fixes some of the preceding issues:

> **WARNING**
>
> The following code:
>
> - Is used to demonstrate the solutions to some problems in the preceding code while not solving all the problems.
> - Is not intended to be used in production apps.

```
private async Task<List<string>> GetListOfStringsFromStreamMoreEfficient(Stream requestBody)
{
    StringBuilder builder = new StringBuilder();
    byte[] buffer = ArrayPool<byte>.Shared.Rent(4096);
    List<string> results = new List<string>();

    while (true)
    {
        var bytesRemaining = await requestBody.ReadAsync(buffer, offset: 0, buffer.Length);

        if (bytesRemaining == 0)
        {
            results.Add(builder.ToString());
            break;
        }

        // Instead of adding the entire buffer into the StringBuilder
        // only add the remainder after the last \n in the array.
        var prevIndex = 0;
        int index;
        while (true)
        {
            index = Array.IndexOf(buffer, (byte)'\n', prevIndex);
            if (index == -1)
            {
                break;
            }

            var encodedString = Encoding.UTF8.GetString(buffer, prevIndex, index - prevIndex);

            if (builder.Length > 0)
            {
                // If there was a remainder in the string buffer, include it in the next string.
                results.Add(builder.Append(encodedString).ToString());
                builder.Clear();
            }
            else
            {
                results.Add(encodedString);
            }

            // Skip past last \n
            prevIndex = index + 1;
        }

        var remainingString = Encoding.UTF8.GetString(buffer, prevIndex, bytesRemaining - prevIndex);
        builder.Append(remainingString);
    }

    ArrayPool<byte>.Shared.Return(buffer);

    return results;
}
```

This preceding example:

- Doesn't buffer the entire request body in a `StringBuilder` unless there aren't any newline characters.
- Doesn't call `Split` on the string.

However, there are still are a few issues:

- If newline characters are sparse, much of the request body is buffered in the string.
- The code continues to create strings (`remainingString`) and adds them to the string buffer, which results in an extra allocation.

These issues are fixable, but the code is becoming progressively more complicated with little improvement. Pipelines provide a way to solve these problems with minimal code complexity.

Pipelines

The following example shows how the same scenario can be handled using a PipeReader:

```
private async Task<List<string>> GetListOfStringFromPipe(PipeReader reader)
{
    List<string> results = new List<string>();

    while (true)
    {
        ReadResult readResult = await reader.ReadAsync();
        var buffer = readResult.Buffer;

        SequencePosition? position = null;

        do
        {
            // Look for a EOL in the buffer
            position = buffer.PositionOf((byte)'\n');

            if (position != null)
            {
                var readOnlySequence = buffer.Slice(0, position.Value);
                AddStringToList(ref results, in readOnlySequence);

                // Skip the line + the \n character (basically position)
                buffer = buffer.Slice(buffer.GetPosition(1, position.Value));
            }
        }
        while (position != null);

        if (readResult.IsCompleted && buffer.Length > 0)
        {
            AddStringToList(ref results, in buffer);
        }

        reader.AdvanceTo(buffer.Start, buffer.End);

        // At this point, buffer will be updated to point one byte after the last
        // \n character.
        if (readResult.IsCompleted)
        {
            break;
        }
    }

    return results;
}

private static void AddStringToList(ref List<string> results, in ReadOnlySequence<byte> readOnlySequence)
{
    // Separate method because Span/ReadOnlySpan cannot be used in async methods
    ReadOnlySpan<byte> span = readOnlySequence.IsSingleSegment ? readOnlySequence.First.Span :
readOnlySequence.ToArray().AsSpan();
    results.Add(Encoding.UTF8.GetString(span));
}
```

This example fixes many issues that the streams implementations had:

- There's no need for a string buffer because the `PipeReader` handles bytes that haven't been used.

- Encoded strings are directly added to the list of returned strings.
- Other than the `ToArray` call, and the memory used by the string, string creation is allocation free.

Adapters

The `Body`, `BodyReader`, and `BodyWriter` properties are available for `HttpRequest` and `HttpResponse`. When you set `Body` to a different stream, a new set of adapters automatically adapt each type to the other. If you set `HttpRequest.Body` to a new stream, `HttpRequest.BodyReader` is automatically set to a new `PipeReader` that wraps `HttpRequest.Body`.

StartAsync

`HttpResponse.StartAsync` is used to indicate that headers are unmodifiable and to run `OnStarting` callbacks. When using Kestrel as a server, calling `StartAsync` before using the `PipeReader` guarantees that memory returned by `GetMemory` belongs to Kestrel's internal Pipe rather than an external buffer.

URL Rewriting Middleware in ASP.NET Core

9/22/2020 • 32 minutes to read • Edit Online

By Mikael Mengistu

This document introduces URL rewriting with instructions on how to use URL Rewriting Middleware in ASP.NET Core apps.

URL rewriting is the act of modifying request URLs based on one or more predefined rules. URL rewriting creates an abstraction between resource locations and their addresses so that the locations and addresses aren't tightly linked. URL rewriting is valuable in several scenarios to:

- Move or replace server resources temporarily or permanently and maintain stable locators for those resources.
- Split request processing across different apps or across areas of one app.
- Remove, add, or reorganize URL segments on incoming requests.
- Optimize public URLs for Search Engine Optimization (SEO).
- Permit the use of friendly public URLs to help visitors predict the content returned by requesting a resource.
- Redirect insecure requests to secure endpoints.
- Prevent hotlinking, where an external site uses a hosted static asset on another site by linking the asset into its own content.

> **NOTE**
> URL rewriting can reduce the performance of an app. Where feasible, limit the number and complexity of rules.

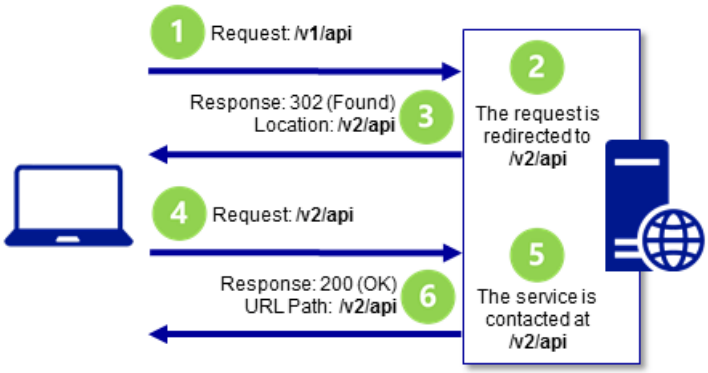
View or download sample code (how to download)

URL redirect and URL rewrite

The difference in wording between *URL redirect* and *URL rewrite* is subtle but has important implications for providing resources to clients. ASP.NET Core's URL Rewriting Middleware is capable of meeting the need for both.

A *URL redirect* involves a client-side operation, where the client is instructed to access a resource at a different address than the client originally requested. This requires a round trip to the server. The redirect URL returned to the client appears in the browser's address bar when the client makes a new request for the resource.

If `/resource` is *redirected* to `/different-resource`, the server responds that the client should obtain the resource at `/different-resource` with a status code indicating that the redirect is either temporary or permanent.



When redirecting requests to a different URL, indicate whether the redirect is permanent or temporary by specifying the status code with the response:

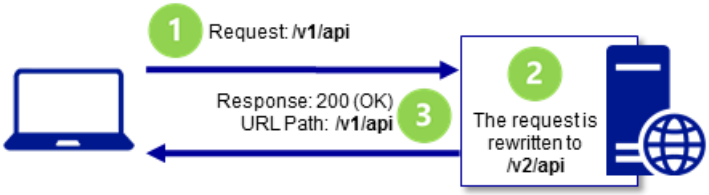
- The *301 - Moved Permanently* status code is used where the resource has a new, permanent URL and you wish to instruct the client that all future requests for the resource should use the new URL. *The client may cache and reuse the response when a 301 status code is received.*
- The *302 - Found* status code is used where the redirection is temporary or generally subject to change. The 302 status code indicates to the client not to store the URL and use it in the future.

For more information on status codes, see RFC 2616: Status Code Definitions.

A *URL rewrite* is a server-side operation that provides a resource from a different resource address than the client requested. Rewriting a URL doesn't require a round trip to the server. The rewritten URL isn't returned to the client and doesn't appear in the browser's address bar.

If `/resource` is *rewritten* to `/different-resource`, the server *internally* fetches and returns the resource at `/different-resource`.

Although the client might be able to retrieve the resource at the rewritten URL, the client isn't informed that the resource exists at the rewritten URL when it makes its request and receives the response.



URL rewriting sample app

You can explore the features of the URL Rewriting Middleware with the sample app. The app applies redirect and rewrite rules and shows the redirected or rewritten URL for several scenarios.

When to use URL Rewriting Middleware

Use URL Rewriting Middleware when you're unable to use the following approaches:

- URL Rewrite module with IIS on Windows Server
- Apache mod_rewrite module on Apache Server
- URL rewriting on Nginx

Also, use the middleware when the app is hosted on HTTP.sys server (formerly called WebListener).

The main reasons to use the server-based URL rewriting technologies in IIS, Apache, and Nginx are:

- The middleware doesn't support the full features of these modules.

  Some of the features of the server modules don't work with ASP.NET Core projects, such as the `IsFile` and `IsDirectory` constraints of the IIS Rewrite module. In these scenarios, use the middleware instead.

- The performance of the middleware probably doesn't match that of the modules.

  Benchmarking is the only way to know for sure which approach degrades performance the most or if degraded performance is negligible.

Package

URL Rewriting Middleware is provided by the Microsoft.AspNetCore.Rewrite package, which is implicitly included

in ASP.NET Core apps.

Extension and options

Establish URL rewrite and redirect rules by creating an instance of the RewriteOptions class with extension methods for each of your rewrite rules. Chain multiple rules in the order that you would like them processed. The `RewriteOptions` are passed into the URL Rewriting Middleware as it's added to the request pipeline with UseRewriter:

```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

Redirect non-www to www

Three options permit the app to redirect non-`www` requests to `www`:

- AddRedirectToWwwPermanent: Permanently redirect the request to the `www` subdomain if the request is non-`www`. Redirects with a Status308PermanentRedirect status code.
- AddRedirectToWww: Redirect the request to the `www` subdomain if the incoming request is non-`www`. Redirects with a Status307TemporaryRedirect status code. An overload permits you to provide the status code for the response. Use a field of the StatusCodes class for a status code assignment.

URL redirect

Use AddRedirect to redirect requests. The first parameter contains your regex for matching on the path of the incoming URL. The second parameter is the replacement string. The third parameter, if present, specifies the status code. If you don't specify the status code, the status code defaults to *302 - Found*, which indicates that the resource is temporarily moved or replaced.

```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

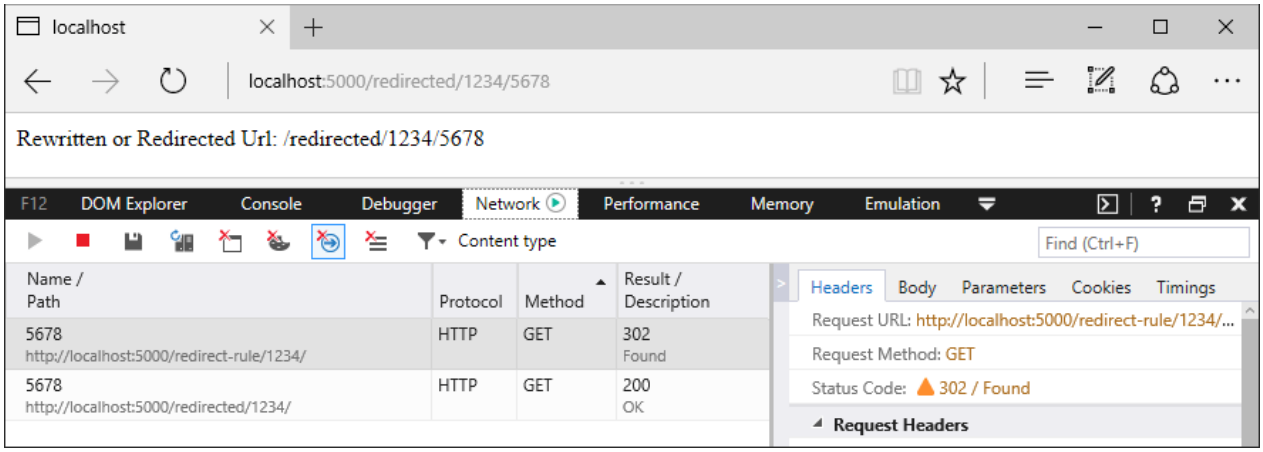
In a browser with developer tools enabled, make a request to the sample app with the path `/redirect-rule/1234/5678`. The regex matches the request path on `redirect-rule/(.*)`, and the path is replaced with `/redirected/1234/5678`. The redirect URL is sent back to the client with a *302 - Found* status code. The browser makes a new request at the redirect URL, which appears in the browser's address bar. Since no rules in the sample app match on the redirect URL:

- The second request receives a *200 - OK* response from the app.
- The body of the response shows the redirect URL.

A round trip is made to the server when a URL is *redirected*.

> **WARNING**
>
> Be cautious when establishing redirect rules. Redirect rules are evaluated on every request to the app, including after a redirect. It's easy to accidentally create a *loop of infinite redirects*.

Original Request: `/redirect-rule/1234/5678`



The part of the expression contained within parentheses is called a *capture group*. The dot (`.`) of the expression means *match any character*. The asterisk (`*`) indicates *match the preceding character zero or more times*. Therefore, the last two path segments of the URL, `1234/5678` , are captured by capture group `(.*)` . Any value you provide in the request URL after `redirect-rule/` is captured by this single capture group.

In the replacement string, captured groups are injected into the string with the dollar sign (`$`) followed by the sequence number of the capture. The first capture group value is obtained with `$1` , the second with `$2` , and they continue in sequence for the capture groups in your regex. There's only one captured group in the redirect rule regex in the sample app, so there's only one injected group in the replacement string, which is `$1` . When the rule is applied, the URL becomes `/redirected/1234/5678` .

URL redirect to a secure endpoint

Use AddRedirectToHttps to redirect HTTP requests to the same host and path using the HTTPS protocol. If the status code isn't supplied, the middleware defaults to *302 - Found*. If the port isn't supplied:

- The middleware defaults to `null` .
- The scheme changes to `https` (HTTPS protocol), and the client accesses the resource on port 443.

The following example shows how to set the status code to *301 - Moved Permanently* and change the port to 5001.

```
public void Configure(IApplicationBuilder app)
{
    var options = new RewriteOptions()
        .AddRedirectToHttps(301, 5001);

    app.UseRewriter(options);
}
```

Use AddRedirectToHttpsPermanent to redirect insecure requests to the same host and path with secure HTTPS protocol on port 443. The middleware sets the status code to *301 - Moved Permanently*.

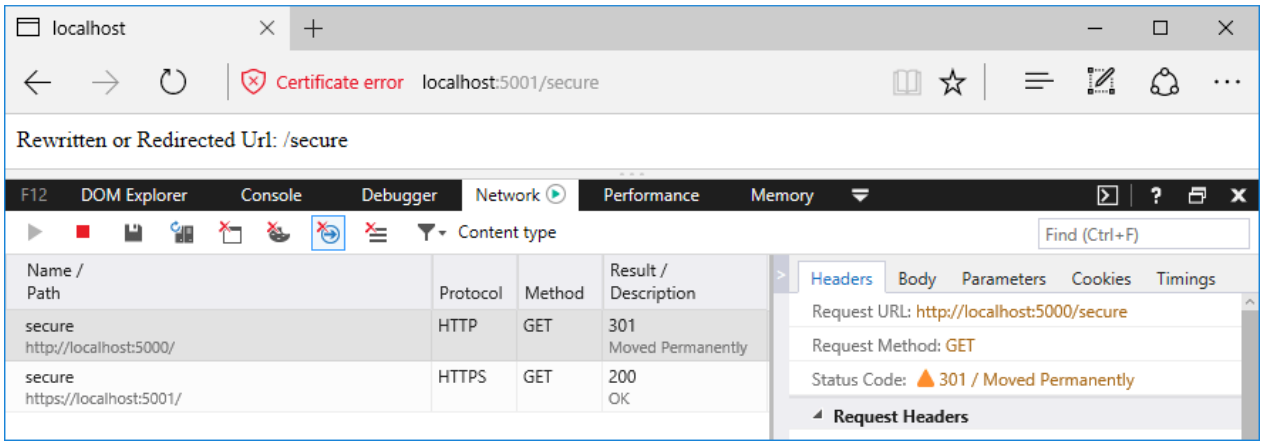
```
public void Configure(IApplicationBuilder app)
{
    var options = new RewriteOptions()
        .AddRedirectToHttpsPermanent();

    app.UseRewriter(options);
}
```

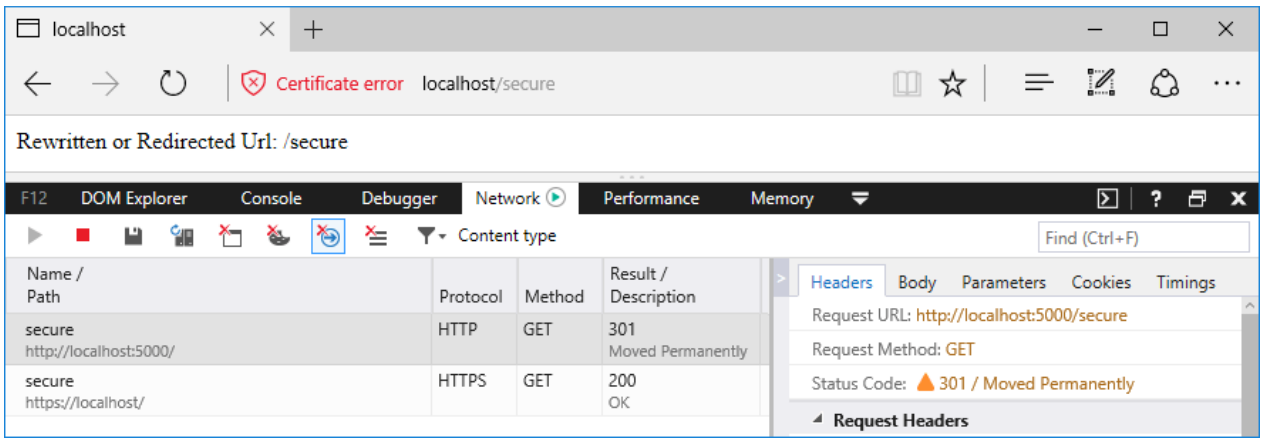
> **NOTE**
> When redirecting to a secure endpoint without the requirement for additional redirect rules, we recommend using HTTPS Redirection Middleware. For more information, see the Enforce HTTPS topic.

The sample app is capable of demonstrating how to use `AddRedirectToHttps` or `AddRedirectToHttpsPermanent` . Add the extension method to the `RewriteOptions` . Make an insecure request to the app at any URL. Dismiss the browser security warning that the self-signed certificate is untrusted or create an exception to trust the certificate.

Original Request using `AddRedirectToHttps(301, 5001)` : `http://localhost:5000/secure`



Original Request using `AddRedirectToHttpsPermanent` : `http://localhost:5000/secure`



URL rewrite

Use AddRewrite to create a rule for rewriting URLs. The first parameter contains the regex for matching on the incoming URL path. The second parameter is the replacement string. The third parameter, `skipRemainingRules: {true|false}`, indicates to the middleware whether or not to skip additional rewrite rules if the current rule is applied.

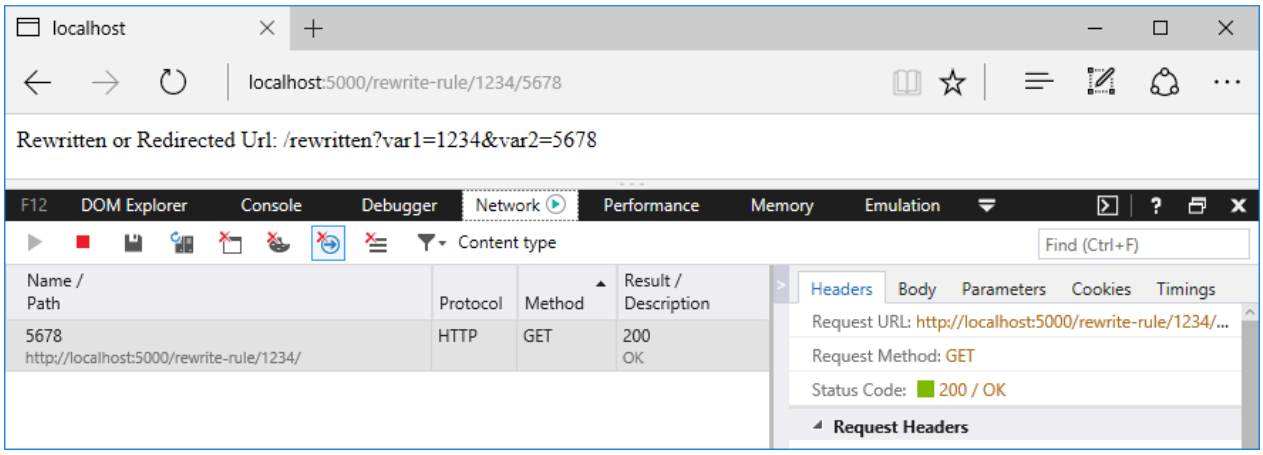
```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

Original Request: `/rewrite-rule/1234/5678`



The carat (`^`) at the beginning of the expression means that matching starts at the beginning of the URL path.

In the earlier example with the redirect rule, `redirect-rule/(.*)`, there's no carat (`^`) at the start of the regex. Therefore, any characters may precede `redirect-rule/` in the path for a successful match.

PATH	MATCH
`/redirect-rule/1234/5678`	Yes
`/my-cool-redirect-rule/1234/5678`	Yes
`/anotherredirect-rule/1234/5678`	Yes

The rewrite rule, `^rewrite-rule/(\d+)/(\d+)`, only matches paths if they start with `rewrite-rule/`. In the following table, note the difference in matching.

PATH	MATCH
`/rewrite-rule/1234/5678`	Yes
`/my-cool-rewrite-rule/1234/5678`	No
`/anotherrewrite-rule/1234/5678`	No

Following the `^rewrite-rule/` portion of the expression, there are two capture groups, `(\d+)/(\d+)`. The `\d` signifies *match a digit (number)*. The plus sign (`+`) means *match one or more of the preceding character*. Therefore, the URL must contain a number followed by a forward-slash followed by another number. These capture groups are injected into the rewritten URL as `$1` and `$2`. The rewrite rule replacement string places the captured groups into the query string. The requested path of `/rewrite-rule/1234/5678` is rewritten to obtain the resource at `/rewritten?var1=1234&var2=5678`. If a query string is present on the original request, it's preserved when the URL is rewritten.

There's no round trip to the server to obtain the resource. If the resource exists, it's fetched and returned to the client with a *200 - OK* status code. Because the client isn't redirected, the URL in the browser's address bar doesn't change. Clients can't detect that a URL rewrite operation occurred on the server.

> **NOTE**
>
> Use `skipRemainingRules: true` whenever possible because matching rules is computationally expensive and increases app response time. For the fastest app response:
>
> - Order rewrite rules from the most frequently matched rule to the least frequently matched rule.
> - Skip the processing of the remaining rules when a match occurs and no additional rule processing is required.

Apache mod_rewrite

Apply Apache mod_rewrite rules with AddApacheModRewrite. Make sure that the rules file is deployed with the app. For more information and examples of mod_rewrite rules, see Apache mod_rewrite.

A StreamReader is used to read the rules from the *ApacheModRewrite.txt* rules file:

```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

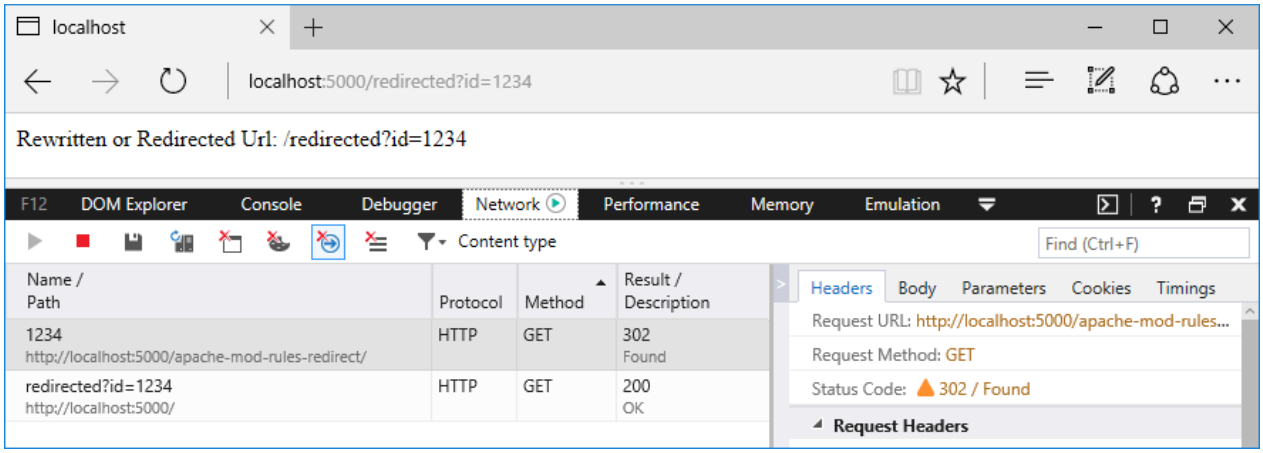
    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

The sample app redirects requests from `/apache-mod-rules-redirect/(.\*)` to `/redirected?id=$1`. The response status code is *302 - Found*.

```
# Rewrite path with additional sub directory
RewriteRule ^/apache-mod-rules-redirect/(.*) /redirected?id=$1 [L,R=302]
```

Original Request: `/apache-mod-rules-redirect/1234`



The middleware supports the following Apache mod_rewrite server variables:

- CONN_REMOTE_ADDR
- HTTP_ACCEPT
- HTTP_CONNECTION
- HTTP_COOKIE
- HTTP_FORWARDED
- HTTP_HOST
- HTTP_REFERER

- HTTP_USER_AGENT
- HTTPS
- IPV6
- QUERY_STRING
- REMOTE_ADDR
- REMOTE_PORT
- REQUEST_FILENAME
- REQUEST_METHOD
- REQUEST_SCHEME
- REQUEST_URI
- SCRIPT_FILENAME
- SERVER_ADDR
- SERVER_PORT
- SERVER_PROTOCOL
- TIME
- TIME_DAY
- TIME_HOUR
- TIME_MIN
- TIME_MON
- TIME_SEC
- TIME_WDAY
- TIME_YEAR

IIS URL Rewrite Module rules

To use the same rule set that applies to the IIS URL Rewrite Module, use AddIISUrlRewrite. Make sure that the rules file is deployed with the app. Don't direct the middleware to use the app's *web.config* file when running on Windows Server IIS. With IIS, these rules should be stored outside of the app's *web.config* file in order to avoid conflicts with the IIS Rewrite module. For more information and examples of IIS URL Rewrite Module rules, see Using Url Rewrite Module 2.0 and URL Rewrite Module Configuration Reference.

A StreamReader is used to read the rules from the *IISUrlRewrite.xml* rules file:

```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

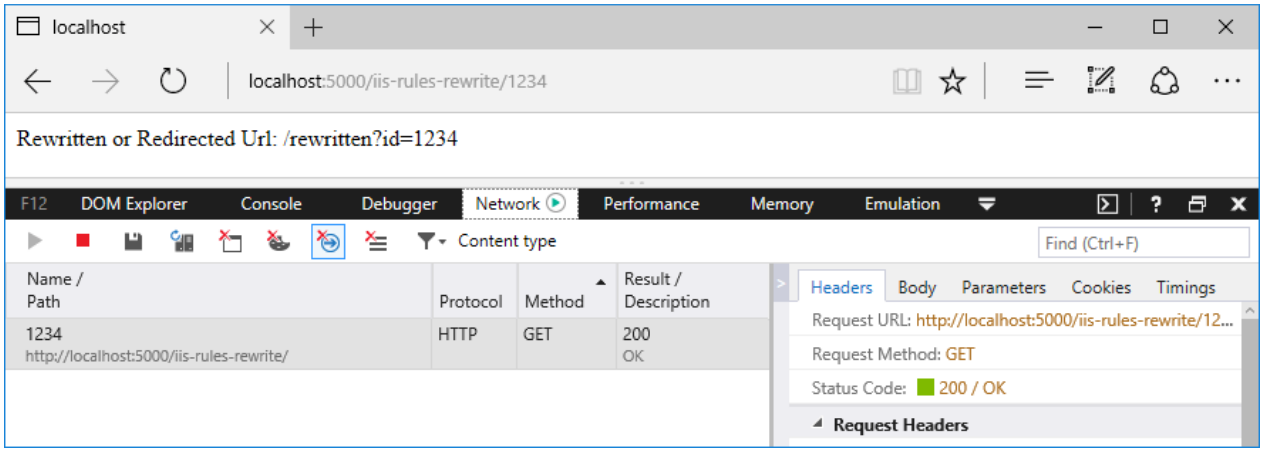
    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

The sample app rewrites requests from `/iis-rules-rewrite/(.*)` to `/rewritten?id=$1`. The response is sent to the client with a *200 - OK* status code.

```
<rewrite>
  <rules>
    <rule name="Rewrite segment to id querystring" stopProcessing="true">
      <match url="^iis-rules-rewrite/(.*)$" />
      <action type="Rewrite" url="rewritten?id={R:1}" appendQueryString="false"/>
    </rule>
  </rules>
</rewrite>
```

Original Request: `/iis-rules-rewrite/1234`



If you have an active IIS Rewrite Module with server-level rules configured that would impact your app in undesirable ways, you can disable the IIS Rewrite Module for an app. For more information, see Disabling IIS modules.

Unsupported features

The middleware released with ASP.NET Core 2.x doesn't support the following IIS URL Rewrite Module features:

- Outbound Rules
- Custom Server Variables
- Wildcards
- LogRewrittenUrl

Supported server variables

The middleware supports the following IIS URL Rewrite Module server variables:

- CONTENT_LENGTH
- CONTENT_TYPE
- HTTP_ACCEPT
- HTTP_CONNECTION
- HTTP_COOKIE
- HTTP_HOST
- HTTP_REFERER
- HTTP_URL
- HTTP_USER_AGENT
- HTTPS
- LOCAL_ADDR
- QUERY_STRING
- REMOTE_ADDR
- REMOTE_PORT
- REQUEST_FILENAME
- REQUEST_URI

> **NOTE**
>
> You can also obtain an IFileProvider via a PhysicalFileProvider. This approach may provide greater flexibility for the location of your rewrite rules files. Make sure that your rewrite rules files are deployed to the server at the path you provide.
>
> ```
> PhysicalFileProvider fileProvider = new PhysicalFileProvider(Directory.GetCurrentDirectory());
> ```

Method-based rule

Use Add to implement your own rule logic in a method. `Add` exposes the RewriteContext, which makes available the HttpContext for use in your method. The RewriteContext.Result determines how additional pipeline processing is handled. Set the value to one of the RuleResult fields described in the following table.

REWRITE CONTEXT RESULT	ACTION
`RuleResult.ContinueRules` (default)	Continue applying rules.
`RuleResult.EndResponse`	Stop applying rules and send the response.
`RuleResult.SkipRemainingRules`	Stop applying rules and send the context to the next middleware.

```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

The sample app demonstrates a method that redirects requests for paths that end with *.xml*. If a request is made for `/file.xml`, the request is redirected to `/xmlfiles/file.xml`. The status code is set to *301 - Moved Permanently*. When the browser makes a new request for */xmlfiles/file.xml*, Static File Middleware serves the file to the client from the *wwwroot/xmlfiles* folder. For a redirect, explicitly set the status code of the response. Otherwise, a *200 - OK* status code is returned, and the redirect doesn't occur on the client.

RewriteRules.cs:

```
public static void RedirectXmlFileRequests(RewriteContext context)
{
    var request = context.HttpContext.Request;

    // Because the client is redirecting back to the same app, stop
    // processing if the request has already been redirected.
    if (request.Path.StartsWithSegments(new PathString("/xmlfiles")))
    {
        return;
    }

    if (request.Path.Value.EndsWith(".xml", StringComparison.OrdinalIgnoreCase))
    {
        var response = context.HttpContext.Response;
        response.StatusCode = StatusCodes.Status301MovedPermanently;
        context.Result = RuleResult.EndResponse;
        response.Headers[HeaderNames.Location] =
            "/xmlfiles" + request.Path + request.QueryString;
    }
}
```

This approach can also rewrite requests. The sample app demonstrates rewriting the path for any text file request to serve the *file.txt* text file from the *wwwroot* folder. Static File Middleware serves the file based on the updated request path:

```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

RewriteRules.cs:

```
public static void RewriteTextFileRequests(RewriteContext context)
{
    var request = context.HttpContext.Request;

    if (request.Path.Value.EndsWith(".txt", StringComparison.OrdinalIgnoreCase))
    {
        context.Result = RuleResult.SkipRemainingRules;
        request.Path = "/file.txt";
    }
}
```

IRule-based rule

Use Add to use rule logic in a class that implements the IRule interface. `IRule` provides greater flexibility over using the method-based rule approach. Your implementation class may include a constructor that allows you can pass in parameters for the ApplyRule method.

```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

The values of the parameters in the sample app for the `extension` and the `newPath` are checked to meet several conditions. The `extension` must contain a value, and the value must be *.png*, *.jpg*, or *.gif*. If the `newPath` isn't valid, an ArgumentException is thrown. If a request is made for *image.png*, the request is redirected to `/png-images/image.png`. If a request is made for *image.jpg*, the request is redirected to `/jpg-images/image.jpg`. The status code is set to *301 - Moved Permanently*, and the `context.Result` is set to stop processing rules and send the response.

```
public class RedirectImageRequests : IRule
{
    private readonly string _extension;
    private readonly PathString _newPath;

    public RedirectImageRequests(string extension, string newPath)
    {
        if (string.IsNullOrEmpty(extension))
        {
            throw new ArgumentException(nameof(extension));
        }

        if (!Regex.IsMatch(extension, @"^\.(png|jpg|gif)$"))
        {
            throw new ArgumentException("Invalid extension", nameof(extension));
        }

        if (!Regex.IsMatch(newPath, @"(/[A-Za-z0-9]+)+?"))
        {
            throw new ArgumentException("Invalid path", nameof(newPath));
        }

        _extension = extension;
        _newPath = new PathString(newPath);
    }

    public void ApplyRule(RewriteContext context)
    {
        var request = context.HttpContext.Request;

        // Because we're redirecting back to the same app, stop
        // processing if the request has already been redirected
        if (request.Path.StartsWithSegments(new PathString(_newPath)))
        {
            return;
        }

        if (request.Path.Value.EndsWith(_extension, StringComparison.OrdinalIgnoreCase))
        {
            var response = context.HttpContext.Response;
            response.StatusCode = StatusCodes.Status301MovedPermanently;
            context.Result = RuleResult.EndResponse;
            response.Headers[HeaderNames.Location] =
                _newPath + request.Path + request.QueryString;
        }
    }
}
```

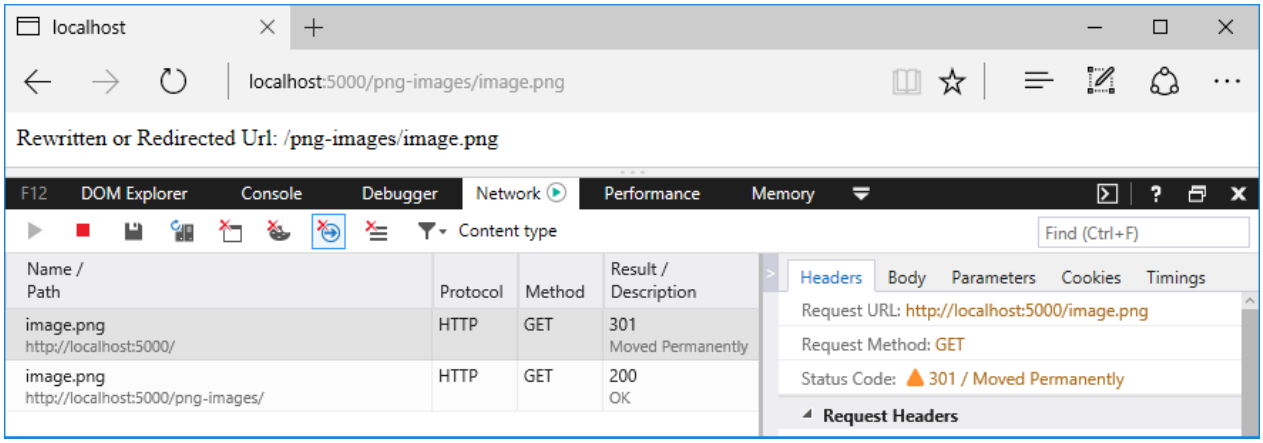
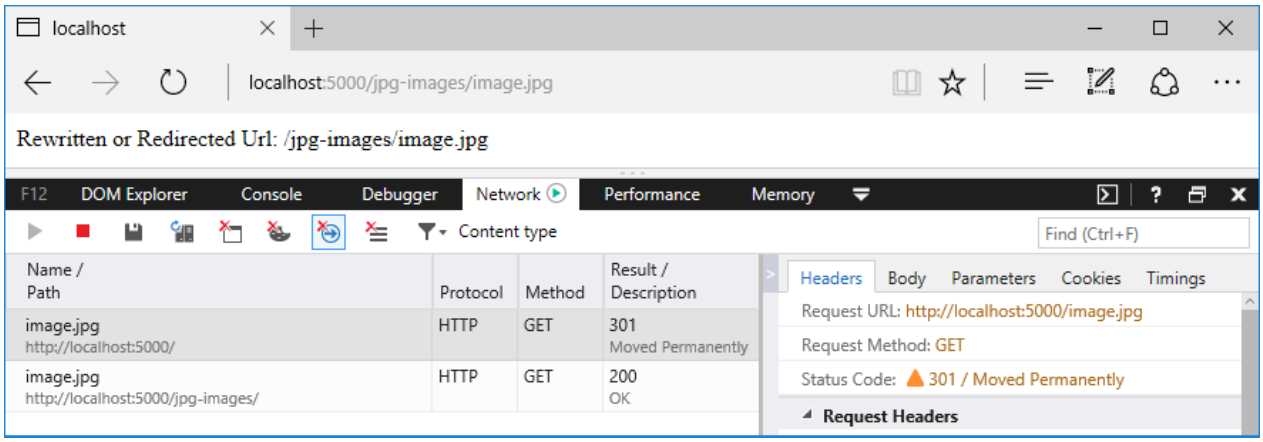
Original Request: `/image.png`



Original Request: `/image.jpg`



Regex examples

GOAL	REGEX STRING & MATCH EXAMPLE	REPLACEMENT STRING & OUTPUT EXAMPLE
Rewrite path into querystring	`^path/(.*)/(.*)` `/path/abc/123`	`path?var1=$1&var2=$2` `/path?var1=abc&var2=123`
Strip trailing slash	`(.*)/$` `/path/`	`$1` `/path`
Enforce trailing slash	`(.*[^/])$` `/path`	`$1/` `/path/`
Avoid rewriting specific requests	`^(.*)(?<!\.axd)$` or `^(?!.*\.axd$)(.*)$` Yes: `/resource.htm` No: `/resource.axd`	`rewritten/$1` `/rewritten/resource.htm` `/resource.axd`
Rearrange URL segments	`path/(.*)/(.*)/(.*)` `path/1/2/3`	`path/$3/$2/$1` `path/3/2/1`
Replace a URL segment	`^(.*)/segment2/(.*)` `/segment1/segment2/segment3`	`$1/replaced/$2` `/segment1/replaced/segment3`

This document introduces URL rewriting with instructions on how to use URL Rewriting Middleware in ASP.NET Core apps.

URL rewriting is the act of modifying request URLs based on one or more predefined rules. URL rewriting creates an abstraction between resource locations and their addresses so that the locations and addresses aren't tightly linked. URL rewriting is valuable in several scenarios to:

- Move or replace server resources temporarily or permanently and maintain stable locators for those resources.
- Split request processing across different apps or across areas of one app.
- Remove, add, or reorganize URL segments on incoming requests.
- Optimize public URLs for Search Engine Optimization (SEO).
- Permit the use of friendly public URLs to help visitors predict the content returned by requesting a resource.
- Redirect insecure requests to secure endpoints.
- Prevent hotlinking, where an external site uses a hosted static asset on another site by linking the asset into its own content.

> **NOTE**
> URL rewriting can reduce the performance of an app. Where feasible, limit the number and complexity of rules.

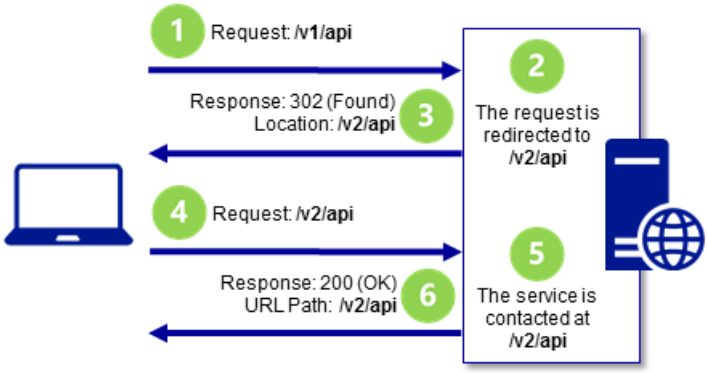
URL redirect and URL rewrite

The difference in wording between *URL redirect* and *URL rewrite* is subtle but has important implications for providing resources to clients. ASP.NET Core's URL Rewriting Middleware is capable of meeting the need for both.

A *URL redirect* involves a client-side operation, where the client is instructed to access a resource at a different address than the client originally requested. This requires a round trip to the server. The redirect URL returned to the client appears in the browser's address bar when the client makes a new request for the resource.

If `/resource` is *redirected* to `/different-resource`, the server responds that the client should obtain the resource at `/different-resource` with a status code indicating that the redirect is either temporary or permanent.



When redirecting requests to a different URL, indicate whether the redirect is permanent or temporary by specifying the status code with the response:

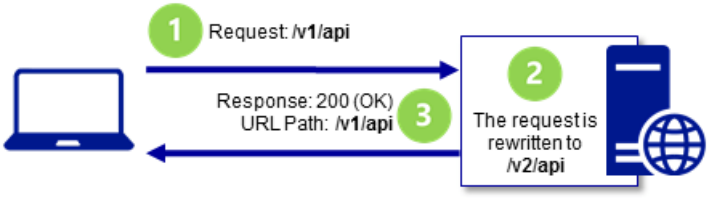
- The *301 - Moved Permanently* status code is used where the resource has a new, permanent URL and you wish to instruct the client that all future requests for the resource should use the new URL. *The client may cache and reuse the response when a 301 status code is received.*
- The *302 - Found* status code is used where the redirection is temporary or generally subject to change. The 302 status code indicates to the client not to store the URL and use it in the future.

For more information on status codes, see RFC 2616: Status Code Definitions.

A *URL rewrite* is a server-side operation that provides a resource from a different resource address than the client requested. Rewriting a URL doesn't require a round trip to the server. The rewritten URL isn't returned to the client and doesn't appear in the browser's address bar.

If `/resource` is *rewritten* to `/different-resource`, the server *internally* fetches and returns the resource at `/different-resource`.

Although the client might be able to retrieve the resource at the rewritten URL, the client isn't informed that the resource exists at the rewritten URL when it makes its request and receives the response.



URL rewriting sample app

You can explore the features of the URL Rewriting Middleware with the sample app. The app applies redirect and rewrite rules and shows the redirected or rewritten URL for several scenarios.

When to use URL Rewriting Middleware

Use URL Rewriting Middleware when you're unable to use the following approaches:

- URL Rewrite module with IIS on Windows Server
- Apache mod_rewrite module on Apache Server
- URL rewriting on Nginx

Also, use the middleware when the app is hosted on HTTP.sys server (formerly called WebListener).

The main reasons to use the server-based URL rewriting technologies in IIS, Apache, and Nginx are:

- The middleware doesn't support the full features of these modules.

  Some of the features of the server modules don't work with ASP.NET Core projects, such as the `IsFile` and `IsDirectory` constraints of the IIS Rewrite module. In these scenarios, use the middleware instead.

- The performance of the middleware probably doesn't match that of the modules.

  Benchmarking is the only way to know for sure which approach degrades performance the most or if degraded performance is negligible.

Package

To include the middleware in your project, add a package reference to the Microsoft.AspNetCore.App metapackage in the project file, which contains the Microsoft.AspNetCore.Rewrite package.

When not using the `Microsoft.AspNetCore.App` metapackage, add a project reference to the `Microsoft.AspNetCore.Rewrite` package.

Extension and options

Establish URL rewrite and redirect rules by creating an instance of the RewriteOptions class with extension methods for each of your rewrite rules. Chain multiple rules in the order that you would like them processed. The `RewriteOptions` are passed into the URL Rewriting Middleware as it's added to the request pipeline with UseRewriter:

```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

Redirect non-www to www

Three options permit the app to redirect non-`www` requests to `www`:

- AddRedirectToWwwPermanent: Permanently redirect the request to the `www` subdomain if the request is non-`www`. Redirects with a Status308PermanentRedirect status code.
- AddRedirectToWww: Redirect the request to the `www` subdomain if the incoming request is non-`www`. Redirects with a Status307TemporaryRedirect status code. An overload permits you to provide the status code for the response. Use a field of the StatusCodes class for a status code assignment.

URL redirect

Use AddRedirect to redirect requests. The first parameter contains your regex for matching on the path of the incoming URL. The second parameter is the replacement string. The third parameter, if present, specifies the status code. If you don't specify the status code, the status code defaults to *302 - Found*, which indicates that the resource is temporarily moved or replaced.

```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

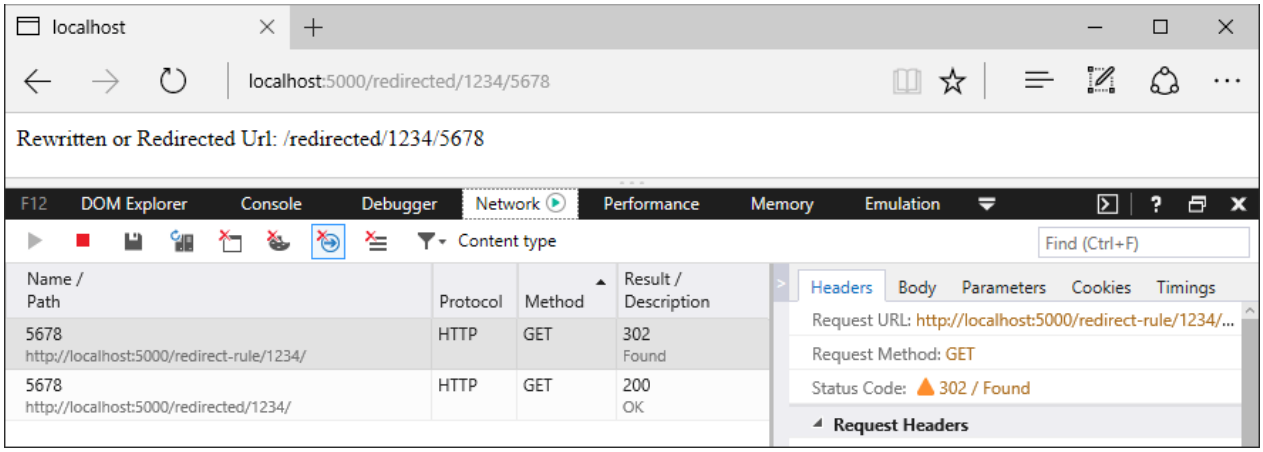
In a browser with developer tools enabled, make a request to the sample app with the path `/redirect-rule/1234/5678`. The regex matches the request path on `redirect-rule/(.*)`, and the path is replaced with `/redirected/1234/5678`. The redirect URL is sent back to the client with a *302 - Found* status code. The browser makes a new request at the redirect URL, which appears in the browser's address bar. Since no rules in the sample app match on the redirect URL:

- The second request receives a *200 - OK* response from the app.
- The body of the response shows the redirect URL.

A round trip is made to the server when a URL is *redirected*.

> **WARNING**
>
> Be cautious when establishing redirect rules. Redirect rules are evaluated on every request to the app, including after a redirect. It's easy to accidentally create a *loop of infinite redirects*.

Original Request: `/redirect-rule/1234/5678`



The part of the expression contained within parentheses is called a *capture group*. The dot (`.`) of the expression means *match any character*. The asterisk (`*`) indicates *match the preceding character zero or more times*. Therefore, the last two path segments of the URL, `1234/5678` , are captured by capture group `(.*)` . Any value you provide in the request URL after `redirect-rule/` is captured by this single capture group.

In the replacement string, captured groups are injected into the string with the dollar sign (`$`) followed by the sequence number of the capture. The first capture group value is obtained with `$1` , the second with `$2` , and they continue in sequence for the capture groups in your regex. There's only one captured group in the redirect rule regex in the sample app, so there's only one injected group in the replacement string, which is `$1` . When the rule is applied, the URL becomes `/redirected/1234/5678` .

URL redirect to a secure endpoint

Use AddRedirectToHttps to redirect HTTP requests to the same host and path using the HTTPS protocol. If the status code isn't supplied, the middleware defaults to *302 - Found*. If the port isn't supplied:

- The middleware defaults to `null` .
- The scheme changes to `https` (HTTPS protocol), and the client accesses the resource on port 443.

The following example shows how to set the status code to *301 - Moved Permanently* and change the port to 5001.

```
public void Configure(IApplicationBuilder app)
{
    var options = new RewriteOptions()
        .AddRedirectToHttps(301, 5001);

    app.UseRewriter(options);
}
```

Use AddRedirectToHttpsPermanent to redirect insecure requests to the same host and path with secure HTTPS protocol on port 443. The middleware sets the status code to *301 - Moved Permanently*.

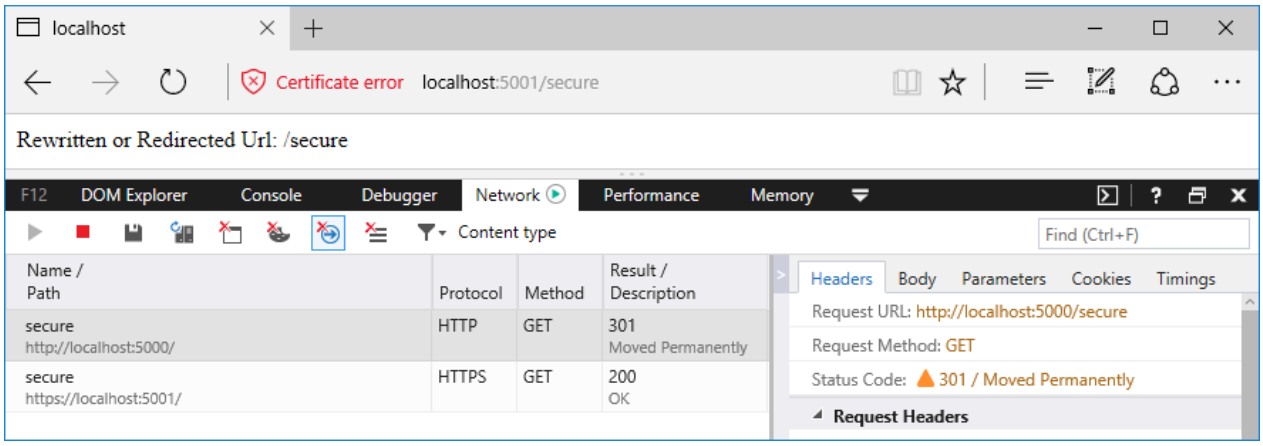
```
public void Configure(IApplicationBuilder app)
{
    var options = new RewriteOptions()
        .AddRedirectToHttpsPermanent();

    app.UseRewriter(options);
}
```

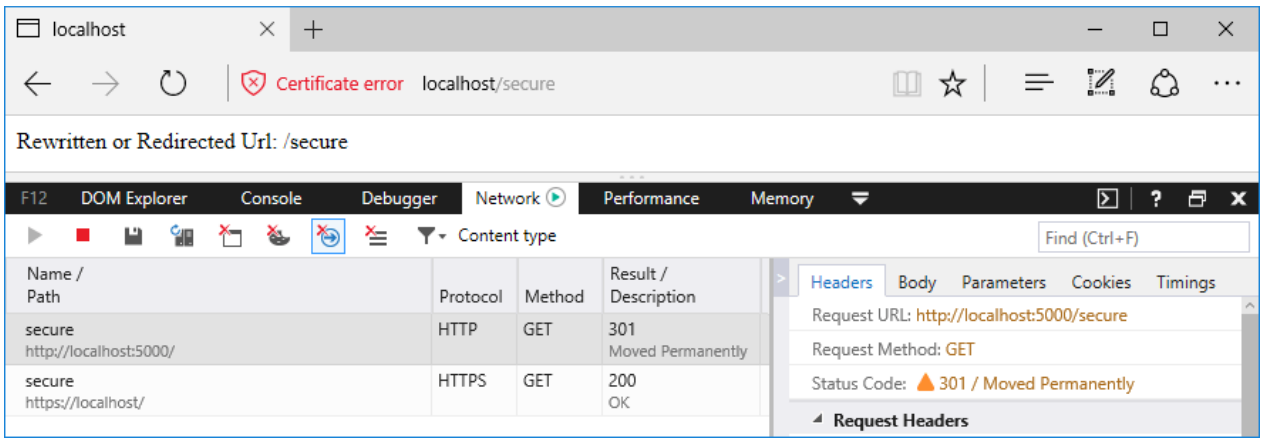
> **NOTE**
> When redirecting to a secure endpoint without the requirement for additional redirect rules, we recommend using HTTPS Redirection Middleware. For more information, see the Enforce HTTPS topic.

The sample app is capable of demonstrating how to use `AddRedirectToHttps` or `AddRedirectToHttpsPermanent` . Add the extension method to the `RewriteOptions` . Make an insecure request to the app at any URL. Dismiss the browser security warning that the self-signed certificate is untrusted or create an exception to trust the certificate.

Original Request using `AddRedirectToHttps(301, 5001)` : `http://localhost:5000/secure`



Original Request using `AddRedirectToHttpsPermanent` : `http://localhost:5000/secure`



URL rewrite

Use AddRewrite to create a rule for rewriting URLs. The first parameter contains the regex for matching on the incoming URL path. The second parameter is the replacement string. The third parameter, `skipRemainingRules: {true|false}`, indicates to the middleware whether or not to skip additional rewrite rules if the current rule is applied.

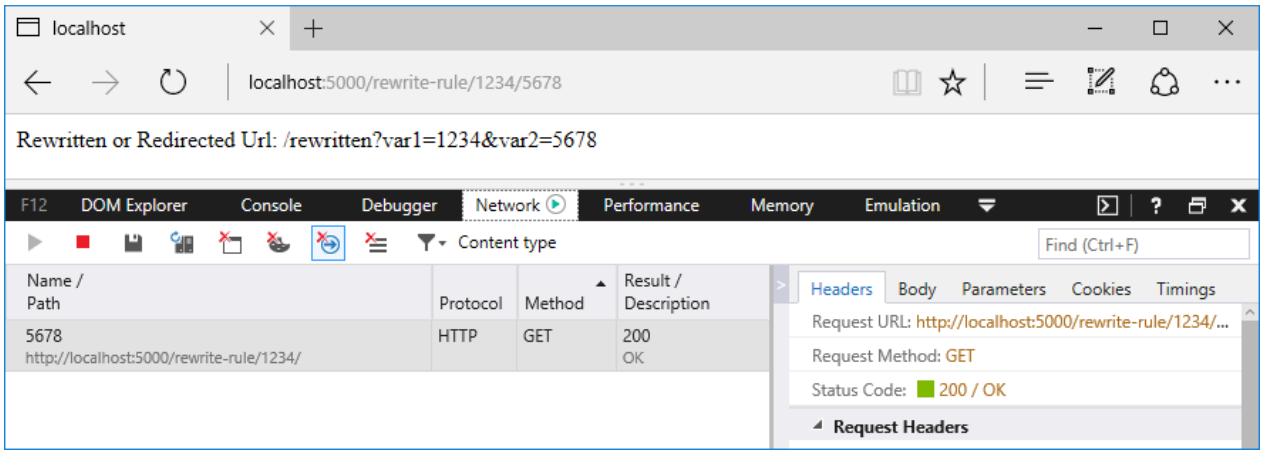
```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

Original Request: `/rewrite-rule/1234/5678`



The carat (`^`) at the beginning of the expression means that matching starts at the beginning of the URL path.

In the earlier example with the redirect rule, `redirect-rule/(.*)`, there's no carat (`^`) at the start of the regex. Therefore, any characters may precede `redirect-rule/` in the path for a successful match.

PATH	MATCH
`/redirect-rule/1234/5678`	Yes
`/my-cool-redirect-rule/1234/5678`	Yes
`/anotherredirect-rule/1234/5678`	Yes

The rewrite rule, `^rewrite-rule/(\d+)/(\d+)`, only matches paths if they start with `rewrite-rule/`. In the following table, note the difference in matching.

PATH	MATCH
`/rewrite-rule/1234/5678`	Yes
`/my-cool-rewrite-rule/1234/5678`	No
`/anotherrewrite-rule/1234/5678`	No

Following the `^rewrite-rule/` portion of the expression, there are two capture groups, `(\d+)/(\d+)`. The `\d` signifies *match a digit (number)*. The plus sign (`+`) means *match one or more of the preceding character*. Therefore, the URL must contain a number followed by a forward-slash followed by another number. These capture groups are injected into the rewritten URL as `$1` and `$2`. The rewrite rule replacement string places the captured groups into the query string. The requested path of `/rewrite-rule/1234/5678` is rewritten to obtain the resource at `/rewritten?var1=1234&var2=5678`. If a query string is present on the original request, it's preserved when the URL is rewritten.

There's no round trip to the server to obtain the resource. If the resource exists, it's fetched and returned to the client with a *200 - OK* status code. Because the client isn't redirected, the URL in the browser's address bar doesn't change. Clients can't detect that a URL rewrite operation occurred on the server.

> **NOTE**
>
> Use `skipRemainingRules: true` whenever possible because matching rules is computationally expensive and increases app response time. For the fastest app response:
>
> - Order rewrite rules from the most frequently matched rule to the least frequently matched rule.
> - Skip the processing of the remaining rules when a match occurs and no additional rule processing is required.

Apache mod_rewrite

Apply Apache mod_rewrite rules with AddApacheModRewrite. Make sure that the rules file is deployed with the app. For more information and examples of mod_rewrite rules, see Apache mod_rewrite.

A StreamReader is used to read the rules from the *ApacheModRewrite.txt* rules file:

```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

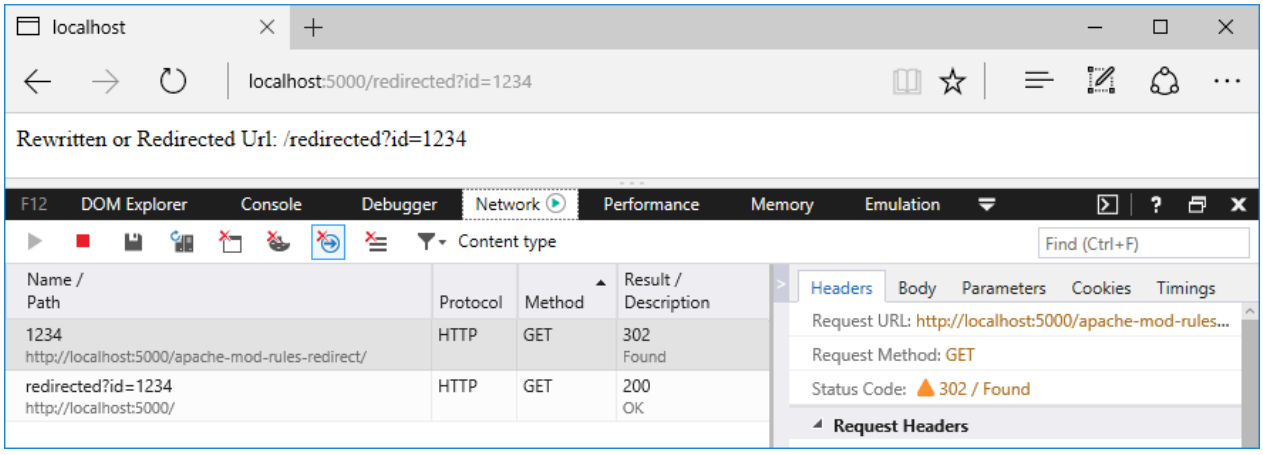
    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

The sample app redirects requests from `/apache-mod-rules-redirect/(.\*)` to `/redirected?id=$1`. The response status code is *302 - Found*.

```
# Rewrite path with additional sub directory
RewriteRule ^/apache-mod-rules-redirect/(.*) /redirected?id=$1 [L,R=302]
```

Original Request: `/apache-mod-rules-redirect/1234`



The middleware supports the following Apache mod_rewrite server variables:

- CONN_REMOTE_ADDR
- HTTP_ACCEPT
- HTTP_CONNECTION
- HTTP_COOKIE
- HTTP_FORWARDED
- HTTP_HOST
- HTTP_REFERER

- HTTP_USER_AGENT
- HTTPS
- IPV6
- QUERY_STRING
- REMOTE_ADDR
- REMOTE_PORT
- REQUEST_FILENAME
- REQUEST_METHOD
- REQUEST_SCHEME
- REQUEST_URI
- SCRIPT_FILENAME
- SERVER_ADDR
- SERVER_PORT
- SERVER_PROTOCOL
- TIME
- TIME_DAY
- TIME_HOUR
- TIME_MIN
- TIME_MON
- TIME_SEC
- TIME_WDAY
- TIME_YEAR

IIS URL Rewrite Module rules

To use the same rule set that applies to the IIS URL Rewrite Module, use AddIISUrlRewrite. Make sure that the rules file is deployed with the app. Don't direct the middleware to use the app's *web.config* file when running on Windows Server IIS. With IIS, these rules should be stored outside of the app's *web.config* file in order to avoid conflicts with the IIS Rewrite module. For more information and examples of IIS URL Rewrite Module rules, see Using Url Rewrite Module 2.0 and URL Rewrite Module Configuration Reference.

A StreamReader is used to read the rules from the *IISUrlRewrite.xml* rules file:

```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

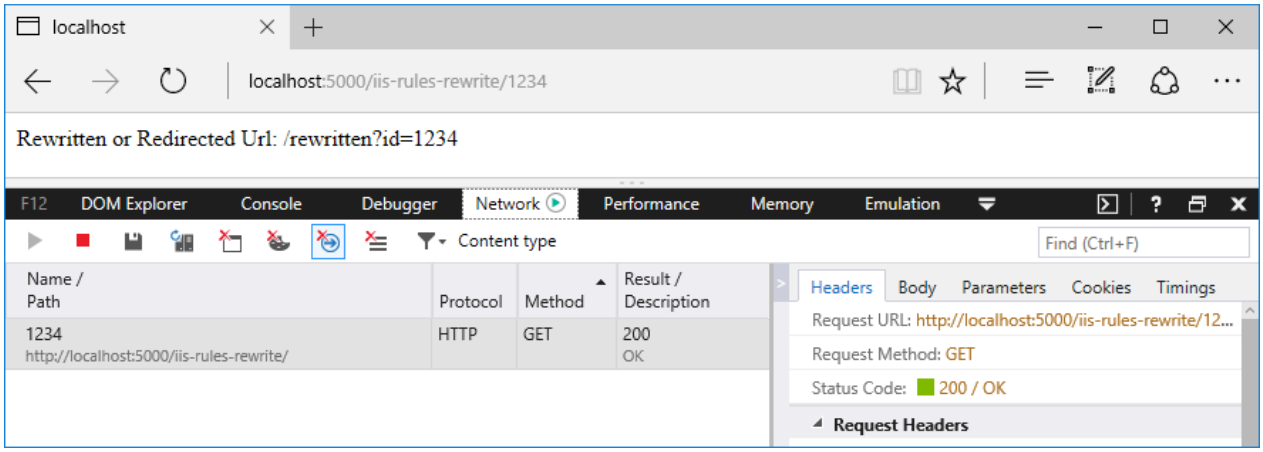
    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

The sample app rewrites requests from `/iis-rules-rewrite/(.*)` to `/rewritten?id=$1`. The response is sent to the client with a *200 - OK* status code.

```
<rewrite>
  <rules>
    <rule name="Rewrite segment to id querystring" stopProcessing="true">
      <match url="^iis-rules-rewrite/(.*)$" />
      <action type="Rewrite" url="rewritten?id={R:1}" appendQueryString="false"/>
    </rule>
  </rules>
</rewrite>
```

Original Request: `/iis-rules-rewrite/1234`



If you have an active IIS Rewrite Module with server-level rules configured that would impact your app in undesirable ways, you can disable the IIS Rewrite Module for an app. For more information, see Disabling IIS modules.

Unsupported features

The middleware released with ASP.NET Core 2.x doesn't support the following IIS URL Rewrite Module features:

- Outbound Rules
- Custom Server Variables
- Wildcards
- LogRewrittenUrl

Supported server variables

The middleware supports the following IIS URL Rewrite Module server variables:

- CONTENT_LENGTH
- CONTENT_TYPE
- HTTP_ACCEPT
- HTTP_CONNECTION
- HTTP_COOKIE
- HTTP_HOST
- HTTP_REFERER
- HTTP_URL
- HTTP_USER_AGENT
- HTTPS
- LOCAL_ADDR
- QUERY_STRING
- REMOTE_ADDR
- REMOTE_PORT
- REQUEST_FILENAME
- REQUEST_URI

> **NOTE**
>
> You can also obtain an IFileProvider via a PhysicalFileProvider. This approach may provide greater flexibility for the location of your rewrite rules files. Make sure that your rewrite rules files are deployed to the server at the path you provide.
>
> ```
> PhysicalFileProvider fileProvider = new PhysicalFileProvider(Directory.GetCurrentDirectory());
> ```

Method-based rule

Use Add to implement your own rule logic in a method. `Add` exposes the RewriteContext, which makes available the HttpContext for use in your method. The RewriteContext.Result determines how additional pipeline processing is handled. Set the value to one of the RuleResult fields described in the following table.

REWRITE CONTEXT RESULT	ACTION
`RuleResult.ContinueRules` (default)	Continue applying rules.
`RuleResult.EndResponse`	Stop applying rules and send the response.
`RuleResult.SkipRemainingRules`	Stop applying rules and send the context to the next middleware.

```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

The sample app demonstrates a method that redirects requests for paths that end with *.xml*. If a request is made for `/file.xml`, the request is redirected to `/xmlfiles/file.xml`. The status code is set to *301 - Moved Permanently*. When the browser makes a new request for */xmlfiles/file.xml*, Static File Middleware serves the file to the client from the *wwwroot/xmlfiles* folder. For a redirect, explicitly set the status code of the response. Otherwise, a *200 - OK* status code is returned, and the redirect doesn't occur on the client.

RewriteRules.cs:

```
public static void RedirectXmlFileRequests(RewriteContext context)
{
    var request = context.HttpContext.Request;

    // Because the client is redirecting back to the same app, stop
    // processing if the request has already been redirected.
    if (request.Path.StartsWithSegments(new PathString("/xmlfiles")))
    {
        return;
    }

    if (request.Path.Value.EndsWith(".xml", StringComparison.OrdinalIgnoreCase))
    {
        var response = context.HttpContext.Response;
        response.StatusCode = StatusCodes.Status301MovedPermanently;
        context.Result = RuleResult.EndResponse;
        response.Headers[HeaderNames.Location] =
            "/xmlfiles" + request.Path + request.QueryString;
    }
}
```

This approach can also rewrite requests. The sample app demonstrates rewriting the path for any text file request to serve the *file.txt* text file from the *wwwroot* folder. Static File Middleware serves the file based on the updated request path:

```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

RewriteRules.cs:

```
public static void RewriteTextFileRequests(RewriteContext context)
{
    var request = context.HttpContext.Request;

    if (request.Path.Value.EndsWith(".txt", StringComparison.OrdinalIgnoreCase))
    {
        context.Result = RuleResult.SkipRemainingRules;
        request.Path = "/file.txt";
    }
}
```

IRule-based rule

Use Add to use rule logic in a class that implements the IRule interface. `IRule` provides greater flexibility over using the method-based rule approach. Your implementation class may include a constructor that allows you can pass in parameters for the ApplyRule method.

```
public void Configure(IApplicationBuilder app)
{
    using (StreamReader apacheModRewriteStreamReader =
        File.OpenText("ApacheModRewrite.txt"))
    using (StreamReader iisUrlRewriteStreamReader =
        File.OpenText("IISUrlRewrite.xml"))
    {
        var options = new RewriteOptions()
            .AddRedirect("redirect-rule/(.*)", "redirected/$1")
            .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?var1=$1&var2=$2",
                skipRemainingRules: true)
            .AddApacheModRewrite(apacheModRewriteStreamReader)
            .AddIISUrlRewrite(iisUrlRewriteStreamReader)
            .Add(MethodRules.RedirectXmlFileRequests)
            .Add(MethodRules.RewriteTextFileRequests)
            .Add(new RedirectImageRequests(".png", "/png-images"))
            .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

        app.UseRewriter(options);
    }

    app.UseStaticFiles();

    app.Run(context => context.Response.WriteAsync(
        $"Rewritten or Redirected Url: " +
        $"{context.Request.Path + context.Request.QueryString}"));
}
```

The values of the parameters in the sample app for the `extension` and the `newPath` are checked to meet several conditions. The `extension` must contain a value, and the value must be *.png*, *.jpg*, or *.gif*. If the `newPath` isn't valid, an ArgumentException is thrown. If a request is made for *image.png*, the request is redirected to `/png-images/image.png`. If a request is made for *image.jpg*, the request is redirected to `/jpg-images/image.jpg`. The status code is set to *301 - Moved Permanently*, and the `context.Result` is set to stop processing rules and send the response.

```
public class RedirectImageRequests : IRule
{
    private readonly string _extension;
    private readonly PathString _newPath;

    public RedirectImageRequests(string extension, string newPath)
    {
        if (string.IsNullOrEmpty(extension))
        {
            throw new ArgumentException(nameof(extension));
        }

        if (!Regex.IsMatch(extension, @"^\.(png|jpg|gif)$"))
        {
            throw new ArgumentException("Invalid extension", nameof(extension));
        }

        if (!Regex.IsMatch(newPath, @"(/[A-Za-z0-9]+)+?"))
        {
            throw new ArgumentException("Invalid path", nameof(newPath));
        }

        _extension = extension;
        _newPath = new PathString(newPath);
    }

    public void ApplyRule(RewriteContext context)
    {
        var request = context.HttpContext.Request;

        // Because we're redirecting back to the same app, stop
        // processing if the request has already been redirected
        if (request.Path.StartsWithSegments(new PathString(_newPath)))
        {
            return;
        }

        if (request.Path.Value.EndsWith(_extension, StringComparison.OrdinalIgnoreCase))
        {
            var response = context.HttpContext.Response;
            response.StatusCode = StatusCodes.Status301MovedPermanently;
            context.Result = RuleResult.EndResponse;
            response.Headers[HeaderNames.Location] =
                _newPath + request.Path + request.QueryString;
        }
    }
}
```

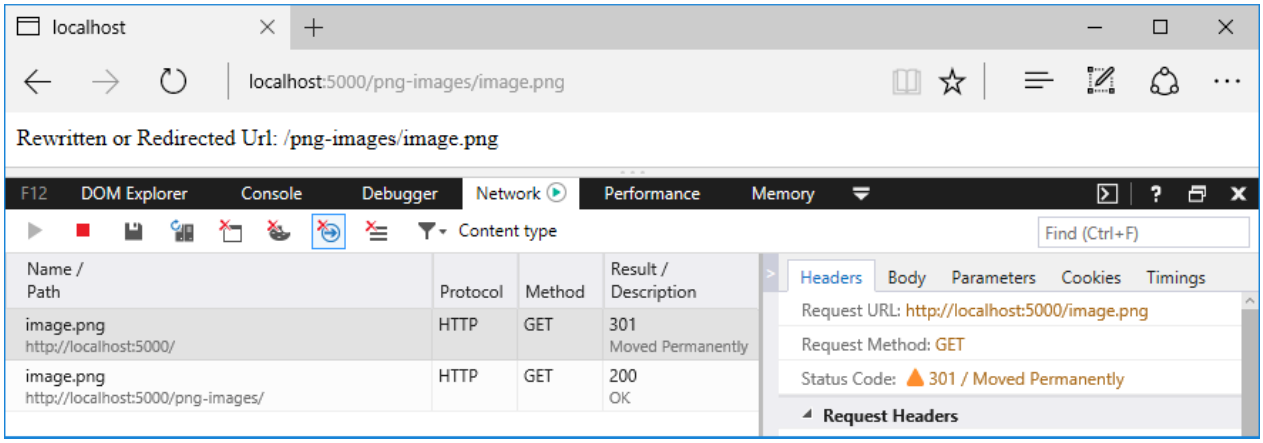
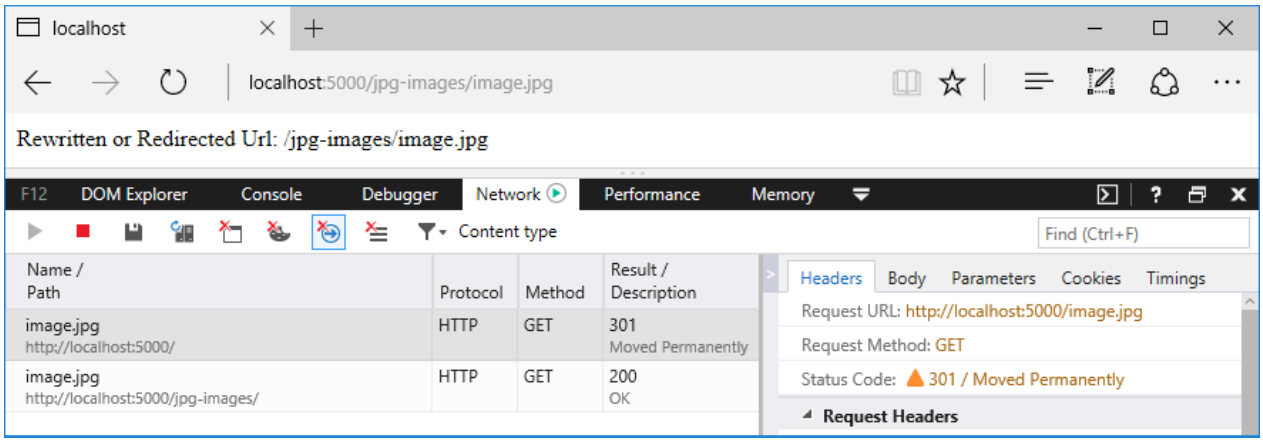
Original Request: `/image.png`



Original Request: `/image.jpg`



Regex examples

GOAL	REGEX STRING & MATCH EXAMPLE	REPLACEMENT STRING & OUTPUT EXAMPLE
Rewrite path into querystring	`^path/(.*)/(.*)` `/path/abc/123`	`path?var1=$1&var2=$2` `/path?var1=abc&var2=123`
Strip trailing slash	`(.*)/$` `/path/`	`$1` `/path`
Enforce trailing slash	`(.*[^/])$` `/path`	`$1/` `/path/`
Avoid rewriting specific requests	`^(.*)(?<!\.axd)$` or `^(?!.*\.axd$)(.*)$` Yes: `/resource.htm` No: `/resource.axd`	`rewritten/$1` `/rewritten/resource.htm` `/resource.axd`
Rearrange URL segments	`path/(.*)/(.*)/(.*)` `path/1/2/3`	`path/$3/$2/$1` `path/3/2/1`
Replace a URL segment	`^(.*)/segment2/(.*)` `/segment1/segment2/segment3`	`$1/replaced/$2` `/segment1/replaced/segment3`

File Providers in ASP.NET Core

9/22/2020 • 10 minutes to read • Edit Online

By Steve Smith

ASP.NET Core abstracts file system access through the use of File Providers. File Providers are used throughout the ASP.NET Core framework. For example:

- IWebHostEnvironment exposes the app's content root and web root as `IFileProvider` types.
- Static File Middleware uses File Providers to locate static files.
- Razor uses File Providers to locate pages and views.
- .NET Core tooling uses File Providers and glob patterns to specify which files should be published.

View or download sample code (how to download)

File Provider interfaces

The primary interface is IFileProvider. `IFileProvider` exposes methods to:

- Obtain file information (IFileInfo).
- Obtain directory information (IDirectoryContents).
- Set up change notifications (using an IChangeToken).

`IFileInfo` provides methods and properties for working with files:

- Exists
- IsDirectory
- Name
- Length (in bytes)
- LastModified date

You can read from the file using the IFileInfo.CreateReadStream method.

The *FileProviderSample* sample app demonstrates how to configure a File Provider in `Startup.ConfigureServices` for use throughout the app via dependency injection.

File Provider implementations

The following table lists implementations of `IFileProvider`.

IMPLEMENTATION	DESCRIPTION
CompositeFileProvider	Used to provide combined access to files and directories from one or more other providers.
ManifestEmbeddedFileProvider	Used to access files embedded in assemblies.
PhysicalFileProvider	Used to access the system's physical files.

PhysicalFileProvider

The PhysicalFileProvider provides access to the physical file system. `PhysicalFileProvider` uses the System.IO.File

type (for the physical provider) and scopes all paths to a directory and its children. This scoping prevents access to the file system outside of the specified directory and its children. The most common scenario for creating and using a `PhysicalFileProvider` is to request an `IFileProvider` in a constructor through dependency injection.

When instantiating this provider directly, an absolute directory path is required and serves as the base path for all requests made using the provider. Glob patterns aren't supported in the directory path.

The following code shows how to use `PhysicalFileProvider` to obtain directory contents and file information:

```
var provider = new PhysicalFileProvider(applicationRoot);
var contents = provider.GetDirectoryContents(string.Empty);
var filePath = Path.Combine("wwwroot", "js", "site.js");
var fileInfo = provider.GetFileInfo(filePath);
```

Types in the preceding example:

- `provider` is an `IFileProvider`.
- `contents` is an `IDirectoryContents`.
- `fileInfo` is an `IFileInfo`.

The File Provider can be used to iterate through the directory specified by `applicationRoot` or call `GetFileInfo` to obtain a file's information. Glob patterns can't be passed to the `GetFileInfo` method. The File Provider has no access outside of the `applicationRoot` directory.

The *FileProviderSample* sample app creates the provider in the `Startup.ConfigureServices` method using IHostingEnvironment.ContentRootFileProvider:

```
var physicalProvider = _env.ContentRootFileProvider;
```

ManifestEmbeddedFileProvider

The ManifestEmbeddedFileProvider is used to access files embedded within assemblies. The `ManifestEmbeddedFileProvider` uses a manifest compiled into the assembly to reconstruct the original paths of the embedded files.

To generate a manifest of the embedded files:

1. Add the Microsoft.Extensions.FileProviders.Embedded NuGet package to your project.
2. Set the `<GenerateEmbeddedFilesManifest>` property to `true`. Specify the files to embed with <EmbeddedResource>:

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.1</TargetFramework>
    <GenerateEmbeddedFilesManifest>true</GenerateEmbeddedFilesManifest>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.Extensions.FileProviders.Embedded" Version="3.1.0" />
  </ItemGroup>

  <ItemGroup>
    <EmbeddedResource Include="Resource.txt" />
  </ItemGroup>

</Project>
```

Use glob patterns to specify one or more files to embed into the assembly.

The *FileProviderSample* sample app creates an `ManifestEmbeddedFileProvider` and passes the currently executing assembly to its constructor.

Startup.cs:

```
var manifestEmbeddedProvider =
    new ManifestEmbeddedFileProvider(typeof(Program).Assembly);
```

Additional overloads allow you to:

- Specify a relative file path.
- Scope files to a last modified date.
- Name the embedded resource containing the embedded file manifest.

OVERLOAD	DESCRIPTION
`ManifestEmbeddedFileProvider(Assembly, String)`	Accepts an optional `root` relative path parameter. Specify the `root` to scope calls to GetDirectoryContents to those resources under the provided path.
`ManifestEmbeddedFileProvider(Assembly, String, DateTimeOffset)`	Accepts an optional `root` relative path parameter and a `lastModified` date (DateTimeOffset) parameter. The `lastModified` date scopes the last modification date for the IFileInfo instances returned by the IFileProvider.
`ManifestEmbeddedFileProvider(Assembly, String, String, DateTimeOffset)`	Accepts an optional `root` relative path, `lastModified` date, and `manifestName` parameters. The `manifestName` represents the name of the embedded resource containing the manifest.

CompositeFileProvider

The CompositeFileProvider combines `IFileProvider` instances, exposing a single interface for working with files from multiple providers. When creating the `CompositeFileProvider`, pass one or more `IFileProvider` instances to its constructor.

In the *FileProviderSample* sample app, a `PhysicalFileProvider` and a `ManifestEmbeddedFileProvider` provide files to a `CompositeFileProvider` registered in the app's service container. The following code is found in the project's `Startup.ConfigureServices` method:

```
var physicalProvider = _env.ContentRootFileProvider;
var manifestEmbeddedProvider =
    new ManifestEmbeddedFileProvider(typeof(Program).Assembly);
var compositeProvider =
    new CompositeFileProvider(physicalProvider, manifestEmbeddedProvider);

services.AddSingleton<IFileProvider>(compositeProvider);
```

Watch for changes

The IFileProvider.Watch method provides a scenario to watch one or more files or directories for changes. The `Watch` method:

- Accepts a file path string, which can use glob patterns to specify multiple files.

- Returns an IChangeToken.

The resulting change token exposes:

- HasChanged: A property that can be inspected to determine if a change has occurred.
- RegisterChangeCallback: Called when changes are detected to the specified path string. Each change token only calls its associated callback in response to a single change. To enable constant monitoring, use a TaskCompletionSource<TResult> (shown below) or recreate `IChangeToken` instances in response to changes.

The *WatchConsole* sample app writes a message whenever a *.txt* file in the *TextFiles* directory is modified:

```
private static readonly string _fileFilter = Path.Combine("TextFiles", "*.txt");

public static void Main(string[] args)
{
    Console.WriteLine($"Monitoring for changes with filter '{_fileFilter}' (Ctrl + C to quit)...");

    while (true)
    {
        MainAsync().GetAwaiter().GetResult();
    }
}

private static async Task MainAsync()
{
    var fileProvider = new PhysicalFileProvider(Directory.GetCurrentDirectory());
    IChangeToken token = fileProvider.Watch(_fileFilter);
    var tcs = new TaskCompletionSource<object>();

    token.RegisterChangeCallback(state =>
        ((TaskCompletionSource<object>)state).TrySetResult(null), tcs);

    await tcs.Task.ConfigureAwait(false);

    Console.WriteLine("file changed");
}
```

Some file systems, such as Docker containers and network shares, may not reliably send change notifications. Set the `DOTNET_USE_POLLING_FILE_WATCHER` environment variable to `1` or `true` to poll the file system for changes every four seconds (not configurable).

Glob patterns

File system paths use wildcard patterns called *glob (or globbing) patterns*. Specify groups of files with these patterns. The two wildcard characters are `*` and `**`:

`*`
Matches anything at the current folder level, any filename, or any file extension. Matches are terminated by `/` and `.` characters in the file path.

`**`
Matches anything across multiple directory levels. Can be used to recursively match many files within a directory hierarchy.

The following table provides common examples of glob patterns.

PATTERN	DESCRIPTION
`directory/file.txt`	Matches a specific file in a specific directory.

PATTERN	DESCRIPTION
`directory/*.txt`	Matches all files with *.txt* extension in a specific directory.
`directory/*/appsettings.json`	Matches all *appsettings.json* files in directories exactly one level below the *directory* folder.
`directory/**/*.txt`	Matches all files with a *.txt* extension found anywhere under the *directory* folder.

ASP.NET Core abstracts file system access through the use of File Providers. File Providers are used throughout the ASP.NET Core framework:

- IHostingEnvironment exposes the app's content root and web root as `IFileProvider` types.
- Static File Middleware uses File Providers to locate static files.
- Razor uses File Providers to locate pages and views.
- .NET Core tooling uses File Providers and glob patterns to specify which files should be published.

View or download sample code (how to download)

File Provider interfaces

The primary interface is IFileProvider. `IFileProvider` exposes methods to:

- Obtain file information (IFileInfo).
- Obtain directory information (IDirectoryContents).
- Set up change notifications (using an IChangeToken).

`IFileInfo` provides methods and properties for working with files:

- Exists
- IsDirectory
- Name
- Length (in bytes)
- LastModified date

You can read from the file using the IFileInfo.CreateReadStream method.

The sample app demonstrates how to configure a File Provider in `Startup.ConfigureServices` for use throughout the app via dependency injection.

File Provider implementations

Three implementations of `IFileProvider` are available.

IMPLEMENTATION	DESCRIPTION
PhysicalFileProvider	The physical provider is used to access the system's physical files.
ManifestEmbeddedFileProvider	The manifest embedded provider is used to access files embedded in assemblies.

IMPLEMENTATION	DESCRIPTION
CompositeFileProvider	The composite provider is used to provide combined access to files and directories from one or more other providers.

PhysicalFileProvider

The PhysicalFileProvider provides access to the physical file system. `PhysicalFileProvider` uses the System.IO.File type (for the physical provider) and scopes all paths to a directory and its children. This scoping prevents access to the file system outside of the specified directory and its children. The most common scenario for creating and using a `PhysicalFileProvider` is to request an `IFileProvider` in a constructor through dependency injection.

When instantiating this provider directly, a directory path is required and serves as the base path for all requests made using the provider.

The following code shows how to create a `PhysicalFileProvider` and use it to obtain directory contents and file information:

```
var provider = new PhysicalFileProvider(applicationRoot);
var contents = provider.GetDirectoryContents(string.Empty);
var fileInfo = provider.GetFileInfo("wwwroot/js/site.js");
```

Types in the preceding example:

- `provider` is an `IFileProvider`.
- `contents` is an `IDirectoryContents`.
- `fileInfo` is an `IFileInfo`.

The File Provider can be used to iterate through the directory specified by `applicationRoot` or call `GetFileInfo` to obtain a file's information. The File Provider has no access outside of the `applicationRoot` directory.

The sample app creates the provider in the app's `Startup.ConfigureServices` class using IHostingEnvironment.ContentRootFileProvider:

```
var physicalProvider = _env.ContentRootFileProvider;
```

ManifestEmbeddedFileProvider

The ManifestEmbeddedFileProvider is used to access files embedded within assemblies. The `ManifestEmbeddedFileProvider` uses a manifest compiled into the assembly to reconstruct the original paths of the embedded files.

To generate a manifest of the embedded files, set the `<GenerateEmbeddedFilesManifest>` property to `true`. Specify the files to embed with <EmbeddedResource>:

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp2.2</TargetFramework>
    <AspNetCoreHostingModel>InProcess</AspNetCoreHostingModel>
    <GenerateEmbeddedFilesManifest>true</GenerateEmbeddedFilesManifest>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

  <ItemGroup>
    <EmbeddedResource Include="Resource.txt" />
  </ItemGroup>

</Project>
```

Use glob patterns to specify one or more files to embed into the assembly.

The sample app creates an `ManifestEmbeddedFileProvider` and passes the currently executing assembly to its constructor.

Startup.cs:

```
var manifestEmbeddedProvider =
    new ManifestEmbeddedFileProvider(typeof(Program).Assembly);
```

Additional overloads allow you to:

- Specify a relative file path.
- Scope files to a last modified date.
- Name the embedded resource containing the embedded file manifest.

OVERLOAD	DESCRIPTION
`ManifestEmbeddedFileProvider(Assembly, String)`	Accepts an optional `root` relative path parameter. Specify the `root` to scope calls to GetDirectoryContents to those resources under the provided path.
`ManifestEmbeddedFileProvider(Assembly, String, DateTimeOffset)`	Accepts an optional `root` relative path parameter and a `lastModified` date (DateTimeOffset) parameter. The `lastModified` date scopes the last modification date for the IFileInfo instances returned by the IFileProvider.
`ManifestEmbeddedFileProvider(Assembly, String, String, DateTimeOffset)`	Accepts an optional `root` relative path, `lastModified` date, and `manifestName` parameters. The `manifestName` represents the name of the embedded resource containing the manifest.

CompositeFileProvider

The CompositeFileProvider combines `IFileProvider` instances, exposing a single interface for working with files from multiple providers. When creating the `CompositeFileProvider`, pass one or more `IFileProvider` instances to its constructor.

In the sample app, a `PhysicalFileProvider` and a `ManifestEmbeddedFileProvider` provide files to a `CompositeFileProvider` registered in the app's service container:

```
var physicalProvider = _env.ContentRootFileProvider;
var manifestEmbeddedProvider =
    new ManifestEmbeddedFileProvider(typeof(Program).Assembly);
var compositeProvider =
    new CompositeFileProvider(physicalProvider, manifestEmbeddedProvider);

services.AddSingleton<IFileProvider>(compositeProvider);
```

Watch for changes

The IFileProvider.Watch method provides a scenario to watch one or more files or directories for changes. `Watch` accepts a path string, which can use glob patterns to specify multiple files. `Watch` returns an IChangeToken. The change token exposes:

- HasChanged: A property that can be inspected to determine if a change has occurred.
- RegisterChangeCallback: Called when changes are detected to the specified path string. Each change token only calls its associated callback in response to a single change. To enable constant monitoring, use a TaskCompletionSource<TResult> (shown below) or recreate `IChangeToken` instances in response to changes.

In the sample app, the *WatchConsole* console app is configured to display a message whenever a text file is modified:

```
private static PhysicalFileProvider _fileProvider =
    new PhysicalFileProvider(Directory.GetCurrentDirectory());

public static void Main(string[] args)
{
    Console.WriteLine("Monitoring quotes.txt for changes (Ctrl-c to quit)...");

    while (true)
    {
        MainAsync().GetAwaiter().GetResult();
    }
}

private static async Task MainAsync()
{
    IChangeToken token = _fileProvider.Watch("quotes.txt");
    var tcs = new TaskCompletionSource<object>();

    token.RegisterChangeCallback(state =>
        ((TaskCompletionSource<object>)state).TrySetResult(null), tcs);

    await tcs.Task.ConfigureAwait(false);

    Console.WriteLine("quotes.txt changed");
}
```

Some file systems, such as Docker containers and network shares, may not reliably send change notifications. Set the `DOTNET_USE_POLLING_FILE_WATCHER` environment variable to `1` or `true` to poll the file system for changes every four seconds (not configurable).

Glob patterns

File system paths use wildcard patterns called *glob (or globbing) patterns*. Specify groups of files with these patterns. The two wildcard characters are `*` and `**`:

`*`

Matches anything at the current folder level, any filename, or any file extension. Matches are terminated by `/` and

`.` characters in the file path.

`**`
Matches anything across multiple directory levels. Can be used to recursively match many files within a directory hierarchy.

Glob pattern examples

`directory/file.txt`
Matches a specific file in a specific directory.

`directory/*.txt`
Matches all files with *.txt* extension in a specific directory.

`directory/*/appsettings.json`
Matches all `appsettings.json` files in directories exactly one level below the *directory* folder.

`directory/**/*.txt`
Matches all files with *.txt* extension found anywhere under the *directory* folder.

Request Features in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

By Steve Smith

Web server implementation details related to HTTP requests and responses are defined in interfaces. These interfaces are used by server implementations and middleware to create and modify the application's hosting pipeline.

Feature interfaces

ASP.NET Core defines a number of HTTP feature interfaces in `Microsoft.AspNetCore.Http.Features` which are used by servers to identify the features they support. The following feature interfaces handle requests and return responses:

`IHttpRequestFeature` Defines the structure of an HTTP request, including the protocol, path, query string, headers, and body.

`IHttpResponseFeature` Defines the structure of an HTTP response, including the status code, headers, and body of the response.

`IHttpAuthenticationFeature` Defines support for identifying users based on a `ClaimsPrincipal` and specifying an authentication handler.

`IHttpUpgradeFeature` Defines support for HTTP Upgrades, which allow the client to specify which additional protocols it would like to use if the server wishes to switch protocols.

`IHttpBufferingFeature` Defines methods for disabling buffering of requests and/or responses.

`IHttpConnectionFeature` Defines properties for local and remote addresses and ports.

`IHttpRequestLifetimeFeature` Defines support for aborting connections, or detecting if a request has been terminated prematurely, such as by a client disconnect.

`IHttpSendFileFeature` Defines a method for sending files asynchronously.

`IHttpWebSocketFeature` Defines an API for supporting web sockets.

`IHttpRequestIdentifierFeature` Adds a property that can be implemented to uniquely identify requests.

`ISessionFeature` Defines `ISessionFactory` and `ISession` abstractions for supporting user sessions.

`ITlsConnectionFeature` Defines an API for retrieving client certificates.

`ITlsTokenBindingFeature` Defines methods for working with TLS token binding parameters.

> **NOTE**
>
> `ISessionFeature` isn't a server feature, but is implemented by the `SessionMiddleware` (see Managing Application State).

Feature collections

The `Features` property of `HttpContext` provides an interface for getting and setting the available HTTP features

for the current request. Since the feature collection is mutable even within the context of a request, middleware can be used to modify the collection and add support for additional features.

Middleware and request features

While servers are responsible for creating the feature collection, middleware can both add to this collection and consume features from the collection. For example, the `StaticFileMiddleware` accesses the `IHttpSendFileFeature` feature. If the feature exists, it's used to send the requested static file from its physical path. Otherwise, a slower alternative method is used to send the file. When available, the `IHttpSendFileFeature` allows the operating system to open the file and perform a direct kernel mode copy to the network card.

Additionally, middleware can add to the feature collection established by the server. Existing features can even be replaced by middleware, allowing the middleware to augment the functionality of the server. Features added to the collection are available immediately to other middleware or the underlying application itself later in the request pipeline.

By combining custom server implementations and specific middleware enhancements, the precise set of features an application requires can be constructed. This allows missing features to be added without requiring a change in server, and ensures only the minimal amount of features are exposed, thus limiting attack surface area and improving performance.

Summary

Feature interfaces define specific HTTP features that a given request may support. Servers define collections of features, and the initial set of features supported by that server, but middleware can be used to enhance these features.

Access HttpContext in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

ASP.NET Core apps access `HttpContext` through the IHttpContextAccessor interface and its default implementation HttpContextAccessor. It's only necessary to use `IHttpContextAccessor` when you need access to the `HttpContext` inside a service.

Use HttpContext from Razor Pages

The Razor Pages PageModel exposes the HttpContext property:

```
public class AboutModel : PageModel
{
    public string Message { get; set; }

    public void OnGet()
    {
        Message = HttpContext.Request.PathBase;
    }
}
```

Use HttpContext from a Razor view

Razor views expose the `HttpContext` directly via a RazorPage.Context property on the view. The following example retrieves the current username in an intranet app using Windows Authentication:

```
@{
    var username = Context.User.Identity.Name;

    ...
}
```

Use HttpContext from a controller

Controllers expose the ControllerBase.HttpContext property:

```
public class HomeController : Controller
{
    public IActionResult About()
    {
        var pathBase = HttpContext.Request.PathBase;

        ...

        return View();
    }
}
```

Use HttpContext from middleware

When working with custom middleware components, `HttpContext` is passed into the `Invoke` or `InvokeAsync` method and can be accessed when the middleware is configured:

```
public class MyCustomMiddleware
{
    public Task InvokeAsync(HttpContext context)
    {
        ...
    }
}
```

Use HttpContext from custom components

For other framework and custom components that require access to `HttpContext`, the recommended approach is to register a dependency using the built-in dependency injection container. The dependency injection container supplies the `IHttpContextAccessor` to any classes that declare it as a dependency in their constructors:

```
public void ConfigureServices(IServiceCollection services)
{
     services.AddControllersWithViews();
     services.AddHttpContextAccessor();
     services.AddTransient<IUserRepository, UserRepository>();
}
```

```
public void ConfigureServices(IServiceCollection services)
{
     services.AddMvc()
         .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
     services.AddHttpContextAccessor();
     services.AddTransient<IUserRepository, UserRepository>();
}
```

In the following example:

- `UserRepository` declares its dependency on `IHttpContextAccessor`.
- The dependency is supplied when dependency injection resolves the dependency chain and creates an instance of `UserRepository`.

```
public class UserRepository : IUserRepository
{
    private readonly IHttpContextAccessor _httpContextAccessor;

    public UserRepository(IHttpContextAccessor httpContextAccessor)
    {
        _httpContextAccessor = httpContextAccessor;
    }

    public void LogCurrentUser()
    {
        var username = _httpContextAccessor.HttpContext.User.Identity.Name;
        service.LogAccessRequest(username);
    }
}
```

HttpContext access from a background thread

`HttpContext` isn't thread-safe. Reading or writing properties of the `HttpContext` outside of processing a request can result in a NullReferenceException.

> **NOTE**
>
> If your app generates sporadic `NullReferenceException` errors, review parts of the code that start background processing or that continue processing after a request completes. Look for mistakes, such as defining a controller method as `async void`.

To safely perform background work with `HttpContext` data:

- Copy the required data during request processing.
- Pass the copied data to a background task.

To avoid unsafe code, never pass the `HttpContext` into a method that performs background work. Pass the required data instead. In the following example, `SendEmailCore` is called to start sending an email. The `correlationId` is passed to `SendEmailCore`, not the `HttpContext`. Code execution doesn't wait for `SendEmailCore` to complete:

```
public class EmailController : Controller
{
    public IActionResult SendEmail(string email)
    {
        var correlationId = HttpContext.Request.Headers["x-correlation-id"].ToString();

        _ = SendEmailCore(correlationId);

        return View();
    }

    private async Task SendEmailCore(string correlationId)
    {
        ...
    }
}
```

Blazor and shared state

Blazor server apps live in server memory. That means that there are multiple apps hosted within the same process. For each app session, Blazor starts a circuit with its own DI container scope. That means that scoped services are unique per Blazor session.

> **WARNING**
>
> We don't recommend apps on the same server share state using singleton services unless extreme care is taken, as this can introduce security vulnerabilities, such as leaking user state across circuits.

You can use stateful singleton services in Blazor apps if they are specifically designed for it. For example, it's ok to use a memory cache as a singleton because it requires a key to access a given entry, assuming users don't have control of what cache keys are used.

Additionally, again for security reasons, you must not use IHttpContextAccessor within Blazor apps. Blazor apps run outside of the context of the ASP.NET Core pipeline. The HttpContext isn't guaranteed to be available within the IHttpContextAccessor, nor is it guaranteed to be holding the context that started the Blazor app.

The recommended way to pass request state to the Blazor app is through parameters to the root component in the initial rendering of the app:

- Define a class with all the data you want to pass to the Blazor app.

- Populate that data from the Razor page using the HttpContext available at that time.
- Pass the data to the Blazor app as a parameter to the root component (App).
- Define a parameter in the root component to hold the data being passed to the app.
- Use the user-specific data within the app; or alternatively, copy that data into a scoped service within OnInitializedAsync so that it can be used across the app.

For more information and example code, see ASP.NET Core Blazor Server additional security scenarios.

Detect changes with change tokens in ASP.NET Core

9/22/2020 • 17 minutes to read • Edit Online

A *change token* is a general-purpose, low-level building block used to track state changes.

View or download sample code (how to download)

IChangeToken interface

IChangeToken propagates notifications that a change has occurred. `IChangeToken` resides in the Microsoft.Extensions.Primitives namespace. The Microsoft.Extensions.Primitives NuGet package is implicitly provided to the ASP.NET Core apps.

`IChangeToken` has two properties:

- ActiveChangeCallbacks indicate if the token proactively raises callbacks. If `ActiveChangedCallbacks` is set to `false`, a callback is never called, and the app must poll `HasChanged` for changes. It's also possible for a token to never be cancelled if no changes occur or the underlying change listener is disposed or disabled.
- HasChanged receives a value that indicates if a change has occurred.

The `IChangeToken` interface includes the RegisterChangeCallback(Action<Object>, Object) method, which registers a callback that's invoked when the token has changed. `HasChanged` must be set before the callback is invoked.

ChangeToken class

ChangeToken is a static class used to propagate notifications that a change has occurred. `ChangeToken` resides in the Microsoft.Extensions.Primitives namespace. The Microsoft.Extensions.Primitives NuGet package is implicitly provided to the ASP.NET Core apps.

The ChangeToken.OnChange(Func<IChangeToken>, Action) method registers an `Action` to call whenever the token changes:

- `Func<IChangeToken>` produces the token.
- `Action` is called when the token changes.

The ChangeToken.OnChange<TState>(Func<IChangeToken>, Action<TState>, TState) overload takes an additional `TState` parameter that's passed into the token consumer `Action`.

`OnChange` returns an IDisposable. Calling Dispose stops the token from listening for further changes and releases the token's resources.

Example uses of change tokens in ASP.NET Core

Change tokens are used in prominent areas of ASP.NET Core to monitor for changes to objects:

- For monitoring changes to files, IFileProvider's Watch method creates an `IChangeToken` for the specified files or folder to watch.
- `IChangeToken` tokens can be added to cache entries to trigger cache evictions on change.
- For `TOptions` changes, the default OptionsMonitor<TOptions> implementation of IOptionsMonitor<TOptions> has an overload that accepts one or more IOptionsChangeTokenSource<TOptions> instances. Each instance returns an `IChangeToken` to register a

change notification callback for tracking options changes.

Monitor for configuration changes

By default, ASP.NET Core templates use JSON configuration files (*appsettings.json*, *appsettings.Development.json*, and *appsettings.Production.json*) to load app configuration settings.

These files are configured using the AddJsonFile(IConfigurationBuilder, String, Boolean, Boolean) extension method on ConfigurationBuilder that accepts a `reloadOnChange` parameter. `reloadOnChange` indicates if configuration should be reloaded on file changes. This setting appears in the Host convenience method CreateDefaultBuilder:

```
config.AddJsonFile("appsettings.json", optional: true, reloadOnChange: true)
      .AddJsonFile($"appsettings.{env.EnvironmentName}.json", optional: true,
          reloadOnChange: true);
```

File-based configuration is represented by FileConfigurationSource. `FileConfigurationSource` uses IFileProvider to monitor files.

By default, the `IFileMonitor` is provided by a PhysicalFileProvider, which uses FileSystemWatcher to monitor for configuration file changes.

The sample app demonstrates two implementations for monitoring configuration changes. If any of the *appsettings* files change, both of the file monitoring implementations execute custom code—the sample app writes a message to the console.

A configuration file's `FileSystemWatcher` can trigger multiple token callbacks for a single configuration file change. To ensure that the custom code is only run once when multiple token callbacks are triggered, the sample's implementation checks file hashes. The sample uses SHA1 file hashing. A retry is implemented with an exponential back-off. The retry is present because file locking may occur that temporarily prevents computing a new hash on a file.

Utilities/Utilities.cs:

```
public static byte[] ComputeHash(string filePath)
{
    var runCount = 1;

    while(runCount < 4)
    {
        try
        {
            if (File.Exists(filePath))
            {
                using (var fs = File.OpenRead(filePath))
                {
                    return System.Security.Cryptography.SHA1
                        .Create().ComputeHash(fs);
                }
            }
            else
            {
                throw new FileNotFoundException();
            }
        }
        catch (IOException ex)
        {
            if (runCount == 3 || ex.HResult != -2147024864)
            {
                throw;
            }
            else
            {
                Thread.Sleep(TimeSpan.FromSeconds(Math.Pow(2, runCount)));
                runCount++;
            }
        }
    }

    return new byte[20];
}
```

Simple startup change token

Register a token consumer `Action` callback for change notifications to the configuration reload token.

In `Startup.Configure`:

```
ChangeToken.OnChange(
    () => config.GetReloadToken(),
    (state) => InvokeChanged(state),
    env);
```

`config.GetReloadToken()` provides the token. The callback is the `InvokeChanged` method:

```
private void InvokeChanged(IWebHostEnvironment env)
{
    byte[] appsettingsHash = ComputeHash("appSettings.json");
    byte[] appsettingsEnvHash =
        ComputeHash($"appSettings.{env.EnvironmentName}.json");

    if (!_appsettingsHash.SequenceEqual(appsettingsHash) ||
        !_appsettingsEnvHash.SequenceEqual(appsettingsEnvHash))
    {
        _appsettingsHash = appsettingsHash;
        _appsettingsEnvHash = appsettingsEnvHash;

        WriteConsole("Configuration changed (Simple Startup Change Token)");
    }
}
```

The `state` of the callback is used to pass in the `IWebHostEnvironment`, which is useful for specifying the correct *appsettings* configuration file to monitor (for example, *appsettings.Development.json* when in the Development environment). File hashes are used to prevent the `WriteConsole` statement from running multiple times due to multiple token callbacks when the configuration file has only changed once.

This system runs as long as the app is running and can't be disabled by the user.

Monitor configuration changes as a service

The sample implements:

- Basic startup token monitoring.
- Monitoring as a service.
- A mechanism to enable and disable monitoring.

The sample establishes an `IConfigurationMonitor` interface.

Extensions/ConfigurationMonitor.cs:

```
public interface IConfigurationMonitor
{
    bool MonitoringEnabled { get; set; }
    string CurrentState { get; set; }
}
```

The constructor of the implemented class, `ConfigurationMonitor`, registers a callback for change notifications:

```
public ConfigurationMonitor(IConfiguration config, IWebHostEnvironment env)
{
    _env = env;

    ChangeToken.OnChange<IConfigurationMonitor>(
        () => config.GetReloadToken(),
        InvokeChanged,
        this);
}

public bool MonitoringEnabled { get; set; } = false;
public string CurrentState { get; set; } = "Not monitoring";
```

`config.GetReloadToken()` supplies the token. `InvokeChanged` is the callback method. The `state` in this instance is a reference to the `IConfigurationMonitor` instance that's used to access the monitoring state. Two properties are used:

- `MonitoringEnabled`: Indicates if the callback should run its custom code.
- `CurrentState`: Describes the current monitoring state for use in the UI.

The `InvokeChanged` method is similar to the earlier approach, except that it:

- Doesn't run its code unless `MonitoringEnabled` is `true`.
- Outputs the current `state` in its `WriteConsole` output.

```
private void InvokeChanged(IConfigurationMonitor state)
{
    if (MonitoringEnabled)
    {
        byte[] appsettingsHash = ComputeHash("appSettings.json");
        byte[] appsettingsEnvHash =
            ComputeHash($"appSettings.{_env.EnvironmentName}.json");

        if (!_appsettingsHash.SequenceEqual(appsettingsHash) ||
            !_appsettingsEnvHash.SequenceEqual(appsettingsEnvHash))
        {
            string message = $"State updated at {DateTime.Now}";

            _appsettingsHash = appsettingsHash;
            _appsettingsEnvHash = appsettingsEnvHash;

            WriteConsole("Configuration changed (ConfigurationMonitor Class) " +
                $"{message}, state:{state.CurrentState}");
        }
    }
}
```

An instance `ConfigurationMonitor` is registered as a service in `Startup.ConfigureServices`:

```
services.AddSingleton<IConfigurationMonitor, ConfigurationMonitor>();
```

The Index page offers the user control over configuration monitoring. The instance of `IConfigurationMonitor` is injected into the `IndexModel`.

Pages/Index.cshtml.cs:

```
public IndexModel(
    IConfiguration config,
    IConfigurationMonitor monitor,
    FileService fileService)
{
    _config = config;
    _monitor = monitor;
    _fileService = fileService;
}
```

The configuration monitor (`_monitor`) is used to enable or disable monitoring and set the current state for UI feedback:

```
public IActionResult OnPostStartMonitoring()
{
    _monitor.MonitoringEnabled = true;
    _monitor.CurrentState = "Monitoring!";

    return RedirectToPage();
}

public IActionResult OnPostStopMonitoring()
{
    _monitor.MonitoringEnabled = false;
    _monitor.CurrentState = "Not monitoring";

    return RedirectToPage();
}
```

When `OnPostStartMonitoring` is triggered, monitoring is enabled, and the current state is cleared. When `OnPostStopMonitoring` is triggered, monitoring is disabled, and the state is set to reflect that monitoring isn't occurring.

Buttons in the UI enable and disable monitoring.

Pages/Index.cshtml:

```
<button class="btn btn-success" asp-page-handler="StartMonitoring">
    Start Monitoring
</button>

<button class="btn btn-danger" asp-page-handler="StopMonitoring">
    Stop Monitoring
</button>
```

Monitor cached file changes

File content can be cached in-memory using IMemoryCache. In-memory caching is described in the Cache in-memory topic. Without taking additional steps, such as the implementation described below, *stale* (outdated) data is returned from a cache if the source data changes.

For example, not taking into account the status of a cached source file when renewing a sliding expiration period leads to stale cached file data. Each request for the data renews the sliding expiration period, but the file is never reloaded into the cache. Any app features that use the file's cached content are subject to possibly receiving stale content.

Using change tokens in a file caching scenario prevents the presence of stale file content in the cache. The sample app demonstrates an implementation of the approach.

The sample uses `GetFileContent` to:

- Return file content.
- Implement a retry algorithm with exponential back-off to cover cases where a file lock temporarily prevents reading a file.

Utilities/Utilities.cs:

```
public async static Task<string> GetFileContent(string filePath)
{
    var runCount = 1;

    while(runCount < 4)
    {
        try
        {
            if (File.Exists(filePath))
            {
                using (var fileStreamReader = File.OpenText(filePath))
                {
                    return await fileStreamReader.ReadToEndAsync();
                }
            }
            else
            {
                throw new FileNotFoundException();
            }
        }
        catch (IOException ex)
        {
            if (runCount == 3 || ex.HResult != -2147024864)
            {
                throw;
            }
            else
            {
                await Task.Delay(TimeSpan.FromSeconds(Math.Pow(2, runCount)));
                runCount++;
            }
        }
    }

    return null;
}
```

A `FileService` is created to handle cached file lookups. The `GetFileContent` method call of the service attempts to obtain file content from the in-memory cache and return it to the caller (*Services/FileService.cs*).

If cached content isn't found using the cache key, the following actions are taken:

1. The file content is obtained using `GetFileContent`.
2. A change token is obtained from the file provider with IFileProviders.Watch. The token's callback is triggered when the file is modified.
3. The file content is cached with a sliding expiration period. The change token is attached with MemoryCacheEntryExtensions.AddExpirationToken to evict the cache entry if the file changes while it's cached.

In the following example, files are stored in the app's content root. `IWebHostEnvironment.ContentRootFileProvider` is used to obtain an IFileProvider pointing at the app's `IWebHostEnvironment.ContentRootPath`. The `filePath` is obtained with IFileInfo.PhysicalPath.

```
public class FileService
{
    private readonly IMemoryCache _cache;
    private readonly IFileProvider _fileProvider;
    private List<string> _tokens = new List<string>();

    public FileService(IMemoryCache cache, IWebHostEnvironment env)
    {
        _cache = cache;
        _fileProvider = env.ContentRootFileProvider;
    }

    public async Task<string> GetFileContents(string fileName)
    {
        var filePath = _fileProvider.GetFileInfo(fileName).PhysicalPath;
        string fileContent;

        // Try to obtain the file contents from the cache.
        if (_cache.TryGetValue(filePath, out fileContent))
        {
            return fileContent;
        }

        // The cache doesn't have the entry, so obtain the file
        // contents from the file itself.
        fileContent = await GetFileContent(filePath);

        if (fileContent != null)
        {
            // Obtain a change token from the file provider whose
            // callback is triggered when the file is modified.
            var changeToken = _fileProvider.Watch(fileName);

            // Configure the cache entry options for a five minute
            // sliding expiration and use the change token to
            // expire the file in the cache if the file is
            // modified.
            var cacheEntryOptions = new MemoryCacheEntryOptions()
                .SetSlidingExpiration(TimeSpan.FromMinutes(5))
                .AddExpirationToken(changeToken);

            // Put the file contents into the cache.
            _cache.Set(filePath, fileContent, cacheEntryOptions);

            return fileContent;
        }

        return string.Empty;
    }
}
```

The `FileService` is registered in the service container along with the memory caching service.

In `Startup.ConfigureServices`:

```
services.AddMemoryCache();
services.AddSingleton<FileService>();
```

The page model loads the file's content using the service.

In the Index page's `OnGet` method (*Pages/Index.cshtml.cs*):

```
var fileContent = await _fileService.GetFileContents("poem.txt");
```

CompositeChangeToken class

For representing one or more `IChangeToken` instances in a single object, use the CompositeChangeToken class.

```
var firstCancellationTokenSource = new CancellationTokenSource();
var secondCancellationTokenSource = new CancellationTokenSource();

var firstCancellationToken = firstCancellationTokenSource.Token;
var secondCancellationToken = secondCancellationTokenSource.Token;

var firstCancellationChangeToken = new CancellationChangeToken(firstCancellationToken);
var secondCancellationChangeToken = new CancellationChangeToken(secondCancellationToken);

var compositeChangeToken =
    new CompositeChangeToken(
        new List<IChangeToken>
        {
            firstCancellationChangeToken,
            secondCancellationChangeToken
        });
```

`HasChanged` on the composite token reports `true` if any represented token `HasChanged` is `true`. `ActiveChangeCallbacks` on the composite token reports `true` if any represented token `ActiveChangeCallbacks` is `true`. If multiple concurrent change events occur, the composite change callback is invoked one time.

A *change token* is a general-purpose, low-level building block used to track state changes.

View or download sample code (how to download)

IChangeToken interface

IChangeToken propagates notifications that a change has occurred. `IChangeToken` resides in the Microsoft.Extensions.Primitives namespace. For apps that don't use the Microsoft.AspNetCore.App metapackage, create a package reference for the Microsoft.Extensions.Primitives NuGet package.

`IChangeToken` has two properties:

- ActiveChangeCallbacks indicate if the token proactively raises callbacks. If `ActiveChangedCallbacks` is set to `false`, a callback is never called, and the app must poll `HasChanged` for changes. It's also possible for a token to never be cancelled if no changes occur or the underlying change listener is disposed or disabled.
- HasChanged receives a value that indicates if a change has occurred.

The `IChangeToken` interface includes the RegisterChangeCallback(Action<Object>, Object) method, which registers a callback that's invoked when the token has changed. `HasChanged` must be set before the callback is invoked.

ChangeToken class

ChangeToken is a static class used to propagate notifications that a change has occurred. `ChangeToken` resides in the Microsoft.Extensions.Primitives namespace. For apps that don't use the Microsoft.AspNetCore.App metapackage, create a package reference for the Microsoft.Extensions.Primitives NuGet package.

The ChangeToken.OnChange(Func<IChangeToken>, Action) method registers an `Action` to call whenever the token changes:

- `Func<IChangeToken>` produces the token.
- `Action` is called when the token changes.

The ChangeToken.OnChange<TState>(Func<IChangeToken>, Action<TState>, TState) overload takes an additional `TState` parameter that's passed into the token consumer `Action`.

`OnChange` returns an IDisposable. Calling Dispose stops the token from listening for further changes and releases the token's resources.

Example uses of change tokens in ASP.NET Core

Change tokens are used in prominent areas of ASP.NET Core to monitor for changes to objects:

- For monitoring changes to files, IFileProvider's Watch method creates an `IChangeToken` for the specified files or folder to watch.
- `IChangeToken` tokens can be added to cache entries to trigger cache evictions on change.
- For `TOptions` changes, the default OptionsMonitor<TOptions> implementation of IOptionsMonitor<TOptions> has an overload that accepts one or more IOptionsChangeTokenSource<TOptions> instances. Each instance returns an `IChangeToken` to register a change notification callback for tracking options changes.

Monitor for configuration changes

By default, ASP.NET Core templates use JSON configuration files (*appsettings.json*, *appsettings.Development.json*, and *appsettings.Production.json*) to load app configuration settings.

These files are configured using the AddJsonFile(IConfigurationBuilder, String, Boolean, Boolean) extension method on ConfigurationBuilder that accepts a `reloadOnChange` parameter. `reloadOnChange` indicates if configuration should be reloaded on file changes. This setting appears in the WebHost convenience method CreateDefaultBuilder:

```
config.AddJsonFile("appsettings.json", optional: true, reloadOnChange: true)
      .AddJsonFile($"appsettings.{env.EnvironmentName}.json", optional: true,
          reloadOnChange: true);
```

File-based configuration is represented by FileConfigurationSource. `FileConfigurationSource` uses IFileProvider to monitor files.

By default, the `IFileMonitor` is provided by a PhysicalFileProvider, which uses FileSystemWatcher to monitor for configuration file changes.

The sample app demonstrates two implementations for monitoring configuration changes. If any of the *appsettings* files change, both of the file monitoring implementations execute custom code—the sample app writes a message to the console.

A configuration file's `FileSystemWatcher` can trigger multiple token callbacks for a single configuration file change. To ensure that the custom code is only run once when multiple token callbacks are triggered, the sample's implementation checks file hashes. The sample uses SHA1 file hashing. A retry is implemented with an exponential back-off. The retry is present because file locking may occur that temporarily prevents computing a new hash on a file.

Utilities/Utilities.cs:

```
public static byte[] ComputeHash(string filePath)
{
    var runCount = 1;

    while(runCount < 4)
    {
        try
        {
            if (File.Exists(filePath))
            {
                using (var fs = File.OpenRead(filePath))
                {
                    return System.Security.Cryptography.SHA1
                        .Create().ComputeHash(fs);
                }
            }
            else
            {
                throw new FileNotFoundException();
            }
        }
        catch (IOException ex)
        {
            if (runCount == 3 || ex.HResult != -2147024864)
            {
                throw;
            }
            else
            {
                Thread.Sleep(TimeSpan.FromSeconds(Math.Pow(2, runCount)));
                runCount++;
            }
        }
    }

    return new byte[20];
}
```

Simple startup change token

Register a token consumer `Action` callback for change notifications to the configuration reload token.

In `Startup.Configure`:

```
ChangeToken.OnChange(
    () => config.GetReloadToken(),
    (state) => InvokeChanged(state),
    env);
```

`config.GetReloadToken()` provides the token. The callback is the `InvokeChanged` method:

```
private void InvokeChanged(IHostingEnvironment env)
{
    byte[] appsettingsHash = ComputeHash("appSettings.json");
    byte[] appsettingsEnvHash =
        ComputeHash($"appSettings.{env.EnvironmentName}.json");

    if (!_appsettingsHash.SequenceEqual(appsettingsHash) ||
        !_appsettingsEnvHash.SequenceEqual(appsettingsEnvHash))
    {
        _appsettingsHash = appsettingsHash;
        _appsettingsEnvHash = appsettingsEnvHash;

        WriteConsole("Configuration changed (Simple Startup Change Token)");
    }
}
```

The `state` of the callback is used to pass in the `IHostingEnvironment`, which is useful for specifying the correct *appsettings* configuration file to monitor (for example, *appsettings.Development.json* when in the Development environment). File hashes are used to prevent the `WriteConsole` statement from running multiple times due to multiple token callbacks when the configuration file has only changed once.

This system runs as long as the app is running and can't be disabled by the user.

Monitor configuration changes as a service

The sample implements:

- Basic startup token monitoring.
- Monitoring as a service.
- A mechanism to enable and disable monitoring.

The sample establishes an `IConfigurationMonitor` interface.

Extensions/ConfigurationMonitor.cs:

```
public interface IConfigurationMonitor
{
    bool MonitoringEnabled { get; set; }
    string CurrentState { get; set; }
}
```

The constructor of the implemented class, `ConfigurationMonitor`, registers a callback for change notifications:

```
public ConfigurationMonitor(IConfiguration config, IHostingEnvironment env)
{
    _env = env;

    ChangeToken.OnChange<IConfigurationMonitor>(
        () => config.GetReloadToken(),
        InvokeChanged,
        this);
}

public bool MonitoringEnabled { get; set; } = false;
public string CurrentState { get; set; } = "Not monitoring";
```

`config.GetReloadToken()` supplies the token. `InvokeChanged` is the callback method. The `state` in this instance is a reference to the `IConfigurationMonitor` instance that's used to access the monitoring state. Two properties are used:

- `MonitoringEnabled`: Indicates if the callback should run its custom code.
- `CurrentState`: Describes the current monitoring state for use in the UI.

The `InvokeChanged` method is similar to the earlier approach, except that it:

- Doesn't run its code unless `MonitoringEnabled` is `true`.
- Outputs the current `state` in its `WriteConsole` output.

```
private void InvokeChanged(IConfigurationMonitor state)
{
    if (MonitoringEnabled)
    {
        byte[] appsettingsHash = ComputeHash("appSettings.json");
        byte[] appsettingsEnvHash =
            ComputeHash($"appSettings.{_env.EnvironmentName}.json");

        if (!_appsettingsHash.SequenceEqual(appsettingsHash) ||
            !_appsettingsEnvHash.SequenceEqual(appsettingsEnvHash))
        {
            string message = $"State updated at {DateTime.Now}";

            _appsettingsHash = appsettingsHash;
            _appsettingsEnvHash = appsettingsEnvHash;

            WriteConsole("Configuration changed (ConfigurationMonitor Class) " +
                $"{message}, state:{state.CurrentState}");
        }
    }
}
```

An instance `ConfigurationMonitor` is registered as a service in `Startup.ConfigureServices`:

```
services.AddSingleton<IConfigurationMonitor, ConfigurationMonitor>();
```

The Index page offers the user control over configuration monitoring. The instance of `IConfigurationMonitor` is injected into the `IndexModel`.

Pages/Index.cshtml.cs:

```
public IndexModel(
    IConfiguration config,
    IConfigurationMonitor monitor,
    FileService fileService)
{
    _config = config;
    _monitor = monitor;
    _fileService = fileService;
}
```

The configuration monitor (`_monitor`) is used to enable or disable monitoring and set the current state for UI feedback:

```
public IActionResult OnPostStartMonitoring()
{
    _monitor.MonitoringEnabled = true;
    _monitor.CurrentState = "Monitoring!";

    return RedirectToPage();
}

public IActionResult OnPostStopMonitoring()
{
    _monitor.MonitoringEnabled = false;
    _monitor.CurrentState = "Not monitoring";

    return RedirectToPage();
}
```

When `OnPostStartMonitoring` is triggered, monitoring is enabled, and the current state is cleared. When `OnPostStopMonitoring` is triggered, monitoring is disabled, and the state is set to reflect that monitoring isn't occurring.

Buttons in the UI enable and disable monitoring.

Pages/Index.cshtml:

```
<button class="btn btn-success" asp-page-handler="StartMonitoring">
    Start Monitoring
</button>

<button class="btn btn-danger" asp-page-handler="StopMonitoring">
    Stop Monitoring
</button>
```

Monitor cached file changes

File content can be cached in-memory using IMemoryCache. In-memory caching is described in the Cache in-memory topic. Without taking additional steps, such as the implementation described below, *stale* (outdated) data is returned from a cache if the source data changes.

For example, not taking into account the status of a cached source file when renewing a sliding expiration period leads to stale cached file data. Each request for the data renews the sliding expiration period, but the file is never reloaded into the cache. Any app features that use the file's cached content are subject to possibly receiving stale content.

Using change tokens in a file caching scenario prevents the presence of stale file content in the cache. The sample app demonstrates an implementation of the approach.

The sample uses `GetFileContent` to:

- Return file content.
- Implement a retry algorithm with exponential back-off to cover cases where a file lock temporarily prevents reading a file.

Utilities/Utilities.cs:

```
public async static Task<string> GetFileContent(string filePath)
{
    var runCount = 1;

    while(runCount < 4)
    {
        try
        {
            if (File.Exists(filePath))
            {
                using (var fileStreamReader = File.OpenText(filePath))
                {
                    return await fileStreamReader.ReadToEndAsync();
                }
            }
            else
            {
                throw new FileNotFoundException();
            }
        }
        catch (IOException ex)
        {
            if (runCount == 3 || ex.HResult != -2147024864)
            {
                throw;
            }
            else
            {
                await Task.Delay(TimeSpan.FromSeconds(Math.Pow(2, runCount)));
                runCount++;
            }
        }
    }

    return null;
}
```

A `FileService` is created to handle cached file lookups. The `GetFileContent` method call of the service attempts to obtain file content from the in-memory cache and return it to the caller (*Services/FileService.cs*).

If cached content isn't found using the cache key, the following actions are taken:

1. The file content is obtained using `GetFileContent`.
2. A change token is obtained from the file provider with IFileProviders.Watch. The token's callback is triggered when the file is modified.
3. The file content is cached with a sliding expiration period. The change token is attached with MemoryCacheEntryExtensions.AddExpirationToken to evict the cache entry if the file changes while it's cached.

In the following example, files are stored in the app's content root. IHostingEnvironment.ContentRootFileProvider is used to obtain an IFileProvider pointing at the app's ContentRootPath. The `filePath` is obtained with IFileInfo.PhysicalPath.

```
public class FileService
{
    private readonly IMemoryCache _cache;
    private readonly IFileProvider _fileProvider;
    private List<string> _tokens = new List<string>();

    public FileService(IMemoryCache cache, IHostingEnvironment env)
    {
        _cache = cache;
        _fileProvider = env.ContentRootFileProvider;
    }

    public async Task<string> GetFileContents(string fileName)
    {
        var filePath = _fileProvider.GetFileInfo(fileName).PhysicalPath;
        string fileContent;

        // Try to obtain the file contents from the cache.
        if (_cache.TryGetValue(filePath, out fileContent))
        {
            return fileContent;
        }

        // The cache doesn't have the entry, so obtain the file
        // contents from the file itself.
        fileContent = await GetFileContent(filePath);

        if (fileContent != null)
        {
            // Obtain a change token from the file provider whose
            // callback is triggered when the file is modified.
            var changeToken = _fileProvider.Watch(fileName);

            // Configure the cache entry options for a five minute
            // sliding expiration and use the change token to
            // expire the file in the cache if the file is
            // modified.
            var cacheEntryOptions = new MemoryCacheEntryOptions()
                .SetSlidingExpiration(TimeSpan.FromMinutes(5))
                .AddExpirationToken(changeToken);

            // Put the file contents into the cache.
            _cache.Set(filePath, fileContent, cacheEntryOptions);

            return fileContent;
        }

        return string.Empty;
    }
}
```

The `FileService` is registered in the service container along with the memory caching service.

In `Startup.ConfigureServices`:

```
services.AddMemoryCache();
services.AddSingleton<FileService>();
```

The page model loads the file's content using the service.

In the Index page's `OnGet` method (*Pages/Index.cshtml.cs*):

```
var fileContent = await _fileService.GetFileContents("poem.txt");
```

CompositeChangeToken class

For representing one or more `IChangeToken` instances in a single object, use the CompositeChangeToken class.

```
var firstCancellationTokenSource = new CancellationTokenSource();
var secondCancellationTokenSource = new CancellationTokenSource();

var firstCancellationToken = firstCancellationTokenSource.Token;
var secondCancellationToken = secondCancellationTokenSource.Token;

var firstCancellationChangeToken = new CancellationChangeToken(firstCancellationToken);
var secondCancellationChangeToken = new CancellationChangeToken(secondCancellationToken);

var compositeChangeToken =
    new CompositeChangeToken(
        new List<IChangeToken>
        {
            firstCancellationChangeToken,
            secondCancellationChangeToken
        });
```

`HasChanged` on the composite token reports `true` if any represented token `HasChanged` is `true`. `ActiveChangeCallbacks` on the composite token reports `true` if any represented token `ActiveChangeCallbacks` is `true`. If multiple concurrent change events occur, the composite change callback is invoked one time.

Open Web Interface for .NET (OWIN) with ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

By Steve Smith and Rick Anderson

ASP.NET Core supports the Open Web Interface for .NET (OWIN). OWIN allows web apps to be decoupled from web servers. It defines a standard way for middleware to be used in a pipeline to handle requests and associated responses. ASP.NET Core applications and middleware can interoperate with OWIN-based applications, servers, and middleware.

OWIN provides a decoupling layer that allows two frameworks with disparate object models to be used together. The `Microsoft.AspNetCore.Owin` package provides two adapter implementations:

- ASP.NET Core to OWIN
- OWIN to ASP.NET Core

This allows ASP.NET Core to be hosted on top of an OWIN compatible server/host or for other OWIN compatible components to be run on top of ASP.NET Core.

> **NOTE**
> Using these adapters comes with a performance cost. Apps using only ASP.NET Core components shouldn't use the `Microsoft.AspNetCore.Owin` package or adapters.

View or download sample code (how to download)

Running OWIN middleware in the ASP.NET Core pipeline

ASP.NET Core's OWIN support is deployed as part of the `Microsoft.AspNetCore.Owin` package. You can import OWIN support into your project by installing this package.

OWIN middleware conforms to the OWIN specification, which requires a `Func<IDictionary<string, object>, Task>` interface, and specific keys be set (such as `owin.ResponseBody`). The following simple OWIN middleware displays "Hello World":

```
public Task OwinHello(IDictionary<string, object> environment)
{
    string responseText = "Hello World via OWIN";
    byte[] responseBytes = Encoding.UTF8.GetBytes(responseText);

    // OWIN Environment Keys: https://owin.org/spec/spec/owin-1.0.0.html
    var responseStream = (Stream)environment["owin.ResponseBody"];
    var responseHeaders = (IDictionary<string, string[]>)environment["owin.ResponseHeaders"];

    responseHeaders["Content-Length"] = new string[] {
responseBytes.Length.ToString(CultureInfo.InvariantCulture) };
    responseHeaders["Content-Type"] = new string[] { "text/plain" };

    return responseStream.WriteAsync(responseBytes, 0, responseBytes.Length);
}
```

The sample signature returns a `Task` and accepts an `IDictionary<string, object>` as required by OWIN.

The following code shows how to add the `OwinHello` middleware (shown above) to the ASP.NET Core pipeline with the `UseOwin` extension method.

```
public void Configure(IApplicationBuilder app)
{
    app.UseOwin(pipeline =>
    {
        pipeline(next => OwinHello);
    });
}
```

You can configure other actions to take place within the OWIN pipeline.

> **NOTE**
> Response headers should only be modified prior to the first write to the response stream.

> **NOTE**
> Multiple calls to `UseOwin` is discouraged for performance reasons. OWIN components will operate best if grouped together.

```
app.UseOwin(pipeline =>
{
    pipeline(next =>
    {
        return async environment =>
        {
            // Do something before.
            await next(environment);
            // Do something after.
        };
    });
});
```

Run ASP.NET Core on an OWIN-based server and use its WebSockets support

Another example of how OWIN-based servers' features can be leveraged by ASP.NET Core is access to features like WebSockets. The .NET OWIN web server used in the previous example has support for Web Sockets built in, which can be leveraged by an ASP.NET Core application. The example below shows a simple web app that supports Web Sockets and echoes back everything sent to the server through WebSockets.

```
public class Startup
{
    public void Configure(IApplicationBuilder app)
    {
        app.Use(async (context, next) =>
        {
            if (context.WebSockets.IsWebSocketRequest)
            {
                WebSocket webSocket = await context.WebSockets.AcceptWebSocketAsync();
                await EchoWebSocket(webSocket);
            }
            else
            {
                await next();
            }
        });

        app.Run(context =>
        {
            return context.Response.WriteAsync("Hello World");
        });
    }

    private async Task EchoWebSocket(WebSocket webSocket)
    {
        byte[] buffer = new byte[1024];
        WebSocketReceiveResult received = await webSocket.ReceiveAsync(
            new ArraySegment<byte>(buffer), CancellationToken.None);

        while (!webSocket.CloseStatus.HasValue)
        {
            // Echo anything we receive
            await webSocket.SendAsync(new ArraySegment<byte>(buffer, 0, received.Count),
                received.MessageType, received.EndOfMessage, CancellationToken.None);

            received = await webSocket.ReceiveAsync(new ArraySegment<byte>(buffer),
                CancellationToken.None);
        }

        await webSocket.CloseAsync(webSocket.CloseStatus.Value,
            webSocket.CloseStatusDescription, CancellationToken.None);
    }
}
```

OWIN environment

You can construct an OWIN environment using the `HttpContext`.

```
var environment = new OwinEnvironment(HttpContext);
var features = new OwinFeatureCollection(environment);
```

OWIN keys

OWIN depends on an `IDictionary<string,object>` object to communicate information throughout an HTTP Request/Response exchange. ASP.NET Core implements the keys listed below. See the primary specification, extensions, and OWIN Key Guidelines and Common Keys.

Request data (OWIN v1.0.0)

KEY	VALUE (TYPE)	DESCRIPTION
owin.RequestScheme	`String`	
owin.RequestMethod	`String`	
owin.RequestPathBase	`String`	
owin.RequestPath	`String`	
owin.RequestQueryString	`String`	
owin.RequestProtocol	`String`	
owin.RequestHeaders	`IDictionary<string,string[]>`	
owin.RequestBody	`Stream`	

Request data (OWIN v1.1.0)

KEY	VALUE (TYPE)	DESCRIPTION
owin.RequestId	`String`	Optional

Response data (OWIN v1.0.0)

KEY	VALUE (TYPE)	DESCRIPTION
owin.ResponseStatusCode	`int`	Optional
owin.ResponseReasonPhrase	`String`	Optional
owin.ResponseHeaders	`IDictionary<string,string[]>`	
owin.ResponseBody	`Stream`	

Other data (OWIN v1.0.0)

KEY	VALUE (TYPE)	DESCRIPTION
owin.CallCancelled	`CancellationToken`	
owin.Version	`String`	

Common keys

KEY	VALUE (TYPE)	DESCRIPTION
ssl.ClientCertificate	`X509Certificate`	
ssl.LoadClientCertAsync	`Func<Task>`	

KEY	VALUE (TYPE)	DESCRIPTION
server.RemoteIpAddress	`String`	
server.RemotePort	`String`	
server.LocalIpAddress	`String`	
server.LocalPort	`String`	
server.IsLocal	`bool`	
server.OnSendingHeaders	`Action<Action<object>,object>`	

SendFiles v0.3.0

KEY	VALUE (TYPE)	DESCRIPTION
sendfile.SendAsync	See delegate signature	Per Request

Opaque v0.3.0

KEY	VALUE (TYPE)	DESCRIPTION
opaque.Version	`String`	
opaque.Upgrade	`OpaqueUpgrade`	See delegate signature
opaque.Stream	`Stream`	
opaque.CallCancelled	`CancellationToken`	

WebSocket v0.3.0

KEY	VALUE (TYPE)	DESCRIPTION
websocket.Version	`String`	
websocket.Accept	`WebSocketAccept`	See delegate signature
websocket.AcceptAlt		Non-spec
websocket.SubProtocol	`String`	See RFC6455 Section 4.2.2 Step 5.5
websocket.SendAsync	`WebSocketSendAsync`	See delegate signature
websocket.ReceiveAsync	`WebSocketReceiveAsync`	See delegate signature
websocket.CloseAsync	`WebSocketCloseAsync`	See delegate signature
websocket.CallCancelled	`CancellationToken`	

KEY	VALUE (TYPE)	DESCRIPTION
websocket.ClientCloseStatus	`int`	Optional
websocket.ClientCloseDescription	`String`	Optional

Background tasks with hosted services in ASP.NET Core

9/22/2020 • 14 minutes to read • Edit Online

By Jeow Li Huan

In ASP.NET Core, background tasks can be implemented as *hosted services*. A hosted service is a class with background task logic that implements the IHostedService interface. This topic provides three hosted service examples:

- Background task that runs on a timer.
- Hosted service that activates a scoped service. The scoped service can use dependency injection (DI).
- Queued background tasks that run sequentially.

View or download sample code (how to download)

Worker Service template

The ASP.NET Core Worker Service template provides a starting point for writing long running service apps. An app created from the Worker Service template specifies the Worker SDK in its project file:

```
<Project Sdk="Microsoft.NET.Sdk.Worker">
```

To use the template as a basis for a hosted services app:

- Visual Studio
- Visual Studio for Mac
- .NET Core CLI

1. Create a new project.
2. Select **Worker Service**. Select **Next**.
3. Provide a project name in the **Project name** field or accept the default project name. Select **Create**.
4. In the **Create a new Worker service** dialog, select **Create**.

Package

An app based on the Worker Service template uses the `Microsoft.NET.Sdk.Worker` SDK and has an explicit package reference to the Microsoft.Extensions.Hosting package. For example, see the sample app's project file (*BackgroundTasksSample.csproj*).

For web apps that use the `Microsoft.NET.Sdk.Web` SDK, the Microsoft.Extensions.Hosting package is referenced implicitly from the shared framework. An explicit package reference in the app's project file isn't required.

IHostedService interface

The IHostedService interface defines two methods for objects that are managed by the host:

- StartAsync(CancellationToken): `StartAsync` contains the logic to start the background task. `StartAsync` is called *before*:

- The app's request processing pipeline is configured (`Startup.Configure`).
- The server is started and IApplicationLifetime.ApplicationStarted is triggered.

The default behavior can be changed so that the hosted service's `StartAsync` runs after the app's pipeline has been configured and `ApplicationStarted` is called. To change the default behavior, add the hosted service (`VideosWatcher` in the following example) after calling `ConfigureWebHostDefaults`:

```
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            })
            .ConfigureServices(services =>
            {
                services.AddHostedService<VideosWatcher>();
            });
}
```

- StopAsync(CancellationToken): Triggered when the host is performing a graceful shutdown. `StopAsync` contains the logic to end the background task. Implement IDisposable and finalizers (destructors) to dispose of any unmanaged resources.

  The cancellation token has a default five second timeout to indicate that the shutdown process should no longer be graceful. When cancellation is requested on the token:

  - Any remaining background operations that the app is performing should be aborted.
  - Any methods called in `StopAsync` should return promptly.

  However, tasks aren't abandoned after cancellation is requested—the caller awaits all tasks to complete.

  If the app shuts down unexpectedly (for example, the app's process fails), `StopAsync` might not be called. Therefore, any methods called or operations conducted in `StopAsync` might not occur.

  To extend the default five second shutdown timeout, set:

  - ShutdownTimeout when using Generic Host. For more information, see .NET Generic Host.
  - Shutdown timeout host configuration setting when using Web Host. For more information, see ASP.NET Core Web Host.

The hosted service is activated once at app startup and gracefully shut down at app shutdown. If an error is thrown during background task execution, `Dispose` should be called even if `StopAsync` isn't called.

BackgroundService base class

BackgroundService is a base class for implementing a long running IHostedService.

ExecuteAsync(CancellationToken) is called to run the background service. The implementation returns a Task that represents the entire lifetime of the background service. No further services are started until

ExecuteAsync becomes asynchronous, such as by calling `await`. Avoid performing long, blocking initialization work in `ExecuteAsync`. The host blocks in StopAsync(CancellationToken) waiting for `ExecuteAsync` to complete.

The cancellation token is triggered when IHostedService.StopAsync is called. Your implementation of `ExecuteAsync` should finish promptly when the cancellation token is fired in order to gracefully shut down the service. Otherwise, the service ungracefully shuts down at the shutdown timeout. For more information, see the IHostedService interface section.

Timed background tasks

A timed background task makes use of the System.Threading.Timer class. The timer triggers the task's `DoWork` method. The timer is disabled on `StopAsync` and disposed when the service container is disposed on `Dispose`:

```
public class TimedHostedService : IHostedService, IDisposable
{
    private int executionCount = 0;
    private readonly ILogger<TimedHostedService> _logger;
    private Timer _timer;

    public TimedHostedService(ILogger<TimedHostedService> logger)
    {
        _logger = logger;
    }

    public Task StartAsync(CancellationToken stoppingToken)
    {
        _logger.LogInformation("Timed Hosted Service running.");

        _timer = new Timer(DoWork, null, TimeSpan.Zero,
            TimeSpan.FromSeconds(5));

        return Task.CompletedTask;
    }

    private void DoWork(object state)
    {
        var count = Interlocked.Increment(ref executionCount);

        _logger.LogInformation(
            "Timed Hosted Service is working. Count: {Count}", count);
    }

    public Task StopAsync(CancellationToken stoppingToken)
    {
        _logger.LogInformation("Timed Hosted Service is stopping.");

        _timer?.Change(Timeout.Infinite, 0);

        return Task.CompletedTask;
    }

    public void Dispose()
    {
        _timer?.Dispose();
    }
}
```

The Timer doesn't wait for previous executions of `DoWork` to finish, so the approach shown might not be suitable for every scenario. Interlocked.Increment is used to increment the execution counter as an atomic operation, which ensures that multiple threads don't update `executionCount` concurrently.

The service is registered in `IHostBuilder.ConfigureServices` (*Program.cs*) with the `AddHostedService` extension method:

```
services.AddHostedService<TimedHostedService>();
```

Consuming a scoped service in a background task

To use scoped services within a BackgroundService, create a scope. No scope is created for a hosted service by default.

The scoped background task service contains the background task's logic. In the following example:

- The service is asynchronous. The `DoWork` method returns a `Task`. For demonstration purposes, a delay of ten seconds is awaited in the `DoWork` method.
- An ILogger is injected into the service.

```
internal interface IScopedProcessingService
{
    Task DoWork(CancellationToken stoppingToken);
}

internal class ScopedProcessingService : IScopedProcessingService
{
    private int executionCount = 0;
    private readonly ILogger _logger;

    public ScopedProcessingService(ILogger<ScopedProcessingService> logger)
    {
        _logger = logger;
    }

    public async Task DoWork(CancellationToken stoppingToken)
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            executionCount++;

            _logger.LogInformation(
                "Scoped Processing Service is working. Count: {Count}", executionCount);

            await Task.Delay(10000, stoppingToken);
        }
    }
}
```

The hosted service creates a scope to resolve the scoped background task service to call its `DoWork` method. `DoWork` returns a `Task`, which is awaited in `ExecuteAsync`:

```
public class ConsumeScopedServiceHostedService : BackgroundService
{
    private readonly ILogger<ConsumeScopedServiceHostedService> _logger;

    public ConsumeScopedServiceHostedService(IServiceProvider services,
        ILogger<ConsumeScopedServiceHostedService> logger)
    {
        Services = services;
        _logger = logger;
    }

    public IServiceProvider Services { get; }

    protected override async Task ExecuteAsync(CancellationToken stoppingToken)
    {
        _logger.LogInformation(
            "Consume Scoped Service Hosted Service running.");

        await DoWork(stoppingToken);
    }

    private async Task DoWork(CancellationToken stoppingToken)
    {
        _logger.LogInformation(
            "Consume Scoped Service Hosted Service is working.");

        using (var scope = Services.CreateScope())
        {
            var scopedProcessingService =
                scope.ServiceProvider
                    .GetRequiredService<IScopedProcessingService>();

            await scopedProcessingService.DoWork(stoppingToken);
        }
    }

    public override async Task StopAsync(CancellationToken stoppingToken)
    {
        _logger.LogInformation(
            "Consume Scoped Service Hosted Service is stopping.");

        await base.StopAsync(stoppingToken);
    }
}
```

The services are registered in `IHostBuilder.ConfigureServices` (*Program.cs*). The hosted service is registered with the `AddHostedService` extension method:

```
services.AddHostedService<ConsumeScopedServiceHostedService>();
services.AddScoped<IScopedProcessingService, ScopedProcessingService>();
```

Queued background tasks

A background task queue is based on the .NET 4.x QueueBackgroundWorkItem:

```
public interface IBackgroundTaskQueue
{
    void QueueBackgroundWorkItem(Func<CancellationToken, Task> workItem);

    Task<Func<CancellationToken, Task>> DequeueAsync(
        CancellationToken cancellationToken);
}

public class BackgroundTaskQueue : IBackgroundTaskQueue
{
    private ConcurrentQueue<Func<CancellationToken, Task>> _workItems =
        new ConcurrentQueue<Func<CancellationToken, Task>>();
    private SemaphoreSlim _signal = new SemaphoreSlim(0);

    public void QueueBackgroundWorkItem(
        Func<CancellationToken, Task> workItem)
    {
        if (workItem == null)
        {
            throw new ArgumentNullException(nameof(workItem));
        }

        _workItems.Enqueue(workItem);
        _signal.Release();
    }

    public async Task<Func<CancellationToken, Task>> DequeueAsync(
        CancellationToken cancellationToken)
    {
        await _signal.WaitAsync(cancellationToken);
        _workItems.TryDequeue(out var workItem);

        return workItem;
    }
}
```

In the following `QueueHostedService` example:

- The `BackgroundProcessing` method returns a `Task`, which is awaited in `ExecuteAsync`.
- Background tasks in the queue are dequeued and executed in `BackgroundProcessing`.
- Work items are awaited before the service stops in `StopAsync`.

```
public class QueuedHostedService : BackgroundService
{
    private readonly ILogger<QueuedHostedService> _logger;

    public QueuedHostedService(IBackgroundTaskQueue taskQueue,
        ILogger<QueuedHostedService> logger)
    {
        TaskQueue = taskQueue;
        _logger = logger;
    }

    public IBackgroundTaskQueue TaskQueue { get; }

    protected override async Task ExecuteAsync(CancellationToken stoppingToken)
    {
        _logger.LogInformation(
            $"Queued Hosted Service is running.{Environment.NewLine}" +
            $"{Environment.NewLine}Tap W to add a work item to the " +
            $"background queue.{Environment.NewLine}");

        await BackgroundProcessing(stoppingToken);
    }

    private async Task BackgroundProcessing(CancellationToken stoppingToken)
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            var workItem =
                await TaskQueue.DequeueAsync(stoppingToken);

            try
            {
                await workItem(stoppingToken);
            }
            catch (Exception ex)
            {
                _logger.LogError(ex,
                    "Error occurred executing {WorkItem}.", nameof(workItem));
            }
        }
    }

    public override async Task StopAsync(CancellationToken stoppingToken)
    {
        _logger.LogInformation("Queued Hosted Service is stopping.");

        await base.StopAsync(stoppingToken);
    }
}
```

A `MonitorLoop` service handles enqueuing tasks for the hosted service whenever the `w` key is selected on an input device:

- The `IBackgroundTaskQueue` is injected into the `MonitorLoop` service.
- `IBackgroundTaskQueue.QueueBackgroundWorkItem` is called to enqueue a work item.
- The work item simulates a long-running background task:
  - Three 5-second delays are executed (`Task.Delay`).
  - A `try-catch` statement traps OperationCanceledException if the task is cancelled.

```
public class MonitorLoop
{
    private readonly IBackgroundTaskQueue _taskQueue;
    private readonly ILogger _logger;
```

```
    private readonly CancellationToken _cancellationToken;

    public MonitorLoop(IBackgroundTaskQueue taskQueue,
        ILogger<MonitorLoop> logger,
        IHostApplicationLifetime applicationLifetime)
    {
        _taskQueue = taskQueue;
        _logger = logger;
        _cancellationToken = applicationLifetime.ApplicationStopping;
    }

    public void StartMonitorLoop()
    {
        _logger.LogInformation("Monitor Loop is starting.");

        // Run a console user input loop in a background thread
        Task.Run(() => Monitor());
    }

    public void Monitor()
    {
        while (!_cancellationToken.IsCancellationRequested)
        {
            var keyStroke = Console.ReadKey();

            if (keyStroke.Key == ConsoleKey.W)
            {
                // Enqueue a background work item
                _taskQueue.QueueBackgroundWorkItem(async token =>
                {
                    // Simulate three 5-second tasks to complete
                    // for each enqueued work item

                    int delayLoop = 0;
                    var guid = Guid.NewGuid().ToString();

                    _logger.LogInformation(
                        "Queued Background Task {Guid} is starting.", guid);

                    while (!token.IsCancellationRequested && delayLoop < 3)
                    {
                        try
                        {
                            await Task.Delay(TimeSpan.FromSeconds(5), token);
                        }
                        catch (OperationCanceledException)
                        {
                            // Prevent throwing if the Delay is cancelled
                        }

                        delayLoop++;

                        _logger.LogInformation(
                            "Queued Background Task {Guid} is running. " +
                            "{DelayLoop}/3", guid, delayLoop);
                    }

                    if (delayLoop == 3)
                    {
                        _logger.LogInformation(
                            "Queued Background Task {Guid} is complete.", guid);
                    }
                    else
                    {
                        _logger.LogInformation(
                            "Queued Background Task {Guid} was cancelled.", guid);
                    }
                });
            }
```

```
        }
    }
}
```

The services are registered in `IHostBuilder.ConfigureServices` (*Program.cs*). The hosted service is registered with the `AddHostedService` extension method:

```
services.AddSingleton<MonitorLoop>();
services.AddHostedService<QueuedHostedService>();
services.AddSingleton<IBackgroundTaskQueue, BackgroundTaskQueue>();
```

`MonitorLoop` is started in `Program.Main`:

```
var monitorLoop = host.Services.GetRequiredService<MonitorLoop>();
monitorLoop.StartMonitorLoop();
```

In ASP.NET Core, background tasks can be implemented as *hosted services*. A hosted service is a class with background task logic that implements the IHostedService interface. This topic provides three hosted service examples:

- Background task that runs on a timer.
- Hosted service that activates a scoped service. The scoped service can use dependency injection (DI)
- Queued background tasks that run sequentially.

View or download sample code (how to download)

Package

Reference the Microsoft.AspNetCore.App metapackage or add a package reference to the Microsoft.Extensions.Hosting package.

IHostedService interface

Hosted services implement the IHostedService interface. The interface defines two methods for objects that are managed by the host:

- StartAsync(CancellationToken): `StartAsync` contains the logic to start the background task. When using the Web Host, `StartAsync` is called after the server has started and IApplicationLifetime.ApplicationStarted is triggered. When using the Generic Host, `StartAsync` is called before `ApplicationStarted` is triggered.

- StopAsync(CancellationToken): Triggered when the host is performing a graceful shutdown. `StopAsync` contains the logic to end the background task. Implement IDisposable and finalizers (destructors) to dispose of any unmanaged resources.

  The cancellation token has a default five second timeout to indicate that the shutdown process should no longer be graceful. When cancellation is requested on the token:

  - Any remaining background operations that the app is performing should be aborted.
  - Any methods called in `StopAsync` should return promptly.

  However, tasks aren't abandoned after cancellation is requested—the caller awaits all tasks to complete.

  If the app shuts down unexpectedly (for example, the app's process fails), `StopAsync` might not be called. Therefore, any methods called or operations conducted in `StopAsync` might not occur.

To extend the default five second shutdown timeout, set:

- ShutdownTimeout when using Generic Host. For more information, see .NET Generic Host.
- Shutdown timeout host configuration setting when using Web Host. For more information, see ASP.NET Core Web Host.

The hosted service is activated once at app startup and gracefully shut down at app shutdown. If an error is thrown during background task execution, `Dispose` should be called even if `StopAsync` isn't called.

Timed background tasks

A timed background task makes use of the System.Threading.Timer class. The timer triggers the task's `DoWork` method. The timer is disabled on `StopAsync` and disposed when the service container is disposed on `Dispose`:

```
internal class TimedHostedService : IHostedService, IDisposable
{
    private readonly ILogger _logger;
    private Timer _timer;

    public TimedHostedService(ILogger<TimedHostedService> logger)
    {
        _logger = logger;
    }

    public Task StartAsync(CancellationToken cancellationToken)
    {
        _logger.LogInformation("Timed Background Service is starting.");

        _timer = new Timer(DoWork, null, TimeSpan.Zero,
            TimeSpan.FromSeconds(5));

        return Task.CompletedTask;
    }

    private void DoWork(object state)
    {
        _logger.LogInformation("Timed Background Service is working.");
    }

    public Task StopAsync(CancellationToken cancellationToken)
    {
        _logger.LogInformation("Timed Background Service is stopping.");

        _timer?.Change(Timeout.Infinite, 0);

        return Task.CompletedTask;
    }

    public void Dispose()
    {
        _timer?.Dispose();
    }
}
```

The Timer doesn't wait for previous executions of `DoWork` to finish, so the approach shown might not be suitable for every scenario.

The service is registered in `Startup.ConfigureServices` with the `AddHostedService` extension method:

```
services.AddHostedService<TimedHostedService>();
```

Consuming a scoped service in a background task

To use scoped services within an `IHostedService`, create a scope. No scope is created for a hosted service by default.

The scoped background task service contains the background task's logic. In the following example, an ILogger is injected into the service:

```
internal interface IScopedProcessingService
{
    void DoWork();
}

internal class ScopedProcessingService : IScopedProcessingService
{
    private readonly ILogger _logger;

    public ScopedProcessingService(ILogger<ScopedProcessingService> logger)
    {
        _logger = logger;
    }

    public void DoWork()
    {
        _logger.LogInformation("Scoped Processing Service is working.");
    }
}
```

The hosted service creates a scope to resolve the scoped background task service to call its `DoWork` method:

```
internal class ConsumeScopedServiceHostedService : IHostedService
{
    private readonly ILogger _logger;

    public ConsumeScopedServiceHostedService(IServiceProvider services,
        ILogger<ConsumeScopedServiceHostedService> logger)
    {
        Services = services;
        _logger = logger;
    }

    public IServiceProvider Services { get; }

    public Task StartAsync(CancellationToken cancellationToken)
    {
        _logger.LogInformation(
            "Consume Scoped Service Hosted Service is starting.");

        DoWork();

        return Task.CompletedTask;
    }

    private void DoWork()
    {
        _logger.LogInformation(
            "Consume Scoped Service Hosted Service is working.");

        using (var scope = Services.CreateScope())
        {
            var scopedProcessingService =
                scope.ServiceProvider
                    .GetRequiredService<IScopedProcessingService>();

            scopedProcessingService.DoWork();
        }
    }

    public Task StopAsync(CancellationToken cancellationToken)
    {
        _logger.LogInformation(
            "Consume Scoped Service Hosted Service is stopping.");

        return Task.CompletedTask;
    }
}
```

The services are registered in `Startup.ConfigureServices`. The `IHostedService` implementation is registered with the `AddHostedService` extension method:

```
services.AddHostedService<ConsumeScopedServiceHostedService>();
services.AddScoped<IScopedProcessingService, ScopedProcessingService>();
```

Queued background tasks

A background task queue is based on the .NET Framework 4.x QueueBackgroundWorkItem (tentatively scheduled to be built-in for ASP.NET Core):

```
public interface IBackgroundTaskQueue
{
    void QueueBackgroundWorkItem(Func<CancellationToken, Task> workItem);

    Task<Func<CancellationToken, Task>> DequeueAsync(
        CancellationToken cancellationToken);
}

public class BackgroundTaskQueue : IBackgroundTaskQueue
{
    private ConcurrentQueue<Func<CancellationToken, Task>> _workItems =
        new ConcurrentQueue<Func<CancellationToken, Task>>();
    private SemaphoreSlim _signal = new SemaphoreSlim(0);

    public void QueueBackgroundWorkItem(
        Func<CancellationToken, Task> workItem)
    {
        if (workItem == null)
        {
            throw new ArgumentNullException(nameof(workItem));
        }

        _workItems.Enqueue(workItem);
        _signal.Release();
    }

    public async Task<Func<CancellationToken, Task>> DequeueAsync(
        CancellationToken cancellationToken)
    {
        await _signal.WaitAsync(cancellationToken);
        _workItems.TryDequeue(out var workItem);

        return workItem;
    }
}
```

In `QueueHostedService`, background tasks in the queue are dequeued and executed as a BackgroundService, which is a base class for implementing a long running `IHostedService`:

```
public class QueuedHostedService : BackgroundService
{
    private readonly ILogger _logger;

    public QueuedHostedService(IBackgroundTaskQueue taskQueue,
        ILoggerFactory loggerFactory)
    {
        TaskQueue = taskQueue;
        _logger = loggerFactory.CreateLogger<QueuedHostedService>();
    }

    public IBackgroundTaskQueue TaskQueue { get; }

    protected async override Task ExecuteAsync(
        CancellationToken cancellationToken)
    {
        _logger.LogInformation("Queued Hosted Service is starting.");

        while (!cancellationToken.IsCancellationRequested)
        {
            var workItem = await TaskQueue.DequeueAsync(cancellationToken);

            try
            {
                await workItem(cancellationToken);
            }
            catch (Exception ex)
            {
                _logger.LogError(ex,
                   "Error occurred executing {WorkItem}.", nameof(workItem));
            }
        }

        _logger.LogInformation("Queued Hosted Service is stopping.");
    }
}
```

The services are registered in `Startup.ConfigureServices`. The `IHostedService` implementation is registered with the `AddHostedService` extension method:

```
services.AddHostedService<QueuedHostedService>();
services.AddSingleton<IBackgroundTaskQueue, BackgroundTaskQueue>();
```

In the Index page model class:

- The `IBackgroundTaskQueue` is injected into the constructor and assigned to `Queue`.
- An IServiceScopeFactory is injected and assigned to `_serviceScopeFactory`. The factory is used to create instances of IServiceScope, which is used to create services within a scope. A scope is created in order to use the app's `AppDbContext` (a scoped service) to write database records in the `IBackgroundTaskQueue` (a singleton service).

```
public class IndexModel : PageModel
{
    private readonly AppDbContext _db;
    private readonly ILogger _logger;
    private readonly IServiceScopeFactory _serviceScopeFactory;

    public IndexModel(AppDbContext db, IBackgroundTaskQueue queue,
        ILogger<IndexModel> logger, IServiceScopeFactory serviceScopeFactory)
    {
        _db = db;
        _logger = logger;
        Queue = queue;
        _serviceScopeFactory = serviceScopeFactory;
    }

    public IBackgroundTaskQueue Queue { get; }
```

When the **Add Task** button is selected on the Index page, the `OnPostAddTask` method is executed. `QueueBackgroundWorkItem` is called to enqueue a work item:

```
public IActionResult OnPostAddTaskAsync()
{
    Queue.QueueBackgroundWorkItem(async token =>
    {
        var guid = Guid.NewGuid().ToString();

        using (var scope = _serviceScopeFactory.CreateScope())
        {
            var scopedServices = scope.ServiceProvider;
            var db = scopedServices.GetRequiredService<AppDbContext>();

            for (int delayLoop = 1; delayLoop < 4; delayLoop++)
            {
                try
                {
                    db.Messages.Add(
                        new Message()
                        {
                            Text = $"Queued Background Task {guid} has " +
                                $"written a step. {delayLoop}/3"
                        });
                    await db.SaveChangesAsync();
                }
                catch (Exception ex)
                {
                    _logger.LogError(ex,
                        "An error occurred writing to the " +
                        "database. Error: {Message}", ex.Message);
                }

                await Task.Delay(TimeSpan.FromSeconds(5), token);
            }
        }

        _logger.LogInformation(
            "Queued Background Task {Guid} is complete. 3/3", guid);
    });

    return RedirectToPage();
}
```

Use hosting startup assemblies in ASP.NET Core

9/22/2020 • 29 minutes to read • Edit Online

By Pavel Krymets

An IHostingStartup (hosting startup) implementation adds enhancements to an app at startup from an external assembly. For example, an external library can use a hosting startup implementation to provide additional configuration providers or services to an app.

View or download sample code (how to download)

HostingStartup attribute

A HostingStartup attribute indicates the presence of a hosting startup assembly to activate at runtime.

The entry assembly or the assembly containing the `Startup` class is automatically scanned for the `HostingStartup` attribute. The list of assemblies to search for `HostingStartup` attributes is loaded at runtime from configuration in the WebHostDefaults.HostingStartupAssembliesKey. The list of assemblies to exclude from discovery is loaded from the WebHostDefaults.HostingStartupExcludeAssembliesKey.

In the following example, the namespace of the hosting startup assembly is `StartupEnhancement`. The class containing the hosting startup code is `StartupEnhancementHostingStartup`:

```
[assembly: HostingStartup(typeof(StartupEnhancement.StartupEnhancementHostingStartup))]
```

The `HostingStartup` attribute is typically located in the hosting startup assembly's `IHostingStartup` implementation class file.

Discover loaded hosting startup assemblies

To discover loaded hosting startup assemblies, enable logging and check the app's logs. Errors that occur when loading assemblies are logged. Loaded hosting startup assemblies are logged at the Debug level, and all errors are logged.

Disable automatic loading of hosting startup assemblies

To disable automatic loading of hosting startup assemblies, use one of the following approaches:

- To prevent all hosting startup assemblies from loading, set one of the following to `true` or `1`:
  - Prevent Hosting Startup host configuration setting:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseSetting(
                    WebHostDefaults.PreventHostingStartupKey, "true")
                .UseStartup<Startup>();
        });
```

  - `ASPNETCORE_PREVENTHOSTINGSTARTUP` environment variable.

- To prevent specific hosting startup assemblies from loading, set one of the following to a semicolon-delimited string of hosting startup assemblies to exclude at startup:
  - Hosting Startup Exclude Assemblies host configuration setting:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseSetting(
                    WebHostDefaults.HostingStartupExcludeAssembliesKey,
                    "{ASSEMBLY1;ASSEMBLY2; ...}")
                .UseStartup<Startup>();
        });
```

  - `ASPNETCORE_HOSTINGSTARTUPEXCLUDEASSEMBLIES` environment variable.

If both the host configuration setting and the environment variable are set, the host setting controls the behavior.

Disabling hosting startup assemblies using the host setting or environment variable disables the assembly globally and may disable several characteristics of an app.

Project

Create a hosting startup with either of the following project types:

- Class library
- Console app without an entry point

Class library

A hosting startup enhancement can be provided in a class library. The library contains a `HostingStartup` attribute.

The sample code includes a Razor Pages app, *HostingStartupApp*, and a class library, *HostingStartupLibrary*. The class library:

- Contains a hosting startup class, `ServiceKeyInjection`, which implements `IHostingStartup`. `ServiceKeyInjection` adds a pair of service strings to the app's configuration using the in-memory configuration provider (AddInMemoryCollection).
- Includes a `HostingStartup` attribute that identifies the hosting startup's namespace and class.

The `ServiceKeyInjection` class's Configure method uses an IWebHostBuilder to add enhancements to an app.

HostingStartupLibrary/ServiceKeyInjection.cs:

```
[assembly: HostingStartup(typeof(HostingStartupLibrary.ServiceKeyInjection))]

namespace HostingStartupLibrary
{
    public class ServiceKeyInjection : IHostingStartup
    {
        public void Configure(IWebHostBuilder builder)
        {
            builder.ConfigureAppConfiguration(config =>
            {
                var dict = new Dictionary<string, string>
                {
                    {"DevAccount_FromLibrary", "DEV_1111111-1111"},
                    {"ProdAccount_FromLibrary", "PROD_2222222-2222"}
                };

                config.AddInMemoryCollection(dict);
            });
        }
    }
}
```

The app's Index page reads and renders the configuration values for the two keys set by the class library's hosting startup assembly:

HostingStartupApp/Pages/Index.cshtml.cs:

```
public class IndexModel : PageModel
{
    public IndexModel(IConfiguration config)
    {
        ServiceKey_Development_Library = config["DevAccount_FromLibrary"];
        ServiceKey_Production_Library = config["ProdAccount_FromLibrary"];
        ServiceKey_Development_Package = config["DevAccount_FromPackage"];
        ServiceKey_Production_Package = config["ProdAccount_FromPackage"];
    }

    public string ServiceKey_Development_Library { get; private set; }
    public string ServiceKey_Production_Library { get; private set; }
    public string ServiceKey_Development_Package { get; private set; }
    public string ServiceKey_Production_Package { get; private set; }

    public void OnGet()
    {
    }
}
```

The sample code also includes a NuGet package project that provides a separate hosting startup, *HostingStartupPackage*. The package has the same characteristics of the class library described earlier. The package:

- Contains a hosting startup class, `ServiceKeyInjection`, which implements `IHostingStartup`. `ServiceKeyInjection` adds a pair of service strings to the app's configuration.
- Includes a `HostingStartup` attribute.

HostingStartupPackage/ServiceKeyInjection.cs:

```
[assembly: HostingStartup(typeof(HostingStartupPackage.ServiceKeyInjection))]

namespace HostingStartupPackage
{
    public class ServiceKeyInjection : IHostingStartup
    {
        public void Configure(IWebHostBuilder builder)
        {
            builder.ConfigureAppConfiguration(config =>
            {
                var dict = new Dictionary<string, string>
                {
                    {"DevAccount_FromPackage", "DEV_3333333-3333"},
                    {"ProdAccount_FromPackage", "PROD_4444444-4444"}
                };

                config.AddInMemoryCollection(dict);
            });
        }
    }
}
```

The app's Index page reads and renders the configuration values for the two keys set by the package's hosting startup assembly:

HostingStartupApp/Pages/Index.cshtml.cs:

```
public class IndexModel : PageModel
{
    public IndexModel(IConfiguration config)
    {
        ServiceKey_Development_Library = config["DevAccount_FromLibrary"];
        ServiceKey_Production_Library = config["ProdAccount_FromLibrary"];
        ServiceKey_Development_Package = config["DevAccount_FromPackage"];
        ServiceKey_Production_Package = config["ProdAccount_FromPackage"];
    }

    public string ServiceKey_Development_Library { get; private set; }
    public string ServiceKey_Production_Library { get; private set; }
    public string ServiceKey_Development_Package { get; private set; }
    public string ServiceKey_Production_Package { get; private set; }

    public void OnGet()
    {
    }
}
```

Console app without an entry point

This approach is only available for .NET Core apps, not .NET Framework.

A dynamic hosting startup enhancement that doesn't require a compile-time reference for activation can be provided in a console app without an entry point that contains a `HostingStartup` attribute. Publishing the console app produces a hosting startup assembly that can be consumed from the runtime store.

A console app without an entry point is used in this process because:

- A dependencies file is required to consume the hosting startup in the hosting startup assembly. A dependencies file is a runnable app asset that's produced by publishing an app, not a library.
- A library can't be added directly to the runtime package store, which requires a runnable project that targets the shared runtime.

In the creation of a dynamic hosting startup:

- A hosting startup assembly is created from the console app without an entry point that:
  - Includes a class that contains the `IHostingStartup` implementation.
  - Includes a HostingStartup attribute to identify the `IHostingStartup` implementation class.
- The console app is published to obtain the hosting startup's dependencies. A consequence of publishing the console app is that unused dependencies are trimmed from the dependencies file.
- The dependencies file is modified to set the runtime location of the hosting startup assembly.
- The hosting startup assembly and its dependencies file is placed into the runtime package store. To discover the hosting startup assembly and its dependencies file, they're listed in a pair of environment variables.

The console app references the Microsoft.AspNetCore.Hosting.Abstractions package:

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.Hosting.Abstractions"
                      Version="3.0.0" />
  </ItemGroup>

</Project>
```

A HostingStartup attribute identifies a class as an implementation of `IHostingStartup` for loading and execution when building the IWebHost. In the following example, the namespace is `StartupEnhancement`, and the class is `StartupEnhancementHostingStartup`:

```
[assembly: HostingStartup(typeof(StartupEnhancement.StartupEnhancementHostingStartup))]
```

A class implements `IHostingStartup`. The class's Configure method uses an IWebHostBuilder to add enhancements to an app. `IHostingStartup.Configure` in the hosting startup assembly is called by the runtime before `Startup.Configure` in user code, which allows user code to overwrite any configuration provided by the hosting startup assembly.

```
namespace StartupEnhancement
{
    public class StartupEnhancementHostingStartup : IHostingStartup
    {
        public void Configure(IWebHostBuilder builder)
        {
            // Use the IWebHostBuilder to add app enhancements.
        }
    }
}
```

When building an `IHostingStartup` project, the dependencies file (*.deps.json*) sets the `runtime` location of the assembly to the *bin* folder:

```
"targets": {
  ".NETCoreApp,Version=v3.0": {
    "StartupEnhancement/1.0.0": {
      "dependencies": {
        "Microsoft.AspNetCore.Hosting.Abstractions": "3.0.0"
      },
      "runtime": {
        "StartupEnhancement.dll": {}
      }
    }
  }
}
```

Only part of the file is shown. The assembly name in the example is `StartupEnhancement`.

Configuration provided by the hosting startup

There are two approaches to handling configuration depending on whether you want the hosting startup's configuration to take precedence or the app's configuration to take precedence:

1. Provide configuration to the app using ConfigureAppConfiguration to load the configuration after the app's ConfigureAppConfiguration delegates execute. Hosting startup configuration takes priority over the app's configuration using this approach.
2. Provide configuration to the app using UseConfiguration to load the configuration before the app's ConfigureAppConfiguration delegates execute. The app's configuration values take priority over those provided by the hosting startup using this approach.

```
public class ConfigurationInjection : IHostingStartup
{
    public void Configure(IWebHostBuilder builder)
    {
        Dictionary<string, string> dict;

        builder.ConfigureAppConfiguration(config =>
        {
            dict = new Dictionary<string, string>
            {
                {"ConfigurationKey1",
                    "From IHostingStartup: Higher priority " +
                    "than the app's configuration."},
            };

            config.AddInMemoryCollection(dict);
        });

        dict = new Dictionary<string, string>
        {
            {"ConfigurationKey2",
                "From IHostingStartup: Lower priority " +
                "than the app's configuration."},
        };

        var builtConfig = new ConfigurationBuilder()
            .AddInMemoryCollection(dict)
            .Build();

        builder.UseConfiguration(builtConfig);
    }
}
```

Specify the hosting startup assembly

For either a class library- or console app-supplied hosting startup, specify the hosting startup assembly's name in the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES` environment variable. The environment variable is a semicolon-delimited list of assemblies.

Only hosting startup assemblies are scanned for the `HostingStartup` attribute. For the sample app, *HostingStartupApp*, to discover the hosting startups described earlier, the environment variable is set to the following value:

```
HostingStartupLibrary;HostingStartupPackage;StartupDiagnostics
```

A hosting startup assembly can also be set using the Hosting Startup Assemblies host configuration setting:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseSetting(
                    WebHostDefaults.HostingStartupAssembliesKey,
                    "{ASSEMBLY1;ASSEMBLY2; ...}")
                .UseStartup<Startup>();
        });
```

When multiple hosting startup assembles are present, their Configure methods are executed in the order that the assemblies are listed.

Activation

Options for hosting startup activation are:

- Runtime store: Activation doesn't require a compile-time reference for activation. The sample app places the hosting startup assembly and dependencies files into a folder, *deployment*, to facilitate deployment of the hosting startup in a multimachine environment. The *deployment* folder also includes a PowerShell script that creates or modifies environment variables on the deployment system to enable the hosting startup.
- Compile-time reference required for activation
  - NuGet package
  - Project bin folder

Runtime store

The hosting startup implementation is placed in the runtime store. A compile-time reference to the assembly isn't required by the enhanced app.

After the hosting startup is built, a runtime store is generated using the manifest project file and the dotnet store command.

```
dotnet store --manifest {MANIFEST FILE} --runtime {RUNTIME IDENTIFIER} --output {OUTPUT LOCATION} --skip-
optimization
```

In the sample app (*RuntimeStore* project) the following command is used:

```
dotnet store --manifest store.manifest.csproj --runtime win7-x64 --output ./deployment/store --skip-
optimization
```

For the runtime to discover the runtime store, the runtime store's location is added to the `DOTNET_SHARED_STORE` environment variable.

Modify and place the hosting startup's dependencies file

To activate the enhancement without a package reference to the enhancement, specify additional dependencies to the runtime with `additionalDeps`. `additionalDeps` allows you to:

- Extend the app's library graph by providing a set of additional *.deps.json* files to merge with the app's own *.deps.json* file on startup.
- Make the hosting startup assembly discoverable and loadable.

The recommended approach for generating the additional dependencies file is to:

1. Execute `dotnet publish` on the runtime store manifest file referenced in the previous section.
2. Remove the manifest reference from libraries and the `runtime` section of the resulting *.deps.json* file.

In the example project, the `store.manifest/1.0.0` property is removed from the `targets` and `libraries` section:

```
{
  "runtimeTarget": {
    "name": ".NETCoreApp,Version=v3.0",
    "signature": ""
  },
  "compilationOptions": {},
  "targets": {
    ".NETCoreApp,Version=v3.0": {
      "store.manifest/1.0.0": {
        "dependencies": {
          "StartupDiagnostics": "1.0.0"
        },
        "runtime": {
          "store.manifest.dll": {}
        }
      },
      "StartupDiagnostics/1.0.0": {
        "runtime": {
          "lib/netcoreapp3.0/StartupDiagnostics.dll": {
            "assemblyVersion": "1.0.0.0",
            "fileVersion": "1.0.0.0"
          }
        }
      }
    }
  },
  "libraries": {
    "store.manifest/1.0.0": {
      "type": "project",
      "serviceable": false,
      "sha512": ""
    },
    "StartupDiagnostics/1.0.0": {
      "type": "package",
      "serviceable": true,
      "sha512": "sha512-
xrhzuNSyM5/f4ZswhooJ9dmIYLP64wMnqUJSyTKVDKDVj5T+qtzypl8JmM/aFJLLpYrf0FYpVWvGujd7/FfMEw==",
      "path": "startupdiagnostics/1.0.0",
      "hashPath": "startupdiagnostics.1.0.0.nupkg.sha512"
    }
  }
}
```

Place the *.deps.json* file into the following location:

```
{ADDITIONAL DEPENDENCIES PATH}/shared/{SHARED FRAMEWORK NAME}/{SHARED FRAMEWORK VERSION}/{ENHANCEMENT
ASSEMBLY NAME}.deps.json
```

- `{ADDITIONAL DEPENDENCIES PATH}`: Location added to the `DOTNET_ADDITIONAL_DEPS` environment variable.
- `{SHARED FRAMEWORK NAME}`: Shared framework required for this additional dependencies file.
- `{SHARED FRAMEWORK VERSION}`: Minimum shared framework version.
- `{ENHANCEMENT ASSEMBLY NAME}`: The enhancement's assembly name.

In the sample app (*RuntimeStore* project), the additional dependencies file is placed into the following location:

```
deployment/additionalDeps/shared/Microsoft.AspNetCore.App/3.0.0/StartupDiagnostics.deps.json
```

For runtime to discover the runtime store location, the additional dependencies file location is added to the `DOTNET_ADDITIONAL_DEPS` environment variable.

In the sample app (*RuntimeStore* project), building the runtime store and generating the additional dependencies file is accomplished using a PowerShell script.

For examples of how to set environment variables for various operating systems, see Use multiple environments.

Deployment

To facilitate the deployment of a hosting startup in a multimachine environment, the sample app creates a *deployment* folder in published output that contains:

- The hosting startup runtime store.
- The hosting startup dependencies file.
- A PowerShell script that creates or modifies the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES`, `DOTNET_SHARED_STORE`, and `DOTNET_ADDITIONAL_DEPS` to support the activation of the hosting startup. Run the script from an administrative PowerShell command prompt on the deployment system.

NuGet package

A hosting startup enhancement can be provided in a NuGet package. The package has a `HostingStartup` attribute. The hosting startup types provided by the package are made available to the app using either of the following approaches:

- The enhanced app's project file makes a package reference for the hosting startup in the app's project file (a compile-time reference). With the compile-time reference in place, the hosting startup assembly and all of its dependencies are incorporated into the app's dependency file (*.deps.json*). This approach applies to a hosting startup assembly package published to nuget.org.
- The hosting startup's dependencies file is made available to the enhanced app as described in the Runtime store section (without a compile-time reference).

For more information on NuGet packages and the runtime store, see the following topics:

- How to Create a NuGet Package with Cross Platform Tools
- Publishing packages
- Runtime package store

Project bin folder

A hosting startup enhancement can be provided by a *bin*-deployed assembly in the enhanced app. The hosting startup types provided by the assembly are made available to the app using one of the following approaches:

- The enhanced app's project file makes an assembly reference to the hosting startup (a compile-time

reference). With the compile-time reference in place, the hosting startup assembly and all of its dependencies are incorporated into the app's dependency file (*.deps.json*). This approach applies when the deployment scenario calls for making a compile-time reference to the hosting startup's assembly (*.dll* file) and moving the assembly to either:
    - The consuming project.
    - A location accessible by the consuming project.
- The hosting startup's dependencies file is made available to the enhanced app as described in the Runtime store section (without a compile-time reference).
- When targeting the .NET Framework, the assembly is loadable in the default load context, which on .NET Framework means that the assembly is located at either of the following locations:
    - Application base path: The *bin* folder where the app's executable (*.exe*) is located.
    - Global Assembly Cache (GAC): The GAC stores assemblies that several .NET Framework apps share. For more information, see How to: Install an assembly into the global assembly cache in the .NET Framework documentation.

Sample code

The sample code (how to download) demonstrates hosting startup implementation scenarios:

- Two hosting startup assemblies (class libraries) set a pair of in-memory configuration key-value pairs each:
    - NuGet package (*HostingStartupPackage*)
    - Class library (*HostingStartupLibrary*)
- A hosting startup is activated from a runtime store-deployed assembly (*StartupDiagnostics*). The assembly adds two middlewares to the app at startup that provide diagnostic information on:
    - Registered services
    - Address (scheme, host, path base, path, query string)
    - Connection (remote IP, remote port, local IP, local port, client certificate)
    - Request headers
    - Environment variables

To run the sample:

Activation from a NuGet package

1. Compile the *HostingStartupPackage* package with the dotnet pack command.
2. Add the package's assembly name of the *HostingStartupPackage* to the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES` environment variable.
3. Compile and run the app. A package reference is present in the enhanced app (a compile-time reference). A `<PropertyGroup>` in the app's project file specifies the package project's output (*../HostingStartupPackage/bin/Debug*) as a package source. This allows the app to use the package without uploading the package to nuget.org. For more information, see the notes in the HostingStartupApp's project file.

    ```
    <PropertyGroup>

    <RestoreSources>$(RestoreSources);https://api.nuget.org/v3/index.json;../HostingStartupPackage/bin/De
    bug</RestoreSources>
    </PropertyGroup>
    ```

4. Observe that the service configuration key values rendered by the Index page match the values set by the package's `ServiceKeyInjection.Configure` method.

If you make changes to the *HostingStartupPackage* project and recompile it, clear the local NuGet package caches to ensure that the *HostingStartupApp* receives the updated package and not a stale package from the local cache. To clear the local NuGet caches, execute the following dotnet nuget locals command:

```
dotnet nuget locals all --clear
```

Activation from a class library

1. Compile the *HostingStartupLibrary* class library with the dotnet build command.
2. Add the class library's assembly name of *HostingStartupLibrary* to the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES` environment variable.
3. *bin*-deploy the class library's assembly to the app by copying the *HostingStartupLibrary.dll* file from the class library's compiled output to the app's *bin/Debug* folder.
4. Compile and run the app. An `<ItemGroup>` in the app's project file references the class library's assembly (*.\bin\Debug\netcoreapp3.0\HostingStartupLibrary.dll*) (a compile-time reference). For more information, see the notes in the HostingStartupApp's project file.

   ```
   <ItemGroup>
     <Reference Include=".\\bin\\Debug\\netcoreapp3.0\\HostingStartupLibrary.dll">
       <HintPath>.\bin\Debug\netcoreapp3.0\HostingStartupLibrary.dll</HintPath>
       <SpecificVersion>False</SpecificVersion>
     </Reference>
   </ItemGroup>
   ```

5. Observe that the service configuration key values rendered by the Index page match the values set by the class library's `ServiceKeyInjection.Configure` method.

Activation from a runtime store-deployed assembly

1. The *StartupDiagnostics* project uses PowerShell to modify its *StartupDiagnostics.deps.json* file. PowerShell is installed by default on Windows starting with Windows 7 SP1 and Windows Server 2008 R2 SP1. To obtain PowerShell on other platforms, see Installing various versions of PowerShell.
2. Execute the *build.ps1* script in the *RuntimeStore* folder. The script:
   - Generates the `StartupDiagnostics` package in the *obj\packages* folder.
   - Generates the runtime store for `StartupDiagnostics` in the *store* folder. The `dotnet store` command in the script uses the `win7-x64` runtime identifier (RID) for a hosting startup deployed to Windows. When providing the hosting startup for a different runtime, substitute the correct RID on line 37 of the script. The runtime store for `StartupDiagnostics` would later be moved to the user's or system's runtime store on the machine where the assembly will be consumed. The user runtime store install location for the `StartupDiagnostics` assembly is *.dotnet/store/x64/netcoreapp3.0/startupdiagnostics/1.0.0/lib/netcoreapp3.0/StartupDiagnostics.dll*.
   - Generates the `additionalDeps` for `StartupDiagnostics` in the *additionalDeps* folder. The additional dependencies would later be moved to the user's or system's additional dependencies. The user `StartupDiagnostics` additional dependencies install location is *.dotnet/x64/additionalDeps/StartupDiagnostics/shared/Microsoft.NETCore.App/3.0.0/StartupDiagnostics.deps.json*.
   - Places the *deploy.ps1* file in the *deployment* folder.
3. Run the *deploy.ps1* script in the *deployment* folder. The script appends:
   - `StartupDiagnostics` to the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES` environment variable.
   - The hosting startup dependencies path (in the RuntimeStore project's *deployment* folder) to the `DOTNET_ADDITIONAL_DEPS` environment variable.

- The runtime store path (in the RuntimeStore project's *deployment* folder) to the `DOTNET_SHARED_STORE` environment variable.

4. Run the sample app.
5. Request the `/services` endpoint to see the app's registered services. Request the `/diag` endpoint to see the diagnostic information.

An IHostingStartup (hosting startup) implementation adds enhancements to an app at startup from an external assembly. For example, an external library can use a hosting startup implementation to provide additional configuration providers or services to an app.

View or download sample code (how to download)

HostingStartup attribute

A HostingStartup attribute indicates the presence of a hosting startup assembly to activate at runtime.

The entry assembly or the assembly containing the `Startup` class is automatically scanned for the `HostingStartup` attribute. The list of assemblies to search for `HostingStartup` attributes is loaded at runtime from configuration in the WebHostDefaults.HostingStartupAssembliesKey. The list of assemblies to exclude from discovery is loaded from the WebHostDefaults.HostingStartupExcludeAssembliesKey. For more information, see Web Host: Hosting Startup Assemblies and Web Host: Hosting Startup Exclude Assemblies.

In the following example, the namespace of the hosting startup assembly is `StartupEnhancement`. The class containing the hosting startup code is `StartupEnhancementHostingStartup`:

```
[assembly: HostingStartup(typeof(StartupEnhancement.StartupEnhancementHostingStartup))]
```

The `HostingStartup` attribute is typically located in the hosting startup assembly's `IHostingStartup` implementation class file.

Discover loaded hosting startup assemblies

To discover loaded hosting startup assemblies, enable logging and check the app's logs. Errors that occur when loading assemblies are logged. Loaded hosting startup assemblies are logged at the Debug level, and all errors are logged.

Disable automatic loading of hosting startup assemblies

To disable automatic loading of hosting startup assemblies, use one of the following approaches:

- To prevent all hosting startup assemblies from loading, set one of the following to `true` or `1`:
  - Prevent Hosting Startup host configuration setting.
  - `ASPNETCORE_PREVENTHOSTINGSTARTUP` environment variable.
- To prevent specific hosting startup assemblies from loading, set one of the following to a semicolon-delimited string of hosting startup assemblies to exclude at startup:
  - Hosting Startup Exclude Assemblies host configuration setting.
  - `ASPNETCORE_HOSTINGSTARTUPEXCLUDEASSEMBLIES` environment variable.

If both the host configuration setting and the environment variable are set, the host setting controls the behavior.

Disabling hosting startup assemblies using the host setting or environment variable disables the assembly globally and may disable several characteristics of an app.

Project

Create a hosting startup with either of the following project types:

- Class library
- Console app without an entry point

Class library

A hosting startup enhancement can be provided in a class library. The library contains a `HostingStartup` attribute.

The sample code includes a Razor Pages app, *HostingStartupApp*, and a class library, *HostingStartupLibrary*. The class library:

- Contains a hosting startup class, `ServiceKeyInjection`, which implements `IHostingStartup`. `ServiceKeyInjection` adds a pair of service strings to the app's configuration using the in-memory configuration provider (AddInMemoryCollection).
- Includes a `HostingStartup` attribute that identifies the hosting startup's namespace and class.

The `ServiceKeyInjection` class's Configure method uses an IWebHostBuilder to add enhancements to an app.

HostingStartupLibrary/ServiceKeyInjection.cs:

```
[assembly: HostingStartup(typeof(HostingStartupLibrary.ServiceKeyInjection))]

namespace HostingStartupLibrary
{
    public class ServiceKeyInjection : IHostingStartup
    {
        public void Configure(IWebHostBuilder builder)
        {
            builder.ConfigureAppConfiguration(config =>
            {
                var dict = new Dictionary<string, string>
                {
                    {"DevAccount_FromLibrary", "DEV_1111111-1111"},
                    {"ProdAccount_FromLibrary", "PROD_2222222-2222"}
                };

                config.AddInMemoryCollection(dict);
            });
        }
    }
}
```

The app's Index page reads and renders the configuration values for the two keys set by the class library's hosting startup assembly:

HostingStartupApp/Pages/Index.cshtml.cs:

```
public class IndexModel : PageModel
{
    public IndexModel(IConfiguration config)
    {
        ServiceKey_Development_Library = config["DevAccount_FromLibrary"];
        ServiceKey_Production_Library = config["ProdAccount_FromLibrary"];
        ServiceKey_Development_Package = config["DevAccount_FromPackage"];
        ServiceKey_Production_Package = config["ProdAccount_FromPackage"];
    }

    public string ServiceKey_Development_Library { get; private set; }
    public string ServiceKey_Production_Library { get; private set; }
    public string ServiceKey_Development_Package { get; private set; }
    public string ServiceKey_Production_Package { get; private set; }

    public void OnGet()
    {
    }
}
```

The sample code also includes a NuGet package project that provides a separate hosting startup, *HostingStartupPackage*. The package has the same characteristics of the class library described earlier. The package:

- Contains a hosting startup class, `ServiceKeyInjection`, which implements `IHostingStartup`. `ServiceKeyInjection` adds a pair of service strings to the app's configuration.
- Includes a `HostingStartup` attribute.

HostingStartupPackage/ServiceKeyInjection.cs:

```
[assembly: HostingStartup(typeof(HostingStartupPackage.ServiceKeyInjection))]

namespace HostingStartupPackage
{
    public class ServiceKeyInjection : IHostingStartup
    {
        public void Configure(IWebHostBuilder builder)
        {
            builder.ConfigureAppConfiguration(config =>
            {
                var dict = new Dictionary<string, string>
                {
                    {"DevAccount_FromPackage", "DEV_3333333-3333"},
                    {"ProdAccount_FromPackage", "PROD_4444444-4444"}
                };

                config.AddInMemoryCollection(dict);
            });
        }
    }
}
```

The app's Index page reads and renders the configuration values for the two keys set by the package's hosting startup assembly:

HostingStartupApp/Pages/Index.cshtml.cs:

```
public class IndexModel : PageModel
{
    public IndexModel(IConfiguration config)
    {
        ServiceKey_Development_Library = config["DevAccount_FromLibrary"];
        ServiceKey_Production_Library = config["ProdAccount_FromLibrary"];
        ServiceKey_Development_Package = config["DevAccount_FromPackage"];
        ServiceKey_Production_Package = config["ProdAccount_FromPackage"];
    }

    public string ServiceKey_Development_Library { get; private set; }
    public string ServiceKey_Production_Library { get; private set; }
    public string ServiceKey_Development_Package { get; private set; }
    public string ServiceKey_Production_Package { get; private set; }

    public void OnGet()
    {
    }
}
```

Console app without an entry point

This approach is only available for .NET Core apps, not .NET Framework.

A dynamic hosting startup enhancement that doesn't require a compile-time reference for activation can be provided in a console app without an entry point that contains a `HostingStartup` attribute. Publishing the console app produces a hosting startup assembly that can be consumed from the runtime store.

A console app without an entry point is used in this process because:

- A dependencies file is required to consume the hosting startup in the hosting startup assembly. A dependencies file is a runnable app asset that's produced by publishing an app, not a library.
- A library can't be added directly to the runtime package store, which requires a runnable project that targets the shared runtime.

In the creation of a dynamic hosting startup:

- A hosting startup assembly is created from the console app without an entry point that:
  - Includes a class that contains the `IHostingStartup` implementation.
  - Includes a HostingStartup attribute to identify the `IHostingStartup` implementation class.
- The console app is published to obtain the hosting startup's dependencies. A consequence of publishing the console app is that unused dependencies are trimmed from the dependencies file.
- The dependencies file is modified to set the runtime location of the hosting startup assembly.
- The hosting startup assembly and its dependencies file is placed into the runtime package store. To discover the hosting startup assembly and its dependencies file, they're listed in a pair of environment variables.

The console app references the Microsoft.AspNetCore.Hosting.Abstractions package:

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netcoreapp2.1</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.Hosting.Abstractions"
                      Version="2.1.1" />
  </ItemGroup>

</Project>
```

A HostingStartup attribute identifies a class as an implementation of `IHostingStartup` for loading and execution when building the IWebHost. In the following example, the namespace is `StartupEnhancement`, and the class is `StartupEnhancementHostingStartup`:

```
[assembly: HostingStartup(typeof(StartupEnhancement.StartupEnhancementHostingStartup))]
```

A class implements `IHostingStartup`. The class's Configure method uses an IWebHostBuilder to add enhancements to an app. `IHostingStartup.Configure` in the hosting startup assembly is called by the runtime before `Startup.Configure` in user code, which allows user code to overwrite any configuration provided by the hosting startup assembly.

```
namespace StartupEnhancement
{
    public class StartupEnhancementHostingStartup : IHostingStartup
    {
        public void Configure(IWebHostBuilder builder)
        {
            // Use the IWebHostBuilder to add app enhancements.
        }
    }
}
```

When building an `IHostingStartup` project, the dependencies file (*.deps.json*) sets the `runtime` location of the assembly to the *bin* folder:

```
"targets": {
  ".NETCoreApp,Version=v2.1": {
    "StartupEnhancement/1.0.0": {
      "dependencies": {
        "Microsoft.AspNetCore.Hosting.Abstractions": "2.1.1"
      },
      "runtime": {
        "StartupEnhancement.dll": {}
      }
    }
  }
}
```

Only part of the file is shown. The assembly name in the example is `StartupEnhancement`.

Configuration provided by the hosting startup

There are two approaches to handling configuration depending on whether you want the hosting startup's configuration to take precedence or the app's configuration to take precedence:

1. Provide configuration to the app using ConfigureAppConfiguration to load the configuration after the app's ConfigureAppConfiguration delegates execute. Hosting startup configuration takes priority over the app's configuration using this approach.
2. Provide configuration to the app using UseConfiguration to load the configuration before the app's ConfigureAppConfiguration delegates execute. The app's configuration values take priority over those provided by the hosting startup using this approach.

```
public class ConfigurationInjection : IHostingStartup
{
    public void Configure(IWebHostBuilder builder)
    {
        Dictionary<string, string> dict;

        builder.ConfigureAppConfiguration(config =>
        {
            dict = new Dictionary<string, string>
            {
                {"ConfigurationKey1",
                    "From IHostingStartup: Higher priority " +
                    "than the app's configuration."},
            };

            config.AddInMemoryCollection(dict);
        });

        dict = new Dictionary<string, string>
        {
            {"ConfigurationKey2",
                "From IHostingStartup: Lower priority " +
                "than the app's configuration."},
        };

        var builtConfig = new ConfigurationBuilder()
            .AddInMemoryCollection(dict)
            .Build();

        builder.UseConfiguration(builtConfig);
    }
}
```

Specify the hosting startup assembly

For either a class library- or console app-supplied hosting startup, specify the hosting startup assembly's name in the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES` environment variable. The environment variable is a semicolon-delimited list of assemblies.

Only hosting startup assemblies are scanned for the `HostingStartup` attribute. For the sample app, *HostingStartupApp*, to discover the hosting startups described earlier, the environment variable is set to the following value:

```
HostingStartupLibrary;HostingStartupPackage;StartupDiagnostics
```

A hosting startup assembly can also be set using the Hosting Startup Assemblies host configuration setting.

When multiple hosting startup assembles are present, their Configure methods are executed in the order that the assemblies are listed.

Activation

Options for hosting startup activation are:

- Runtime store: Activation doesn't require a compile-time reference for activation. The sample app places the hosting startup assembly and dependencies files into a folder, *deployment*, to facilitate deployment of the hosting startup in a multimachine environment. The *deployment* folder also includes a PowerShell script that creates or modifies environment variables on the deployment system to enable the hosting startup.
- Compile-time reference required for activation

- NuGet package
- Project bin folder

Runtime store

The hosting startup implementation is placed in the runtime store. A compile-time reference to the assembly isn't required by the enhanced app.

After the hosting startup is built, a runtime store is generated using the manifest project file and the dotnet store command.

```
dotnet store --manifest {MANIFEST FILE} --runtime {RUNTIME IDENTIFIER} --output {OUTPUT LOCATION} --skip-optimization
```

In the sample app (*RuntimeStore* project) the following command is used:

```
dotnet store --manifest store.manifest.csproj --runtime win7-x64 --output ./deployment/store --skip-optimization
```

For the runtime to discover the runtime store, the runtime store's location is added to the `DOTNET_SHARED_STORE` environment variable.

Modify and place the hosting startup's dependencies file

To activate the enhancement without a package reference to the enhancement, specify additional dependencies to the runtime with `additionalDeps`. `additionalDeps` allows you to:

- Extend the app's library graph by providing a set of additional *.deps.json* files to merge with the app's own *.deps.json* file on startup.
- Make the hosting startup assembly discoverable and loadable.

The recommended approach for generating the additional dependencies file is to:

1. Execute `dotnet publish` on the runtime store manifest file referenced in the previous section.
2. Remove the manifest reference from libraries and the `runtime` section of the resulting *.deps.json* file.

In the example project, the `store.manifest/1.0.0` property is removed from the `targets` and `libraries` section:

```
{
  "runtimeTarget": {
    "name": ".NETCoreApp,Version=v2.1",
    "signature": "4ea77c7b75ad1895ae1ea65e6ba2399010514f99"
  },
  "compilationOptions": {},
  "targets": {
    ".NETCoreApp,Version=v2.1": {
      "store.manifest/1.0.0": {
        "dependencies": {
          "StartupDiagnostics": "1.0.0"
        },
        "runtime": {
          "store.manifest.dll": {}
        }
      },
      "StartupDiagnostics/1.0.0": {
        "runtime": {
          "lib/netcoreapp2.1/StartupDiagnostics.dll": {
            "assemblyVersion": "1.0.0.0",
            "fileVersion": "1.0.0.0"
          }
        }
      }
    }
  },
  "libraries": {
    "store.manifest/1.0.0": {
      "type": "project",
      "serviceable": false,
      "sha512": ""
    },
    "StartupDiagnostics/1.0.0": {
      "type": "package",
      "serviceable": true,
      "sha512": "sha512-
oiQr60vBQW7+nBTmgKLSldj06WNLRTdhOZpAdEbCuapoZ+M2DJH2uQbRLvFT8EGAAv4TAKzNtcztpx5YOgBXQQ==",
      "path": "startupdiagnostics/1.0.0",
      "hashPath": "startupdiagnostics.1.0.0.nupkg.sha512"
    }
  }
}
```

Place the *.deps.json* file into the following location:

```
{ADDITIONAL DEPENDENCIES PATH}/shared/{SHARED FRAMEWORK NAME}/{SHARED FRAMEWORK VERSION}/{ENHANCEMENT
ASSEMBLY NAME}.deps.json
```

- `{ADDITIONAL DEPENDENCIES PATH}`: Location added to the `DOTNET_ADDITIONAL_DEPS` environment variable.
- `{SHARED FRAMEWORK NAME}`: Shared framework required for this additional dependencies file.
- `{SHARED FRAMEWORK VERSION}`: Minimum shared framework version.
- `{ENHANCEMENT ASSEMBLY NAME}`: The enhancement's assembly name.

In the sample app (*RuntimeStore* project), the additional dependencies file is placed into the following location:

```
deployment/additionalDeps/shared/Microsoft.AspNetCore.App/2.1.0/StartupDiagnostics.deps.json
```

For runtime to discover the runtime store location, the additional dependencies file location is added to the `DOTNET_ADDITIONAL_DEPS` environment variable.

In the sample app (*RuntimeStore* project), building the runtime store and generating the additional

dependencies file is accomplished using a PowerShell script.

For examples of how to set environment variables for various operating systems, see Use multiple environments.

Deployment

To facilitate the deployment of a hosting startup in a multimachine environment, the sample app creates a *deployment* folder in published output that contains:

- The hosting startup runtime store.
- The hosting startup dependencies file.
- A PowerShell script that creates or modifies the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES`, `DOTNET_SHARED_STORE`, and `DOTNET_ADDITIONAL_DEPS` to support the activation of the hosting startup. Run the script from an administrative PowerShell command prompt on the deployment system.

NuGet package

A hosting startup enhancement can be provided in a NuGet package. The package has a `HostingStartup` attribute. The hosting startup types provided by the package are made available to the app using either of the following approaches:

- The enhanced app's project file makes a package reference for the hosting startup in the app's project file (a compile-time reference). With the compile-time reference in place, the hosting startup assembly and all of its dependencies are incorporated into the app's dependency file (*.deps.json*). This approach applies to a hosting startup assembly package published to nuget.org.
- The hosting startup's dependencies file is made available to the enhanced app as described in the Runtime store section (without a compile-time reference).

For more information on NuGet packages and the runtime store, see the following topics:

- How to Create a NuGet Package with Cross Platform Tools
- Publishing packages
- Runtime package store

Project bin folder

A hosting startup enhancement can be provided by a *bin*-deployed assembly in the enhanced app. The hosting startup types provided by the assembly are made available to the app using one of the following approaches:

- The enhanced app's project file makes an assembly reference to the hosting startup (a compile-time reference). With the compile-time reference in place, the hosting startup assembly and all of its dependencies are incorporated into the app's dependency file (*.deps.json*). This approach applies when the deployment scenario calls for making a compile-time reference to the hosting startup's assembly (*.dll* file) and moving the assembly to either:
  - The consuming project.
  - A location accessible by the consuming project.
- The hosting startup's dependencies file is made available to the enhanced app as described in the Runtime store section (without a compile-time reference).
- When targeting the .NET Framework, the assembly is loadable in the default load context, which on .NET Framework means that the assembly is located at either of the following locations:
  - Application base path: The *bin* folder where the app's executable (*.exe*) is located.
  - Global Assembly Cache (GAC): The GAC stores assemblies that several .NET Framework apps share. For more information, see How to: Install an assembly into the global assembly cache in the .NET Framework documentation.

Sample code

The sample code (how to download) demonstrates hosting startup implementation scenarios:

- Two hosting startup assemblies (class libraries) set a pair of in-memory configuration key-value pairs each:
  - NuGet package (*HostingStartupPackage*)
  - Class library (*HostingStartupLibrary*)
- A hosting startup is activated from a runtime store-deployed assembly (*StartupDiagnostics*). The assembly adds two middlewares to the app at startup that provide diagnostic information on:
  - Registered services
  - Address (scheme, host, path base, path, query string)
  - Connection (remote IP, remote port, local IP, local port, client certificate)
  - Request headers
  - Environment variables

To run the sample:

Activation from a NuGet package

1. Compile the *HostingStartupPackage* package with the dotnet pack command.
2. Add the package's assembly name of the *HostingStartupPackage* to the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES` environment variable.
3. Compile and run the app. A package reference is present in the enhanced app (a compile-time reference). A `<PropertyGroup>` in the app's project file specifies the package project's output (*../HostingStartupPackage/bin/Debug*) as a package source. This allows the app to use the package without uploading the package to nuget.org. For more information, see the notes in the HostingStartupApp's project file.

   ```
   <PropertyGroup>

   <RestoreSources>$(RestoreSources);https://api.nuget.org/v3/index.json;../HostingStartupPackage/bin/De
   bug</RestoreSources>
   </PropertyGroup>
   ```

4. Observe that the service configuration key values rendered by the Index page match the values set by the package's `ServiceKeyInjection.Configure` method.

If you make changes to the *HostingStartupPackage* project and recompile it, clear the local NuGet package caches to ensure that the *HostingStartupApp* receives the updated package and not a stale package from the local cache. To clear the local NuGet caches, execute the following dotnet nuget locals command:

```
dotnet nuget locals all --clear
```

Activation from a class library

1. Compile the *HostingStartupLibrary* class library with the dotnet build command.
2. Add the class library's assembly name of *HostingStartupLibrary* to the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES` environment variable.
3. *bin*-deploy the class library's assembly to the app by copying the *HostingStartupLibrary.dll* file from the class library's compiled output to the app's *bin/Debug* folder.
4. Compile and run the app. An `<ItemGroup>` in the app's project file references the class library's assembly

(*.\bin\Debug\netcoreapp2.1\HostingStartupLibrary.dll*) (a compile-time reference). For more information, see the notes in the HostingStartupApp's project file.

```
<ItemGroup>
  <Reference Include=".\\bin\\Debug\\netcoreapp2.1\\HostingStartupLibrary.dll">
    <HintPath>.\bin\Debug\netcoreapp2.1\HostingStartupLibrary.dll</HintPath>
    <SpecificVersion>False</SpecificVersion>
  </Reference>
</ItemGroup>
```

5. Observe that the service configuration key values rendered by the Index page match the values set by the class library's `ServiceKeyInjection.Configure` method.

Activation from a runtime store-deployed assembly

1. The *StartupDiagnostics* project uses PowerShell to modify its *StartupDiagnostics.deps.json* file. PowerShell is installed by default on Windows starting with Windows 7 SP1 and Windows Server 2008 R2 SP1. To obtain PowerShell on other platforms, see Installing various versions of PowerShell.
2. Execute the *build.ps1* script in the *RuntimeStore* folder. The script:
   - Generates the `StartupDiagnostics` package in the *obj\packages* folder.
   - Generates the runtime store for `StartupDiagnostics` in the *store* folder. The `dotnet store` command in the script uses the `win7-x64` runtime identifier (RID) for a hosting startup deployed to Windows. When providing the hosting startup for a different runtime, substitute the correct RID on line 37 of the script. The runtime store for `StartupDiagnostics` would later be moved to the user's or system's runtime store on the machine where the assembly will be consumed. The user runtime store install location for the `StartupDiagnostics` assembly is *.dotnet/store/x64/netcoreapp2.2/startupdiagnostics/1.0.0/lib/netcoreapp2.2/StartupDiagnostics.dll*.
   - Generates the `additionalDeps` for `StartupDiagnostics` in the *additionalDeps* folder. The additional dependencies would later be moved to the user's or system's additional dependencies. The user `StartupDiagnostics` additional dependencies install location is *.dotnet/x64/additionalDeps/StartupDiagnostics/shared/Microsoft.NETCore.App/2.2.0/StartupDiagnostics.deps.json*.
   - Places the *deploy.ps1* file in the *deployment* folder.
3. Run the *deploy.ps1* script in the *deployment* folder. The script appends:
   - `StartupDiagnostics` to the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES` environment variable.
   - The hosting startup dependencies path (in the RuntimeStore project's *deployment* folder) to the `DOTNET_ADDITIONAL_DEPS` environment variable.
   - The runtime store path (in the RuntimeStore project's *deployment* folder) to the `DOTNET_SHARED_STORE` environment variable.
4. Run the sample app.
5. Request the `/services` endpoint to see the app's registered services. Request the `/diag` endpoint to see the diagnostic information.

Use ASP.NET Core APIs in a class library

9/22/2020 • 9 minutes to read • Edit Online

By Scott Addie

This document provides guidance for using ASP.NET Core APIs in a class library. For all other library guidance, see Open-source library guidance.

Determine which ASP.NET Core versions to support

ASP.NET Core adheres to the .NET Core support policy. Consult the support policy when determining which ASP.NET Core versions to support in a library. A library should:

- Make an effort to support all ASP.NET Core versions classified as *Long-Term Support* (LTS).
- Not feel obligated to support ASP.NET Core versions classified as *End of Life* (EOL).

As preview releases of ASP.NET Core are made available, breaking changes are posted in the aspnet/Announcements GitHub repository. Compatibility testing of libraries can be conducted as framework features are being developed.

Use the ASP.NET Core shared framework

With the release of .NET Core 3.0, many ASP.NET Core assemblies are no longer published to NuGet as packages. Instead, the assemblies are included in the `Microsoft.AspNetCore.App` shared framework, which is installed with the .NET Core SDK and runtime installers. For a list of packages no longer being published, see Remove obsolete package references.

As of .NET Core 3.0, projects using the `Microsoft.NET.Sdk.Web` MSBuild SDK implicitly reference the shared framework. Projects using the `Microsoft.NET.Sdk` or `Microsoft.NET.Sdk.Razor` SDK must reference ASP.NET Core to use ASP.NET Core APIs in the shared framework.

To reference ASP.NET Core, add the following `<FrameworkReference>` element to your project file:

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

</Project>
```

Referencing ASP.NET Core in this manner is only supported for projects targeting .NET Core 3.x.

Include Blazor extensibility

Blazor supports WebAssembly (WASM) and Server hosting models. Unless there's a specific reason not to, a Razor components library should support both hosting models. A Razor components library must use the Microsoft.NET.Sdk.Razor SDK.

Support both hosting models

To support Razor component consumption from both Blazor Server and Blazor WASM projects, use the following instructions for your editor.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Use the **Razor Class Library** project template. The template's **Support pages and views** checkbox should be deselected.

The project generated from the template does the following things:

- Targets .NET Standard 2.0.
- Sets the `RazorLangVersion` property to `3.0`. `3.0` is the default value for .NET Core 3.x.
- Adds the following package references:
  - Microsoft.AspNetCore.Components
  - Microsoft.AspNetCore.Components.Web

For example:

```
<Project Sdk="Microsoft.NET.Sdk.Razor">

  <PropertyGroup>
    <TargetFrameworks>netstandard2.0</TargetFrameworks>
    <RazorLangVersion>3.0</RazorLangVersion>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.Components" Version="3.0.0" />
    <PackageReference Include="Microsoft.AspNetCore.Components.Web" Version="3.0.0" />
  </ItemGroup>

</Project>
```

Support a specific hosting model

It's far less common to support a single Blazor hosting model. As an example, to support Razor component consumption from Blazor Server projects only:

- Target .NET Core 3.x.
- Add a `<FrameworkReference>` element for the shared framework.

For example:

```
<Project Sdk="Microsoft.NET.Sdk.Razor">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

</Project>
```

For more information on libraries containing Razor components, see ASP.NET Core Razor components class libraries.

Include MVC extensibility

This section outlines recommendations for libraries that include:

- Razor views or Razor Pages
- Tag Helpers
- View components

This section doesn't discuss multi-targeting to support multiple versions of MVC. For guidance on supporting multiple ASP.NET Core versions, see Support multiple ASP.NET Core versions.

Razor views or Razor Pages

A project that includes Razor views or Razor Pages must use the Microsoft.NET.Sdk.Razor SDK.

If the project targets .NET Core 3.x, it requires:

- An `AddRazorSupportForMvc` MSBuild property set to `true`.
- A `<FrameworkReference>` element for the shared framework.

The **Razor Class Library** project template satisfies the preceding requirements for projects targeting .NET Core 3.x. Use the following instructions for your editor.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Use the **Razor Class Library** project template. The template's **Support pages and views** checkbox should be selected.

For example:

```
<Project Sdk="Microsoft.NET.Sdk.Razor">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
    <AddRazorSupportForMvc>true</AddRazorSupportForMvc>
  </PropertyGroup>

  <ItemGroup>
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

</Project>
```

If the project targets .NET Standard instead, a Microsoft.AspNetCore.Mvc package reference is required. The `Microsoft.AspNetCore.Mvc` package moved into the shared framework in ASP.NET Core 3.0 and is therefore no longer published. For example:

```
<Project Sdk="Microsoft.NET.Sdk.Razor">

  <PropertyGroup>
    <TargetFramework>netstandard2.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.Mvc" Version="2.2.0" />
  </ItemGroup>

</Project>
```

Tag Helpers

A project that includes Tag Helpers should use the `Microsoft.NET.Sdk` SDK. If targeting .NET Core 3.x, add a `<FrameworkReference>` element for the shared framework. For example:

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

</Project>
```

If targeting .NET Standard (to support versions earlier than ASP.NET Core 3.x), add a package reference to Microsoft.AspNetCore.Mvc.Razor. The `Microsoft.AspNetCore.Mvc.Razor` package moved into the shared framework and is therefore no longer published. For example:

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netstandard2.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.Mvc" Version="2.2.0" />
  </ItemGroup>

</Project>
```

View components

A project that includes View components should use the `Microsoft.NET.Sdk` SDK. If targeting .NET Core 3.x, add a `<FrameworkReference>` element for the shared framework. For example:

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

</Project>
```

If targeting .NET Standard (to support versions earlier than ASP.NET Core 3.x), add a package reference to Microsoft.AspNetCore.Mvc.ViewFeatures. The `Microsoft.AspNetCore.Mvc.ViewFeatures` package moved into the shared framework and is therefore no longer published. For example:

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netstandard2.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.Mvc.ViewFeatures" Version="2.2.0" />
  </ItemGroup>

</Project>
```

Support multiple ASP.NET Core versions

Multi-targeting is required to author a library that supports multiple variants of ASP.NET Core. Consider a scenario in which a Tag Helpers library must support the following ASP.NET Core variants:

- ASP.NET Core 2.1 targeting .NET Framework 4.6.1
- ASP.NET Core 2.x targeting .NET Core 2.x
- ASP.NET Core 3.x targeting .NET Core 3.x

The following project file supports these variants via the `TargetFrameworks` property:

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFrameworks>netcoreapp2.1;netcoreapp3.0;net461</TargetFrameworks>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Markdig" Version="0.16.0" />
  </ItemGroup>

  <ItemGroup Condition="'$(TargetFramework)' != 'netcoreapp3.0'">
    <PackageReference Include="Microsoft.AspNetCore.Mvc.Razor" Version="2.1.0" />
  </ItemGroup>

  <ItemGroup Condition="'$(TargetFramework)' == 'netcoreapp3.0'">
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>
</Project>
```

With the preceding project file:

- The `Markdig` package is added for all consumers.
- A reference to Microsoft.AspNetCore.Mvc.Razor is added for consumers targeting .NET Framework 4.6.1 or later or .NET Core 2.x. Version 2.1.0 of the package works with ASP.NET Core 2.2 because of backwards compatibility.
- The shared framework is referenced for consumers targeting .NET Core 3.x. The `Microsoft.AspNetCore.Mvc.Razor` package is included in the shared framework.

Alternatively, .NET Standard 2.0 could be targeted instead of targeting both .NET Core 2.1 and .NET Framework 4.6.1:

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFrameworks>netstandard2.0;netcoreapp3.0</TargetFrameworks>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Markdig" Version="0.16.0" />
  </ItemGroup>

  <ItemGroup Condition="'$(TargetFramework)' != 'netcoreapp3.0'">
    <PackageReference Include="Microsoft.AspNetCore.Mvc.Razor" Version="2.1.0" />
  </ItemGroup>

  <ItemGroup Condition="'$(TargetFramework)' == 'netcoreapp3.0'">
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>
</Project>
```

With the preceding project file, the following caveats exist:

- Since the library only contains Tag Helpers, it's more straightforward to target the specific platforms on which ASP.NET Core runs: .NET Core and .NET Framework. Tag Helpers can't be used by other .NET Standard 2.0-compliant target frameworks such as Unity, UWP, and Xamarin.
- Using .NET Standard 2.0 from .NET Framework has some issues that were addressed in .NET Framework 4.7.2. You can improve the experience for consumers using .NET Framework 4.6.1 through 4.7.1 by targeting .NET Framework 4.6.1.

If your library needs to call platform-specific APIs, target specific .NET implementations instead of .NET Standard. For more information, see Multi-targeting.

Use an API that hasn't changed

Imagine a scenario in which you're upgrading a middleware library from .NET Core 2.2 to 3.0. The ASP.NET Core middleware APIs being used in the library haven't changed between ASP.NET Core 2.2 and 3.0. To continue supporting the middleware library in .NET Core 3.0, take the following steps:

- Follow the standard library guidance.
- Add a package reference for each API's NuGet package if the corresponding assembly doesn't exist in the shared framework.

Use an API that changed

Imagine a scenario in which you're upgrading a library from .NET Core 2.2 to .NET Core 3.0. An ASP.NET Core API being used in the library has a breaking change in ASP.NET Core 3.0. Consider whether the library can be rewritten to not use the broken API in all versions.

If you can rewrite the library, do so and continue to target an earlier target framework (for example, .NET Standard 2.0 or .NET Framework 4.6.1) with package references.

If you can't rewrite the library, take the following steps:

- Add a target for .NET Core 3.0.
- Add a `<FrameworkReference>` element for the shared framework.
- Use the #if preprocessor directive with the appropriate target framework symbol to conditionally compile code.

For example, synchronous reads and writes on HTTP request and response streams are disabled by default as of ASP.NET Core 3.0. ASP.NET Core 2.2 supports the synchronous behavior by default. Consider a middleware library

in which synchronous reads and writes should be enabled where I/O is occurring. The library should enclose the code to enable synchronous features in the appropriate preprocessor directive. For example:

```
public async Task Invoke(HttpContext httpContext)
{
    if (httpContext.Request.Path.StartsWithSegments(_path, StringComparison.Ordinal))
    {
        httpContext.Response.StatusCode = 200;
        httpContext.Response.ContentType = "application/json";
        httpContext.Response.ContentLength = _bufferSize;

#if !NETCOREAPP3_0 && !NETCOREAPP5_0
        var syncIOFeature = httpContext.Features.Get<IHttpBodyControlFeature>();
        if (syncIOFeature != null)
        {
            syncIOFeature.AllowSynchronousIO = true;
        }

        using (var sw = new StreamWriter(
            httpContext.Response.Body, _encoding, bufferSize: _bufferSize))
        {
            _json.Serialize(sw, new JsonMessage { message = "Hello, World!" });
        }
#else
        await JsonSerializer.SerializeAsync<JsonMessage>(
            httpContext.Response.Body, new JsonMessage { message = "Hello, World!" });
#endif
        return;
    }

    await _next(httpContext);
}
```

Use an API introduced in 3.0

Imagine that you want to use an ASP.NET Core API that was introduced in ASP.NET Core 3.0. Consider the following questions:

1. Does the library functionally require the new API?
2. Can the library implement this feature in a different way?

If the library functionally requires the API and there's no way to implement it down-level:

- Target .NET Core 3.x only.
- Add a `<FrameworkReference>` element for the shared framework.

If the library can implement the feature in a different way:

- Add .NET Core 3.x as a target framework.
- Add a `<FrameworkReference>` element for the shared framework.
- Use the #if preprocessor directive with the appropriate target framework symbol to conditionally compile code.

For example, the following Tag Helper uses the IWebHostEnvironment interface introduced in ASP.NET Core 3.0. Consumers targeting .NET Core 3.0 execute the code path defined by the `NETCOREAPP3_0` target framework symbol. The Tag Helper's constructor parameter type changes to IHostingEnvironment for .NET Core 2.1 and .NET Framework 4.6.1 consumers. This change was necessary because ASP.NET Core 3.0 marked `IHostingEnvironment` as obsolete and recommended `IWebHostEnvironment` as the replacement.

```
[HtmlTargetElement("script", Attributes = "asp-inline")]
public class ScriptInliningTagHelper : TagHelper
{
    private readonly IFileProvider _wwwroot;

#if NETCOREAPP3_0
    public ScriptInliningTagHelper(IWebHostEnvironment env)
#else
    public ScriptInliningTagHelper(IHostingEnvironment env)
#endif
    {
        _wwwroot = env.WebRootFileProvider;
    }

    // code omitted for brevity
}
```

The following multi-targeted project file supports this Tag Helper scenario:

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFrameworks>netcoreapp2.1;netcoreapp3.0;net461</TargetFrameworks>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Markdig" Version="0.16.0" />
  </ItemGroup>

  <ItemGroup Condition="'$(TargetFramework)' != 'netcoreapp3.0'">
    <PackageReference Include="Microsoft.AspNetCore.Mvc.Razor" Version="2.1.0" />
  </ItemGroup>

  <ItemGroup Condition="'$(TargetFramework)' == 'netcoreapp3.0'">
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>
</Project>
```

Use an API removed from the shared framework

To use an ASP.NET Core assembly that was removed from the shared framework, add the appropriate package reference. For a list of packages removed from the shared framework in ASP.NET Core 3.0, see Remove obsolete package references.

For example, to add the web API client:

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNet.WebApi.Client" Version="5.2.7" />
  </ItemGroup>

</Project>
```

Microsoft.AspNetCore.App for ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

The ASP.NET Core shared framework (`Microsoft.AspNetCore.App`) contains assemblies that are developed and supported by Microsoft. `Microsoft.AspNetCore.App` is installed when the .NET Core 3.0 or later SDK is installed. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and includes a runtime component and a targeting pack. For more information, see The shared framework.

- Projects that target the `Microsoft.NET.Sdk.Web` SDK implicitly reference the `Microsoft.AspNetCore.App` framework.

No additional references are required for these projects:

```
<Project Sdk="Microsoft.NET.Sdk.Web">
  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>
    ...
</Project>
```

The ASP.NET Core shared framework:

- Doesn't include third-party dependencies.
- Includes all supported packages by the ASP.NET Core team.

This feature requires ASP.NET Core 2.x targeting .NET Core 2.x.

The Microsoft.AspNetCore.App metapackage for ASP.NET Core:

- Does not include third-party dependencies except for Json.NET, Remotion.Linq, and IX-Async. These 3rd-party dependencies are deemed necessary to ensure the major frameworks features function.
- Includes all supported packages by the ASP.NET Core team except those that contain third-party dependencies (other than those previously mentioned).
- Includes all supported packages by the Entity Framework Core team except those that contain third-party dependencies (other than those previously mentioned).

All the features of ASP.NET Core 2.x and Entity Framework Core 2.x are included in the `Microsoft.AspNetCore.App` package. The default project templates targeting ASP.NET Core 2.x use this package. We recommend applications targeting ASP.NET Core 2.x and Entity Framework Core 2.x use the `Microsoft.AspNetCore.App` package.

The version number of the `Microsoft.AspNetCore.App` metapackage represents the minimum ASP.NET Core version and Entity Framework Core version.

Using the `Microsoft.AspNetCore.App` metapackage provides version restrictions that protect your app:

- If a package is included that has a transitive (not direct) dependency on a package in `Microsoft.AspNetCore.App` , and those version numbers differ, NuGet will generate an error.
- Other packages added to your app cannot change the version of packages included in

`Microsoft.AspNetCore.App`.

- Version consistency ensures a reliable experience. `Microsoft.AspNetCore.App` was designed to prevent untested version combinations of related bits being used together in the same app.

Applications that use the `Microsoft.AspNetCore.App` metapackage automatically take advantage of the ASP.NET Core shared framework. When you use the `Microsoft.AspNetCore.App` metapackage, **no** assets from the referenced ASP.NET Core NuGet packages are deployed with the application—the ASP.NET Core shared framework contains these assets. The assets in the shared framework are precompiled to improve application startup time. For more information, see The shared framework.

The following project file references the `Microsoft.AspNetCore.App` metapackage for ASP.NET Core and represents a typical ASP.NET Core 2.2 template:

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp2.2</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

</Project>
```

The preceding markup represents a typical ASP.NET Core 2.x template. It doesn't specify a version number for the `Microsoft.AspNetCore.App` package reference. When the version is not specified, an implicit version is specified by the SDK, that is, `Microsoft.NET.Sdk.Web`. We recommend relying on the implicit version specified by the SDK and not explicitly setting the version number on the package reference. If you have questions on this approach, leave a GitHub comment at the Discussion for the Microsoft.AspNetCore.App implicit version.

The implicit version is set to `major.minor.0` for portable apps. The shared framework roll-forward mechanism will run the app on the latest compatible version among the installed shared frameworks. To guarantee the same version is used in development, test, and production, ensure the same version of the shared framework is installed in all environments. For self contained apps, the implicit version number is set to the `major.minor.patch` of the shared framework bundled in the installed SDK.

Specifying a version number on the `Microsoft.AspNetCore.App` reference does **not** guarantee that version of the shared framework will be chosen. For example, suppose version "2.2.1" is specified, but "2.2.3" is installed. In that case, the app will use "2.2.3". Although not recommended, you can disable roll forward (patch and/or minor). For more information regarding dotnet host roll-forward and how to configure its behavior, see dotnet host roll forward.

`<Project Sdk` must be set to `Microsoft.NET.Sdk.Web` to use the implicit version `Microsoft.AspNetCore.App`. When `<Project Sdk="Microsoft.NET.Sdk">` (without the trailing `.Web`) is used:

- The following warning is generated:

  Warning NU1604: Project dependency Microsoft.AspNetCore.App does not contain an inclusive lower bound. Include a lower bound in the dependency version to ensure consistent restore results.

- This is a known issue with the .NET Core 2.1 SDK.

Update ASP.NET Core

The `Microsoft.AspNetCore.App` metapackage isn't a traditional package that's updated from NuGet. Similar to `Microsoft.NETCore.App`, `Microsoft.AspNetCore.App` represents a shared runtime, which has special versioning semantics handled outside of NuGet. For more information, see Packages, metapackages and frameworks.

To update ASP.NET Core:

- On development machines and build servers: Download and install the .NET Core SDK.
- On deployment servers: Download and install the .NET Core runtime.

Applications will roll forward to the latest installed version on application restart. It's not necessary to update the `Microsoft.AspNetCore.App` version number in the project file. For more information, see Framework-dependent apps roll forward.

If your application previously used `Microsoft.AspNetCore.All`, see Migrating from Microsoft.AspNetCore.All to Microsoft.AspNetCore.App.

Microsoft.AspNetCore.All metapackage for ASP.NET Core 2.0

9/22/2020 • 3 minutes to read • Edit Online

The `Microsoft.AspNetCore.All` metapackage isn't included in ASP.NET Core 3.0 and later. For more information, see this GitHub issue.

> **NOTE**
> We recommend applications targeting ASP.NET Core 2.1 and later use the Microsoft.AspNetCore.App metapackage rather than this package. See Migrating from Microsoft.AspNetCore.All to Microsoft.AspNetCore.App in this article.

This feature requires ASP.NET Core 2.x targeting .NET Core 2.x.

Microsoft.AspNetCore.All is a metapackage that refers to a shared framework. A *shared framework* is a set of assemblies (*.dll* files) that are not in the app's folders. The shared framework must be installed on the machine to run the app. For more information, see The shared framework.

The shared framework that `Microsoft.AspNetCore.All` refers to includes:

- All supported packages by the ASP.NET Core team.
- All supported packages by the Entity Framework Core.
- Internal and 3rd-party dependencies used by ASP.NET Core and Entity Framework Core.

All the features of ASP.NET Core 2.x and Entity Framework Core 2.x are included in the `Microsoft.AspNetCore.All` package. The default project templates targeting ASP.NET Core 2.0 use this package.

The version number of the `Microsoft.AspNetCore.All` metapackage represents the minimum ASP.NET Core version and Entity Framework Core version.

The following *.csproj* file references the `Microsoft.AspNetCore.All` metapackage for ASP.NET Core:

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp2.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.All" Version="2.0.9" />
  </ItemGroup>

</Project>
```

Implicit versioning

In ASP.NET Core 2.1 or later, you can specify the `Microsoft.AspNetCore.All` package reference without a version. When the version isn't specified, an implicit version is specified by the SDK (`Microsoft.NET.Sdk.Web`). We recommend relying on the implicit version specified by the SDK and not explicitly setting the version number on the package reference. If you have questions about this approach, leave a GitHub comment at the Discussion for the Microsoft.AspNetCore.App implicit version.

The implicit version is set to `major.minor.0` for portable apps. The shared framework roll-forward mechanism runs the app on the latest compatible version among the installed shared frameworks. To guarantee the same version is used in development, test, and production, ensure the same version of the shared framework is installed in all environments. For self-contained apps, the implicit version number is set to the `major.minor.patch` of the shared framework bundled in the installed SDK.

Specifying a version number on the `Microsoft.AspNetCore.All` package reference does **not** guarantee that version of the shared framework is chosen. For example, suppose version "2.1.1" is specified, but "2.1.3" is installed. In that case, the app will use "2.1.3". Although not recommended, you can disable roll forward (patch and/or minor). For more information regarding dotnet host roll-forward and how to configure its behavior, see dotnet host roll forward.

The project's SDK must be set to `Microsoft.NET.Sdk.Web` in the project file to use the implicit version of `Microsoft.AspNetCore.All`. When the `Microsoft.NET.Sdk` SDK is specified (`<Project Sdk="Microsoft.NET.Sdk">` at the top of the project file), the following warning is generated:

Warning NU1604: Project dependency Microsoft.AspNetCore.All does not contain an inclusive lower bound. Include a lower bound in the dependency version to ensure consistent restore results.

This is a known issue with the .NET Core 2.1 SDK and will be fixed in the .NET Core 2.2 SDK.

Migrating from Microsoft.AspNetCore.All to Microsoft.AspNetCore.App

The following packages are included in `Microsoft.AspNetCore.All` but not the `Microsoft.AspNetCore.App` package.

- `Microsoft.AspNetCore.ApplicationInsights.HostingStartup`
- `Microsoft.AspNetCore.AzureAppServices.HostingStartup`
- `Microsoft.AspNetCore.AzureAppServicesIntegration`
- `Microsoft.AspNetCore.DataProtection.AzureKeyVault`
- `Microsoft.AspNetCore.DataProtection.AzureStorage`
- `Microsoft.AspNetCore.Server.Kestrel.Transport.Libuv`
- `Microsoft.AspNetCore.SignalR.Redis`
- `Microsoft.Data.Sqlite`
- `Microsoft.Data.Sqlite.Core`
- `Microsoft.EntityFrameworkCore.Sqlite`
- `Microsoft.EntityFrameworkCore.Sqlite.Core`
- `Microsoft.Extensions.Caching.Redis`
- `Microsoft.Extensions.Configuration.AzureKeyVault`
- `Microsoft.Extensions.Logging.AzureAppServices`
- `Microsoft.VisualStudio.Web.BrowserLink`

To move from `Microsoft.AspNetCore.All` to `Microsoft.AspNetCore.App`, if your app uses any APIs from the above packages, or packages brought in by those packages, add references to those packages in your project.

Any dependencies of the preceding packages that otherwise aren't dependencies of `Microsoft.AspNetCore.App` are not included implicitly. For example:

- `StackExchange.Redis` as a dependency of `Microsoft.Extensions.Caching.Redis`
- `Microsoft.ApplicationInsights` as a dependency of `Microsoft.AspNetCore.ApplicationInsights.HostingStartup`

Update ASP.NET Core 2.1

We recommend migrating to the `Microsoft.AspNetCore.App` metapackage for 2.1 and later. To keep using the

`Microsoft.AspNetCore.All` metapackage and ensure the latest patch version is deployed:

- On development machines and build servers: Install the latest .NET Core SDK.
- On deployment servers: Install the latest .NET Core runtime. Your app will roll forward to the latest installed version on an application restart.

High-performance logging with LoggerMessage in ASP.NET Core

9/22/2020 • 14 minutes to read • Edit Online

LoggerMessage features create cacheable delegates that require fewer object allocations and reduced computational overhead compared to logger extension methods, such as LogInformation and LogDebug. For high-performance logging scenarios, use the LoggerMessage pattern.

LoggerMessage provides the following performance advantages over Logger extension methods:

- Logger extension methods require "boxing" (converting) value types, such as `int`, into `object`. The LoggerMessage pattern avoids boxing by using static Action fields and extension methods with strongly-typed parameters.
- Logger extension methods must parse the message template (named format string) every time a log message is written. LoggerMessage only requires parsing a template once when the message is defined.

View or download sample code (how to download)

The sample app demonstrates LoggerMessage features with a basic quote tracking system. The app adds and deletes quotes using an in-memory database. As these operations occur, log messages are generated using the LoggerMessage pattern.

LoggerMessage.Define

Define(LogLevel, EventId, String) creates an Action delegate for logging a message. Define overloads permit passing up to six type parameters to a named format string (template).

The string provided to the Define method is a template and not an interpolated string. Placeholders are filled in the order that the types are specified. Placeholder names in the template should be descriptive and consistent across templates. They serve as property names within structured log data. We recommend Pascal casing for placeholder names. For example, `{Count}`, `{FirstName}`.

Each log message is an Action held in a static field created by LoggerMessage.Define. For example, the sample app creates a field to describe a log message for a GET request for the Index page (*Internal/LoggerExtensions.cs*):

```
private static readonly Action<ILogger, Exception> _indexPageRequested;
```

For the Action, specify:

- The log level.
- A unique event identifier (EventId) with the name of the static extension method.
- The message template (named format string).

A request for the Index page of the sample app sets the:

- Log level to `Information`.
- Event id to `1` with the name of the `IndexPageRequested` method.
- Message template (named format string) to a string.

```
_indexPageRequested = LoggerMessage.Define(
    LogLevel.Information,
    new EventId(1, nameof(IndexPageRequested)),
    "GET request for Index page");
```

Structured logging stores may use the event name when it's supplied with the event id to enrich logging. For example, Serilog uses the event name.

The Action is invoked through a strongly-typed extension method. The `IndexPageRequested` method logs a message for an Index page GET request in the sample app:

```
public static void IndexPageRequested(this ILogger logger)
{
    _indexPageRequested(logger, null);
}
```

`IndexPageRequested` is called on the logger in the `OnGetAsync` method in *Pages/Index.cshtml.cs*:

```
public async Task OnGetAsync()
{
    _logger.IndexPageRequested();

    Quotes = await _db.Quotes.AsNoTracking().ToListAsync();
}
```

Inspect the app's console output:

```
info: LoggerMessageSample.Pages.IndexModel[1]
      => RequestId:0HL90M6E7PHK4:00000001 RequestPath:/ => /Index
      GET request for Index page
```

To pass parameters to a log message, define up to six types when creating the static field. The sample app logs a string when adding a quote by defining a `string` type for the Action field:

```
private static readonly Action<ILogger, string, Exception> _quoteAdded;
```

The delegate's log message template receives its placeholder values from the types provided. The sample app defines a delegate for adding a quote where the quote parameter is a `string`:

```
_quoteAdded = LoggerMessage.Define<string>(
    LogLevel.Information,
    new EventId(2, nameof(QuoteAdded)),
    "Quote added (Quote = '{Quote}')");
```

The static extension method for adding a quote, `QuoteAdded`, receives the quote argument value and passes it to the Action delegate:

```
public static void QuoteAdded(this ILogger logger, string quote)
{
    _quoteAdded(logger, quote, null);
}
```

In the Index page's page model (*Pages/Index.cshtml.cs*), `QuoteAdded` is called to log the message:

```
public async Task<IActionResult> OnPostAddQuoteAsync()
{
    _db.Quotes.Add(Quote);
    await _db.SaveChangesAsync();

    _logger.QuoteAdded(Quote.Text);

    return RedirectToPage();
}
```

Inspect the app's console output:

```
info: LoggerMessageSample.Pages.IndexModel[2]
      => RequestId:0HL90M6E7PHK5:0000000A RequestPath:/ => /Index
      Quote added (Quote = 'You can avoid reality, but you cannot avoid the
          consequences of avoiding reality. - Ayn Rand')
```

The sample app implements a try-catch pattern for quote deletion. An informational message is logged for a successful delete operation. An error message is logged for a delete operation when an exception is thrown. The log message for the unsuccessful delete operation includes the exception stack trace (*Internal/LoggerExtensions.cs*):

```
private static readonly Action<ILogger, string, int, Exception> _quoteDeleted;
private static readonly Action<ILogger, int, Exception> _quoteDeleteFailed;
```

```
_quoteDeleted = LoggerMessage.Define<string, int>(
    LogLevel.Information,
    new EventId(4, nameof(QuoteDeleted)),
    "Quote deleted (Quote = '{Quote}' Id = {Id})");

_quoteDeleteFailed = LoggerMessage.Define<int>(
    LogLevel.Error,
    new EventId(5, nameof(QuoteDeleteFailed)),
    "Quote delete failed (Id = {Id})");
```

Note how the exception is passed to the delegate in `QuoteDeleteFailed`:

```
public static void QuoteDeleted(this ILogger logger, string quote, int id)
{
    _quoteDeleted(logger, quote, id, null);
}

public static void QuoteDeleteFailed(this ILogger logger, int id, Exception ex)
{
    _quoteDeleteFailed(logger, id, ex);
}
```

In the page model for the Index page, a successful quote deletion calls the `QuoteDeleted` method on the logger. When a quote isn't found for deletion, an ArgumentNullException is thrown. The exception is trapped by the try-catch statement and logged by calling the `QuoteDeleteFailed` method on the logger in the catch block (*Pages/Index.cshtml.cs*):

```
public async Task<IActionResult> OnPostDeleteQuoteAsync(int id)
{
    try
    {
        var quote = await _db.Quotes.FindAsync(id);
        _db.Quotes.Remove(quote);
        await _db.SaveChangesAsync();

        _logger.QuoteDeleted(quote.Text, id);
    }
    catch (NullReferenceException ex)
    {
        _logger.QuoteDeleteFailed(id, ex);
    }

    return RedirectToPage();
}
```

When a quote is successfully deleted, inspect the app's console output:

```
info: LoggerMessageSample.Pages.IndexModel[4]
      => RequestId:0HL90M6E7PHK5:00000016 RequestPath:/ => /Index
      Quote deleted (Quote = 'You can avoid reality, but you cannot avoid the
          consequences of avoiding reality. - Ayn Rand' Id = 1)
```

When quote deletion fails, inspect the app's console output. Note that the exception is included in the log message:

```
LoggerMessageSample.Pages.IndexModel: Error: Quote delete failed (Id = 999)

System.NullReferenceException: Object reference not set to an instance of an object.

```

LoggerMessage.DefineScope

DefineScope(String) creates a Func<TResult> delegate for defining a log scope. DefineScope overloads permit passing up to three type parameters to a named format string (template).

As is the case with the Define method, the string provided to the DefineScope method is a template and not an interpolated string. Placeholders are filled in the order that the types are specified. Placeholder names in the template should be descriptive and consistent across templates. They serve as property names within structured log data. We recommend Pascal casing for placeholder names. For example, `{Count}`, `{FirstName}`.

Define a log scope to apply to a series of log messages using the DefineScope method.

The sample app has a **Clear All** button for deleting all of the quotes in the database. The quotes are deleted by removing them one at a time. Each time a quote is deleted, the `QuoteDeleted` method is called on the logger. A log scope is added to these log messages.

Enable `IncludeScopes` in the console logger section of *appsettings.json*:

```
{
  "Logging": {
    "Console": {
      "IncludeScopes": true
    },
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*"
}
```

To create a log scope, add a field to hold a Func<TResult> delegate for the scope. The sample app creates a field called `_allQuotesDeletedScope` (*Internal/LoggerExtensions.cs*):

```
private static Func<ILogger, int, IDisposable> _allQuotesDeletedScope;
```

Use DefineScope to create the delegate. Up to three types can be specified for use as template arguments when the delegate is invoked. The sample app uses a message template that includes the number of deleted quotes (an `int` type):

```
_allQuotesDeletedScope =
    LoggerMessage.DefineScope<int>("All quotes deleted (Count = {Count})");
```

Provide a static extension method for the log message. Include any type parameters for named properties that appear in the message template. The sample app takes in a `count` of quotes to delete and returns `_allQuotesDeletedScope`:

```
public static IDisposable AllQuotesDeletedScope(
    this ILogger logger, int count)
{
    return _allQuotesDeletedScope(logger, count);
}
```

The scope wraps the logging extension calls in a using block:

```
public async Task<IActionResult> OnPostDeleteAllQuotesAsync()
{
    var quoteCount = await _db.Quotes.CountAsync();

    using (_logger.AllQuotesDeletedScope(quoteCount))
    {
        foreach (Quote quote in _db.Quotes)
        {
            _db.Quotes.Remove(quote);

            _logger.QuoteDeleted(quote.Text, quote.Id);
        }
        await _db.SaveChangesAsync();
    }

    return RedirectToPage();
}
```

Inspect the log messages in the app's console output. The following result shows three quotes deleted with the log scope message included:

```
info: LoggerMessageSample.Pages.IndexModel[4]
      => RequestId:0HL90M6E7PHK5:0000002E RequestPath:/ => /Index =>
          All quotes deleted (Count = 3)
      Quote deleted (Quote = 'Quote 1' Id = 2)
info: LoggerMessageSample.Pages.IndexModel[4]
      => RequestId:0HL90M6E7PHK5:0000002E RequestPath:/ => /Index =>
          All quotes deleted (Count = 3)
      Quote deleted (Quote = 'Quote 2' Id = 3)
info: LoggerMessageSample.Pages.IndexModel[4]
      => RequestId:0HL90M6E7PHK5:0000002E RequestPath:/ => /Index =>
          All quotes deleted (Count = 3)
      Quote deleted (Quote = 'Quote 3' Id = 4)
```

LoggerMessage features create cacheable delegates that require fewer object allocations and reduced computational overhead compared to logger extension methods, such as LogInformation and LogDebug. For high-performance logging scenarios, use the LoggerMessage pattern.

LoggerMessage provides the following performance advantages over Logger extension methods:

- Logger extension methods require "boxing" (converting) value types, such as `int`, into `object`. The LoggerMessage pattern avoids boxing by using static Action fields and extension methods with strongly-typed parameters.
- Logger extension methods must parse the message template (named format string) every time a log message is written. LoggerMessage only requires parsing a template once when the message is defined.

View or download sample code (how to download)

The sample app demonstrates LoggerMessage features with a basic quote tracking system. The app adds and deletes quotes using an in-memory database. As these operations occur, log messages are generated using the LoggerMessage pattern.

LoggerMessage.Define

Define(LogLevel, EventId, String) creates an Action delegate for logging a message. Define overloads permit passing up to six type parameters to a named format string (template).

The string provided to the Define method is a template and not an interpolated string. Placeholders are filled in the order that the types are specified. Placeholder names in the template should be descriptive and consistent across templates. They serve as property names within structured log data. We recommend Pascal casing for placeholder names. For example, `{Count}`, `{FirstName}`.

Each log message is an Action held in a static field created by LoggerMessage.Define. For example, the sample app creates a field to describe a log message for a GET request for the Index page (*Internal/LoggerExtensions.cs*):

```
private static readonly Action<ILogger, Exception> _indexPageRequested;
```

For the Action, specify:

- The log level.
- A unique event identifier (EventId) with the name of the static extension method.
- The message template (named format string).

A request for the Index page of the sample app sets the:

- Log level to `Information`.
- Event id to `1` with the name of the `IndexPageRequested` method.
- Message template (named format string) to a string.

```
_indexPageRequested = LoggerMessage.Define(
    LogLevel.Information,
    new EventId(1, nameof(IndexPageRequested)),
    "GET request for Index page");
```

Structured logging stores may use the event name when it's supplied with the event id to enrich logging. For example, Serilog uses the event name.

The Action is invoked through a strongly-typed extension method. The `IndexPageRequested` method logs a message for an Index page GET request in the sample app:

```
public static void IndexPageRequested(this ILogger logger)
{
    _indexPageRequested(logger, null);
}
```

`IndexPageRequested` is called on the logger in the `OnGetAsync` method in *Pages/Index.cshtml.cs*:

```
public async Task OnGetAsync()
{
    _logger.IndexPageRequested();

    Quotes = await _db.Quotes.AsNoTracking().ToListAsync();
}
```

Inspect the app's console output:

```
info: LoggerMessageSample.Pages.IndexModel[1]
      => RequestId:0HL90M6E7PHK4:00000001 RequestPath:/ => /Index
      GET request for Index page
```

To pass parameters to a log message, define up to six types when creating the static field. The sample app logs a string when adding a quote by defining a `string` type for the Action field:

```
private static readonly Action<ILogger, string, Exception> _quoteAdded;
```

The delegate's log message template receives its placeholder values from the types provided. The sample app defines a delegate for adding a quote where the quote parameter is a `string`:

```
_quoteAdded = LoggerMessage.Define<string>(
    LogLevel.Information,
    new EventId(2, nameof(QuoteAdded)),
    "Quote added (Quote = '{Quote}')");
```

The static extension method for adding a quote, `QuoteAdded`, receives the quote argument value and passes it to the Action delegate:

```
public static void QuoteAdded(this ILogger logger, string quote)
{
    _quoteAdded(logger, quote, null);
}
```

In the Index page's page model (*Pages/Index.cshtml.cs*), `QuoteAdded` is called to log the message:

```
public async Task<IActionResult> OnPostAddQuoteAsync()
{
    _db.Quotes.Add(Quote);
    await _db.SaveChangesAsync();

    _logger.QuoteAdded(Quote.Text);

    return RedirectToPage();
}
```

Inspect the app's console output:

```
info: LoggerMessageSample.Pages.IndexModel[2]
      => RequestId:0HL90M6E7PHK5:0000000A RequestPath:/ => /Index
      Quote added (Quote = 'You can avoid reality, but you cannot avoid the
          consequences of avoiding reality. - Ayn Rand')
```

The sample app implements a try-catch pattern for quote deletion. An informational message is logged for a successful delete operation. An error message is logged for a delete operation when an exception is thrown. The log message for the unsuccessful delete operation includes the exception stack trace (*Internal/LoggerExtensions.cs*):

```
private static readonly Action<ILogger, string, int, Exception> _quoteDeleted;
private static readonly Action<ILogger, int, Exception> _quoteDeleteFailed;
```

```
_quoteDeleted = LoggerMessage.Define<string, int>(
    LogLevel.Information,
    new EventId(4, nameof(QuoteDeleted)),
    "Quote deleted (Quote = '{Quote}' Id = {Id})");

_quoteDeleteFailed = LoggerMessage.Define<int>(
    LogLevel.Error,
    new EventId(5, nameof(QuoteDeleteFailed)),
    "Quote delete failed (Id = {Id})");
```

Note how the exception is passed to the delegate in `QuoteDeleteFailed`:

```
public static void QuoteDeleted(this ILogger logger, string quote, int id)
{
    _quoteDeleted(logger, quote, id, null);
}

public static void QuoteDeleteFailed(this ILogger logger, int id, Exception ex)
{
    _quoteDeleteFailed(logger, id, ex);
}
```

In the page model for the Index page, a successful quote deletion calls the `QuoteDeleted` method on the logger. When a quote isn't found for deletion, an ArgumentNullException is thrown. The exception is trapped by the try-

catch statement and logged by calling the `QuoteDeleteFailed` method on the logger in the catch block (*Pages/Index.cshtml.cs*):

```
public async Task<IActionResult> OnPostDeleteQuoteAsync(int id)
{
    var quote = await _db.Quotes.FindAsync(id);

    // DO NOT use this approach in production code!
    // You should check quote to see if it's null before removing
    // it and saving changes to the database. A try-catch is used
    // here for demonstration purposes of LoggerMessage features.
    try
    {
        _db.Quotes.Remove(quote);
        await _db.SaveChangesAsync();

        _logger.QuoteDeleted(quote.Text, id);
    }
    catch (ArgumentNullException ex)
    {
        _logger.QuoteDeleteFailed(id, ex);
    }

    return RedirectToPage();
}
```

When a quote is successfully deleted, inspect the app's console output:

```
info: LoggerMessageSample.Pages.IndexModel[4]
      => RequestId:0HL90M6E7PHK5:00000016 RequestPath:/ => /Index
      Quote deleted (Quote = 'You can avoid reality, but you cannot avoid the
          consequences of avoiding reality. - Ayn Rand' Id = 1)
```

When quote deletion fails, inspect the app's console output. Note that the exception is included in the log message:

```
fail: LoggerMessageSample.Pages.IndexModel[5]
      => RequestId:0HL90M6E7PHK5:00000010 RequestPath:/ => /Index
      Quote delete failed (Id = 999)
System.ArgumentNullException: Value cannot be null.

   at LoggerMessageSample.Pages.IndexModel.<OnPostDeleteQuoteAsync>d__14.MoveNext()
      in <PATH>\sample\Pages\Index.cshtml.cs:line 87
```

LoggerMessage.DefineScope

DefineScope(String) creates a Func<TResult> delegate for defining a log scope. DefineScope overloads permit passing up to three type parameters to a named format string (template).

As is the case with the Define method, the string provided to the DefineScope method is a template and not an interpolated string. Placeholders are filled in the order that the types are specified. Placeholder names in the template should be descriptive and consistent across templates. They serve as property names within structured log data. We recommend Pascal casing for placeholder names. For example, `{Count}`, `{FirstName}`.

Define a log scope to apply to a series of log messages using the DefineScope method.

The sample app has a **Clear All** button for deleting all of the quotes in the database. The quotes are deleted by

removing them one at a time. Each time a quote is deleted, the `QuoteDeleted` method is called on the logger. A log scope is added to these log messages.

Enable `IncludeScopes` in the console logger section of *appsettings.json*:

```
{
  "Logging": {
    "Console": {
      "IncludeScopes": true
    },
    "LogLevel": {
      "Default": "Warning"
    }
  },
  "AllowedHosts": "*"
}
```

To create a log scope, add a field to hold a Func<TResult> delegate for the scope. The sample app creates a field called `_allQuotesDeletedScope` (*Internal/LoggerExtensions.cs*):

```
private static Func<ILogger, int, IDisposable> _allQuotesDeletedScope;
```

Use DefineScope to create the delegate. Up to three types can be specified for use as template arguments when the delegate is invoked. The sample app uses a message template that includes the number of deleted quotes (an `int` type):

```
_allQuotesDeletedScope =
    LoggerMessage.DefineScope<int>("All quotes deleted (Count = {Count})");
```

Provide a static extension method for the log message. Include any type parameters for named properties that appear in the message template. The sample app takes in a `count` of quotes to delete and returns `_allQuotesDeletedScope`:

```
public static IDisposable AllQuotesDeletedScope(
    this ILogger logger, int count)
{
    return _allQuotesDeletedScope(logger, count);
}
```

The scope wraps the logging extension calls in a using block:

```
public async Task<IActionResult> OnPostDeleteAllQuotesAsync()
{
    var quoteCount = await _db.Quotes.CountAsync();

    using (_logger.AllQuotesDeletedScope(quoteCount))
    {
        foreach (Quote quote in _db.Quotes)
        {
            _db.Quotes.Remove(quote);

            _logger.QuoteDeleted(quote.Text, quote.Id);
        }
        await _db.SaveChangesAsync();
    }

    return RedirectToPage();
}
```

Inspect the log messages in the app's console output. The following result shows three quotes deleted with the log scope message included:

```
info: LoggerMessageSample.Pages.IndexModel[4]
      => RequestId:0HL90M6E7PHK5:0000002E RequestPath:/ => /Index =>
          All quotes deleted (Count = 3)
      Quote deleted (Quote = 'Quote 1' Id = 2)
info: LoggerMessageSample.Pages.IndexModel[4]
      => RequestId:0HL90M6E7PHK5:0000002E RequestPath:/ => /Index =>
          All quotes deleted (Count = 3)
      Quote deleted (Quote = 'Quote 2' Id = 3)
info: LoggerMessageSample.Pages.IndexModel[4]
      => RequestId:0HL90M6E7PHK5:0000002E RequestPath:/ => /Index =>
          All quotes deleted (Count = 3)
      Quote deleted (Quote = 'Quote 3' Id = 4)
```

Develop ASP.NET Core apps using a file watcher

9/22/2020 • 5 minutes to read • Edit Online

By Rick Anderson and Victor Hurdugaci

`dotnet watch` is a tool that runs a .NET Core CLI command when source files change. For example, a file change can trigger compilation, test execution, or deployment.

This tutorial uses an existing web API with two endpoints: one that returns a sum and one that returns a product. The product method has a bug, which is fixed in this tutorial.

Download the sample app. It consists of two projects: *WebApp* (an ASP.NET Core web API) and *WebAppTests* (unit tests for the web API).

In a command shell, navigate to the *WebApp* folder. Run the following command:

```
dotnet run
```

NOTE

You can use `dotnet run --project <PROJECT>` to specify a project to run. For example, running `dotnet run --project WebApp` from the root of the sample app will also run the *WebApp* project.

The console output shows messages similar to the following (indicating that the app is running and awaiting requests):

```
$ dotnet run
Hosting environment: Development
Content root path: C:/Docs/aspnetcore/tutorials/dotnet-watch/sample/WebApp
Now listening on: http://localhost:5000
Application started. Press Ctrl+C to shut down.
```

In a web browser, navigate to `http://localhost:<port number>/api/math/sum?a=4&b=5`. You should see the result of `9`.

Navigate to the product API (`http://localhost:<port number>/api/math/product?a=4&b=5`). It returns `9`, not `20` as you'd expect. That problem is fixed later in the tutorial.

Add `dotnet watch` to a project

The `dotnet watch` file watcher tool is included with version 2.1.300 of the .NET Core SDK. The following steps are required when using an earlier version of the .NET Core SDK.

1. Add a `Microsoft.DotNet.Watcher.Tools` package reference to the *.csproj* file:

   ```
   <ItemGroup>
       <DotNetCliToolReference Include="Microsoft.DotNet.Watcher.Tools" Version="2.0.0" />
   </ItemGroup>
   ```

2. Install the `Microsoft.DotNet.Watcher.Tools` package by running the following command:

```
dotnet restore
```

Run .NET Core CLI commands using `dotnet watch`

Any .NET Core CLI command can be run with `dotnet watch`. For example:

COMMAND	COMMAND WITH WATCH
dotnet run	dotnet watch run
dotnet run -f netcoreapp3.1	dotnet watch run -f netcoreapp3.1
dotnet run -f netcoreapp3.1 -- --arg1	dotnet watch run -f netcoreapp3.1 -- --arg1
dotnet test	dotnet watch test

Run `dotnet watch run` in the *WebApp* folder. The console output indicates `watch` has started.

Running `dotnet watch run` on a web app launches a browser that navigates to the app's URL once ready. `dotnet watch` does this by reading the app's console output and waiting for the the ready message displayed by WebHost.

`dotnet watch` refreshes the browser when it detects changes to watched files. To do this, the watch command injects a middleware to the app that modifies HTML responses created by the app. The middleware adds a JavaScript script block to the page that allows `dotnet watch` to instruct the browser to refresh. Currently, changes to all watched files, including static content such as *.html* and *.css* files cause the app to be rebuilt.

`dotnet watch`:

- Only watches files that impact builds by default.
- Any additionally watched files (via configuration) still results in a build taking place.

For more information on configuration, see dotnet-watch configuration in this document

> **NOTE**
> You can use `dotnet watch --project <PROJECT>` to specify a project to watch. For example, running `dotnet watch --project WebApp run` from the root of the sample app will also run and watch the *WebApp* project.

Make changes with `dotnet watch`

Make sure `dotnet watch` is running.

Fix the bug in the `Product` method of *MathController.cs* so it returns the product and not the sum:

```
public static int Product(int a, int b)
{
    return a * b;
}
```

Save the file. The console output indicates that `dotnet watch` detected a file change and restarted the app.

Verify `http://localhost:<port number>/api/math/product?a=4&b=5` returns the correct result.

Run tests using `dotnet watch`

1. Change the `Product` method of *MathController.cs* back to returning the sum. Save the file.
2. In a command shell, navigate to the *WebAppTests* folder.
3. Run dotnet restore.
4. Run `dotnet watch test`. Its output indicates that a test failed and that the watcher is awaiting file changes:

```
Total tests: 2. Passed: 1. Failed: 1. Skipped: 0.
Test Run Failed.
```

5. Fix the `Product` method code so it returns the product. Save the file.

`dotnet watch` detects the file change and reruns the tests. The console output indicates the tests passed.

Customize files list to watch

By default, `dotnet-watch` tracks all files matching the following glob patterns:

- `**/*.cs`
- `*.csproj`
- `**/*.resx`

More items can be added to the watch list by editing the *.csproj* file. Items can be specified individually or by using glob patterns.

```
<ItemGroup>
    <!-- extends watching group to include *.js files -->
    <Watch Include="**\*.js" Exclude="node_modules\**\*;**\*.js.map;obj\**\*;bin\**\*" />
</ItemGroup>
```

Opt-out of files to be watched

`dotnet-watch` can be configured to ignore its default settings. To ignore specific files, add the `Watch="false"` attribute to an item's definition in the *.csproj* file:

```
<ItemGroup>
    <!-- exclude Generated.cs from dotnet-watch -->
    <Compile Include="Generated.cs" Watch="false" />

    <!-- exclude Strings.resx from dotnet-watch -->
    <EmbeddedResource Include="Strings.resx" Watch="false" />

    <!-- exclude changes in this referenced project -->
    <ProjectReference Include="..\ClassLibrary1\ClassLibrary1.csproj" Watch="false" />
</ItemGroup>
```

Custom watch projects

`dotnet-watch` isn't restricted to C# projects. Custom watch projects can be created to handle different scenarios. Consider the following project layout:

- **test/**
  - *UnitTests/UnitTests.csproj*

- *IntegrationTests/IntegrationTests.csproj*

If the goal is to watch both projects, create a custom project file configured to watch both projects:

```
<Project>
    <ItemGroup>
        <TestProjects Include="**\*.csproj" />
        <Watch Include="**\*.cs" />
    </ItemGroup>

    <Target Name="Test">
        <MSBuild Targets="VSTest" Projects="@(TestProjects)" />
    </Target>

    <Import Project="$(MSBuildExtensionsPath)\Microsoft.Common.targets" />
</Project>
```

To start file watching on both projects, change to the *test* folder. Execute the following command:

```
dotnet watch msbuild /t:Test
```

VSTest executes when any file changes in either test project.

dotnet-watch configuration

Some configuration options can be passed to `dotnet watch` through environment variables. The available variables are:

SETTING	DESCRIPTION
`DOTNET_USE_POLLING_FILE_WATCHER`	If set to "1" or "true", `dotnet watch` uses a polling file watcher instead of CoreFx's `FileSystemWatcher`. Used when watching files on network shares or Docker mounted volumes.
`DOTNET_WATCH_SUPPRESS_MSBUILD_INCREMENTALISM`	By default, `dotnet watch` optimizes the build by avoiding certain operations such as running restore or re-evaluating the set of watched files on every file change. If set to "1" or "true", these optimizations are disabled.
`DOTNET_WATCH_SUPPRESS_LAUNCH_BROWSER`	`dotnet watch run` attempts to launch browsers for web apps with `launchBrowser` configured in *launchSettings.json*. If set to "1" or "true", this behavior is suppressed.
`DOTNET_WATCH_SUPPRESS_BROWSER_REFRESH`	`dotnet watch run` attempts to refresh browsers when it detects file changes. If set to "1" or "true", this behavior is suppressed. This behavior is also suppressed if `DOTNET_WATCH_SUPPRESS_LAUNCH_BROWSER` is set.

`dotnet-watch` in GitHub

`dotnet-watch` is part of the GitHub dotnet/AspNetCore repository.

Factory-based middleware activation in ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

IMiddlewareFactory/IMiddleware is an extensibility point for middleware activation.

UseMiddleware extension methods check if a middleware's registered type implements IMiddleware. If it does, the IMiddlewareFactory instance registered in the container is used to resolve the IMiddleware implementation instead of using the convention-based middleware activation logic. The middleware is registered as a scoped or transient service in the app's service container.

Benefits:

- Activation per client request (injection of scoped services)
- Strong typing of middleware

IMiddleware is activated per client request (connection), so scoped services can be injected into the middleware's constructor.

View or download sample code (how to download)

IMiddleware

IMiddleware defines middleware for the app's request pipeline. The InvokeAsync(HttpContext, RequestDelegate) method handles requests and returns a Task that represents the execution of the middleware.

Middleware activated by convention:

```
public class ConventionalMiddleware
{
    private readonly RequestDelegate _next;

    public ConventionalMiddleware(RequestDelegate next)
    {
        _next = next;
    }

    public async Task InvokeAsync(HttpContext context, AppDbContext db)
    {
        var keyValue = context.Request.Query["key"];

        if (!string.IsNullOrWhiteSpace(keyValue))
        {
            db.Add(new Request()
                {
                    DT = DateTime.UtcNow,
                    MiddlewareActivation = "ConventionalMiddleware",
                    Value = keyValue
                });

            await db.SaveChangesAsync();
        }

        await _next(context);
    }
}
```

Middleware activated by MiddlewareFactory:

```
public class FactoryActivatedMiddleware : IMiddleware
{
    private readonly AppDbContext _db;

    public FactoryActivatedMiddleware(AppDbContext db)
    {
        _db = db;
    }

    public async Task InvokeAsync(HttpContext context, RequestDelegate next)
    {
        var keyValue = context.Request.Query["key"];

        if (!string.IsNullOrWhiteSpace(keyValue))
        {
            _db.Add(new Request()
                {
                    DT = DateTime.UtcNow,
                    MiddlewareActivation = "FactoryActivatedMiddleware",
                    Value = keyValue
                });

            await _db.SaveChangesAsync();
        }

        await next(context);
    }
}
```

Extensions are created for the middlewares:

```
public static class MiddlewareExtensions
{
    public static IApplicationBuilder UseConventionalMiddleware(
        this IApplicationBuilder builder)
    {
        return builder.UseMiddleware<ConventionalMiddleware>();
    }

    public static IApplicationBuilder UseFactoryActivatedMiddleware(
        this IApplicationBuilder builder)
    {
        return builder.UseMiddleware<FactoryActivatedMiddleware>();
    }
}
```

It isn't possible to pass objects to the factory-activated middleware with UseMiddleware:

```
public static IApplicationBuilder UseFactoryActivatedMiddleware(
    this IApplicationBuilder builder, bool option)
{
    // Passing 'option' as an argument throws a NotSupportedException at runtime.
    return builder.UseMiddleware<FactoryActivatedMiddleware>(option);
}
```

The factory-activated middleware is added to the built-in container in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<AppDbContext>(options =>
        options.UseInMemoryDatabase("InMemoryDb"));

    services.AddTransient<FactoryActivatedMiddleware>();

    services.AddRazorPages();
}
```

Both middlewares are registered in the request processing pipeline in `Startup.Configure`:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
    }

    app.UseConventionalMiddleware();
    app.UseFactoryActivatedMiddleware();

    app.UseStaticFiles();
    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

IMiddlewareFactory

IMiddlewareFactory provides methods to create middleware. The middleware factory implementation is registered in the container as a scoped service.

The default IMiddlewareFactory implementation, MiddlewareFactory, is found in the Microsoft.AspNetCore.Http package.

IMiddlewareFactory/IMiddleware is an extensibility point for middleware activation.

UseMiddleware extension methods check if a middleware's registered type implements IMiddleware. If it does, the IMiddlewareFactory instance registered in the container is used to resolve the IMiddleware implementation instead of using the convention-based middleware activation logic. The middleware is registered as a scoped or transient service in the app's service container.

Benefits:

- Activation per client request (injection of scoped services)
- Strong typing of middleware

IMiddleware is activated per client request (connection), so scoped services can be injected into the middleware's constructor.

View or download sample code (how to download)

IMiddleware

IMiddleware defines middleware for the app's request pipeline. The InvokeAsync(HttpContext, RequestDelegate) method handles requests and returns a Task that represents the execution of the middleware.

Middleware activated by convention:

```
public class ConventionalMiddleware
{
    private readonly RequestDelegate _next;

    public ConventionalMiddleware(RequestDelegate next)
    {
        _next = next;
    }

    public async Task InvokeAsync(HttpContext context, AppDbContext db)
    {
        var keyValue = context.Request.Query["key"];

        if (!string.IsNullOrWhiteSpace(keyValue))
        {
            db.Add(new Request()
                {
                    DT = DateTime.UtcNow,
                    MiddlewareActivation = "ConventionalMiddleware",
                    Value = keyValue
                });

            await db.SaveChangesAsync();
        }

        await _next(context);
    }
}
```

Middleware activated by MiddlewareFactory:

```
public class FactoryActivatedMiddleware : IMiddleware
{
    private readonly AppDbContext _db;

    public FactoryActivatedMiddleware(AppDbContext db)
    {
        _db = db;
    }

    public async Task InvokeAsync(HttpContext context, RequestDelegate next)
    {
        var keyValue = context.Request.Query["key"];

        if (!string.IsNullOrWhiteSpace(keyValue))
        {
            _db.Add(new Request()
                {
                    DT = DateTime.UtcNow,
                    MiddlewareActivation = "FactoryActivatedMiddleware",
                    Value = keyValue
                });

            await _db.SaveChangesAsync();
        }

        await next(context);
    }
}
```

Extensions are created for the middlewares:

```
public static class MiddlewareExtensions
{
    public static IApplicationBuilder UseConventionalMiddleware(
        this IApplicationBuilder builder)
    {
        return builder.UseMiddleware<ConventionalMiddleware>();
    }

    public static IApplicationBuilder UseFactoryActivatedMiddleware(
        this IApplicationBuilder builder)
    {
        return builder.UseMiddleware<FactoryActivatedMiddleware>();
    }
}
```

It isn't possible to pass objects to the factory-activated middleware with UseMiddleware:

```
public static IApplicationBuilder UseFactoryActivatedMiddleware(
    this IApplicationBuilder builder, bool option)
{
    // Passing 'option' as an argument throws a NotSupportedException at runtime.
    return builder.UseMiddleware<FactoryActivatedMiddleware>(option);
}
```

The factory-activated middleware is added to the built-in container in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<AppDbContext>(options =>
        options.UseInMemoryDatabase("InMemoryDb"));

    services.AddTransient<FactoryActivatedMiddleware>();

    services.AddMvc()
        .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

Both middlewares are registered in the request processing pipeline in `Startup.Configure`:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
    }

    app.UseConventionalMiddleware();
    app.UseFactoryActivatedMiddleware();

    app.UseStaticFiles();
    app.UseMvc();
}
```

IMiddlewareFactory

IMiddlewareFactory provides methods to create middleware. The middleware factory implementation is registered in the container as a scoped service.

The default IMiddlewareFactory implementation, MiddlewareFactory, is found in the Microsoft.AspNetCore.Http package.

Middleware activation with a third-party container in ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

This article demonstrates how to use IMiddlewareFactory and IMiddleware as an extensibility point for middleware activation with a third-party container. For introductory information on `IMiddlewareFactory` and `IMiddleware`, see Factory-based middleware activation in ASP.NET Core.

View or download sample code (how to download)

The sample app demonstrates middleware activation by an `IMiddlewareFactory` implementation, `SimpleInjectorMiddlewareFactory`. The sample uses the Simple Injector dependency injection (DI) container.

The sample's middleware implementation records the value provided by a query string parameter (`key`). The middleware uses an injected database context (a scoped service) to record the query string value in an in-memory database.

> **NOTE**
> The sample app uses Simple Injector purely for demonstration purposes. Use of Simple Injector isn't an endorsement. Middleware activation approaches described in the Simple Injector documentation and GitHub issues are recommended by the maintainers of Simple Injector. For more information, see the Simple Injector documentation and Simple Injector GitHub repository.

IMiddlewareFactory

IMiddlewareFactory provides methods to create middleware.

In the sample app, a middleware factory is implemented to create an `SimpleInjectorActivatedMiddleware` instance. The middleware factory uses the Simple Injector container to resolve the middleware:

```
public class SimpleInjectorMiddlewareFactory : IMiddlewareFactory
{
    private readonly Container _container;

    public SimpleInjectorMiddlewareFactory(Container container)
    {
        _container = container;
    }

    public IMiddleware Create(Type middlewareType)
    {
        return _container.GetInstance(middlewareType) as IMiddleware;
    }

    public void Release(IMiddleware middleware)
    {
        // The container is responsible for releasing resources.
    }
}
```

IMiddleware

IMiddleware defines middleware for the app's request pipeline.

Middleware activated by an `IMiddlewareFactory` implementation (*Middleware/SimpleInjectorActivatedMiddleware.cs*):

```
public class SimpleInjectorActivatedMiddleware : IMiddleware
{
    private readonly AppDbContext _db;

    public SimpleInjectorActivatedMiddleware(AppDbContext db)
    {
        _db = db;
    }

    public async Task InvokeAsync(HttpContext context, RequestDelegate next)
    {
        var keyValue = context.Request.Query["key"];

        if (!string.IsNullOrWhiteSpace(keyValue))
        {
            _db.Add(new Request()
                {
                    DT = DateTime.UtcNow,
                    MiddlewareActivation = "SimpleInjectorActivatedMiddleware",
                    Value = keyValue
                });

            await _db.SaveChangesAsync();
        }

        await next(context);
    }
}
```

An extension is created for the middleware (*Middleware/MiddlewareExtensions.cs*):

```
public static class MiddlewareExtensions
{
    public static IApplicationBuilder UseSimpleInjectorActivatedMiddleware(
        this IApplicationBuilder builder)
    {
        return builder.UseMiddleware<SimpleInjectorActivatedMiddleware>();
    }
}
```

`Startup.ConfigureServices` must perform several tasks:

- Set up the Simple Injector container.
- Register the factory and middleware.
- Make the app's database context available from the Simple Injector container.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();

    // Replace the default middleware factory with the
    // SimpleInjectorMiddlewareFactory.
    services.AddTransient<IMiddlewareFactory>(_ =>
    {
        return new SimpleInjectorMiddlewareFactory(_container);
    });

    // Wrap ASP.NET Core requests in a Simple Injector execution
    // context.
    services.UseSimpleInjectorAspNetRequestScoping(_container);

    // Provide the database context from the Simple
    // Injector container whenever it's requested from
    // the default service container.
    services.AddScoped<AppDbContext>(provider =>
        _container.GetInstance<AppDbContext>());

    _container.Options.DefaultScopedLifestyle = new AsyncScopedLifestyle();

    _container.Register<AppDbContext>(() =>
    {
        var optionsBuilder = new DbContextOptionsBuilder<DbContext>();
        optionsBuilder.UseInMemoryDatabase("InMemoryDb");
        return new AppDbContext(optionsBuilder.Options);
    }, Lifestyle.Scoped);

    _container.Register<SimpleInjectorActivatedMiddleware>();

    _container.Verify();
}
```

The middleware is registered in the request processing pipeline in `Startup.Configure`:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
    }

    app.UseSimpleInjectorActivatedMiddleware();

    app.UseStaticFiles();
    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

This article demonstrates how to use IMiddlewareFactory and IMiddleware as an extensibility point for middleware activation with a third-party container. For introductory information on `IMiddlewareFactory` and `IMiddleware`, see Factory-based middleware activation in ASP.NET Core.

View or download sample code (how to download)

The sample app demonstrates middleware activation by an `IMiddlewareFactory` implementation, `SimpleInjectorMiddlewareFactory`. The sample uses the Simple Injector dependency injection (DI) container.

The sample's middleware implementation records the value provided by a query string parameter (`key`). The middleware uses an injected database context (a scoped service) to record the query string value in an in-memory database.

> **NOTE**
>
> The sample app uses Simple Injector purely for demonstration purposes. Use of Simple Injector isn't an endorsement. Middleware activation approaches described in the Simple Injector documentation and GitHub issues are recommended by the maintainers of Simple Injector. For more information, see the Simple Injector documentation and Simple Injector GitHub repository.

IMiddlewareFactory

IMiddlewareFactory provides methods to create middleware.

In the sample app, a middleware factory is implemented to create an `SimpleInjectorActivatedMiddleware` instance. The middleware factory uses the Simple Injector container to resolve the middleware:

```
public class SimpleInjectorMiddlewareFactory : IMiddlewareFactory
{
    private readonly Container _container;

    public SimpleInjectorMiddlewareFactory(Container container)
    {
        _container = container;
    }

    public IMiddleware Create(Type middlewareType)
    {
        return _container.GetInstance(middlewareType) as IMiddleware;
    }

    public void Release(IMiddleware middleware)
    {
        // The container is responsible for releasing resources.
    }
}
```

IMiddleware

IMiddleware defines middleware for the app's request pipeline.

Middleware activated by an `IMiddlewareFactory` implementation (*Middleware/SimpleInjectorActivatedMiddleware.cs*):

```
public class SimpleInjectorActivatedMiddleware : IMiddleware
{
    private readonly AppDbContext _db;

    public SimpleInjectorActivatedMiddleware(AppDbContext db)
    {
        _db = db;
    }

    public async Task InvokeAsync(HttpContext context, RequestDelegate next)
    {
        var keyValue = context.Request.Query["key"];

        if (!string.IsNullOrWhiteSpace(keyValue))
        {
            _db.Add(new Request()
                {
                    DT = DateTime.UtcNow,
                    MiddlewareActivation = "SimpleInjectorActivatedMiddleware",
                    Value = keyValue
                });

            await _db.SaveChangesAsync();
        }

        await next(context);
    }
}
```

An extension is created for the middleware (*Middleware/MiddlewareExtensions.cs*):

```
public static class MiddlewareExtensions
{
    public static IApplicationBuilder UseSimpleInjectorActivatedMiddleware(
        this IApplicationBuilder builder)
    {
        return builder.UseMiddleware<SimpleInjectorActivatedMiddleware>();
    }
}
```

`Startup.ConfigureServices` must perform several tasks:

- Set up the Simple Injector container.
- Register the factory and middleware.
- Make the app's database context available from the Simple Injector container.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    // Replace the default middleware factory with the
    // SimpleInjectorMiddlewareFactory.
    services.AddTransient<IMiddlewareFactory>(_ =>
    {
        return new SimpleInjectorMiddlewareFactory(_container);
    });

    // Wrap ASP.NET Core requests in a Simple Injector execution
    // context.
    services.UseSimpleInjectorAspNetRequestScoping(_container);

    // Provide the database context from the Simple
    // Injector container whenever it's requested from
    // the default service container.
    services.AddScoped<AppDbContext>(provider =>
        _container.GetInstance<AppDbContext>());

    _container.Options.DefaultScopedLifestyle = new AsyncScopedLifestyle();

    _container.Register<AppDbContext>(() =>
    {
        var optionsBuilder = new DbContextOptionsBuilder<DbContext>();
        optionsBuilder.UseInMemoryDatabase("InMemoryDb");
        return new AppDbContext(optionsBuilder.Options);
    }, Lifestyle.Scoped);

    _container.Register<SimpleInjectorActivatedMiddleware>();

    _container.Verify();
}
```

The middleware is registered in the request processing pipeline in `Startup.Configure`:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
    }

    app.UseSimpleInjectorActivatedMiddleware();

    app.UseStaticFiles();
    app.UseMvc();
}
```

Migrate from ASP.NET Core 3.1 to 5.0

9/22/2020 • 2 minutes to read • Edit Online

By Scott Addie

This article explains how to update an existing ASP.NET Core 3.1 project to ASP.NET Core 5.0.

> **IMPORTANT**
> ASP.NET Core 5.0 is currently in preview.

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 16.8 or later with the **ASP.NET and web development** workload
- .NET 5.0 SDK or later

Update .NET Core SDK version in global.json

If you rely upon a global.json file to target a specific .NET Core SDK version, update the `version` property to the .NET 5.0 SDK version that's installed. For example:

```
{
  "sdk": {
-    "version": "3.1.200"
+    "version": "5.0.100-rc.1.20452.10"
  }
}
```

Update the target framework

If updating a Blazor WebAssembly project, skip to the Update Blazor WebAssembly projects section. For any other ASP.NET Core project type, update the project file's Target Framework Moniker (TFM) to `net5.0`:

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
-    <TargetFramework>netcoreapp3.1</TargetFramework>
+    <TargetFramework>net5.0</TargetFramework>
  </PropertyGroup>

</Project>
```

Update Blazor WebAssembly projects

For Blazor WebAssembly projects, apply the following changes in the project file:

1. Update the SDK from `Microsoft.NET.Sdk.Web` to `Microsoft.NET.Sdk.BlazorWebAssembly`:

```
- <Project Sdk="Microsoft.NET.Sdk.Web">
+ <Project Sdk="Microsoft.NET.Sdk.BlazorWebAssembly">
```

2. Update the following properties:

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
-     <TargetFramework>netstandard2.1</TargetFramework>
-     <RazorLangVersion>3.0</RazorLangVersion>
+     <TargetFramework>net5.0</TargetFramework>
  </PropertyGroup>
```

3. Remove the package reference to Microsoft.AspNetCore.Components.WebAssembly.Build:

```
<ItemGroup>
-    <PackageReference Include="Microsoft.AspNetCore.Components.WebAssembly.Build" Version="3.2.1"
PrivateAssets="all" />
```

Update package references

In the project file, update each Microsoft.AspNetCore.*, Microsoft.Extensions.*, and System.Net.Http.Json package reference's `Version` attribute to 5.0.0 or later. For example:

```
<ItemGroup>
-    <PackageReference Include="Microsoft.AspNetCore.JsonPatch" Version="3.1.6" />
-    <PackageReference Include="Microsoft.Extensions.Caching.Abstractions" Version="3.1.6" />
-    <PackageReference Include="System.Net.Http.Json" Version="3.2.1" />
+    <PackageReference Include="Microsoft.AspNetCore.JsonPatch" Version="5.0.0-rc.1.*" />
+    <PackageReference Include="Microsoft.Extensions.Caching.Abstractions" Version="5.0.0-rc.1.*" />
+    <PackageReference Include="System.Net.Http.Json" Version="5.0.0-rc.1.*" />
</ItemGroup>
```

Update Docker images

For apps using Docker, update your *Dockerfile* `FROM` statements and scripts. Use a base image that includes the ASP.NET Core 5.0 runtime. Consider the following `docker pull` command difference between ASP.NET Core 3.1 and 5.0:

```
- docker pull mcr.microsoft.com/dotnet/core/aspnet:3.1
+ docker pull mcr.microsoft.com/dotnet/aspnet:5.0
```

As part of the move to ".NET" as the product name, the Docker images moved from the `mcr.microsoft.com/dotnet/core` repositories to `mcr.microsoft.com/dotnet`. For more information, see dotnet/dotnet-docker#1939.

Review breaking changes

For breaking changes from .NET Core 3.1 to .NET 5.0, see Breaking changes for migration from version 3.1 to 5.0. ASP.NET Core and Entity Framework Core are also included in the list.

Migrate from ASP.NET Core 3.0 to 3.1

9/22/2020 • 2 minutes to read • Edit Online

By Scott Addie

This article explains how to update an existing ASP.NET Core 3.0 project to ASP.NET Core 3.1.

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 16.4 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

Update .NET Core SDK version in global.json

If you rely upon a global.json file to target a specific .NET Core SDK version, update the `version` property to the 3.1 SDK version that's installed. For example:

```
{
  "sdk": {
-    "version": "3.0.101"
+    "version": "3.1.101"
  }
}
```

Update the target framework

In the project file, update the Target Framework Moniker (TFM) to `netcoreapp3.1`:

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
-    <TargetFramework>netcoreapp3.0</TargetFramework>
+    <TargetFramework>netcoreapp3.1</TargetFramework>
  </PropertyGroup>

</Project>
```

Update package references

In the project file, update each `Microsoft.AspNetCore.*` package reference's `Version` attribute to 3.1.0 or later. For example:

```
<ItemGroup>
-    <PackageReference Include="Microsoft.AspNetCore.Mvc.NewtonsoftJson" Version="3.0.0" />
-    <PackageReference Include="Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation" Version="3.0.0"
Condition="'$(Configuration)' == 'Debug'" />
+    <PackageReference Include="Microsoft.AspNetCore.Mvc.NewtonsoftJson" Version="3.1.1" />
+    <PackageReference Include="Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation" Version="3.1.1"
Condition="'$(Configuration)' == 'Debug'" />
</ItemGroup>
```

Update Docker images

For apps using Docker, use a base image that includes ASP.NET Core 3.1. For example:

```
docker pull mcr.microsoft.com/dotnet/core/aspnet:3.1
```

React to SameSite cookie changes

The `SameSite` attribute implementations for HTTP cookies changed between ASP.NET Core 3.0 and 3.1. For actions to be taken, see the following resources:

- Work with SameSite cookies in ASP.NET Core
- aspnet/Announcements#390
- Upcoming SameSite cookie changes in ASP.NET and ASP.NET Core

Review breaking changes

Review 3.0-to-3.1 breaking changes across .NET Core, ASP.NET Core, and Entity Framework Core at Breaking changes for migration from version 3.0 to 3.1.

Optional changes

The following changes are optional.

Use the Component Tag Helper

ASP.NET Core 3.1 introduces a `Component` Tag Helper. The Tag Helper can replace the `RenderComponentAsync<TComponent>` HTML helper method in a Blazor project. For example:

```
- @(await Html.RenderComponentAsync<Counter>(RenderMode.ServerPrerendered, new { IncrementAmount = 10 }))
+ <component type="typeof(Counter)" render-mode="ServerPrerendered" param-IncrementAmount="10" />
```

For more information, see Integrate ASP.NET Core Razor components into Razor Pages and MVC apps.

Migrate from ASP.NET Core 2.2 to 3.0

9/22/2020 • 27 minutes to read • Edit Online

By Scott Addie and Rick Anderson

This article explains how to update an existing ASP.NET Core 2.2 project to ASP.NET Core 3.0. It might be helpful to create a new ASP.NET Core 3.0 project to:

- Compare with the ASP.NET Core 2.2 code.
- Copy the relevant changes to your ASP.NET Core 3.0 project.

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core 3.0 SDK or later

Update .NET Core SDK version in global.json

If your solution relies upon a global.json file to target a specific .NET Core SDK version, update its `version` property to the 3.0 version installed on your machine:

```
{
  "sdk": {
    "version": "3.0.100"
  }
}
```

Update the project file

Update the Target Framework

ASP.NET Core 3.0 and later only run on .NET Core. Set the Target Framework Moniker (TFM) to `netcoreapp3.0`:

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>

</Project>
```

Remove obsolete package references

A large number of NuGet packages aren't produced for ASP.NET Core 3.0. Such package references should be removed from your project file. Consider the following project file for an ASP.NET Core 2.2 web app:

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp2.2</TargetFramework>
    <AspNetCoreHostingModel>InProcess</AspNetCoreHostingModel>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.App"/>
    <PackageReference Include="Microsoft.AspNetCore.Razor.Design" Version="2.2.0" PrivateAssets="All" />
  </ItemGroup>

</Project>
```

The updated project file for ASP.NET Core 3.0:

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>

</Project>
```

The updated ASP.NET Core 3.0 project file:

- In the `<PropertyGroup>`:
  - Updates the TFM to `netcoreapp3.0`
  - Removes the `<AspNetCoreHostingModel>` element. For more information, see In-process hosting model in this document.
- In the `<ItemGroup>`:
  - `Microsoft.AspNetCore.App` is removed. For more information, see Framework reference in this document.
  - `Microsoft.AspNetCore.Razor.Design` is removed and in the following list of packages no longer being produced.

To see the full list of packages that are no longer produced, select the following expand list:

▶ Click to expand the list of packages no longer being produced

Review breaking changes

Review breaking changes

Framework reference

Features of ASP.NET Core that were available through one of the packages listed above are available as part of the `Microsoft.AspNetCore.App` shared framework. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and includes a runtime component and a targeting pack. For more information, see The shared framework.

- Projects that target the `Microsoft.NET.Sdk.Web` SDK implicitly reference the `Microsoft.AspNetCore.App` framework.

  No additional references are required for these projects:

```
<Project Sdk="Microsoft.NET.Sdk.Web">
  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>
    ...
</Project>
```

- Projects that target `Microsoft.NET.Sdk` or `Microsoft.NET.Sdk.Razor` SDK, should add an explicit `FrameworkReference` to `Microsoft.AspNetCore.App`:

```
<Project Sdk="Microsoft.NET.Sdk.Razor">
  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>
    ...
</Project>
```

Framework-dependent builds using Docker

Framework-dependent builds of console apps that use a package that depends on the ASP.NET Core shared framework may give the following runtime error:

```
It was not possible to find any compatible framework version
The specified framework 'Microsoft.AspNetCore.App', version '3.0.0' was not found.
  - No frameworks were found.
```

`Microsoft.AspNetCore.App` is the shared framework containing the ASP.NET Core runtime and is only present on the dotnet/core/aspnet Docker image. The 3.0 SDK reduces the size of framework-dependent builds using ASP.NET Core by not including duplicate copies of libraries that are available in the shared framework. This is a potential savings of up to 18 MB, but it requires that the ASP.NET Core runtime be present / installed to run the app.

To determine if the app has a dependency (either direct or indirect) on the ASP.NET Core shared framework, examine the *runtimeconfig.json* file generated during a build/publish of your app. The following JSON file shows a dependency on the ASP.NET Core shared framework:

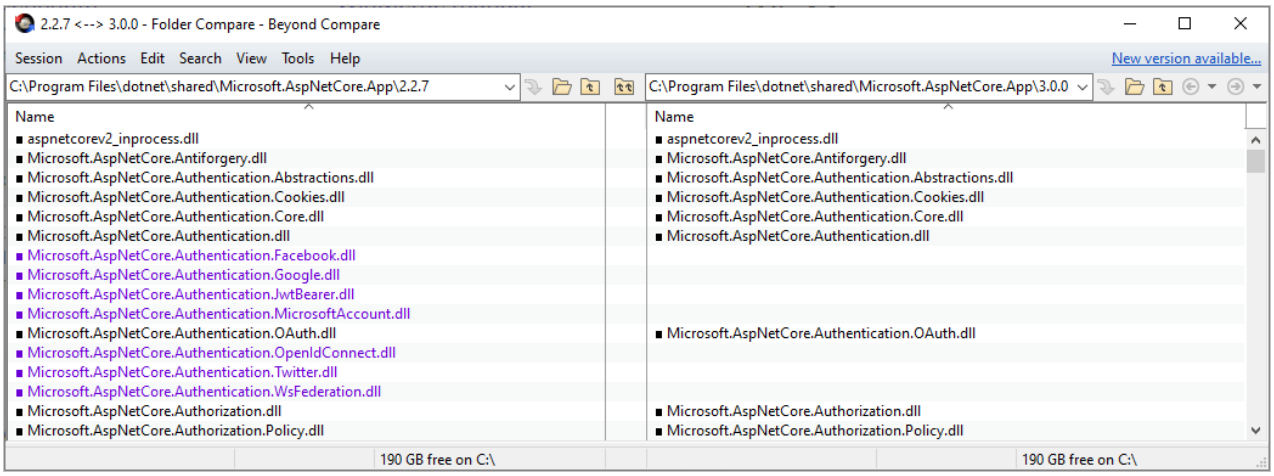
```
{
  "runtimeOptions": {
    "tfm": "netcoreapp3.0",
    "framework": {
      "name": "Microsoft.AspNetCore.App",
      "version": "3.0.0"
    },
    "configProperties": {
      "System.GC.Server": true
    }
  }
}
```

If your app is using Docker, use a base image that includes ASP.NET Core 3.0. For example, `docker pull mcr.microsoft.com/dotnet/core/aspnet:3.0`.

Add package references for removed assemblies

ASP.NET Core 3.0 removes some assemblies that were previously part of the `Microsoft.AspNetCore.App` package reference. To visualize which assemblies were removed, compare the two shared framework folders. For example,

a comparison of versions 2.2.7 and 3.0.0:



To continue using features provided by the removed assemblies, reference the 3.0 versions of the corresponding packages:

- A template-generated web app with **Individual User Accounts** requires adding the following packages:

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
    <UserSecretsId>My-secret</UserSecretsId>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore" Version="3.0.0" />
    <PackageReference Include="Microsoft.AspNetCore.Identity.EntityFrameworkCore" Version="3.0.0" />
    <PackageReference Include="Microsoft.AspNetCore.Identity.UI" Version="3.0.0" />
    <PackageReference Include="Microsoft.EntityFrameworkCore.SqlServer" Version="3.0.0" />
    <PackageReference Include="Microsoft.EntityFrameworkCore.Tools" Version="3.0.0" />
  </ItemGroup>

</Project>
```

- Microsoft.EntityFrameworkCore

  For more information on referencing the database provider-specific package, see Database Providers.

- Identity UI

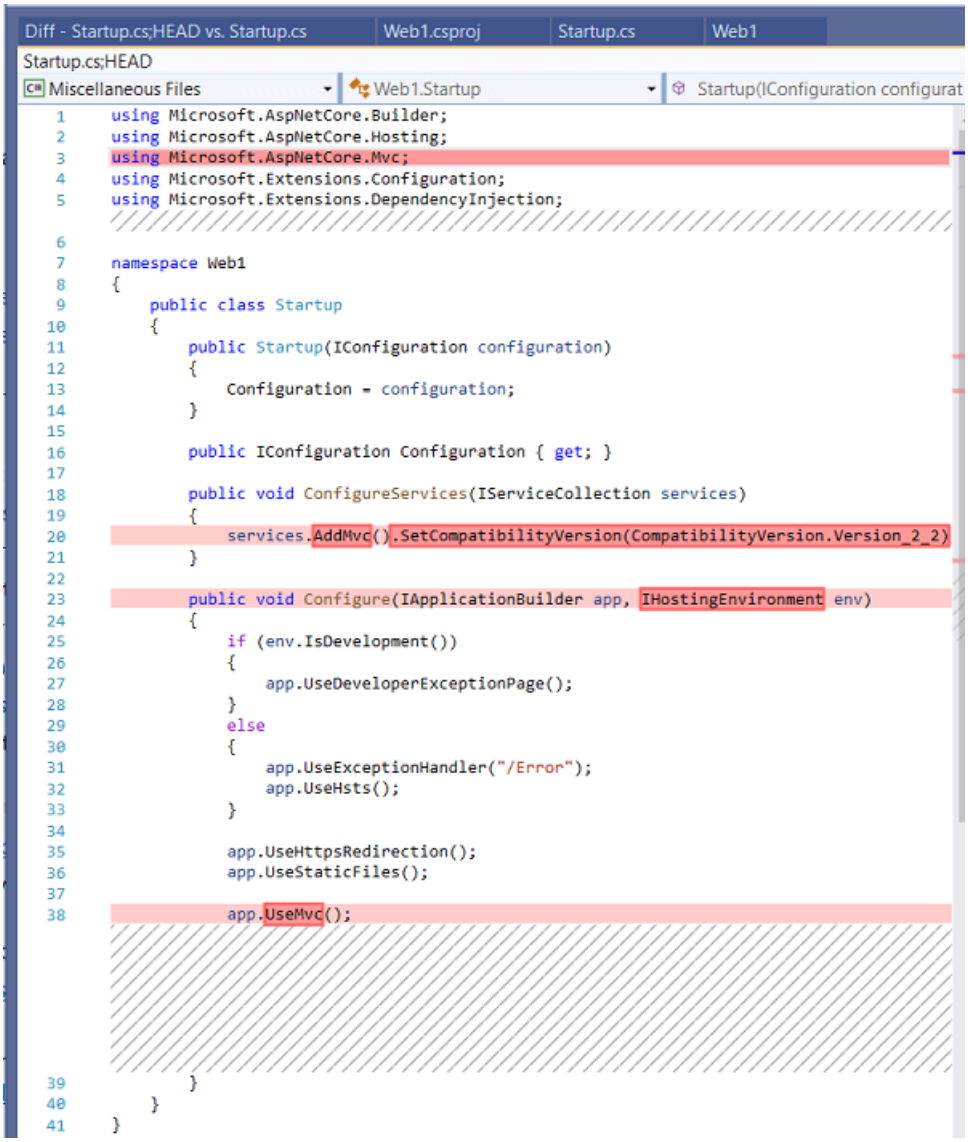
  Support for Identity UI can be added by referencing the Microsoft.AspNetCore.Identity.UI package.

- SPA Services
  - Microsoft.AspNetCore.SpaServices
  - Microsoft.AspNetCore.SpaServices.Extensions
- Authentication: Support for third-party authentication flows are available as NuGet packages:
  - Facebook OAuth (Microsoft.AspNetCore.Authentication.Facebook)
  - Google OAuth (Microsoft.AspNetCore.Authentication.Google)
  - Microsoft Account authentication (Microsoft.AspNetCore.Authentication.MicrosoftAccount)
  - OpenID Connect authentication (Microsoft.AspNetCore.Authentication.OpenIdConnect)
  - OpenID Connect bearer token (Microsoft.AspNetCore.Authentication.JwtBearer)
  - Twitter OAuth (Microsoft.AspNetCore.Authentication.Twitter)
  - WsFederation authentication (Microsoft.AspNetCore.Authentication.WsFederation)

- Formatting and content negotiation support for `System.Net.HttpClient`: The Microsoft.AspNet.WebApi.Client NuGet package provides useful extensibility to `System.Net.HttpClient` with APIs such as `ReadAsAsync` and `PostJsonAsync`.
- Razor runtime compilation: Support for runtime compilation of Razor views and pages is now part of Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation.
- MVC `Newtonsoft.Json` (Json.NET) support: Support for using MVC with `Newtonsoft.Json` is now part of `Microsoft.AspNetCore.Mvc.NewtonsoftJson`.

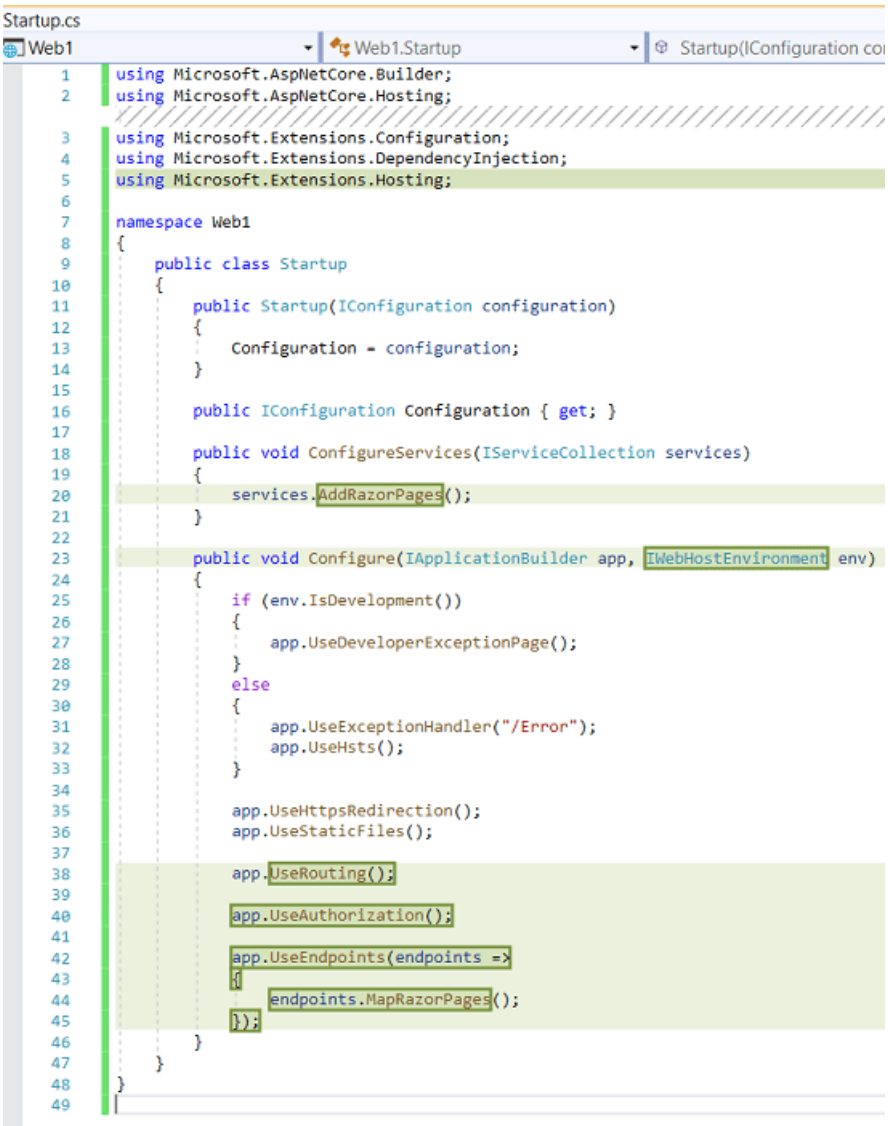
Startup changes

The following image shows the deleted and changed lines in an ASP.NET Core 2.2 Razor Pages Web app:



In the preceding image, deleted code is shown in red. The deleted code doesn't show cookie options code, which was deleted prior to comparing the files.

The following image shows the added and changed lines in an ASP.NET Core 3.0 Razor Pages Web app:



In the preceding image, added code is shown in green. For information on the following changes:

- `services.AddMvc` to `services.AddRazorPages`, see MVC service registration in this document.
- `CompatibilityVersion`, see Compatibility version for ASP.NET Core MVC.
- `IHostingEnvironment` to `IWebHostEnvironment`, see this GitHub announcement.
- `app.UseAuthorization` was added to the templates to show the order authorization middleware must be added. If the app doesn't use authorization, you can safely remove the call to `app.UseAuthorization`.
- `app.UseEndpoints`, see Razor Pages or Migrate Startup.Configure in this document.

Analyzer support

Projects that target `Microsoft.NET.Sdk.Web` implicitly reference analyzers previously shipped as part of the Microsoft.AspNetCore.Mvc.Analyzers package. No additional references are required to enable these.

If your app uses API analyzers previously shipped using the Microsoft.AspNetCore.Mvc.Api.Analyzers package, edit your project file to reference the analyzers shipped as part of the .NET Core Web SDK:

```
<Project Sdk="Microsoft.NET.Sdk.Web">
    <PropertyGroup>
        <TargetFramework>netcoreapp3.0</TargetFramework>
        <IncludeOpenAPIAnalyzers>true</IncludeOpenAPIAnalyzers>
    </PropertyGroup>

    ...
</Project>
```

Razor Class Library

Razor Class Library projects that provide UI components for MVC must set the `AddRazorSupportForMvc` property in the project file:

```
<PropertyGroup>
  <AddRazorSupportForMvc>true</AddRazorSupportForMvc>
</PropertyGroup>
```

In-process hosting model

Projects default to the in-process hosting model in ASP.NET Core 3.0 or later. You may optionally remove the `<AspNetCoreHostingModel>` property in the project file if its value is `InProcess`.

Kestrel

Configuration

Migrate Kestrel configuration to the web host builder provided by `ConfigureWebHostDefaults` (*Program.cs*):

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.ConfigureKestrel(serverOptions =>
            {
                // Set properties and call methods on options
            })
            .UseStartup<Startup>();
        });
```

If the app creates the host manually with `HostBuilder`, call `UseKestrel` on the web host builder in `ConfigureWebHostDefaults`:

```
public static void Main(string[] args)
{
    var host = new HostBuilder()
        .UseContentRoot(Directory.GetCurrentDirectory())
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseKestrel(serverOptions =>
            {
                // Set properties and call methods on options
            })
            .UseIISIntegration()
            .UseStartup<Startup>();
        })
        .Build();

    host.Run();
}
```

Connection Middleware replaces Connection Adapters

Connection Adapters (`Microsoft.AspNetCore.Server.Kestrel.Core.Adapter.Internal.IConnectionAdapter`) have been removed from Kestrel. Replace Connection Adapters with Connection Middleware. Connection Middleware is similar to HTTP Middleware in the ASP.NET Core pipeline but for lower-level connections. HTTPS and connection logging:

- Have been moved from Connection Adapters to Connection Middleware.
- These extension methods work as in previous versions of ASP.NET Core.

For more information, see the TlsFilterConnectionHandler example in the ListenOptions.Protocols section of the Kestrel article.

Transport abstractions moved and made public

The Kestrel transport layer has been exposed as a public interface in `Connections.Abstractions`. As part of these updates:

- `Microsoft.AspNetCore.Server.Kestrel.Transport.Abstractions` and associated types have been removed.
- NoDelay was moved from ListenOptions to the transport options.
- `Microsoft.AspNetCore.Server.Kestrel.Transport.Abstractions.Internal.SchedulingMode` was removed from KestrelServerOptions.

For more information, see the following GitHub resources:

- Client/server networking abstractions (dotnet/AspNetCore #10308)
- Implement new bedrock listener abstraction and re-plat Kestrel on top (dotnet/AspNetCore #10321)

Kestrel Request trailer headers

For apps that target earlier versions of ASP.NET Core:

- Kestrel adds HTTP/1.1 chunked trailer headers into the request headers collection.
- Trailers are available after the request body is read to the end.

This causes some concerns about ambiguity between headers and trailers, so the trailers have been moved to a new collection (`RequestTrailerExtensions`) in 3.0.

HTTP/2 request trailers are:

- Not available in ASP.NET Core 2.2.
- Available in 3.0 as `RequestTrailerExtensions`.

New request extension methods are present to access these trailers. As with HTTP/1.1, trailers are available after the request body is read to the end.

For the 3.0 release, the following `RequestTrailerExtensions` methods are available:

- `GetDeclaredTrailers`: Gets the request `Trailer` header that lists which trailers to expect after the body.
- `SupportsTrailers`: Indicates if the request supports receiving trailer headers.
- `CheckTrailersAvailable`: Checks if the request supports trailers and if they're available to be read. This check doesn't assume that there are trailers to read. There might be no trailers to read even if `true` is returned by this method.
- `GetTrailer`: Gets the requested trailing header from the response. Check `SupportsTrailers` before calling `GetTrailer`, or a NotSupportedException may occur if the request doesn't support trailing headers.

For more information, see Put request trailers in a separate collection (dotnet/AspNetCore #10410).

AllowSynchronousIO disabled

`AllowSynchronousIO` enables or disables synchronous I/O APIs, such as `HttpRequest.Body.Read`, `HttpResponse.Body.Write`, and `Stream.Flush`. These APIs are a source of thread starvation leading to app crashes. In 3.0, `AllowSynchronousIO` is disabled by default. For more information, see the Synchronous I/O section in the Kestrel article.

If synchronous I/O is needed, it can be enabled by configuring the `AllowSynchronousIO` option on the server being used (when calling `ConfigureKestrel`, for example, if using Kestrel). Note that servers (Kestrel, HttpSys, TestServer, etc.) all have their own `AllowSynchronousIO` option that won't affect other servers. Synchronous I/O can be enabled

for all servers on a per-request basis using the `IHttpBodyControlFeature.AllowSynchronousIO` option:

```
var syncIOFeature = HttpContext.Features.Get<IHttpBodyControlFeature>();

if (syncIOFeature != null)
{
    syncIOFeature.AllowSynchronousIO = true;
}
```

If you have trouble with TextWriter implementations or other streams that call synchronous APIs in Dispose, call the new DisposeAsync API instead.

For more information, see [Announcement] AllowSynchronousIO disabled in all servers (dotnet/AspNetCore #7644).

Output formatter buffering

Newtonsoft.Json, XmlSerializer, and DataContractSerializer based output formatters only support synchronous serialization. To allow these formatters to work with the AllowSynchronousIO restrictions of the server, MVC buffers the output of these formatters before writing to disk. As a result of buffering, MVC will include the Content-Length header when responding using these formatters.

System.Text.Json supports asynchronous serialization and consequently the `System.Text.Json` based formatter does not buffer. Consider using this formatter for improved performance.

To disable buffering, applications can configure SuppressOutputFormatterBuffering in their startup:

```
services.AddControllers(options => options.SuppressOutputFormatterBuffering = true)
```

Note that this may result in the application throwing a runtime exception if `AllowSynchronousIO` isn't also configured.

Microsoft.AspNetCore.Server.Kestrel.Https assembly removed

In ASP.NET Core 2.1, the contents of *Microsoft.AspNetCore.Server.Kestrel.Https.dll* were moved to *Microsoft.AspNetCore.Server.Kestrel.Core.dll*. This was a non-breaking update using `TypeForwardedTo` attributes. For 3.0, the empty *Microsoft.AspNetCore.Server.Kestrel.Https.dll* assembly and the NuGet package have been removed.

Libraries referencing Microsoft.AspNetCore.Server.Kestrel.Https should update ASP.NET Core dependencies to 2.1 or later.

Apps and libraries targeting ASP.NET Core 2.1 or later should remove any direct references to the Microsoft.AspNetCore.Server.Kestrel.Https package.

Newtonsoft.Json (Json.NET) support

As part of the work to improve the ASP.NET Core shared framework, Newtonsoft.Json (Json.NET) has been removed from the ASP.NET Core shared framework.

The default JSON serializer for ASP.NET Core is now System.Text.Json, which is new in .NET Core 3.0. Consider using `System.Text.Json` when possible. It's high-performance and doesn't require an additional library dependency. However, since `System.Text.Json` is new, it might currently be missing features that your app needs. For more information, see How to migrate from Newtonsoft.Json to System.Text.Json.

Use Newtonsoft.Json in an ASP.NET Core 3.0 SignalR project

- Install the Microsoft.AspNetCore.SignalR.Protocols.NewtonsoftJson NuGet package.

- On the client, chain an `AddNewtonsoftJsonProtocol` method call to the `HubConnectionBuilder` instance:

```
new HubConnectionBuilder()
    .WithUrl("/chathub")
    .AddNewtonsoftJsonProtocol(...)
    .Build();
```

- On the server, chain an `AddNewtonsoftJsonProtocol` method call to the `AddSignalR` method call in `Startup.ConfigureServices`:

```
services.AddSignalR()
    .AddNewtonsoftJsonProtocol(...);
```

Use Newtonsoft.Json in an ASP.NET Core 3.0 MVC project

- Install the `Microsoft.AspNetCore.Mvc.NewtonsoftJson` package.
- Update `Startup.ConfigureServices` to call `AddNewtonsoftJson`.

```
services.AddMvc()
    .AddNewtonsoftJson();
```

`AddNewtonsoftJson` is compatible with the new MVC service registration methods:

  - `AddRazorPages`
  - `AddControllersWithViews`
  - `AddControllers`

```
services.AddControllers()
    .AddNewtonsoftJson();
```

`Newtonsoft.Json` settings can be set in the call to `AddNewtonsoftJson`:

```
services.AddMvc()
    .AddNewtonsoftJson(options =>
           options.SerializerSettings.ContractResolver =
              new CamelCasePropertyNamesContractResolver());
```

Note: If the `AddNewtonsoftJson` method isn't available, make sure that you installed the `Microsoft.AspNetCore.Mvc.NewtonsoftJson` package. A common error is to install the Newtonsoft.Json package instead of the `Microsoft.AspNetCore.Mvc.NewtonsoftJson` package.

MVC service registration

ASP.NET Core 3.0 adds new options for registering MVC scenarios inside `Startup.ConfigureServices`.

Three new top-level extension methods related to MVC scenarios on `IServiceCollection` are available. Templates use these new methods instead of `AddMvc`. However, `AddMvc` continues to behave as it has in previous releases.

The following example adds support for controllers and API-related features, but not views or pages. The API template uses this code:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllers();
}
```

The following example adds support for controllers, API-related features, and views, but not pages. The Web Application (MVC) template uses this code:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();
}
```

The following example adds support for Razor Pages and minimal controller support. The Web Application template uses this code:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();
}
```

The new methods can also be combined. The following example is equivalent to calling `AddMvc` in ASP.NET Core 2.2:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();
    services.AddRazorPages();
}
```

Routing startup code

If an app calls `UseMvc` or `UseSignalR`, migrate the app to Endpoint Routing if possible. To improve Endpoint Routing compatibility with previous versions of MVC, we've reverted some of the changes in URL generation introduced in ASP.NET Core 2.2. If you experienced problems using Endpoint Routing in 2.2, expect improvements in ASP.NET Core 3.0 with the following exceptions:

- If the app implements `IRouter` or inherits from `Route`, use DynamicRouteValuesTransformer as the replacement.
- If the app directly accesses `RouteData.Routers` inside MVC to parse URLs, you can replace this with use of LinkParser.ParsePathByEndpointName.
  - Define the route with a route name.
  - Use `LinkParser.ParsePathByEndpointName` and pass in the desired route name.

Endpoint Routing supports the same route pattern syntax and route pattern authoring features as `IRouter`. Endpoint Routing supports `IRouteConstraint`. Endpoint routing supports `[Route]`, `[HttpGet]`, and the other MVC routing attributes.

For most applications, only `Startup` requires changes.

Migrate Startup.Configure

General advice:

- Add `UseRouting`.

- If the app calls `UseStaticFiles`, place `UseStaticFiles` **before** `UseRouting`.
- If the app uses authentication/authorization features such as `AuthorizePage` or `[Authorize]`, place the call to `UseAuthentication` and `UseAuthorization`: **after**, `UseRouting` and `UseCors`, but before `UseEndpoints`:

```
public void Configure(IApplicationBuilder app)
{
  ...

  app.UseStaticFiles();

  app.UseRouting();
  app.UseCors();

  app.UseAuthentication();
  app.UseAuthorization();

  app.UseEndpoints(endpoints => {
     endpoints.MapControllers();
  });
```

- Replace `UseMvc` or `UseSignalR` with `UseEndpoints`.
- If the app uses CORS scenarios, such as `[EnableCors]`, place the call to `UseCors` before any other middleware that use CORS (for example, place `UseCors` before `UseAuthentication`, `UseAuthorization`, and `UseEndpoints`).
- Replace `IHostingEnvironment` with `IWebHostEnvironment` and add a `using` statement for the Microsoft.Extensions.Hosting namespace.
- Replace `IApplicationLifetime` with IHostApplicationLifetime (Microsoft.Extensions.Hosting namespace).
- Replace `EnvironmentName` with Environments (Microsoft.Extensions.Hosting namespace).

The following code is an example of `Startup.Configure` in a typical ASP.NET Core 2.2 app:

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseStaticFiles();

    app.UseAuthentication();

    app.UseSignalR(hubs =>
    {
        hubs.MapHub<ChatHub>("/chat");
    });

    app.UseMvc(routes =>
    {
        routes.MapRoute("default", "{controller=Home}/{action=Index}/{id?}");
    });
}
```

After updating the previous `Startup.Configure` code:

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseStaticFiles();

    app.UseRouting();

    app.UseCors();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapHub<ChatHub>("/chat");
        endpoints.MapControllerRoute("default", "{controller=Home}/{action=Index}/{id?}");
    });
}
```

WARNING

For most apps, calls to `UseAuthentication`, `UseAuthorization`, and `UseCors` must appear between the calls to `UseRouting` and `UseEndpoints` to be effective.

Health Checks

Health Checks use endpoint routing with the Generic Host. In `Startup.Configure`, call `MapHealthChecks` on the endpoint builder with the endpoint URL or relative path:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health");
});
```

Health Checks endpoints can:

- Specify one or more permitted hosts/ports.
- Require authorization.
- Require CORS.

For more information, see Health checks in ASP.NET Core.

Security middleware guidance

Support for authorization and CORS is unified around the middleware approach. This allows use of the same middleware and functionality across these scenarios. An updated authorization middleware is provided in this release, and CORS Middleware is enhanced so that it can understand the attributes used by MVC controllers.

CORS

Previously, CORS could be difficult to configure. Middleware was provided for use in some use cases, but MVC filters were intended to be used **without** the middleware in other use cases. With ASP.NET Core 3.0, we recommend that all apps that require CORS use the CORS Middleware in tandem with Endpoint Routing. `UseCors` can be provided with a default policy, and `[EnableCors]` and `[DisableCors]` attributes can be used to override the default policy where required.

In the following example:

- CORS is enabled for all endpoints with the `default` named policy.

- The `MyController` class disables CORS with the `[DisableCors]` attribute.

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseCors("default");

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}

[DisableCors]
public class MyController : ControllerBase
{
    ...
}
```

Authorization

In earlier versions of ASP.NET Core, authorization support was provided via the `[Authorize]` attribute. Authorization middleware wasn't available. In ASP.NET Core 3.0, authorization middleware is required. We recommend placing the ASP.NET Core Authorization Middleware (`UseAuthorization`) immediately after `UseAuthentication` . The Authorization Middleware can also be configured with a default policy, which can be overridden.

In ASP.NET Core 3.0 or later, `UseAuthorization` is called in `Startup.Configure` , and the following `HomeController` requires a signed in user:

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}

public class HomeController : Controller
{
    [Authorize]
    public IActionResult BuyWidgets()
    {
        ...
    }
}
```

When using endpoint routing, we recommend against configuring `<xref:Microsoft.AspNetCore.Mvc.Authorization.AuthorizeFilter>` and instead relying on the Authorization middleware. If the app uses an `AuthorizeFilter` as a global filter in MVC, we recommend refactoring the code to provide a policy in the call to `AddAuthorization` .

The `DefaultPolicy` is initially configured to require authentication, so no additional configuration is required. In the following example, MVC endpoints are marked as `RequireAuthorization` so that all requests must be authorized based on the `DefaultPolicy`. However, the `HomeController` allows access without the user signing into the app due to `[AllowAnonymous]`:

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute().RequireAuthorization();
    });
}

[AllowAnonymous]
public class HomeController : Controller
{
    ...
}
```

Authorization for specific endpoints

Authorization can also be configured for specific classes of endpoints. The following code is an example of converting an MVC app that configured a global `AuthorizeFilter` to an app with a specific policy requiring authorization:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    static readonly string _RequireAuthenticatedUserPolicy =
                           "RequireAuthenticatedUserPolicy";
    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddDbContext<ApplicationDbContext>(options =>
            options.UseSqlServer(
                Configuration.GetConnectionString("DefaultConnection")));
        services.AddDefaultIdentity<IdentityUser>(
                 options => options.SignIn.RequireConfirmedAccount = true)
            .AddEntityFrameworkStores<ApplicationDbContext>();

        // Pre 3.0:
        // services.AddMvc(options => options.Filters.Add(new AuthorizeFilter(...));

        services.AddControllersWithViews();
        services.AddRazorPages();
        services.AddAuthorization(o => o.AddPolicy(_RequireAuthenticatedUserPolicy,
                        builder => builder.RequireAuthenticatedUser()));

    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
            app.UseDatabaseErrorPage();
        }
        else
        {
            app.UseExceptionHandler("/Home/Error");
            app.UseHsts();
        }
        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthentication();
        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapDefaultControllerRoute()
                .RequireAuthorization(_RequireAuthenticatedUserPolicy);
            endpoints.MapRazorPages();
        });
    }
}
```

Policies can also be customized. The `DefaultPolicy` is configured to require authentication:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddDbContext<ApplicationDbContext>(options =>
            options.UseSqlServer(
                Configuration.GetConnectionString("DefaultConnection")));
        services.AddDefaultIdentity<IdentityUser>(
                 options => options.SignIn.RequireConfirmedAccount = true)
            .AddEntityFrameworkStores<ApplicationDbContext>();

        services.AddControllersWithViews();
        services.AddRazorPages();
        services.AddAuthorization(options =>
        {
            options.DefaultPolicy = new AuthorizationPolicyBuilder()
              .RequireAuthenticatedUser()
              .Build();
        });

    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
            app.UseDatabaseErrorPage();
        }
        else
        {
            app.UseExceptionHandler("/Home/Error");
            app.UseHsts();
        }
        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthentication();
        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapDefaultControllerRoute().RequireAuthorization();
            endpoints.MapRazorPages();
        });
    }
}
```

```
[AllowAnonymous]
public class HomeController : Controller
{
```

Alternatively, all endpoints can be configured to require authorization without `[Authorize]` or `RequireAuthorization` by configuring a `FallbackPolicy`. The `FallbackPolicy` is different from the `DefaultPolicy`. The `DefaultPolicy` is triggered by `[Authorize]` or `RequireAuthorization`, while the `FallbackPolicy` is triggered

when no other policy is set. `FallbackPolicy` is initially configured to allow requests without authorization.

The following example is the same as the preceding `DefaultPolicy` example but uses the `FallbackPolicy` to always require authentication on all endpoints except when `[AllowAnonymous]` is specified:

```
public void ConfigureServices(IServiceCollection services)
{
    ...

    services.AddAuthorization(options =>
    {
        options.FallbackPolicy = new AuthorizationPolicyBuilder()
          .RequireAuthenticatedUser()
          .Build();
    });
}

public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}

[AllowAnonymous]
public class HomeController : Controller
{
    ...
}
```

Authorization by middleware works without the framework having any specific knowledge of authorization. For instance, health checks has no specific knowledge of authorization, but health checks can have a configurable authorization policy applied by the middleware.

Additionally, each endpoint can customize its authorization requirements. In the following example, `UseAuthorization` processes authorization with the `DefaultPolicy`, but the `/healthz` health check endpoint requires an `admin` user:

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints
            .MapHealthChecks("/healthz")
            .RequireAuthorization(new AuthorizeAttribute(){ Roles = "admin", });
    });
}
```

Protection is implemented for some scenarios. Endpoints Middleware throws an exception if an authorization or CORS policy is skipped due to missing middleware. Analyzer support to provide additional feedback about misconfiguration is in progress.

Custom authorization handlers

If the app uses custom authorization handlers, endpoint routing passes a different resource type to handlers than MVC. Handlers that expect the authorization handler context resource to be of type AuthorizationFilterContext (the resource type provided by MVC filters) will need to be updated to handle resources of type RouteEndpoint (the resource type given to authorization handlers by endpoint routing).

MVC still uses `AuthorizationFilterContext` resources, so if the app uses MVC authorization filters along with endpoint routing authorization, it may be necessary to handle both types of resources.

SignalR

Mapping of SignalR hubs now takes place inside `UseEndpoints`.

Map each hub with `MapHub`. As in previous versions, each hub is explicitly listed.

In the following example, support for the `ChatHub` SignalR hub is added:

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapHub<ChatHub>();
    });
}
```

There is a new option for controlling message size limits from clients. For example, in `Startup.ConfigureServices`:

```
services.AddSignalR(hubOptions =>
{
    hubOptions.MaximumReceiveMessageSize = 32768;
});
```

In ASP.NET Core 2.2, you could set the `TransportMaxBufferSize` and that would effectively control the maximum message size. In ASP.NET Core 3.0, that option now only controls the maximum size before backpressure is observed.

MVC controllers

Mapping of controllers now takes place inside `UseEndpoints`.

Add `MapControllers` if the app uses attribute routing. Since routing includes support for many frameworks in ASP.NET Core 3.0 or later, adding attribute-routed controllers is opt-in.

Replace the following:

- `MapRoute` with `MapControllerRoute`
- `MapAreaRoute` with `MapAreaControllerRoute`

Since routing now includes support for more than just MVC, the terminology has changed to make these methods clearly state what they do. Conventional routes such as `MapControllerRoute` / `MapAreaControllerRoute` / `MapDefaultControllerRoute` are applied in the order that they're added. Place more specific routes (such as routes for an area) first.

In the following example:

- `MapControllers` adds support for attribute-routed controllers.
- `MapAreaControllerRoute` adds a conventional route for controllers in an area.
- `MapControllerRoute` adds a conventional route for controllers.

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
        endpoints.MapAreaControllerRoute(
            "admin",
            "admin",
            "Admin/{controller=Home}/{action=Index}/{id?}");
        endpoints.MapControllerRoute(
            "default", "{controller=Home}/{action=Index}/{id?}");
    });
}
```

Async suffix removal from controller action names

In ASP.NET Core 3.0, ASP.NET Core MVC removes the `Async` suffix from controller action names. Both routing and link generation are impacted by this new default. For example:

```
public class ProductsController : Controller
{
    public async Task<IActionResult> ListAsync()
    {
        var model = await _dbContext.Products.ToListAsync();
        return View(model);
    }
}
```

Prior to ASP.NET Core 3.0:

- The preceding action could be accessed at the *Products/ListAsync* route.
- Link generation required specifying the `Async` suffix. For example:

  ```
  <a asp-controller="Products" asp-action="ListAsync">List</a>
  ```

In ASP.NET Core 3.0:

- The preceding action can be accessed at the *Products/List* route.
- Link generation doesn't require specifying the `Async` suffix. For example:

  ```
  <a asp-controller="Products" asp-action="List">List</a>
  ```

This change doesn't affect names specified using the `[ActionName]` attribute. The default behavior can be disabled with the following code in `Startup.ConfigureServices`:

```
services.AddMvc(options =>
    options.SuppressAsyncSuffixInActionNames = false);
```

Changes to link generation

As explained in documentation on differences from earlier versions of routing, there are some differences in link generation (using `Url.Link` and similar APIs, for example). These include:

- By default, when using endpoint routing, casing of route parameters in generated URIs is not necessarily preserved. This behavior can be controlled with the `IOutboundParameterTransformer` interface.
- Generating a URI for an invalid route (a controller/action or page that doesn't exist) will produce an empty string under endpoint routing instead of producing an invalid URI.
- Ambient values (route parameters from the current context) are not automatically used in link generation with endpoint routing. Previously, when generating a link to another action (or page), unspecified route values would be inferred from the *current* routes ambient values. When using endpoint routing, all route parameters must be specified explicitly during link generation.

Razor Pages

Mapping Razor Pages now takes place inside `UseEndpoints`.

Add `MapRazorPages` if the app uses Razor Pages. Since Endpoint Routing includes support for many frameworks, adding Razor Pages is now opt-in.

In the following `Startup.Configure` method, `MapRazorPages` adds support for Razor Pages:

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

Use MVC without Endpoint Routing

Using MVC via `UseMvc` or `UseMvcWithDefaultRoute` in ASP.NET Core 3.0 requires an explicit opt-in inside `Startup.ConfigureServices`. This is required because MVC must know whether it can rely on the authorization and CORS Middleware during initialization. An analyzer is provided that warns if the app attempts to use an unsupported configuration.

If the app requires legacy `IRouter` support, disable `EnableEndpointRouting` using any of the following approaches in `Startup.ConfigureServices`:

```
services.AddMvc(options => options.EnableEndpointRouting = false);
```

```
services.AddControllers(options => options.EnableEndpointRouting = false);
```

```
services.AddControllersWithViews(options => options.EnableEndpointRouting = false);
```

```
services.AddRazorPages().AddMvcOptions(options => options.EnableEndpointRouting = false);
```

Health checks

Health checks can be used as a *router-ware* with Endpoint Routing.

Add `MapHealthChecks` to use health checks with Endpoint Routing. The `MapHealthChecks` method accepts arguments similar to `UseHealthChecks`. The advantage of using `MapHealthChecks` over `UseHealthChecks` is the ability to apply authorization and to have greater fine-grained control over the matching policy.

In the following example, `MapHealthChecks` is called for a health check endpoint at `/healthz`:

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapHealthChecks("/healthz", new HealthCheckOptions() { });
    });
}
```

HostBuilder replaces WebHostBuilder

The ASP.NET Core 3.0 templates use Generic Host. Previous versions used Web Host. The following code shows the ASP.NET Core 3.0 template generated `Program` class:

```
// requires using Microsoft.AspNetCore.Hosting;
// requires using Microsoft.Extensions.Hosting;

public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The following code shows the ASP.NET Core 2.2 template-generated `Program` class:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

IWebHostBuilder remains in 3.0 and is the type of the `webBuilder` seen in the preceding code sample. WebHostBuilder will be deprecated in a future release and replaced by `HostBuilder`.

The most significant change from `WebHostBuilder` to `HostBuilder` is in dependency injection (DI). When using `HostBuilder`, you can only inject the following into `Startup`'s constructor:

- IConfiguration
- IHostEnvironment
- IWebHostEnvironment

The `HostBuilder` DI constraints:

- Enable the DI container to be built only one time.
- Avoids the resulting object lifetime issues like resolving multiple instances of singletons.

For more information, see Avoiding Startup service injection in ASP.NET Core 3.

AddAuthorization moved to a different assembly

The ASP.NET Core 2.2 and lower `AddAuthorization` methods in *Microsoft.AspNetCore.Authorization.dll*:

- Have been renamed `AddAuthorizationCore`.
- Have been moved to *Microsoft.AspNetCore.Authorization.Policy.dll*.

Apps that are using both *Microsoft.AspNetCore.Authorization.dll* and *Microsoft.AspNetCore.Authorization.Policy.dll* aren't impacted.

Apps that are not using *Microsoft.AspNetCore.Authorization.Policy.dll* should do one of the following:

- Add a reference to *Microsoft.AspNetCore.Authorization.Policy.dll*. This approach works for most apps and is all that is required.
- Switch to using `AddAuthorizationCore`

For more information, see Breaking change in `AddAuthorization(o =>`) overload lives in a different assembly #386.

Identity UI

Identity UI updates for ASP.NET Core 3.0:

- Add a package reference to Microsoft.AspNetCore.Identity.UI.
- Apps that don't use Razor Pages must call `MapRazorPages`. See Razor Pages in this document.
- Bootstrap 4 is the default UI framework. Set an `IdentityUIFrameworkVersion` project property to change the default. For more information, see this GitHub announcement.

SignalR

The SignalR JavaScript client has changed from `@aspnet/signalr` to `@microsoft/signalr`. To react to this change, change the references in *package.json* files, `require` statements, and ECMAScript `import` statements.

System.Text.Json is the default protocol

`System.Text.Json` is now the default Hub protocol used by both the client and server.

In `Startup.ConfigureServices`, call `AddJsonProtocol` to set serializer options.

Server:

```
services.AddSignalR(...)
        .AddJsonProtocol(options =>
        {
            options.PayloadSerializerOptions.WriteIndented = false;
        })
```

Client:

```
new HubConnectionBuilder()
    .WithUrl("/chathub")
    .AddJsonProtocol(options =>
    {
        options.PayloadSerializerOptions.WriteIndented = false;
    })
    .Build();
```

Switch to Newtonsoft.Json

If you're using features of Newtonsoft.Json that aren't supported in System.Text.Json, you can switch back to `Newtonsoft.Json`. See Use Newtonsoft.Json in an ASP.NET Core 3.0 SignalR project earlier in this article.

Redis distributed caches

The Microsoft.Extensions.Caching.Redis package isn't available for ASP.NET Core 3.0 or later apps. Replace the package reference with Microsoft.Extensions.Caching.StackExchangeRedis. For more information, see Distributed caching in ASP.NET Core.

Opt in to runtime compilation

Prior to ASP.NET Core 3.0, runtime compilation of views was an implicit feature of the framework. Runtime compilation supplements build-time compilation of views. It allows the framework to compile Razor views and pages (*.cshtml* files) when the files are modified, without having to rebuild the entire app. This feature supports the scenario of making a quick edit in the IDE and refreshing the browser to view the changes.

In ASP.NET Core 3.0, runtime compilation is an opt-in scenario. Build-time compilation is the only mechanism for view compilation that's enabled by default. The runtime relies on Visual Studio or dotnet-watch in Visual Studio Code to rebuild the project when it detects changes to *.cshtml* files. In Visual Studio, changes to *.cs*, *.cshtml*, or *.razor* files in the project being run (`Ctrl+F5`), but not debugged (`F5`), trigger recompilation of the project.

To enable runtime compilation in your ASP.NET Core 3.0 project:

1. Install the Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation NuGet package.
2. Update `Startup.ConfigureServices` to call `AddRazorRuntimeCompilation`:

   For ASP.NET Core MVC, use the following code:

```
services.AddControllersWithViews()
    .AddRazorRuntimeCompilation(...);
```

For ASP.NET Core Razor Pages, use the following code:

```
services.AddRazorPages()
    .AddRazorRuntimeCompilation(...);
```

The sample at https://github.com/aspnet/samples/tree/master/samples/aspnetcore/mvc/runtimecompilation shows an example of enabling runtime compilation conditionally in Development environments.

For more information on Razor file compilation, see Razor file compilation in ASP.NET Core.

Migrate libraries via multi-targeting

Libraries often need to support multiple versions of ASP.NET Core. Most libraries that were compiled against previous versions of ASP.NET Core should continue working without issues. The following conditions require the app to be cross-compiled:

- The library relies on a feature that has a binary breaking change.
- The library wants to take advantage of new features in ASP.NET Core 3.0.

For example:

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <TargetFrameworks>netcoreapp3.0;netstandard2.0</TargetFrameworks>
  </PropertyGroup>

  <ItemGroup Condition="'$(TargetFramework)' == 'netcoreapp3.0'">
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

  <ItemGroup Condition="'$(TargetFramework)' == 'netstandard2.0'">
    <PackageReference Include="Microsoft.AspNetCore" Version="2.1.0" />
  </ItemGroup>
</Project>
```

Use `#ifdefs` to enable ASP.NET Core 3.0-specific APIs:

```
var webRootFileProvider =
#if NETCOREAPP3_0
    GetRequiredService<IWebHostEnvironment>().WebRootFileProvider;
#elif NETSTANDARD2_0
    GetRequiredService<IHostingEnvironment>().WebRootFileProvider;
#else
#error unknown target framework
#endif
```

For more information on using ASP.NET Core APIs in a class library, see Use ASP.NET Core APIs in a class library.

Miscellaneous changes

The validation system in .NET Core 3.0 and later treats non-nullable parameters or bound properties as if they had a `[Required]` attribute. For more information, see [Required] attribute.

Publish

Delete the *bin* and *obj* folders in the project directory.

TestServer

For apps that use TestServer directly with the Generic Host, create the `TestServer` on an IWebHostBuilder in ConfigureWebHost:

```
[Fact]
public async Task GenericCreateAndStartHost_GetTestServer()
{
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .Configure(app => { });
        })
    .StartAsync();

    var response = await host.GetTestServer().CreateClient().GetAsync("/");

    Assert.Equal(HttpStatusCode.NotFound, response.StatusCode);
}
```

Breaking API changes

Review breaking changes:

- Complete list of breaking changes in the ASP.NET Core 3.0 release
- Breaking API changes in Antiforgery, CORS, Diagnostics, MVC, and Routing. This list includes breaking changes for compatibility switches.
- For a summary of 2.2-to-3.0 breaking changes across .NET Core, ASP.NET Core, and Entity Framework Core, see Breaking changes for migration from version 2.2 to 3.0.

Endpoint routing with catch-all parameter

WARNING

A **catch-all** parameter may match routes incorrectly due to a bug in routing. Apps impacted by this bug have the following characteristics:

- A catch-all route, for example, `{**slug}"`
- The catch-all route fails to match requests it should match.
- Removing other routes makes catch-all route start working.

See GitHub bugs 18677 and 16579 for example cases that hit this bug.

An opt-in fix for this bug is contained in .NET Core 3.1.301 SDK and later. The following code sets an internal switch that fixes this bug:

```
public static void Main(string[] args)
{
   AppContext.SetSwitch("Microsoft.AspNetCore.Routing.UseCorrectCatchAllBehavior",
                        true);
   CreateHostBuilder(args).Build().Run();
}
// Remaining code removed for brevity.
```

.NET Core 3.0 on Azure App Service

The rollout of .NET Core to Azure App Service is finished. .NET Core 3.0 is available in all Azure App Service datacenters.

Migrate from ASP.NET Core 2.1 to 2.2

9/22/2020 • 5 minutes to read • Edit Online

By Scott Addie

This article explains how to update an existing ASP.NET Core 2.1 project to ASP.NET Core 2.2.

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core SDK 2.2 or later

> **WARNING**
> If you use Visual Studio 2017, see dotnet/sdk issue #3124 for information about .NET Core SDK versions that don't work with Visual Studio.

Update Target Framework Moniker (TFM)

Projects targeting .NET Core should use the TFM of a version greater than or equal to .NET Core 2.2. In the project file, update the `<TargetFramework>` node's inner text with `netcoreapp2.2`:

```
<TargetFramework>netcoreapp2.2</TargetFramework>
```

Projects targeting .NET Framework may continue to use the TFM of a version greater than or equal to .NET Framework 4.6.1:

```
<TargetFramework>net461</TargetFramework>
```

Adopt the IIS in-process hosting model

To adopt the in-process hosting model for IIS, add the `<AspNetCoreHostingModel>` property with a value of `InProcess` to a `<PropertyGroup>` in the project file:

```
<AspNetCoreHostingModel>InProcess</AspNetCoreHostingModel>
```

The in-process hosting model isn't supported for ASP.NET Core apps targeting .NET Framework.

For more information, see ASP.NET Core Module.

Update a custom web.config file

For projects that use a custom *web.config* file in the project root to generate their published *web.config* file:

- In the `<handlers>` entry that adds the ASP.NET Core Module (`name="aspNetCore"`), change the `modules` attribute value from `AspNetCoreModule` to `AspNetCoreModuleV2`.
- In the `<aspNetCore>` element, add the hosting model attribute (`hostingModel="InProcess"`).

For more information and example *web.config* files, see ASP.NET Core Module.

Update package references

If targeting .NET Core, remove the metapackage reference's `Version` attribute in the project file. Inclusion of a `Version` attribute results in the following warning:

```
A PackageReference to 'Microsoft.AspNetCore.App' specified a Version of `2.2.0`. Specifying the version of this
package is not recommended. For more information, see https://aka.ms/sdkimplicitrefs
```

For more information, see Microsoft.AspNetCore.App metapackage for ASP.NET Core.

The metapackage reference should resemble the following `<PackageReference />` node:

```
<ItemGroup>
  <PackageReference Include="Microsoft.AspNetCore.App" />
</ItemGroup>
```

If targeting .NET Framework, update each package reference's `Version` attribute to 2.2.0 or later. Here are the package references in a typical ASP.NET Core 2.2 project targeting .NET Framework:

```
<ItemGroup>
  <PackageReference Include="Microsoft.AspNetCore" Version="2.2.0" />
  <PackageReference Include="Microsoft.AspNetCore.CookiePolicy" Version="2.2.0" />
  <PackageReference Include="Microsoft.AspNetCore.HttpsPolicy" Version="2.2.0" />
  <PackageReference Include="Microsoft.AspNetCore.Mvc" Version="2.2.0" />
  <PackageReference Include="Microsoft.AspNetCore.StaticFiles" Version="2.2.0" />
</ItemGroup>
```

If referencing the Microsoft.AspNetCore.Razor.Design package, update its `Version` attribute to 2.2.0 or later. Failure to do so results in the following error:

```
Detected package downgrade: Microsoft.AspNetCore.Razor.Design from 2.2.0 to 2.1.2. Reference the package
directly from the project to select a different version.
```

Update .NET Core SDK version in global.json

If your solution relies upon a global.json file to target a specific .NET Core SDK version, update its `version` property to the 2.2 version installed on your machine:

```
{
  "sdk": {
    "version": "2.2.100"
  }
}
```

Update launch settings

If using Visual Studio Code, update the project's launch settings file (*.vscode/launch.json*). The `program` path should

reference the new TFM:

```
{
    "version": "0.2.0",
    "configurations": [
        {
            "name": ".NET Core Launch (web)",
            "type": "coreclr",
            "request": "launch",
            "preLaunchTask": "build",
            "program": "${workspaceFolder}/bin/Debug/netcoreapp2.2/test-app.dll",
            "args": [],
            "cwd": "${workspaceFolder}",
            "stopAtEntry": false,
            "internalConsoleOptions": "openOnSessionStart",
            "launchBrowser": {
                "enabled": true,
                "args": "${auto-detect-url}",
                "windows": {
                    "command": "cmd.exe",
                    "args": "/C start ${auto-detect-url}"
                },
                "osx": {
                    "command": "open"
                },
                "linux": {
                    "command": "xdg-open"
                }
            },
            "env": {
                "ASPNETCORE_ENVIRONMENT": "Development"
            },
            "sourceFileMap": {
                "/Views": "${workspaceFolder}/Views"
            }
        },
        {
            "name": ".NET Core Attach",
            "type": "coreclr",
            "request": "attach",
            "processId": "${command:pickProcess}"
        }
    ]
}
```

Update Kestrel configuration

If the app calls UseKestrel by calling `CreateDefaultBuilder` in the CreateWebHostBuilder method of the `Program` class, call `ConfigureKestrel` to configure Kestrel server instead of `UseKestrel` in order to avoid conflicts with the IIS in-process hosting model:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, options) =>
        {
            // Set properties and call methods on options
        });
```

If the app doesn't call `CreateDefaultBuilder` and builds the host manually in the `Program` class, call UseKestrel **before** calling `ConfigureKestrel`:

```
public static void Main(string[] args)
{
    var host = new WebHostBuilder()
        .UseContentRoot(Directory.GetCurrentDirectory())
        .UseKestrel()
        .UseIISIntegration()
        .UseStartup<Startup>()
        .ConfigureKestrel((context, options) =>
        {
            // Set properties and call methods on options
        })
        .Build();

    host.Run();
}
```

For more information, see Kestrel web server implementation in ASP.NET Core.

Update compatibility version

Update the compatibility version in `Startup.ConfigureServices` to `Version_2_2`:

```
services.AddMvc()
        .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

Update CORS policy

In ASP.NET Core 2.2, the CORS middleware responds with a wildcard origin (`*`) if a policy allows any origin and allows credentials. Credentials aren't supported when a wildcard origin (`*`) is specified, and browsers will disallow the CORS request. For more information, including options for correcting the problem on the client, see the MDN web docs.

To correct this problem on the server, take one of the following actions:

- Modify the CORS policy to no longer allow credentials. That is, remove the call to AllowCredentials when configuring the policy.
- If credentials are required for the CORS request to succeed, modify the policy to specify allowed hosts. For example, use `builder.WithOrigins("https://api.example1.com", "https://example2.com")` instead of using AllowAnyOrigin.

Update Docker images

The following table shows the Docker image tag changes:

2.1	2.2
`microsoft/dotnet:2.1-aspnetcore-runtime`	`mcr.microsoft.com/dotnet/core/aspnet:2.2`
`microsoft/dotnet:2.1-sdk`	`mcr.microsoft.com/dotnet/core/sdk:2.2`

Change the `FROM` lines in your *Dockerfile* to use the new image tags in the preceding table's 2.2 column.

Build manually in Visual Studio when using IIS in-process hosting

Visual Studio's **Auto build on browser request** experience doesn't function with the IIS in-process hosting

model. You must manually rebuild the project when using in-process hosting. Improvements to this experience are planned for a future release of Visual Studio.

Update logging code

Recommended logging configuration code didn't change from 2.1 to 2.2, but some 1.x coding patterns that still worked in 2.1 no longer work in 2.2.

If your app does logging provider initialization, filtering, and configuration loading in the `Startup` class, move that code to `Program.Main`:

- Provider initialization:

  1.x example:

  ```
  public void Configure(IApplicationBuilder app, ILoggerFactory loggerFactory)
  {
      loggerFactory.AddConsole();
  }
  ```

  2.2 example:

  ```
  public static void Main(string[] args)
  {
      var webHost = new WebHostBuilder()
          // ...
          .ConfigureLogging((hostingContext, logging) =>
          {
              logging.AddConsole();
          })
          // ...
  }
  ```

- Filtering:

  1.x example:

  ```
  public void Configure(IApplicationBuilder app, ILoggerFactory loggerFactory)
  {
      loggerFactory.AddConsole(LogLevel.Information);
      // or
      loggerFactory.AddConsole((category, level) =>
          category == "A" || level == LogLevel.Critical);
  }
  ```

  2.2 example:

```
public static void Main(string[] args)
{
    var webHost = new WebHostBuilder()
        // ...
        .ConfigureLogging((hostingContext, logging) =>
        {
            logging.AddConsole()
                   .AddFilter<ConsoleLoggerProvider>
                       (category: null, level: LogLevel.Information)
                   // or
                   .AddFilter<ConsoleLoggerProvider>
                       ((category, level) => category == "A" ||
                           level == LogLevel.Critical)
            );
        })
        // ...
}
```

- Configuration loading:

  1.x example:

  ```
  public void Configure(IApplicationBuilder app, ILoggerFactory loggerFactory)
  {
      loggerFactory.AddConsole(Configuration);
  }
  ```

  2.2 example:

  ```
  public static void Main(string[] args)
  {
      var webHost = new WebHostBuilder()
          // ...
          .ConfigureLogging((hostingContext, logging) =>
          {
              logging.AddConfiguration(hostingContext.Configuration.GetSection("Logging"));
              logging.AddConsole();
          })
          // ...
  }
  ```

For more information, see Logging in .NET Core and ASP.NET Core

Migrate from ASP.NET Core 2.0 to 2.1

9/22/2020 • 10 minutes to read • Edit Online

By Rick Anderson

See What's new in ASP.NET Core 2.1 for an overview of the new features in ASP.NET Core 2.1.

This article:

- Covers the basics of migrating an ASP.NET Core 2.0 app to 2.1.
- Provides an overview of the changes to the ASP.NET Core web application templates.

A quick way to get an overview of the changes in 2.1 is to:

- Create an ASP.NET Core 2.0 web app named WebApp1.
- Commit the WebApp1 in a source control system.
- Delete WebApp1 and create an ASP.NET Core 2.1 web app named WebApp1 in the same place.
- Review the changes in the 2.1 version.

This article provides an overview on migration to ASP.NET Core 2.1. It doesn't contain a complete list of all changes needed to migrate to version 2.1. Some projects might require more steps depending on the options selected when the project was created and modifications made to the project.

Update the project file to use 2.1 versions

Update the project file:

- Change the target framework to .NET Core 2.1 by updating the project file to `<TargetFramework>netcoreapp2.1</TargetFramework>`.
- Replace the package reference for `Microsoft.AspNetCore.All` with a package reference for `Microsoft.AspNetCore.App`. You may need to add dependencies that were removed from `Microsoft.AspNetCore.All`. For more information, see Microsoft.AspNetCore.All metapackage for ASP.NET Core 2.0 and Microsoft.AspNetCore.App metapackage for ASP.NET Core.
- Remove the "Version" attribute on the package reference to `Microsoft.AspNetCore.App`. Projects that use `<Project Sdk="Microsoft.NET.Sdk.Web">` don't need to set the version. The version is implied by the target framework and selected to best match the way ASP.NET Core 2.1 works. For more information, see the Rules for projects targeting the shared framework section.
- For apps that target the .NET Framework, update each package reference to 2.1.
- Remove references to **<DotNetCliToolReference>** elements for the following packages. These tools are bundled by default in the .NET Core CLI and don't need to be installed separately.
  - Microsoft.DotNet.Watcher.Tools (`dotnet watch`)
  - Microsoft.EntityFrameworkCore.Tools.DotNet (`dotnet ef`)
  - Microsoft.Extensions.Caching.SqlConfig.Tools (`dotnet sql-cache`)
  - Microsoft.Extensions.SecretManager.Tools (`dotnet user-secrets`)
- Optional: you can remove the **<DotNetCliToolReference>** element for `Microsoft.VisualStudio.Web.CodeGeneration.Tools`. You can replace this tool with a globally installed version by running `dotnet tool install -g dotnet-aspnet-codegenerator`.
- For 2.1, a Razor Class Library is the recommended solution to distribute Razor files. If your app uses embedded views, or otherwise relies on runtime compilation of Razor files, add

`<CopyRefAssembliesToPublishDirectory>true</CopyRefAssembliesToPublishDirectory>` to a `<PropertyGroup>` in your project file.

The following markup shows the template-generated 2.0 project file:

```
<Project Sdk="Microsoft.NET.Sdk.Web">
  <PropertyGroup>
    <TargetFramework>netcoreapp2.0</TargetFramework>
    <UserSecretsId>aspnet-{Project Name}-{GUID}</UserSecretsId>
  </PropertyGroup>
  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.All" Version="2.0.9" />
    <PackageReference Include="Microsoft.EntityFrameworkCore.Tools" Version="2.0.3" PrivateAssets="All" />
    <PackageReference Include="Microsoft.VisualStudio.Web.CodeGeneration.Design" Version="2.0.4"
PrivateAssets="All" />
  </ItemGroup>
  <ItemGroup>
    <DotNetCliToolReference Include="Microsoft.EntityFrameworkCore.Tools.DotNet" Version="2.0.3" />
    <DotNetCliToolReference Include="Microsoft.Extensions.SecretManager.Tools" Version="2.0.2" />
    <DotNetCliToolReference Include="Microsoft.VisualStudio.Web.CodeGeneration.Tools" Version="2.0.4" />
  </ItemGroup>
</Project>
```

The following markup shows the template-generated 2.1 project file:

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp2.1</TargetFramework>
    <UserSecretsId>aspnet-{Project Name}-{GUID}</UserSecretsId>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.App" />
    <PackageReference Include="Microsoft.VisualStudio.Web.CodeGeneration.Design" Version="2.1.1"
PrivateAssets="All" />
  </ItemGroup>

</Project>
```

Rules for projects targeting the shared framework

A *shared framework* is a set of assemblies (*.dll* files) that are not in the app's folders. The shared framework must be installed on the machine to run the app. For more information, see The shared framework.

ASP.NET Core 2.1 includes the following shared frameworks:

- Microsoft.AspNetCore.App
- Microsoft.AspNetCore.All

The version specified by the package reference is the *minimum required* version. For example, a project referencing the 2.1.1 versions of these packages won't run on a machine with only the 2.1.0 runtime installed.

Known issues for projects targeting a shared framework:

- The .NET Core 2.1.300 SDK (first included in Visual Studio 15.6) set the implicit version of `Microsoft.AspNetCore.App` to 2.1.0 which caused conflicts with Entity Framework Core 2.1.1. The recommended solution is to upgrade the .NET Core SDK to 2.1.301 or later. For more information, see Packages that share dependencies with Microsoft.AspNetCore.App cannot reference patch versions.

- All projects that must use `Microsoft.AspNetCore.All` or `Microsoft.AspNetCore.App` should add a package reference for the package in the project file, even if they contain a project reference to another project using `Microsoft.AspNetCore.All` or `Microsoft.AspNetCore.App`.

  Example:

  - `MyApp` has a package reference to `Microsoft.AspNetCore.App`.
  - `MyApp.Tests` has a project reference to `MyApp.csproj`.

  Add a package reference for `Microsoft.AspNetCore.App` to `MyApp.Tests`. For more information, see Integration testing is hard to set up and may break on shared framework servicing.

Update to the 2.1 Docker images

In ASP.NET Core 2.1, the Docker images migrated to the dotnet/dotnet-docker GitHub repository. The following table shows the Docker image and tag changes:

2.0	2.1
microsoft/aspnetcore:2.0	microsoft/dotnet:2.1-aspnetcore-runtime
microsoft/aspnetcore-build:2.0	microsoft/dotnet:2.1-sdk

Change the `FROM` lines in your *Dockerfile* to use the new image names and tags in the preceding table's 2.1 column. For more information, see Migrating from aspnetcore docker repos to dotnet.

Changes to take advantage of the new code-based idioms that are recommended in ASP.NET Core 2.1

Changes to Main

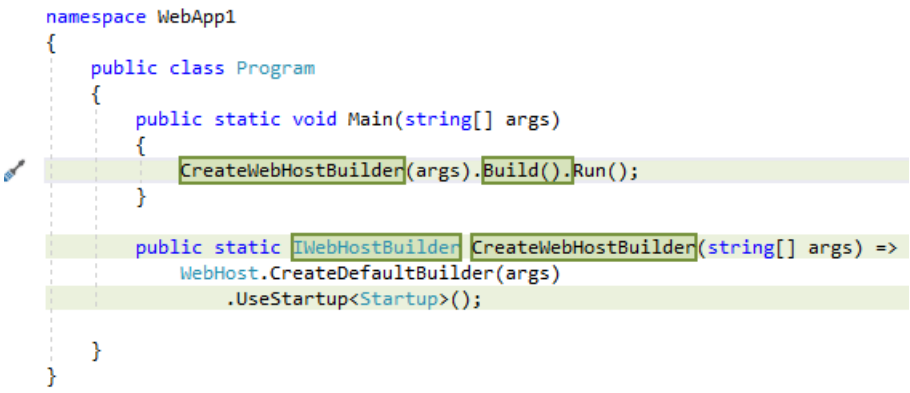
The following images show the changes made to the templated generated *Program.cs* file.

```
namespace WebApp1
{
    public class Program
    {
        public static void Main(string[] args)
        {
            BuildWebHost(args).Run();
        }

        public static IWebHost BuildWebHost(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>()
                .Build();
    }
}
```

The preceding image shows the 2.0 version with the deletions in red.

The following image shows the 2.1 code. The code in green replaced the 2.0 version:



```
namespace WebApp1
{
    public class Program
    {
        public static void Main(string[] args)
        {
            CreateWebHostBuilder(args).Build().Run();
        }

        public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>();

    }
}
```

The following code shows the 2.1 version of *Program.cs*:

```
namespace WebApp1
{
    public class Program
    {
        public static void Main(string[] args)
        {
            CreateWebHostBuilder(args).Build().Run();
        }

        public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>();
    }
}
```

The new `Main` replaces the call to `BuildWebHost` with CreateWebHostBuilder. IWebHostBuilder was added to support a new integration test infrastructure.

Changes to Startup

The following code shows the changes to 2.1 template generated code. All changes are newly added code, except that `UseBrowserLink` has been removed:

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.AspNetCore.Http;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;

namespace WebApp1
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        public void ConfigureServices(IServiceCollection services)
        {
            services.Configure<CookiePolicyOptions>(options =>
            {
                // This lambda determines whether user consent for non-essential cookies is needed for a given
request.
                options.CheckConsentNeeded = context => true;
                options.MinimumSameSitePolicy = SameSiteMode.None;
            });

            services.AddMvc()
                .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
        }

        public void Configure(IApplicationBuilder app, IHostingEnvironment env)
        {
            if (env.IsDevelopment())
            {
                app.UseDeveloperExceptionPage();
            }
            else
            {
                app.UseExceptionHandler("/Error");
                app.UseHsts();
            }

            app.UseHttpsRedirection();
            app.UseStaticFiles();
            app.UseCookiePolicy();
            // If the app uses Session or TempData based on Session:
            // app.UseSession();

            app.UseMvc();
        }
    }
}
```

The preceding code changes are detailed in:

- GDPR support in ASP.NET Core for `CookiePolicyOptions` and `UseCookiePolicy`.
- HTTP Strict Transport Security Protocol (HSTS) for `UseHsts`.
- Require HTTPS for `UseHttpsRedirection`.
- SetCompatibilityVersion for `SetCompatibilityVersion(CompatibilityVersion.Version_2_1)`.

Changes to authentication code

ASP.NET Core 2.1 provides ASP.NET Core Identity as a Razor Class Library (RCL).

The default 2.1 Identity UI doesn't currently provide significant new features over the 2.0 version. Replacing Identity with the RCL package is optional. The advantages to replacing the template generated Identity code with the RCL version include:

- Many files are moved out of your source tree.
- Any bug fixes or new features to Identity are included in the Microsoft.AspNetCore.App metapackage. You automatically get the updated Identity when `Microsoft.AspNetCore.App` is updated.

If you've made non-trivial changes to the template generated Identity code:

- The preceding advantages probably do **not** justify converting to the RCL version.
- You can keep your ASP.NET Core 2.0 Identity code, it's fully supported.

Identity 2.1 exposes endpoints with the `Identity` area. For example, the follow table shows examples of Identity endpoints that change from 2.0 to 2.1:

2.0 URL	2.1 URL
/Account/Login	/Identity/Account/Login
/Account/Logout	/Identity/Account/Logout
/Account/Manage	/Identity/Account/Manage

Applications that have code using Identity and replace 2.0 Identity UI with the 2.1 Identity Library need to take into account Identity URLs have `/Identity` segment prepended to the URIs. One way to handle the new Identity endpoints is to set up redirects, for example from `/Account/Login` to `/Identity/Account/Login`.

Update Identity to version 2.1

The following options are available to update Identity to 2.1.

- Use the Identity UI 2.0 code with no changes. Using Identity UI 2.0 code is fully supported. This is a good approach when significant changes have been made to the generated Identity code.
- Delete your existing Identity 2.0 code and Scaffold Identity into your project. Your project will use the ASP.NET Core Identity Razor Class Library. You can generate code and UI for any of the Identity UI code that you modified. Apply your code changes to the newly scaffolded UI code.
- Delete your existing Identity 2.0 code and Scaffold Identity into your project with the option to **Override all files**.

Replace Identity 2.0 UI with the Identity 2.1 Razor Class Library

This section outlines the steps to replace the ASP.NET Core 2.0 template generated Identity code with the ASP.NET Core Identity Razor Class Library. The following steps are for a Razor Pages project, but the approach for an MVC project is similar.

- Verify the project file is updated to use 2.1 versions
- Delete the following folders and all the files in them:
  - *Controllers*
  - *Pages/Account/*
  - *Extensions*
- Build the project.

- Scaffold Identity into your project:
  - Select the projects exiting *_Layout.cshtml* file.
  - Select the **+** icon on the right side of the **Data context class**. Accept the default name.
  - Select **Add** to create a new Data context class. Creating a new data context is required for to scaffold. You remove the new data context in the next section.

Update after scaffolding Identity

- Delete the Identity scaffolder generated `IdentityDbContext` derived class in the *Areas/Identity/Data/* folder.
- Delete *Areas/Identity/IdentityHostingStartup.cs*.
- Update the *_LoginPartial.cshtml* file:
  - Move *Pages/_LoginPartial.cshtml* to *Pages/Shared/_LoginPartial.cshtml*.
  - Add `asp-area="Identity"` to the form and anchor links.
  - Update the `<form />` element to
    `<form asp-area="Identity" asp-page="/Account/Logout" asp-route-returnUrl="@Url.Page("/Index", new { area = "" })" method="post" id="logoutForm" class="navbar-right">`
    .

  The following code shows the updated *_LoginPartial.cshtml* file:

```
@using Microsoft.AspNetCore.Identity

@inject SignInManager<ApplicationUser> SignInManager
@inject UserManager<ApplicationUser> UserManager

@if (SignInManager.IsSignedIn(User))
{
    <form asp-area="Identity" asp-page="/Account/Logout" asp-route-returnUrl="@Url.Page("/Index", new {
area = "" })" method="post" id="logoutForm" class="navbar-right">
        <ul class="nav navbar-nav navbar-right">
            <li>
                <a asp-area="Identity" asp-page="/Account/Manage/Index" title="Manage">Hello
@UserManager.GetUserName(User)!</a>
            </li>
            <li>
                <button type="submit" class="btn btn-link navbar-btn navbar-link">Log out</button>
            </li>
        </ul>
    </form>
}
else
{
    <ul class="nav navbar-nav navbar-right">
        <li><a asp-area="Identity" asp-page="/Account/Register">Register</a></li>
        <li><a asp-area="Identity" asp-page="/Account/Login">Log in</a></li>
    </ul>
}
```

Update `ConfigureServices` with the following code:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(Configuration.GetConnectionString("DefaultConnection")));

    services.AddDefaultIdentity<ApplicationUser>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultTokenProviders();

    services.AddMvc();

    // Register no-op EmailSender used by account confirmation and password reset
    // during development
    services.AddSingleton<IEmailSender, EmailSender>();
}
```

Changes to Razor Pages projects Razor files

The layout file

- Move *Pages/_Layout.cshtml* to *Pages/Shared/_Layout.cshtml*
- In *Areas/Identity/Pages/_ViewStart.cshtml*, change `Layout = "/Pages/_Layout.cshtml"` to `Layout = "/Pages/Shared/_Layout.cshtml"`.
- The *_Layout.cshtml* file has the following changes:
  - `<partial name="_CookieConsentPartial" />` is added. For more information, see GDPR support in ASP.NET Core.
  - jQuery changes from 2.2.0 to 3.3.1.

_ValidationScriptsPartial.cshtml

- *Pages/_ValidationScriptsPartial.cshtml* moves to *Pages/Shared/_ValidationScriptsPartial.cshtml*.
- *jquery.validate/1.14.0* changes to *jquery.validate/1.17.0*.

New files

The following files are added:

- *Privacy.cshtml*
- *Privacy.cshtml.cs*

See GDPR support in ASP.NET Core for information on the preceding files.

Changes to MVC projects Razor files

The layout file

The *Layout.cshtml* file has the following changes:

- `<partial name="_CookieConsentPartial" />` is added.
- jQuery changes from 2.2.0 to 3.3.1

_ValidationScriptsPartial.cshtml

jquery.validate/1.14.0 changes to *jquery.validate/1.17.0*

New files and action methods

The following are added:

- *Views/Home/Privacy.cshtml*

- The `Privacy` action method is added to the Home controller.

See GDPR support in ASP.NET Core for information on the preceding files.

Changes to the launchSettings.json file

As ASP.NET Core apps now use HTTPS by default, the *Properties/launchSettings.json* file has changed.

The following JSON shows the earlier 2.0 template-generated *launchSettings.json* file:

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iisExpress": {
      "applicationUrl": "http://localhost:1799/",
      "sslPort": 0
    }
  },
  "profiles": {
    "IIS Express": {
      "commandName": "IISExpress",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    },
    "WebApp1": {
      "commandName": "Project",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      },
      "applicationUrl": "http://localhost:1798/"
    }
  }
}
```

The following JSON shows the new 2.1 template-generated *launchSettings.json* file:

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iisExpress": {
      "applicationUrl": "http://localhost:39191",
      "sslPort": 44390
    }
  },
  "profiles": {
    "IIS Express": {
      "commandName": "IISExpress",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    },
    "WebApp1": {
      "commandName": "Project",
      "launchBrowser": true,
      "applicationUrl": "https://localhost:5001;http://localhost:5000",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    }
  }
}
```

For more information, see Enforce HTTPS in ASP.NET Core.

Breaking changes

FileResult Range header

FileResult no longer processes the Accept-Ranges header by default. To enable the `Accept-Ranges` header, set EnableRangeProcessing to `true`.

ControllerBase.File and PhysicalFile Range header

The following ControllerBase methods no longer processes the Accept-Ranges header by default:

- Overloads of ControllerBase.File
- ControllerBase.PhysicalFile

To enable the `Accept-Ranges` header, set the `EnableRangeProcessing` parameter to `true`.

Additional changes

- If hosting the app on Windows with IIS, install the latest .NET Core Hosting Bundle.
- SetCompatibilityVersion
- Transport configuration

Migrate from ASP.NET Core 1.x to 2.0

9/22/2020 • 7 minutes to read • Edit Online

By Scott Addie

In this article, we walk you through updating an existing ASP.NET Core 1.x project to ASP.NET Core 2.0. Migrating your application to ASP.NET Core 2.0 enables you to take advantage of many new features and performance improvements.

Existing ASP.NET Core 1.x applications are based off of version-specific project templates. As the ASP.NET Core framework evolves, so do the project templates and the starter code contained within them. In addition to updating the ASP.NET Core framework, you need to update the code for your application.

Prerequisites

See Get Started with ASP.NET Core.

Update Target Framework Moniker (TFM)

Projects targeting .NET Core should use the TFM of a version greater than or equal to .NET Core 2.0. Search for the `<TargetFramework>` node in the *.csproj* file, and replace its inner text with `netcoreapp2.0`:

```
<TargetFramework>netcoreapp2.0</TargetFramework>
```

Projects targeting .NET Framework should use the TFM of a version greater than or equal to .NET Framework 4.6.1. Search for the `<TargetFramework>` node in the *.csproj* file, and replace its inner text with `net461`:

```
<TargetFramework>net461</TargetFramework>
```

> **NOTE**
> .NET Core 2.0 offers a much larger surface area than .NET Core 1.x. If you're targeting .NET Framework solely because of missing APIs in .NET Core 1.x, targeting .NET Core 2.0 is likely to work.

If the project file contains `<RuntimeFrameworkVersion>1.{sub-version}</RuntimeFrameworkVersion>`, see this GitHub issue.

Update .NET Core SDK version in global.json

If your solution relies upon a global.json file to target a specific .NET Core SDK version, update its `version` property to use the 2.0 version installed on your machine:

```
{
  "sdk": {
    "version": "2.0.0"
  }
}
```

Update package references

The *.csproj* file in a 1.x project lists each NuGet package used by the project.

In an ASP.NET Core 2.0 project targeting .NET Core 2.0, a single metapackage reference in the *.csproj* file replaces the collection of packages:

```
<ItemGroup>
  <PackageReference Include="Microsoft.AspNetCore.All" Version="2.0.9" />
</ItemGroup>
```

All the features of ASP.NET Core 2.0 and Entity Framework Core 2.0 are included in the metapackage.

ASP.NET Core 2.0 projects targeting .NET Framework should continue to reference individual NuGet packages. Update the `Version` attribute of each `<PackageReference />` node to 2.0.0.

For example, here's the list of `<PackageReference />` nodes used in a typical ASP.NET Core 2.0 project targeting .NET Framework:

```
<ItemGroup>
  <PackageReference Include="Microsoft.AspNetCore" Version="2.0.0" />
  <PackageReference Include="Microsoft.AspNetCore.Authentication.Cookies" Version="2.0.0" />
  <PackageReference Include="Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore" Version="2.0.0" />
  <PackageReference Include="Microsoft.AspNetCore.Identity.EntityFrameworkCore" Version="2.0.0" />
  <PackageReference Include="Microsoft.AspNetCore.Mvc" Version="2.0.0" />
  <PackageReference Include="Microsoft.AspNetCore.Mvc.Razor.ViewCompilation" Version="2.0.0"
PrivateAssets="All" />
  <PackageReference Include="Microsoft.AspNetCore.StaticFiles" Version="2.0.0" />
  <PackageReference Include="Microsoft.EntityFrameworkCore.Design" Version="2.0.0" PrivateAssets="All" />
  <PackageReference Include="Microsoft.EntityFrameworkCore.SqlServer" Version="2.0.0" />
  <PackageReference Include="Microsoft.EntityFrameworkCore.Tools" Version="2.0.0" PrivateAssets="All" />
  <PackageReference Include="Microsoft.VisualStudio.Web.BrowserLink" Version="2.0.0" />
  <PackageReference Include="Microsoft.VisualStudio.Web.CodeGeneration.Design" Version="2.0.0"
PrivateAssets="All" />
</ItemGroup>
```

Update .NET Core CLI tools

In the *.csproj* file, update the `Version` attribute of each `<DotNetCliToolReference />` node to 2.0.0.

For example, here's the list of CLI tools used in a typical ASP.NET Core 2.0 project targeting .NET Core 2.0:

```
<ItemGroup>
  <DotNetCliToolReference Include="Microsoft.EntityFrameworkCore.Tools.DotNet" Version="2.0.0" />
  <DotNetCliToolReference Include="Microsoft.Extensions.SecretManager.Tools" Version="2.0.0" />
  <DotNetCliToolReference Include="Microsoft.VisualStudio.Web.CodeGeneration.Tools" Version="2.0.0" />
</ItemGroup>
```

Rename Package Target Fallback property

The *.csproj* file of a 1.x project used a `PackageTargetFallback` node and variable:

```
<PackageTargetFallback>$(PackageTargetFallback);portable-net45+win8+wp8+wpa81;</PackageTargetFallback>
```

Rename both the node and variable to `AssetTargetFallback`:

```
<AssetTargetFallback>$(AssetTargetFallback);portable-net45+win8+wp8+wpa81;</AssetTargetFallback>
```

Update Main method in Program.cs

In 1.x projects, the `Main` method of *Program.cs* looked like this:

```
using System.IO;
using Microsoft.AspNetCore.Hosting;

namespace AspNetCoreDotNetCore1App
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = new WebHostBuilder()
                .UseKestrel()
                .UseContentRoot(Directory.GetCurrentDirectory())
                .UseIISIntegration()
                .UseStartup<Startup>()
                .UseApplicationInsights()
                .Build();

            host.Run();
        }
    }
}
```

In 2.0 projects, the `Main` method of *Program.cs* has been simplified:

```
using Microsoft.AspNetCore;
using Microsoft.AspNetCore.Hosting;

namespace AspNetCoreDotNetCore2App
{
    public class Program
    {
        public static void Main(string[] args)
        {
            BuildWebHost(args).Run();
        }

        public static IWebHost BuildWebHost(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>()
                .Build();
    }
}
```

The adoption of this new 2.0 pattern is highly recommended and is required for product features like Entity Framework (EF) Core Migrations to work. For example, running `Update-Database` from the Package Manager Console window or `dotnet ef database update` from the command line (on projects converted to ASP.NET Core 2.0) generates the following error:

```
Unable to create an object of type '<Context>'. Add an implementation of
'IDesignTimeDbContextFactory<Context>' to the project, or see https://go.microsoft.com/fwlink/?linkid=851728
for additional patterns supported at design time.
```

Add configuration providers

In 1.x projects, adding configuration providers to an app was accomplished via the `Startup` constructor. The steps involved creating an instance of `ConfigurationBuilder`, loading applicable providers (environment variables, app settings, etc.), and initializing a member of `IConfigurationRoot`.

```
public Startup(IHostingEnvironment env)
{
    var builder = new ConfigurationBuilder()
        .SetBasePath(env.ContentRootPath)
        .AddJsonFile("appsettings.json", optional: false, reloadOnChange: true)
        .AddJsonFile($"appsettings.{env.EnvironmentName}.json", optional: true);

    if (env.IsDevelopment())
    {
        builder.AddUserSecrets<Startup>();
    }

    builder.AddEnvironmentVariables();
    Configuration = builder.Build();
}

public IConfigurationRoot Configuration { get; }
```

The preceding example loads the `Configuration` member with configuration settings from *appsettings.json* as well as any *appsettings.<EnvironmentName>.json* file matching the `IHostingEnvironment.EnvironmentName` property. The location of these files is at the same path as *Startup.cs*.

In 2.0 projects, the boilerplate configuration code inherent to 1.x projects runs behind-the-scenes. For example, environment variables and app settings are loaded at startup. The equivalent *Startup.cs* code is reduced to `IConfiguration` initialization with the injected instance:

```
public Startup(IConfiguration configuration)
{
    Configuration = configuration;
}

public IConfiguration Configuration { get; }
```

To remove the default providers added by `WebHostBuilder.CreateDefaultBuilder`, invoke the `Clear` method on the `IConfigurationBuilder.Sources` property inside of `ConfigureAppConfiguration`. To add providers back, utilize the `ConfigureAppConfiguration` method in *Program.cs*:

```
public static void Main(string[] args)
{
    BuildWebHost(args).Run();
}

public static IWebHost BuildWebHost(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureAppConfiguration((hostContext, config) =>
        {
            // delete all default configuration providers
            config.Sources.Clear();
            config.AddJsonFile("myconfig.json", optional: true);
        })
        .Build();
```

The configuration used by the `CreateDefaultBuilder` method in the preceding code snippet can be seen here.

For more information, see Configuration in ASP.NET Core.

Move database initialization code

In 1.x projects using EF Core 1.x, a command such as `dotnet ef migrations add` does the following:

1. Instantiates a `Startup` instance
2. Invokes the `ConfigureServices` method to register all services with dependency injection (including `DbContext` types)
3. Performs its requisite tasks

In 2.0 projects using EF Core 2.0, `Program.BuildWebHost` is invoked to obtain the application services. Unlike 1.x, this has the additional side effect of invoking `Startup.Configure`. If your 1.x app invoked database initialization code in its `Configure` method, unexpected problems can occur. For example, if the database doesn't yet exist, the seeding code runs before the EF Core Migrations command execution. This problem causes a `dotnet ef migrations list` command to fail if the database doesn't yet exist.

Consider the following 1.x seed initialization code in the `Configure` method of *Startup.cs*:

```
app.UseMvc(routes =>
{
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");
});

SeedData.Initialize(app.ApplicationServices);
```

In 2.0 projects, move the `SeedData.Initialize` call to the `Main` method of *Program.cs*:

```
var host = BuildWebHost(args);

using (var scope = host.Services.CreateScope())
{
    var services = scope.ServiceProvider;

    try
    {
        // Requires using RazorPagesMovie.Models;
        SeedData.Initialize(services);
    }
    catch (Exception ex)
    {
        var logger = services.GetRequiredService<ILogger<Program>>();
        logger.LogError(ex, "An error occurred seeding the DB.");
    }
}

host.Run();
```

As of 2.0, it's bad practice to do anything in `BuildWebHost` except build and configure the web host. Anything that's about running the application should be handled outside of `BuildWebHost` — typically in the `Main` method of *Program.cs*.

Review Razor view compilation setting

Faster application startup time and smaller published bundles are of utmost importance to you. For these reasons, Razor view compilation is enabled by default in ASP.NET Core 2.0.

Setting the `MvcRazorCompileOnPublish` property to true is no longer required. Unless you're disabling view compilation, the property may be removed from the *.csproj* file.

When targeting .NET Framework, you still need to explicitly reference the Microsoft.AspNetCore.Mvc.Razor.ViewCompilation NuGet package in your *.csproj* file:

```
<PackageReference Include="Microsoft.AspNetCore.Mvc.Razor.ViewCompilation" Version="2.0.0" PrivateAssets="All"
/>
```

Rely on Application Insights "light-up" features

Effortless setup of application performance instrumentation is important. You can now rely on the new Application Insights "light-up" features available in the Visual Studio 2017 tooling.

ASP.NET Core 1.1 projects created in Visual Studio 2017 added Application Insights by default. If you're not using the Application Insights SDK directly, outside of *Program.cs* and *Startup.cs*, follow these steps:

1. If targeting .NET Core, remove the following `<PackageReference />` node from the *.csproj* file:

   ```
   <PackageReference Include="Microsoft.ApplicationInsights.AspNetCore" Version="2.0.0" />
   ```

2. If targeting .NET Core, remove the `UseApplicationInsights` extension method invocation from *Program.cs*:

   ```
   public static void Main(string[] args)
   {
       var host = new WebHostBuilder()
           .UseKestrel()
           .UseContentRoot(Directory.GetCurrentDirectory())
           .UseIISIntegration()
           .UseStartup<Startup>()
           .UseApplicationInsights()
           .Build();

       host.Run();
   }
   ```

3. Remove the Application Insights client-side API call from *_Layout.cshtml*. It comprises the following two lines of code:

   ```
   @inject Microsoft.ApplicationInsights.AspNetCore.JavaScriptSnippet JavaScriptSnippet
   @Html.Raw(JavaScriptSnippet.FullScript)
   ```

If you are using the Application Insights SDK directly, continue to do so. The 2.0 metapackage includes the latest version of Application Insights, so a package downgrade error appears if you're referencing an older version.

Adopt authentication/Identity improvements

ASP.NET Core 2.0 has a new authentication model and a number of significant changes to ASP.NET Core Identity. If you created your project with Individual User Accounts enabled, or if you have manually added authentication or Identity, see Migrate Authentication and Identity to ASP.NET Core 2.0.

Additional resources

- Breaking Changes in ASP.NET Core 2.0

Migrate authentication and Identity to ASP.NET Core 2.0

9/22/2020 • 9 minutes to read • Edit Online

By Scott Addie and Hao Kung

ASP.NET Core 2.0 has a new model for authentication and Identity that simplifies configuration by using services. ASP.NET Core 1.x applications that use authentication or Identity can be updated to use the new model as outlined below.

Update namespaces

In 1.x, classes such `IdentityRole` and `IdentityUser` were found in the `Microsoft.AspNetCore.Identity.EntityFrameworkCore` namespace.

In 2.0, the Microsoft.AspNetCore.Identity namespace became the new home for several of such classes. With the default Identity code, affected classes include `ApplicationUser` and `Startup`. Adjust your `using` statements to resolve the affected references.

Authentication Middleware and services

In 1.x projects, authentication is configured via middleware. A middleware method is invoked for each authentication scheme you want to support.

The following 1.x example configures Facebook authentication with Identity in *Startup.cs*:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddIdentity<ApplicationUser, IdentityRole>()
            .AddEntityFrameworkStores<ApplicationDbContext>();
}

public void Configure(IApplicationBuilder app, ILoggerFactory loggerfactory)
{
    app.UseIdentity();
    app.UseFacebookAuthentication(new FacebookOptions {
        AppId = Configuration["auth:facebook:appid"],
        AppSecret = Configuration["auth:facebook:appsecret"]
    });
}
```

In 2.0 projects, authentication is configured via services. Each authentication scheme is registered in the `ConfigureServices` method of *Startup.cs*. The `UseIdentity` method is replaced with `UseAuthentication`.

The following 2.0 example configures Facebook authentication with Identity in *Startup.cs*:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddIdentity<ApplicationUser, IdentityRole>()
            .AddEntityFrameworkStores<ApplicationDbContext>();

    // If you want to tweak Identity cookies, they're no longer part of IdentityOptions.
    services.ConfigureApplicationCookie(options => options.LoginPath = "/Account/LogIn");
    services.AddAuthentication()
            .AddFacebook(options =>
            {
                options.AppId = Configuration["auth:facebook:appid"];
                options.AppSecret = Configuration["auth:facebook:appsecret"];
            });
}

public void Configure(IApplicationBuilder app, ILoggerFactory loggerfactory) {
    app.UseAuthentication();
}
```

The `UseAuthentication` method adds a single authentication middleware component, which is responsible for automatic authentication and the handling of remote authentication requests. It replaces all of the individual middleware components with a single, common middleware component.

Below are 2.0 migration instructions for each major authentication scheme.

Cookie-based authentication

Select one of the two options below, and make the necessary changes in *Startup.cs*:

1. Use cookies with Identity
   - Replace `UseIdentity` with `UseAuthentication` in the `Configure` method:

     ```
     app.UseAuthentication();
     ```

   - Invoke the `AddIdentity` method in the `ConfigureServices` method to add the cookie authentication services.
   - Optionally, invoke the `ConfigureApplicationCookie` or `ConfigureExternalCookie` method in the `ConfigureServices` method to tweak the Identity cookie settings.

     ```
     services.AddIdentity<ApplicationUser, IdentityRole>()
             .AddEntityFrameworkStores<ApplicationDbContext>()
             .AddDefaultTokenProviders();

     services.ConfigureApplicationCookie(options => options.LoginPath = "/Account/LogIn");
     ```

2. Use cookies without Identity
   - Replace the `UseCookieAuthentication` method call in the `Configure` method with `UseAuthentication`:

     ```
     app.UseAuthentication();
     ```

   - Invoke the `AddAuthentication` and `AddCookie` methods in the `ConfigureServices` method:

```
// If you don't want the cookie to be automatically authenticated and assigned to
HttpContext.User,
// remove the CookieAuthenticationDefaults.AuthenticationScheme parameter passed to
AddAuthentication.
services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
        .AddCookie(options =>
        {
            options.LoginPath = "/Account/LogIn";
            options.LogoutPath = "/Account/LogOff";
        });
```

JWT Bearer Authentication

Make the following changes in *Startup.cs*:

- Replace the `UseJwtBearerAuthentication` method call in the `Configure` method with `UseAuthentication`:

```
app.UseAuthentication();
```

- Invoke the `AddJwtBearer` method in the `ConfigureServices` method:

```
services.AddAuthentication(JwtBearerDefaults.AuthenticationScheme)
        .AddJwtBearer(options =>
        {
            options.Audience = "http://localhost:5001/";
            options.Authority = "http://localhost:5000/";
        });
```

  This code snippet doesn't use Identity, so the default scheme should be set by passing `JwtBearerDefaults.AuthenticationScheme` to the `AddAuthentication` method.

OpenID Connect (OIDC) authentication

Make the following changes in *Startup.cs*:

- Replace the `UseOpenIdConnectAuthentication` method call in the `Configure` method with `UseAuthentication`:

```
app.UseAuthentication();
```

- Invoke the `AddOpenIdConnect` method in the `ConfigureServices` method:

```
services.AddAuthentication(options =>
{
    options.DefaultScheme = CookieAuthenticationDefaults.AuthenticationScheme;
    options.DefaultChallengeScheme = OpenIdConnectDefaults.AuthenticationScheme;
})
.AddCookie()
.AddOpenIdConnect(options =>
{
    options.Authority = Configuration["auth:oidc:authority"];
    options.ClientId = Configuration["auth:oidc:clientid"];
});
```

- Replace the `PostLogoutRedirectUri` property in the `OpenIdConnectOptions` action with `SignedOutRedirectUri`:

```
.AddOpenIdConnect(options =>
{
    options.SignedOutRedirectUri = "https://contoso.com";
});
```

Facebook authentication

Make the following changes in *Startup.cs*:

- Replace the `UseFacebookAuthentication` method call in the `Configure` method with `UseAuthentication`:

```
app.UseAuthentication();
```

- Invoke the `AddFacebook` method in the `ConfigureServices` method:

```
services.AddAuthentication()
        .AddFacebook(options =>
        {
            options.AppId = Configuration["auth:facebook:appid"];
            options.AppSecret = Configuration["auth:facebook:appsecret"];
        });
```

Google authentication

Make the following changes in *Startup.cs*:

- Replace the `UseGoogleAuthentication` method call in the `Configure` method with `UseAuthentication`:

```
app.UseAuthentication();
```

- Invoke the `AddGoogle` method in the `ConfigureServices` method:

```
services.AddAuthentication()
        .AddGoogle(options =>
        {
            options.ClientId = Configuration["auth:google:clientid"];
            options.ClientSecret = Configuration["auth:google:clientsecret"];
        });
```

Microsoft Account authentication

For more information on Microsoft account authentication, see this GitHub issue.

Make the following changes in *Startup.cs*:

- Replace the `UseMicrosoftAccountAuthentication` method call in the `Configure` method with `UseAuthentication`:

```
app.UseAuthentication();
```

- Invoke the `AddMicrosoftAccount` method in the `ConfigureServices` method:

```
services.AddAuthentication()
        .AddMicrosoftAccount(options =>
        {
            options.ClientId = Configuration["auth:microsoft:clientid"];
            options.ClientSecret = Configuration["auth:microsoft:clientsecret"];
        });
```

Twitter authentication

Make the following changes in *Startup.cs*:

- Replace the `UseTwitterAuthentication` method call in the `Configure` method with `UseAuthentication`:

```
app.UseAuthentication();
```

- Invoke the `AddTwitter` method in the `ConfigureServices` method:

```
services.AddAuthentication()
        .AddTwitter(options =>
        {
            options.ConsumerKey = Configuration["auth:twitter:consumerkey"];
            options.ConsumerSecret = Configuration["auth:twitter:consumersecret"];
        });
```

Setting default authentication schemes

In 1.x, the `AutomaticAuthenticate` and `AutomaticChallenge` properties of the AuthenticationOptions base class were intended to be set on a single authentication scheme. There was no good way to enforce this.

In 2.0, these two properties have been removed as properties on the individual `AuthenticationOptions` instance. They can be configured in the `AddAuthentication` method call within the `ConfigureServices` method of *Startup.cs*:

```
services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme);
```

In the preceding code snippet, the default scheme is set to `CookieAuthenticationDefaults.AuthenticationScheme` ("Cookies").

Alternatively, use an overloaded version of the `AddAuthentication` method to set more than one property. In the following overloaded method example, the default scheme is set to `CookieAuthenticationDefaults.AuthenticationScheme`. The authentication scheme may alternatively be specified within your individual `[Authorize]` attributes or authorization policies.

```
services.AddAuthentication(options =>
{
    options.DefaultScheme = CookieAuthenticationDefaults.AuthenticationScheme;
    options.DefaultChallengeScheme = OpenIdConnectDefaults.AuthenticationScheme;
});
```

Define a default scheme in 2.0 if one of the following conditions is true:

- You want the user to be automatically signed in
- You use the `[Authorize]` attribute or authorization policies without specifying schemes

An exception to this rule is the `AddIdentity` method. This method adds cookies for you and sets the default authenticate and challenge schemes to the application cookie `IdentityConstants.ApplicationScheme`. Additionally, it sets the default sign-in scheme to the external cookie `IdentityConstants.ExternalScheme`.

Use HttpContext authentication extensions

The `IAuthenticationManager` interface is the main entry point into the 1.x authentication system. It has been replaced with a new set of `HttpContext` extension methods in the `Microsoft.AspNetCore.Authentication` namespace.

For example, 1.x projects reference an `Authentication` property:

```
// Clear the existing external cookie to ensure a clean login process
await HttpContext.Authentication.SignOutAsync(_externalCookieScheme);
```

In 2.0 projects, import the `Microsoft.AspNetCore.Authentication` namespace, and delete the `Authentication` property references:

```
// Clear the existing external cookie to ensure a clean login process
await HttpContext.SignOutAsync(IdentityConstants.ExternalScheme);
```

Windows Authentication (HTTP.sys / IISIntegration)

There are two variations of Windows authentication:

- The host only allows authenticated users. This variation isn't affected by the 2.0 changes.
- The host allows both anonymous and authenticated users. This variation is affected by the 2.0 changes. For example, the app should allow anonymous users at the IIS or HTTP.sys layer but authorize users at the controller level. In this scenario, set the default scheme in the `Startup.ConfigureServices` method.

  For Microsoft.AspNetCore.Server.IISIntegration, set the default scheme to `IISDefaults.AuthenticationScheme` :

  ```
  using Microsoft.AspNetCore.Server.IISIntegration;

  services.AddAuthentication(IISDefaults.AuthenticationScheme);
  ```

  For Microsoft.AspNetCore.Server.HttpSys, set the default scheme to `HttpSysDefaults.AuthenticationScheme` :

  ```
  using Microsoft.AspNetCore.Server.HttpSys;

  services.AddAuthentication(HttpSysDefaults.AuthenticationScheme);
  ```

  Failure to set the default scheme prevents the authorize (challenge) request from working with the following exception:

  > `System.InvalidOperationException` : No authenticationScheme was specified, and there was no DefaultChallengeScheme found.

For more information, see Configure Windows Authentication in ASP.NET Core.

IdentityCookieOptions instances

A side effect of the 2.0 changes is the switch to using named options instead of cookie options instances. The ability to customize the Identity cookie scheme names is removed.

For example, 1.x projects use constructor injection to pass an `IdentityCookieOptions` parameter into

AccountController.cs and *ManageController.cs*. The external cookie authentication scheme is accessed from the provided instance:

```
public AccountController(
    UserManager<ApplicationUser> userManager,
    SignInManager<ApplicationUser> signInManager,
    IOptions<IdentityCookieOptions> identityCookieOptions,
    IEmailSender emailSender,
    ISmsSender smsSender,
    ILoggerFactory loggerFactory)
{
    _userManager = userManager;
    _signInManager = signInManager;
    _externalCookieScheme = identityCookieOptions.Value.ExternalCookieAuthenticationScheme;
    _emailSender = emailSender;
    _smsSender = smsSender;
    _logger = loggerFactory.CreateLogger<AccountController>();
}
```

The aforementioned constructor injection becomes unnecessary in 2.0 projects, and the `_externalCookieScheme` field can be deleted:

```
public AccountController(
    UserManager<ApplicationUser> userManager,
    SignInManager<ApplicationUser> signInManager,
    IEmailSender emailSender,
    ISmsSender smsSender,
    ILoggerFactory loggerFactory)
{
    _userManager = userManager;
    _signInManager = signInManager;
    _emailSender = emailSender;
    _smsSender = smsSender;
    _logger = loggerFactory.CreateLogger<AccountController>();
}
```

1.x projects used the `_externalCookieScheme` field as follows:

```
// Clear the existing external cookie to ensure a clean login process
await HttpContext.Authentication.SignOutAsync(_externalCookieScheme);
```

In 2.0 projects, replace the preceding code with the following. The `IdentityConstants.ExternalScheme` constant can be used directly.

```
// Clear the existing external cookie to ensure a clean login process
await HttpContext.SignOutAsync(IdentityConstants.ExternalScheme);
```

Resolve the newly added `SignOutAsync` call by importing the following namespace:

```
using Microsoft.AspNetCore.Authentication;
```

Add IdentityUser POCO navigation properties

The Entity Framework (EF) Core navigation properties of the base `IdentityUser` POCO (Plain Old CLR Object) have been removed. If your 1.x project used these properties, manually add them back to the 2.0 project:

```
/// <summary>
/// Navigation property for the roles this user belongs to.
/// </summary>
public virtual ICollection<IdentityUserRole<int>> Roles { get; } = new List<IdentityUserRole<int>>();

/// <summary>
/// Navigation property for the claims this user possesses.
/// </summary>
public virtual ICollection<IdentityUserClaim<int>> Claims { get; } = new List<IdentityUserClaim<int>>();

/// <summary>
/// Navigation property for this users login accounts.
/// </summary>
public virtual ICollection<IdentityUserLogin<int>> Logins { get; } = new List<IdentityUserLogin<int>>();
```

To prevent duplicate foreign keys when running EF Core Migrations, add the following to your `IdentityDbContext` class' `OnModelCreating` method (after the `base.OnModelCreating();` call):

```
protected override void OnModelCreating(ModelBuilder builder)
{
    base.OnModelCreating(builder);
    // Customize the ASP.NET Core Identity model and override the defaults if needed.
    // For example, you can rename the ASP.NET Core Identity table names and more.
    // Add your customizations after calling base.OnModelCreating(builder);

    builder.Entity<ApplicationUser>()
        .HasMany(e => e.Claims)
        .WithOne()
        .HasForeignKey(e => e.UserId)
        .IsRequired()
        .OnDelete(DeleteBehavior.Cascade);

    builder.Entity<ApplicationUser>()
        .HasMany(e => e.Logins)
        .WithOne()
        .HasForeignKey(e => e.UserId)
        .IsRequired()
        .OnDelete(DeleteBehavior.Cascade);

    builder.Entity<ApplicationUser>()
        .HasMany(e => e.Roles)
        .WithOne()
        .HasForeignKey(e => e.UserId)
        .IsRequired()
        .OnDelete(DeleteBehavior.Cascade);
}
```

Replace GetExternalAuthenticationSchemes

The synchronous method `GetExternalAuthenticationSchemes` was removed in favor of an asynchronous version. 1.x projects have the following code in *Controllers/ManageController.cs*:

```
var otherLogins = _signInManager.GetExternalAuthenticationSchemes().Where(auth => userLogins.All(ul =>
auth.AuthenticationScheme != ul.LoginProvider)).ToList();
```

This method appears in *Views/Account/Login.cshtml* too:

```
@{
    var loginProviders = SignInManager.GetExternalAuthenticationSchemes().ToList();
    if (loginProviders.Count == 0)
    {
        <div>
            <p>
                There are no external authentication services configured. See <a
href="https://go.microsoft.com/fwlink/?LinkID=532715">this article</a>
                for details on setting up this ASP.NET application to support logging in via external
services.
            </p>
        </div>
    }
    else
    {
        <form asp-controller="Account" asp-action="ExternalLogin" asp-route-returnurl="@ViewData["ReturnUrl"]"
method="post" class="form-horizontal">
            <div>
                <p>
                    @foreach (var provider in loginProviders)
                    {
                        <button type="submit" class="btn btn-default" name="provider"
value="@provider.AuthenticationScheme" title="Log in using your @provider.DisplayName
account">@provider.AuthenticationScheme</button>
                    }
                </p>
            </div>
        </form>
    }
}
```

In 2.0 projects, use the GetExternalAuthenticationSchemesAsync method. The change in *ManageController.cs* resembles the following code:

```
var schemes = await _signInManager.GetExternalAuthenticationSchemesAsync();
var otherLogins = schemes.Where(auth => userLogins.All(ul => auth.Name != ul.LoginProvider)).ToList();
```

In *Login.cshtml*, the `AuthenticationScheme` property accessed in the `foreach` loop changes to `Name`:

```
@{
    var loginProviders = (await SignInManager.GetExternalAuthenticationSchemesAsync()).ToList();
    if (loginProviders.Count == 0)
    {
        <div>
            <p>
                There are no external authentication services configured. See <a
href="https://go.microsoft.com/fwlink/?LinkID=532715">this article</a>
                for details on setting up this ASP.NET application to support logging in via external
services.
            </p>
        </div>
    }
    else
    {
        <form asp-controller="Account" asp-action="ExternalLogin" asp-route-returnurl="@ViewData["ReturnUrl"]"
method="post" class="form-horizontal">
            <div>
                <p>
                    @foreach (var provider in loginProviders)
                    {
                        <button type="submit" class="btn btn-default" name="provider" value="@provider.Name"
title="Log in using your @provider.DisplayName account">@provider.DisplayName</button>
                    }
                </p>
            </div>
        </form>
    }
}
```

ManageLoginsViewModel property change

A `ManageLoginsViewModel` object is used in the `ManageLogins` action of *ManageController.cs*. In 1.x projects, the object's `OtherLogins` property return type is `IList<AuthenticationDescription>`. This return type requires an import of `Microsoft.AspNetCore.Http.Authentication`:

```
using System.Collections.Generic;
using Microsoft.AspNetCore.Http.Authentication;
using Microsoft.AspNetCore.Identity;

namespace AspNetCoreDotNetCore1App.Models.ManageViewModels
{
    public class ManageLoginsViewModel
    {
        public IList<UserLoginInfo> CurrentLogins { get; set; }

        public IList<AuthenticationDescription> OtherLogins { get; set; }
    }
}
```

In 2.0 projects, the return type changes to `IList<AuthenticationScheme>`. This new return type requires replacing the `Microsoft.AspNetCore.Http.Authentication` import with a `Microsoft.AspNetCore.Authentication` import.

```
using System.Collections.Generic;
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Identity;

namespace AspNetCoreDotNetCore2App.Models.ManageViewModels
{
    public class ManageLoginsViewModel
    {
        public IList<UserLoginInfo> CurrentLogins { get; set; }

        public IList<AuthenticationScheme> OtherLogins { get; set; }
    }
}
```

Migrate from ASP.NET to ASP.NET Core

9/22/2020 • 8 minutes to read • Edit Online

By Isaac Levin

This article serves as a reference guide for migrating ASP.NET apps to ASP.NET Core.

Prerequisites

.NET Core SDK 2.2 or later

Target frameworks

ASP.NET Core projects offer developers the flexibility of targeting .NET Core, .NET Framework, or both. See Choosing between .NET Core and .NET Framework for server apps to determine which target framework is most appropriate.

When targeting .NET Framework, projects need to reference individual NuGet packages.

Targeting .NET Core allows you to eliminate numerous explicit package references, thanks to the ASP.NET Core metapackage. Install the `Microsoft.AspNetCore.App` metapackage in your project:

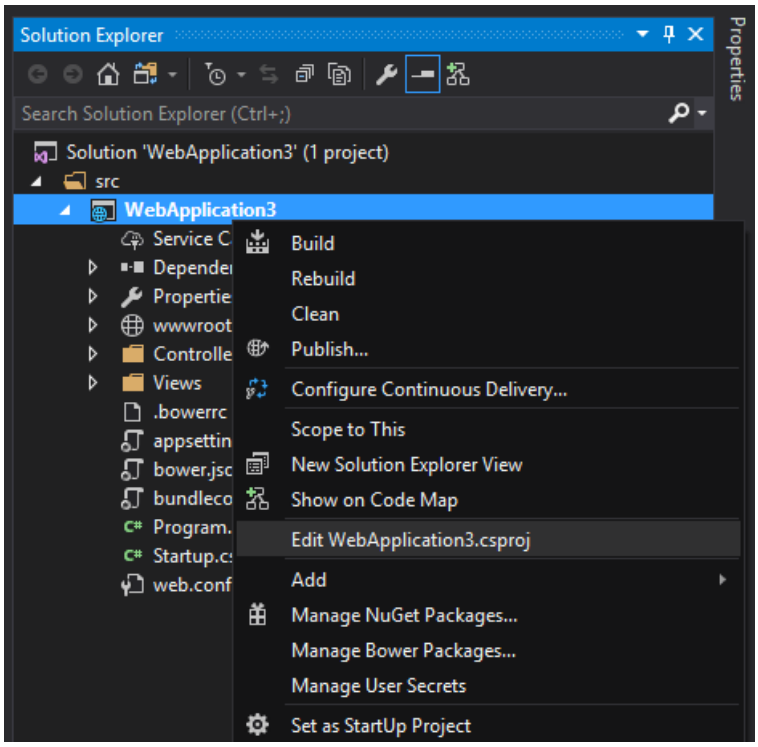
```
<ItemGroup>
   <PackageReference Include="Microsoft.AspNetCore.App" />
</ItemGroup>
```

When the metapackage is used, no packages referenced in the metapackage are deployed with the app. The .NET Core Runtime Store includes these assets, and they're precompiled to improve performance. See Microsoft.AspNetCore.App metapackage for ASP.NET Core for more detail.

Project structure differences

The *.csproj* file format has been simplified in ASP.NET Core. Some notable changes include:

- Explicit inclusion of files isn't necessary for them to be considered part of the project. This reduces the risk of XML merge conflicts when working on large teams.
- There are no GUID-based references to other projects, which improves file readability.
- The file can be edited without unloading it in Visual Studio:



Global.asax file replacement

ASP.NET Core introduced a new mechanism for bootstrapping an app. The entry point for ASP.NET applications is the *Global.asax* file. Tasks such as route configuration and filter and area registrations are handled in the *Global.asax* file.

```
public class MvcApplication : System.Web.HttpApplication
{
    protected void Application_Start()
    {
        AreaRegistration.RegisterAllAreas();
        FilterConfig.RegisterGlobalFilters(GlobalFilters.Filters);
        RouteConfig.RegisterRoutes(RouteTable.Routes);
        BundleConfig.RegisterBundles(BundleTable.Bundles);
    }
}
```

This approach couples the application and the server to which it's deployed in a way that interferes with the implementation. In an effort to decouple, OWIN was introduced to provide a cleaner way to use multiple frameworks together. OWIN provides a pipeline to add only the modules needed. The hosting environment takes a Startup function to configure services and the app's request pipeline. `Startup` registers a set of middleware with the application. For each request, the application calls each of the middleware components with the head pointer of a linked list to an existing set of handlers. Each middleware component can add one or more handlers to the request handling pipeline. This is accomplished by returning a reference to the handler that's the new head of the list. Each handler is responsible for remembering and invoking the next handler in the list. With ASP.NET Core, the entry point to an application is `Startup`, and you no longer have a dependency on *Global.asax*. When using OWIN with .NET Framework, use something like the following as a pipeline:

```
using Owin;
using System.Web.Http;

namespace WebApi
{
    // Note: By default all requests go through this OWIN pipeline. Alternatively you can turn this off by
adding an appSetting owin:AutomaticAppStartup with value “false”.
    // With this turned off you can still have OWIN apps listening on specific routes by adding routes in
global.asax file using MapOwinPath or MapOwinRoute extensions on RouteTable.Routes
    public class Startup
    {
        // Invoked once at startup to configure your application.
        public void Configuration(IAppBuilder builder)
        {
            HttpConfiguration config = new HttpConfiguration();
            config.Routes.MapHttpRoute("Default", "{controller}/{customerID}", new { controller = "Customer",
customerID = RouteParameter.Optional });

            config.Formatters.XmlFormatter.UseXmlSerializer = true;
            config.Formatters.Remove(config.Formatters.JsonFormatter);
            // config.Formatters.JsonFormatter.UseDataContractJsonSerializer = true;

            builder.UseWebApi(config);
        }
    }
}
```

This configures your default routes, and defaults to XmlSerialization over Json. Add other Middleware to this pipeline as needed (loading services, configuration settings, static files, etc.).

ASP.NET Core uses a similar approach, but doesn't rely on OWIN to handle the entry. Instead, that's done through the *Program.cs* `Main` method (similar to console applications) and `Startup` is loaded through there.

```
using Microsoft.AspNetCore;
using Microsoft.AspNetCore.Hosting;

namespace WebApplication2
{
    public class Program
    {
        public static void Main(string[] args)
        {
            CreateWebHostBuilder(args).Build().Run();
        }

        public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>();
    }
}
```

`Startup` must include a `Configure` method. In `Configure`, add the necessary middleware to the pipeline. In the following example (from the default web site template), extension methods configure the pipeline with support for:

- Error pages
- HTTP Strict Transport Security
- HTTP redirection to HTTPS
- ASP.NET Core MVC

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseMvc();
}
```

The host and application have been decoupled, which provides the flexibility of moving to a different platform in the future.

> **NOTE**
>
> For a more in-depth reference to ASP.NET Core Startup and Middleware, see Startup in ASP.NET Core

Store configurations

ASP.NET supports storing settings. These setting are used, for example, to support the environment to which the applications were deployed. A common practice was to store all custom key-value pairs in the `<appSettings>` section of the *Web.config* file:

```
<appSettings>
  <add key="UserName" value="User" />
  <add key="Password" value="Password" />
</appSettings>
```

Applications read these settings using the `ConfigurationManager.AppSettings` collection in the `System.Configuration` namespace:

```
string userName = System.Web.Configuration.ConfigurationManager.AppSettings["UserName"];
string password = System.Web.Configuration.ConfigurationManager.AppSettings["Password"];
```

ASP.NET Core can store configuration data for the application in any file and load them as part of middleware bootstrapping. The default file used in the project templates is *appsettings.json*:

```
{
  "Logging": {
    "IncludeScopes": false,
    "LogLevel": {
      "Default": "Debug",
      "System": "Information",
      "Microsoft": "Information"
    }
  },
  "AppConfiguration": {
    "UserName": "UserName",
    "Password": "Password"
  }
}
```

Loading this file into an instance of `IConfiguration` inside your application is done in *Startup.cs*:

```
public Startup(IConfiguration configuration)
{
    Configuration = configuration;
}

public IConfiguration Configuration { get; }
```

The app reads from `Configuration` to get the settings:

```
string userName = Configuration.GetSection("AppConfiguration")["UserName"];
string password = Configuration.GetSection("AppConfiguration")["Password"];
```

There are extensions to this approach to make the process more robust, such as using Dependency Injection (DI) to load a service with these values. The DI approach provides a strongly-typed set of configuration objects.

```
// Assume AppConfiguration is a class representing a strongly-typed version of AppConfiguration section
services.Configure<AppConfiguration>(Configuration.GetSection("AppConfiguration"));
```

> **NOTE**
>
> For a more in-depth reference to ASP.NET Core configuration, see Configuration in ASP.NET Core.

Native dependency injection

An important goal when building large, scalable applications is the loose coupling of components and services. Dependency Injection is a popular technique for achieving this, and it's a native component of ASP.NET Core.

In ASP.NET apps, developers rely on a third-party library to implement Dependency Injection. One such library is Unity, provided by Microsoft Patterns & Practices.

An example of setting up Dependency Injection with Unity is implementing `IDependencyResolver` that wraps a `UnityContainer`:

```
using Microsoft.Practices.Unity;
using System;
using System.Collections.Generic;
using System.Web.Http.Dependencies;

public class UnityResolver : IDependencyResolver
{
    protected IUnityContainer container;

    public UnityResolver(IUnityContainer container)
    {
        if (container == null)
        {
            throw new ArgumentNullException("container");
        }
        this.container = container;
    }

    public object GetService(Type serviceType)
    {
        try
        {
            return container.Resolve(serviceType);
        }
        catch (ResolutionFailedException)
        {
            return null;
        }
    }

    public IEnumerable<object> GetServices(Type serviceType)
    {
        try
        {
            return container.ResolveAll(serviceType);
        }
        catch (ResolutionFailedException)
        {
            return new List<object>();
        }
    }

    public IDependencyScope BeginScope()
    {
        var child = container.CreateChildContainer();
        return new UnityResolver(child);
    }

    public void Dispose()
    {
        Dispose(true);
    }

    protected virtual void Dispose(bool disposing)
    {
        container.Dispose();
    }
}
```

Create an instance of your `UnityContainer`, register your service, and set the dependency resolver of `HttpConfiguration` to the new instance of `UnityResolver` for your container:

```
public static void Register(HttpConfiguration config)
{
    var container = new UnityContainer();
    container.RegisterType<IProductRepository, ProductRepository>(new HierarchicalLifetimeManager());
    config.DependencyResolver = new UnityResolver(container);

    // Other Web API configuration not shown.
}
```

Inject `IProductRepository` where needed:

```
public class ProductsController : ApiController
{
    private IProductRepository _repository;

    public ProductsController(IProductRepository repository)
    {
        _repository = repository;
    }

    // Other controller methods not shown.
}
```

Because Dependency Injection is part of ASP.NET Core, you can add your service in the `ConfigureServices` method of *Startup.cs*:

```
public void ConfigureServices(IServiceCollection services)
{
    // Add application services.
    services.AddTransient<IProductRepository, ProductRepository>();
}
```

The repository can be injected anywhere, as was true with Unity.

> **NOTE**
> For more information on dependency injection, see Dependency injection.

Serve static files

An important part of web development is the ability to serve static, client-side assets. The most common examples of static files are HTML, CSS, Javascript, and images. These files need to be saved in the published location of the app (or CDN) and referenced so they can be loaded by a request. This process has changed in ASP.NET Core.

In ASP.NET, static files are stored in various directories and referenced in the views.

In ASP.NET Core, static files are stored in the "web root" (*<content root>/wwwroot*), unless configured otherwise. The files are loaded into the request pipeline by invoking the `UseStaticFiles` extension method from `Startup.Configure`:

```
public void Configure(IApplicationBuilder app)
{
    app.UseStaticFiles();
}
```

> **NOTE**
> If targeting .NET Framework, install the NuGet package `Microsoft.AspNetCore.StaticFiles`.

For example, an image asset in the *wwwroot/images* folder is accessible to the browser at a location such as `http://<app>/images/<imageFileName>`.

> **NOTE**
> For a more in-depth reference to serving static files in ASP.NET Core, see Static files.

Multi-value cookies

Multi-value cookies aren't supported in ASP.NET Core. Create one cookie per value.

Partial app migration

One approach to partial app migration is to create an IIS sub-application and only move certain routes from ASP.NET 4.x to ASP.NET Core while preserving the URL structure the app. For example, consider the URL structure of the app from the *applicationHost.config* file:

```
<sites>
    <site name="Default Web Site" id="1" serverAutoStart="true">
        <application path="/">
            <virtualDirectory path="/" physicalPath="D:\sites\MainSite\" />
        </application>
        <application path="/api" applicationPool="DefaultAppPool">
            <virtualDirectory path="/" physicalPath="D:\sites\netcoreapi" />
        </application>
        <bindings>
            <binding protocol="http" bindingInformation="*:80:" />
            <binding protocol="https" bindingInformation="*:443:" sslFlags="0" />
        </bindings>
    </site>
 ...
</sites>
```

Directory structure:

```
.
├── MainSite
│   ├── ...
│   └── Web.config
└── NetCoreApi
    ├── ...
    └── web.config
```

[BIND] and Input Formatters

Previous versions of ASP.NET used the `[Bind]` attribute to protect against overposting attacks. Input formatters work differently in ASP.NET Core. The `[Bind]` attribute is no longer designed to prevent overposting when used with input formatters to parse JSON or XML. These attributes affect model binding when the source of data is form data posted with the `x-www-form-urlencoded` content type.

For apps that post JSON information to controllers and use JSON Input Formatters to parse the data, we

recommend replacing the `[Bind]` attribute with a view model that matches the properties defined by the `[Bind]` attribute.

Migrate from ASP.NET MVC to ASP.NET Core MVC

9/22/2020 • 22 minutes to read • Edit Online

This article shows how to start migrating an ASP.NET MVC project to ASP.NET Core MVC. In the process, it highlights related changes from ASP.NET MVC.

Migrating from ASP.NET MVC is a multi-step process. This article covers:

- Initial setup.
- Basic controllers and views.
- Static content.
- Client-side dependencies.

For migrating configuration and Identity code, see Migrate configuration to ASP.NET Core and Migrate Authentication and Identity to ASP.NET Core.

Prerequisites

- Visual Studio 2019 16.4 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

Create the starter ASP.NET MVC project

Create an example ASP.NET MVC project in Visual Studio to migrate:

1. From the **File** menu, select **New** > **Project**.
2. Select **ASP.NET Web Application (.NET Framework)** and then select **Next**.
3. Name the project *WebApp1* so the namespace matches the ASP.NET Core project created in the next step. Select **Create**.
4. Select **MVC**, and then select **Create**.

Create the ASP.NET Core project

Create a new solution with a new ASP.NET Core project to migrate to:

1. Launch a second instance of Visual Studio.
2. From the **File** menu, select **New** > **Project**.
3. Select **ASP.NET Web Core Web Application** and then select **Next**.
4. In the **Configure your new project** dialog, Name the project *WebApp1*.
5. Set the location to a different directory than the previous project to use the same project name. Using the same namespace makes it easier to copy code between the two projects. Select **Create**.
6. In the **Create a new ASP.NET Core Web Application** dialog, confirm that **.NET Core** and **ASP.NET Core 3.1** are selected. Select the **Web Application (Model-View-Controller)** project template, and select **Create**.

Configure the ASP.NET Core site to use MVC

In ASP.NET Core 3.0 and later projects, .NET Framework is no longer a supported target framework. Your project must target .NET Core. The ASP.NET Core shared framework, which includes MVC, is part of the .NET Core runtime installation. The shared framework is automatically referenced when using the `Microsoft.NET.Sdk.Web` SDK in the project file:

```
<Project Sdk="Microsoft.NET.Sdk.Web">
```

For more information, see Framework reference.

In ASP.NET Core, the `Startup` class:

- Replaces *Global.asax*.
- Handles all app startup tasks.

For more information, see App startup in ASP.NET Core.

In the ASP.NET Core project, open the *Startup.cs* file:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    // This method gets called by the runtime. Use this method to add services to the container.
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddControllersWithViews();
    }

    // This method gets called by the runtime. Use this method to configure the HTTP request pipeline.
    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Home/Error");
            // The default HSTS value is 30 days. You may want to change this for production scenarios, see
https://aka.ms/aspnetcore-hsts.
            app.UseHsts();
        }
        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapControllerRoute(
                name: "default",
                pattern: "{controller=Home}/{action=Index}/{id?}");
        });
    }
}
```

ASP.NET Core apps must opt in to framework features with middleware. The previous template-generated code adds the following services and middleware:

- The AddControllersWithViews extension method registers MVC service support for controllers, API-related features, and views. For more information on MVC service registration options, see MVC service registration

- The UseStaticFiles extension method adds the static file handler `Microsoft.AspNetCore.StaticFiles`. The `UseStaticFiles` extension method must be called before `UseRouting`. For more information, see Static files in ASP.NET Core.
- The UseRouting extension method adds routing. For more information, see Routing in ASP.NET Core.

This existing configuration includes what is needed to migrate the example ASP.NET MVC project. For more information on ASP.NET Core middleware options, see App startup in ASP.NET Core.

Migrate controllers and views

In the ASP.NET Core project, a new empty controller class and view class would be added to serve as placeholders using the same names as the controller and view classes in any ASP.NET MVC project to migrate from.

The ASP.NET Core *WebApp1* project already includes a minimal example controller and view by the same name as the ASP.NET MVC project. So those will serve as placeholders for the ASP.NET MVC controller and views to be migrated from the ASP.NET MVC *WebApp1* project.

1. Copy the methods from the ASP.NET MVC `HomeController` to replace the new ASP.NET Core `HomeController` methods. There's no need to change the return type of the action methods. The ASP.NET MVC built-in template's controller action method return type is /dotnet/api/system.web.mvc.actionresult?view=aspnet-mvc-5.2; in ASP.NET Core MVC, the action methods return `IActionResult` instead. `ActionResult` implements `IActionResult`.
2. In the ASP.NET Core project, right-click the *Views/Home* directory, select **Add** > **Existing Item**.
3. In the **Add Existing Item** dialog, navigate to the ASP.NET MVC *WebApp1* project's *Views/Home* directory.
4. Select the *About.cshtml*, *Contact.cshtml*, and *Index.cshtml* Razor view files, then select **Add**, replacing the existing files.

For more information, see Handle requests with controllers in ASP.NET Core MVC and Views in ASP.NET Core MVC.

Test each method

Each controller endpoint can be tested, however, layout and styles are covered later in the document.

1. Run the ASP.NET Core app.
2. Invoke the rendered views from the browser on the running ASP.NET Core app by replacing the current port number with the port number used in the ASP.NET Core project. For example, `https://localhost:44375/home/about`.

Migrate static content

In ASP.NET MVC 5 and earlier, static content was hosted from the web project's root directory and was intermixed with server-side files. In ASP.NET Core, static files are stored within the project's web root directory. The default directory is *{content root}/wwwroot*, but it can be changed. For more information, see Static files in ASP.NET Core.

Copy the static content from the ASP.NET MVC *WebApp1* project to the *wwwroot* directory in the ASP.NET Core *WebApp1* project:

1. In the ASP.NET Core project, right-click the *wwwroot* directory, select **Add** > **Existing Item**.
2. In the **Add Existing Item** dialog, navigate to the ASP.NET MVC *WebApp1* project.
3. Select the *favicon.ico* file, then select **Add**, replacing the existing file.

Migrate the layout files

Copy the ASP.NET MVC project layout files to the ASP.NET Core project:

1. In the ASP.NET Core project, right-click the *Views* directory, select **Add** > **Existing Item**.
2. In the **Add Existing Item** dialog, navigate to the ASP.NET MVC *WebApp1* project's *Views* directory.
3. Select the *_ViewStart.cshtml* file then select **Add**.

Copy the ASP.NET MVC project shared layout files to the ASP.NET Core project:

1. In the ASP.NET Core project, right-click the *Views/Shared* directory, select **Add** > **Existing Item**.
2. In the **Add Existing Item** dialog, navigate to the ASP.NET MVC *WebApp1* project's *Views/Shared* directory.
3. Select the *_Layout.cshtml* file, then select **Add**, replacing the existing file.

In the ASP.NET Core project, open the *_Layout.cshtml* file. Make the following changes to match the completed code shown below:

Update the Bootstrap CSS inclusion to match the completed code below:

1. Replace `@Styles.Render("~/Content/css")` with a `<link>` element to load *bootstrap.css* (see below).
2. Remove `@Scripts.Render("~/bundles/modernizr")`.

The completed replacement markup for Bootstrap CSS inclusion:

```
<link rel="stylesheet"
    href="https://maxcdn.bootstrapcdn.com/bootstrap/3.3.7/css/bootstrap.min.css"
    integrity="sha384-BVYiiSIFeK1dGmJRAkycuHAHRg32OmUcww7on3RYdg4Va+PmSTsz/K68vbdEjh4u"
    crossorigin="anonymous">
```

Update the jQuery and Bootstrap JavaScript inclusion to match the completed code below:

1. Replace `@Scripts.Render("~/bundles/jquery")` with a `<script>` element (see below).
2. Replace `@Scripts.Render("~/bundles/bootstrap")` with a `<script>` element (see below).

The completed replacement markup for jQuery and Bootstrap JavaScript inclusion:

```
<script src="https://code.jquery.com/jquery-3.3.1.min.js"></script>
<script src="https://maxcdn.bootstrapcdn.com/bootstrap/3.3.7/js/bootstrap.min.js"
    integrity="sha384-Tc5IQib027qvyjSMfHjOMaLkfuWVxZxUPnCJA7l2mCWNIpG9mGCD8wGNIcPD7Txa"
crossorigin="anonymous"></script>
```

The updated *_Layout.cshtml* file is shown below:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0">
    <title>@ViewBag.Title - My ASP.NET Application</title>
    <link rel="stylesheet"
          href="https://maxcdn.bootstrapcdn.com/bootstrap/3.3.7/css/bootstrap.min.css"
          integrity="sha384-BVYiiSIFeK1dGmJRAkycuHAHRg32OmUcww7on3RYdg4Va+PmSTsz/K68vbdEjh4u"
          crossorigin="anonymous">
</head>
<body>
    <div class="navbar navbar-inverse navbar-fixed-top">
        <div class="container">
            <div class="navbar-header">
                <button type="button" class="navbar-toggle" data-toggle="collapse" data-target=".navbar-
collapse">
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                </button>
                @Html.ActionLink("Application name", "Index", "Home", new { area = "" }, new { @class =
"navbar-brand" })
            </div>
            <div class="navbar-collapse collapse">
                <ul class="nav navbar-nav">
                    <li>@Html.ActionLink("Home", "Index", "Home")</li>
                    <li>@Html.ActionLink("About", "About", "Home")</li>
                    <li>@Html.ActionLink("Contact", "Contact", "Home")</li>
                </ul>
            </div>
        </div>
    </div>
    <div class="container body-content">
        @RenderBody()
        <hr />
        <footer>
            <p>&copy; @DateTime.Now.Year - My ASP.NET Application</p>
        </footer>
    </div>

    <script src="https://code.jquery.com/jquery-3.3.1.min.js"></script>
    <script src="https://maxcdn.bootstrapcdn.com/bootstrap/3.3.7/js/bootstrap.min.js"
            integrity="sha384-Tc5IQib027qvyjSMfHjOMaLkfuWVxZxUPnCJA7l2mCWNIpG9mGCD8wGNIcPD7Txa"
crossorigin="anonymous"></script>
    @RenderSection("scripts", required: false)
</body>
</html>
```

View the site in the browser. It should render with the expected styles in place.

Configure bundling and minification

ASP.NET Core is compatible with several open-source bundling and minification solutions such as WebOptimizer and other similar libraries. ASP.NET Core doesn't provide a native bundling and minification solution. For information on configuring bundling and minification, see Bundling and Minification.

Solve HTTP 500 errors

There are many problems that can cause an HTTP 500 error message that contains no information on the source of the problem. For example, if the *Views/_ViewImports.cshtml* file contains a namespace that doesn't exist in the project, an HTTP 500 error is generated. By default in ASP.NET Core apps, the `UseDeveloperExceptionPage` extension is added to the `IApplicationBuilder` and executed when the environment is *Development*. This is detailed in the

following code:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    // This method gets called by the runtime. Use this method to add services to the container.
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddControllersWithViews();
    }

    // This method gets called by the runtime. Use this method to configure the HTTP request pipeline.
    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Home/Error");
            // The default HSTS value is 30 days. You may want to change this for production scenarios, see
https://aka.ms/aspnetcore-hsts.
            app.UseHsts();
        }
        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapControllerRoute(
                name: "default",
                pattern: "{controller=Home}/{action=Index}/{id?}");
        });
    }
}
```

ASP.NET Core converts unhandled exceptions into HTTP 500 error responses. Normally, error details aren't included in these responses to prevent disclosure of potentially sensitive information about the server. For more information, see Developer Exception Page.

Next steps

- Migrate Authentication and Identity to ASP.NET Core

Additional resources

- Introduction to ASP.NET Core Blazor
- Tag Helpers in ASP.NET Core

This article shows how to start migrating an ASP.NET MVC project to ASP.NET Core MVC 2.2. In the process, it highlights many of the things that have changed from ASP.NET MVC. Migrating from ASP.NET MVC is a multi-step process. This article covers:

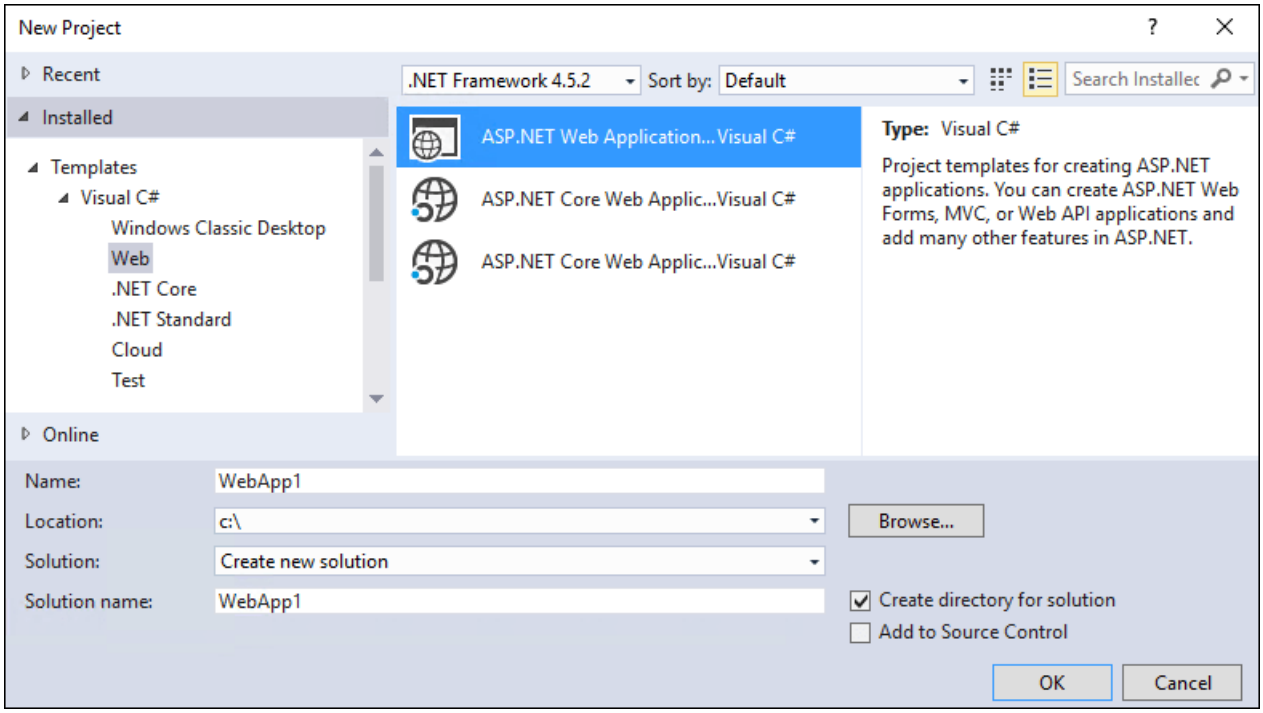
- Initial setup
- Basic controllers and views
- Static content
- Client-side dependencies.

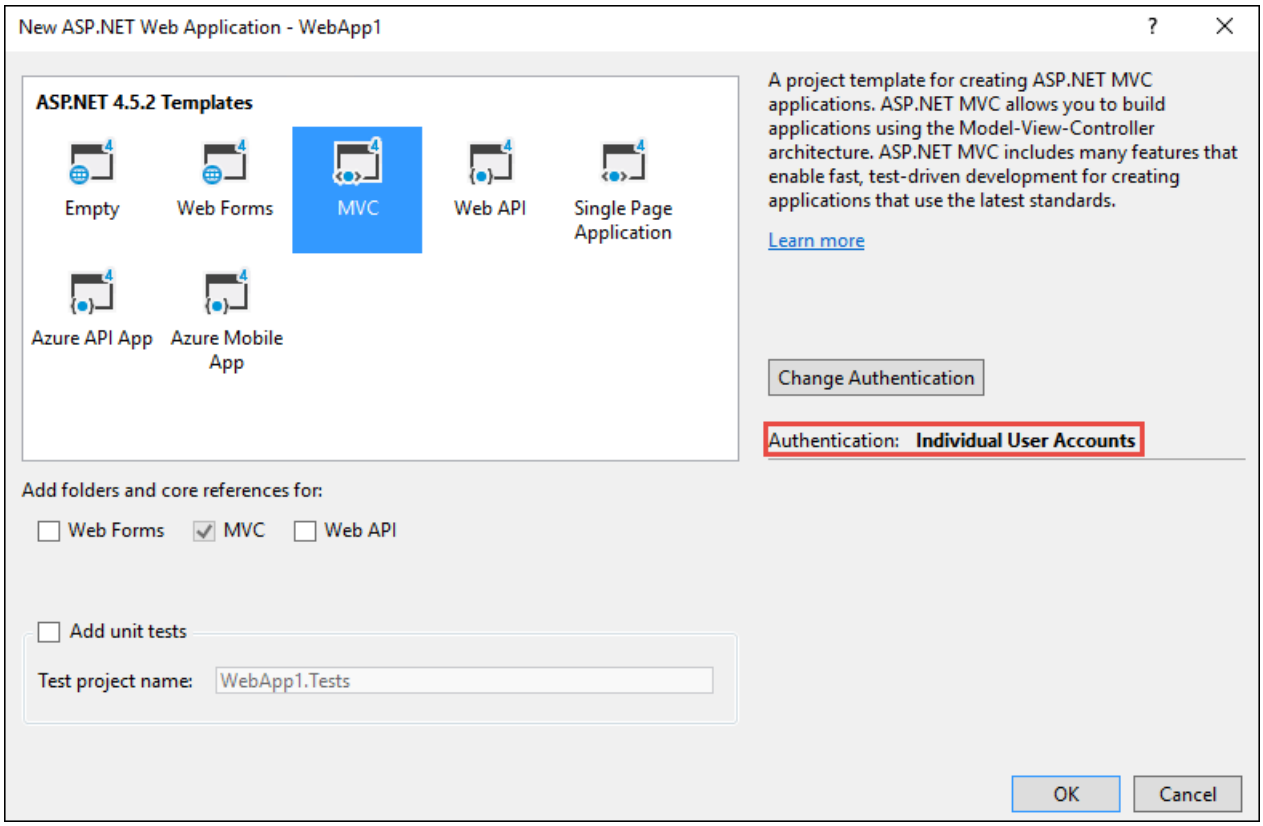
For migrating configuration and Identity code, see Migrate configuration to ASP.NET Core and Migrate Authentication and Identity to ASP.NET Core.

> **NOTE**
> The version numbers in the samples might not be current, update the projects accordingly.

Create the starter ASP.NET MVC project

To demonstrate the upgrade, we'll start by creating an ASP.NET MVC app. Create it with the name *WebApp1* so the namespace matches the ASP.NET Core project created in the next step.

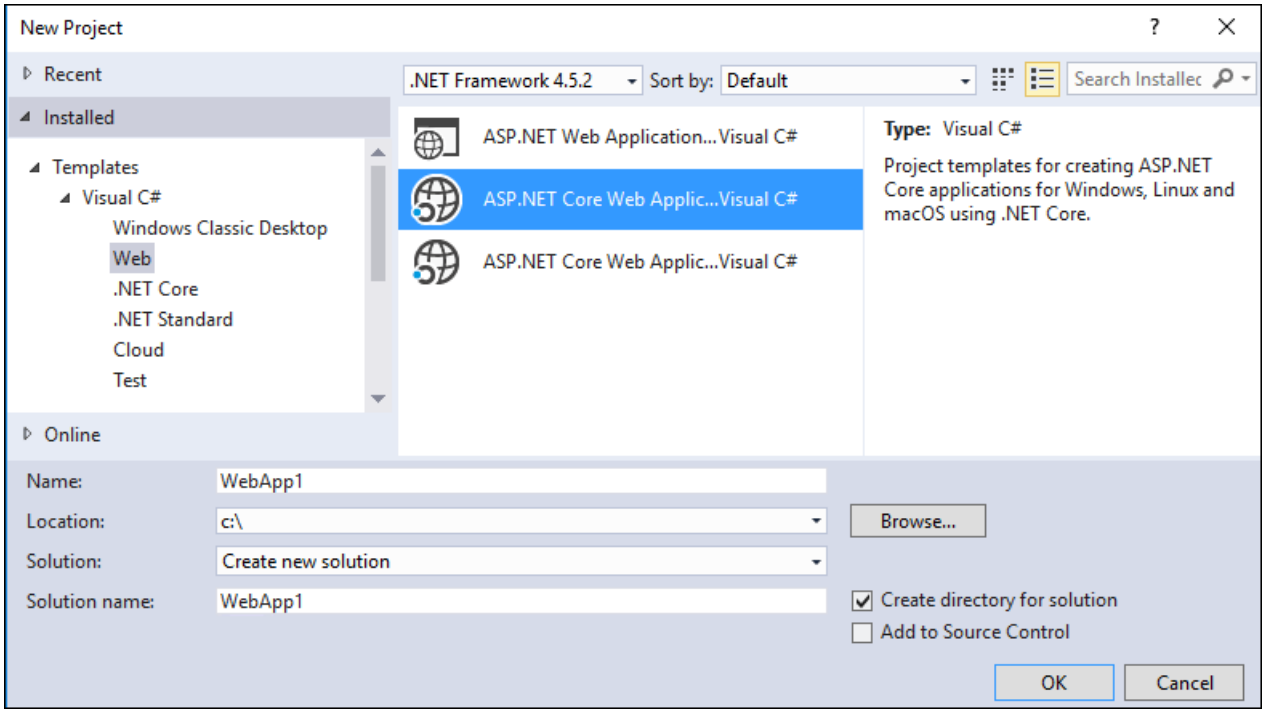


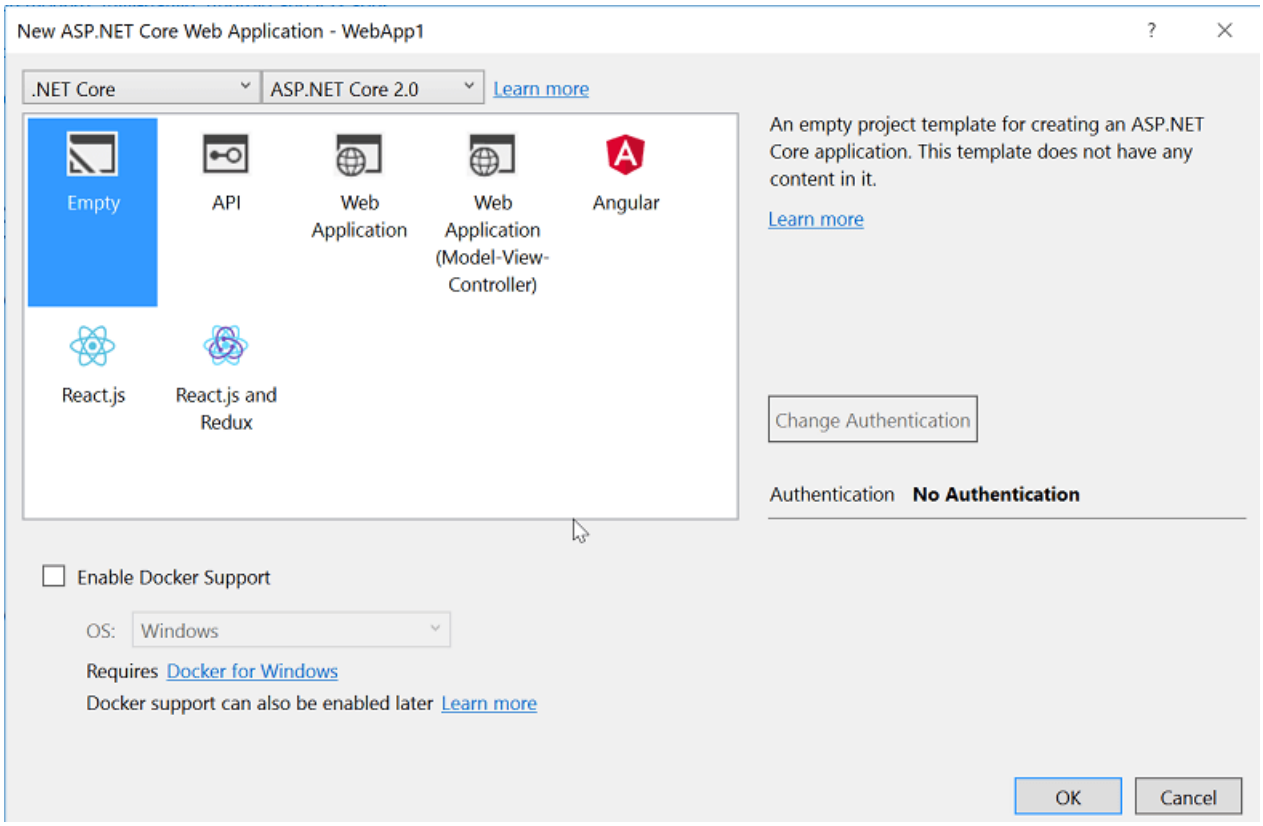


Optional: Change the name of the Solution from *WebApp1* to *Mvc5*. Visual Studio displays the new solution name (*Mvc5*), which makes it easier to tell this project from the next project.

Create the ASP.NET Core project

Create a new *empty* ASP.NET Core web app with the same name as the previous project (*WebApp1*) so the namespaces in the two projects match. Having the same namespace makes it easier to copy code between the two projects. Create this project in a different directory than the previous project to use the same name.





- *Optional:* Create a new ASP.NET Core app using the *Web Application* project template. Name the project *WebApp1*, and select an authentication option of **Individual User Accounts**. Rename this app to *FullAspNetCore*. Creating this project saves time in the conversion. The end result can be viewed in the template-generated code, code can be copied to the conversion project, or compared with the template-generated project.

Configure the site to use MVC

- When targeting .NET Core, the Microsoft.AspNetCore.App metapackage is referenced by default. This package contains packages commonly used by MVC apps. If targeting .NET Framework, package references must be listed individually in the project file.

`Microsoft.AspNetCore.Mvc` is the ASP.NET Core MVC framework. `Microsoft.AspNetCore.StaticFiles` is the static file handler. ASP.NET Core apps explicitly opt in for middleware, such as for serving static files. For more information, see Static files.

- Open the *Startup.cs* file and change the code to match the following:

```
public class Startup
{
    // This method gets called by the runtime. Use this method to add services to the container.
    // For more information on how to configure your application, visit https://go.microsoft.com/fwlink/?
LinkID=398940
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddMvc();
    }

    // This method gets called by the runtime. Use this method to configure the HTTP request pipeline.
    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        app.UseStaticFiles();

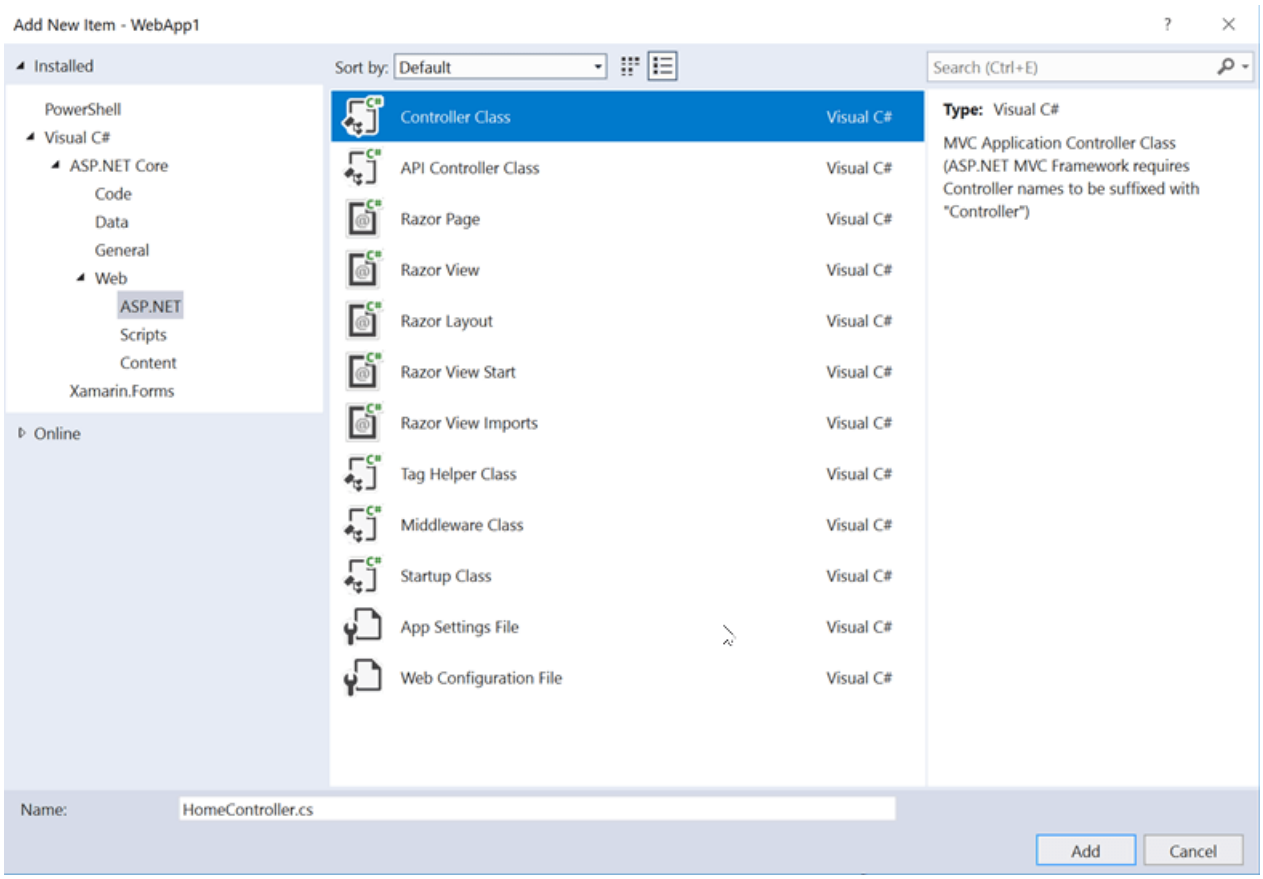
        app.UseMvc(routes =>
        {
            routes.MapRoute(
                name: "default",
                template: "{controller=Home}/{action=Index}/{id?}");
        });
    }
}
```

The UseStaticFiles extension method adds the static file handler. For more information, see Application Startup and Routing.

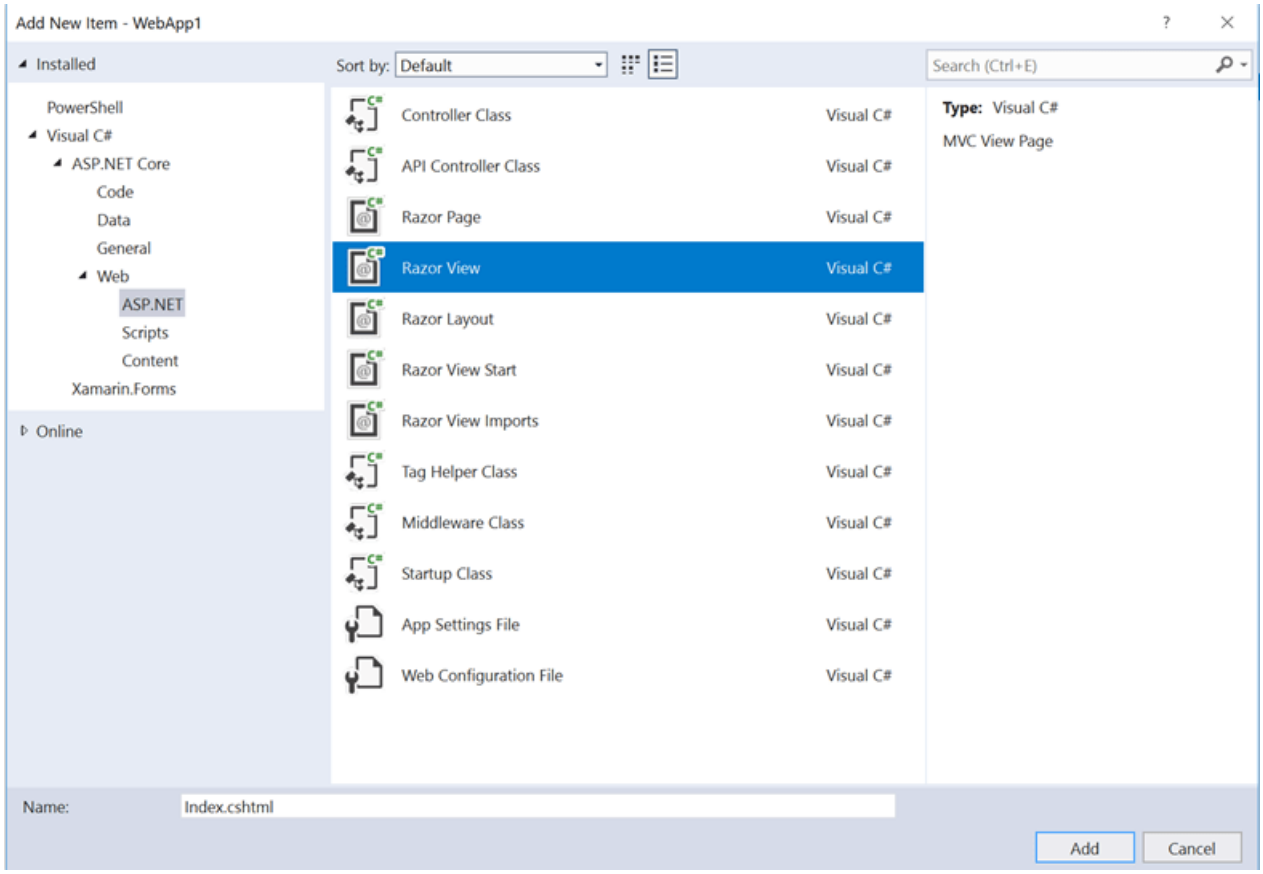
Add a controller and view

In this section, a minimal controller and view are added to serve as placeholders for the ASP.NET MVC controller and views migrated in the next section.

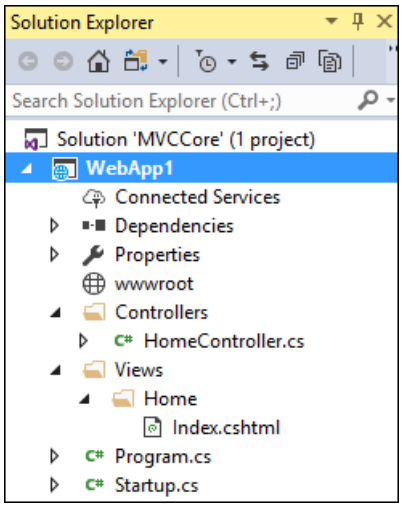
- Add a *Controllers* directory.
- Add a **Controller Class** named *HomeController.cs* to the *Controllers* directory.



- Add a *Views* directory.
- Add a *Views/Home* directory.
- Add a **Razor View** named *Index.cshtml* to the *Views/Home* directory.



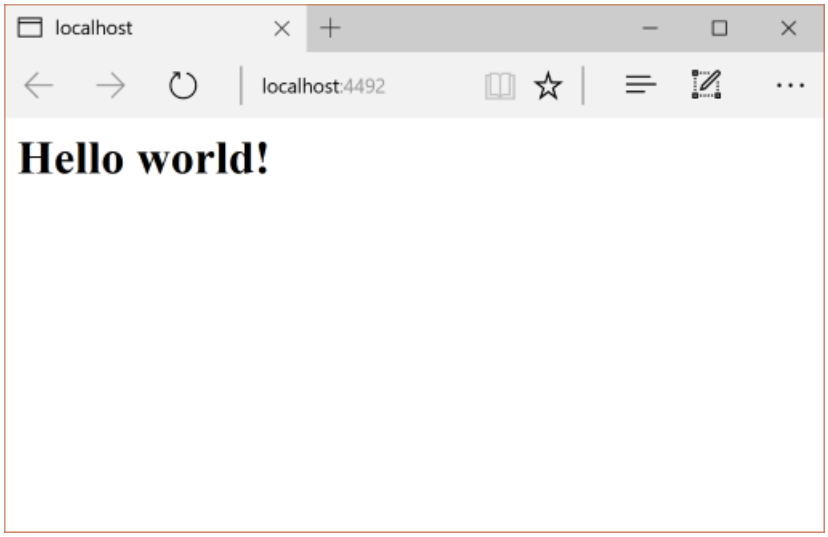
The project structure is shown below:



Replace the contents of the *Views/Home/Index.cshtml* file with the following markup:

```
<h1>Hello world!</h1>
```

Run the app.



For more information, see Controllers and Views.

The following functionality requires migration from the example ASP.NET MVC project to the ASP.NET Core project:

- client-side content (CSS, fonts, and scripts)
- controllers
- views
- models
- bundling
- filters
- Log in/out, Identity (This is done in the next tutorial.)

Controllers and views

- Copy each of the methods from the ASP.NET MVC `HomeController` to the new `HomeController`. In ASP.NET MVC, the built-in template's controller action method return type is

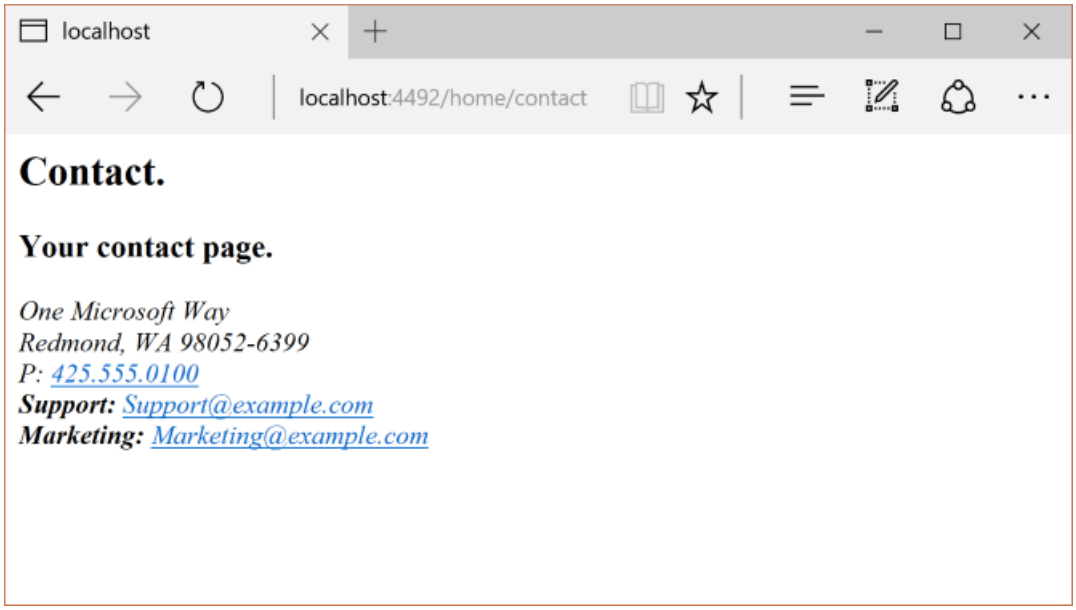
/dotnet/api/system.web.mvc.actionresult?view=aspnet-mvc-5.2; in ASP.NET Core MVC, the action methods return `IActionResult` instead. `ActionResult` implements `IActionResult`, so there's no need to change the return type of the action methods.

- Copy the *About.cshtml*, *Contact.cshtml*, and *Index.cshtml* Razor view files from the ASP.NET MVC project to the ASP.NET Core project.

Test each method

The layout file and styles have not been migrated yet, so the rendered views only contain the content in the view files. The layout file generated links for the `About` and `Contact` views will not be available yet.

Invoke the rendered views from the browser on the running ASP.NET core app by replacing the current port number with the port number used in the ASP.NET core project. For example: `https://localhost:44375/home/about`.



Note the lack of styling and menu items. The styling will be fixed in the next section.

Static content

In ASP.NET MVC 5 and earlier, static content was hosted from the root of the web project and was intermixed with server-side files. In ASP.NET Core, static content is hosted in the *wwwroot* directory. Copy the static content from the ASP.NET MVC app to the *wwwroot* directory in the ASP.NET Core project. In this sample conversion:

- Copy the *favicon.ico* file from the ASP.NET MVC project to the *wwwroot* directory in the ASP.NET Core project.

The ASP.NET MVC project uses Bootstrap for its styling and stores the Bootstrap files in the *Content* and *Scripts* directories. The template, which generated the ASP.NET MVC project, references Bootstrap in the layout file (*Views/Shared/_Layout.cshtml*). The *bootstrap.js* and *bootstrap.css* files could be copied from the ASP.NET MVC project to the *wwwroot* directory in the new project. Instead, this document adds support for Bootstrap (and other client-side libraries) using CDNs, in the next section.

Migrate the layout file

- Copy the *_ViewStart.cshtml* file from the ASP.NET MVC project's *Views* directory into the ASP.NET Core project's *Views* directory. The *_ViewStart.cshtml* file has not changed in ASP.NET Core MVC.
- Create a *Views/Shared* directory.
- *Optional:* Copy *_ViewImports.cshtml* from the *FullAspNetCore* MVC project's *Views* directory into the ASP.NET Core project's *Views* directory. Remove any namespace declaration in the *_ViewImports.cshtml* file.

The *_ViewImports.cshtml* file provides namespaces for all the view files and brings in Tag Helpers. Tag Helpers are used in the new layout file. The *_ViewImports.cshtml* file is new for ASP.NET Core.

- Copy the *_Layout.cshtml* file from the ASP.NET MVC project's *Views/Shared* directory into the ASP.NET Core project's *Views/Shared* directory.

Open *_Layout.cshtml* file and make the following changes (the completed code is shown below):

- Replace `@Styles.Render("~/Content/css")` with a `<link>` element to load *bootstrap.css* (see below).
- Remove `@Scripts.Render("~/bundles/modernizr")`.
- Comment out the `@Html.Partial("_LoginPartial")` line (surround the line with `@*...*@`). For more information, see Migrate Authentication and Identity to ASP.NET Core
- Replace `@Scripts.Render("~/bundles/jquery")` with a `<script>` element (see below).
- Replace `@Scripts.Render("~/bundles/bootstrap")` with a `<script>` element (see below).

The replacement markup for Bootstrap CSS inclusion:

```
<link rel="stylesheet"
    href="https://maxcdn.bootstrapcdn.com/bootstrap/3.3.7/css/bootstrap.min.css"
    integrity="sha384-BVYiiSIFeK1dGmJRAkycuHAHRg32OmUcww7on3RYdg4Va+PmSTsz/K68vbdEjh4u"
    crossorigin="anonymous">
```

The replacement markup for jQuery and Bootstrap JavaScript inclusion:

```
<script src="https://code.jquery.com/jquery-3.3.1.min.js"></script>
<script src="https://maxcdn.bootstrapcdn.com/bootstrap/3.3.7/js/bootstrap.min.js"
    integrity="sha384-Tc5IQib027qvyjSMfHjOMaLkfuWVxZxUPnCJA7l2mCWNIpG9mGCD8wGNIcPD7Txa"
crossorigin="anonymous"></script>
```

The updated *_Layout.cshtml* file is shown below:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0">
    <title>@ViewBag.Title - My ASP.NET Application</title>
    <link rel="stylesheet"
          href="https://maxcdn.bootstrapcdn.com/bootstrap/3.3.7/css/bootstrap.min.css"
          integrity="sha384-BVYiiSIFeK1dGmJRAkycuHAHRg32OmUcww7on3RYdg4Va+PmSTsz/K68vbdEjh4u"
          crossorigin="anonymous">
</head>
<body>
    <div class="navbar navbar-inverse navbar-fixed-top">
        <div class="container">
            <div class="navbar-header">
                <button type="button" class="navbar-toggle" data-toggle="collapse" data-target=".navbar-
collapse">
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                </button>
                @Html.ActionLink("Application name", "Index", "Home", new { area = "" }, new { @class =
"navbar-brand" })
            </div>
            <div class="navbar-collapse collapse">
                <ul class="nav navbar-nav">
                    <li>@Html.ActionLink("Home", "Index", "Home")</li>
                    <li>@Html.ActionLink("About", "About", "Home")</li>
                    <li>@Html.ActionLink("Contact", "Contact", "Home")</li>
                </ul>
                @*@Html.Partial("_LoginPartial")*@
            </div>
        </div>
    </div>
    <div class="container body-content">
        @RenderBody()
        <hr />
        <footer>
            <p>&copy; @DateTime.Now.Year - My ASP.NET Application</p>
        </footer>
    </div>

    <script src="https://code.jquery.com/jquery-3.3.1.min.js"></script>
    <script src="https://maxcdn.bootstrapcdn.com/bootstrap/3.3.7/js/bootstrap.min.js"
            integrity="sha384-Tc5IQib027qvyjSMfHjOMaLkfuWVxZxUPnCJA7l2mCWNIpG9mGCD8wGNIcPD7Txa"
            crossorigin="anonymous"></script>
    @RenderSection("scripts", required: false)
</body>
</html>
```

View the site in the browser. It should now load correctly, with the expected styles in place.

- *Optional:* Try using the new layout file. Copy the layout file from the *FullAspNetCore* project. The new layout file uses Tag Helpers and has other improvements.

Configure bundling and minification

For information about how to configure bundling and minification, see Bundling and Minification.

Solve HTTP 500 errors

There are many problems that can cause an HTTP 500 error messages that contain no information on the source of the problem. For example, if the *Views/_ViewImports.cshtml* file contains a namespace that doesn't exist in the

project, a HTTP 500 error is generated. By default in ASP.NET Core apps, the `UseDeveloperExceptionPage` extension is added to the `IApplicationBuilder` and executed when the configuration is *Development*. See an example in the following code:

```
public class Startup
{
    // This method gets called by the runtime. Use this method to add services to the container.
    // For more information on how to configure your application, visit https://go.microsoft.com/fwlink/?
LinkID=398940
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddMvc();
    }

    // This method gets called by the runtime. Use this method to configure the HTTP request pipeline.
    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        app.UseStaticFiles();

        app.UseMvc(routes =>
        {
            routes.MapRoute(
                name: "default",
                template: "{controller=Home}/{action=Index}/{id?}");
        });
    }
}
```

ASP.NET Core converts unhandled exceptions into HTTP 500 error responses. Normally, error details aren't included in these responses to prevent disclosure of potentially sensitive information about the server. For more information, see Developer Exception Page.

- Introduction to ASP.NET Core Blazor
- Tag Helpers in ASP.NET Core

This article shows how to start migrating an ASP.NET MVC project to ASP.NET Core MVC 2.1. In the process, it highlights many of the things that have changed from ASP.NET MVC. Migrating from ASP.NET MVC is a multi-step process. This article covers:

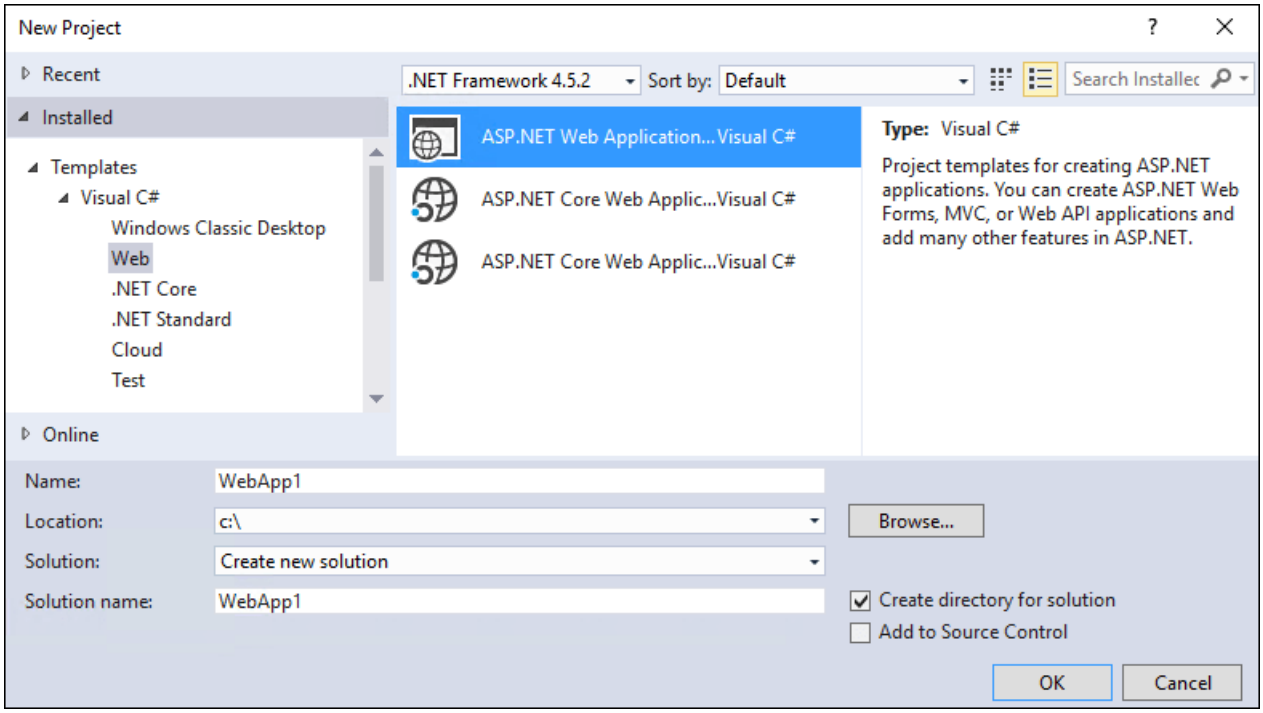
- Initial setup
- Basic controllers and views
- Static content
- Client-side dependencies.

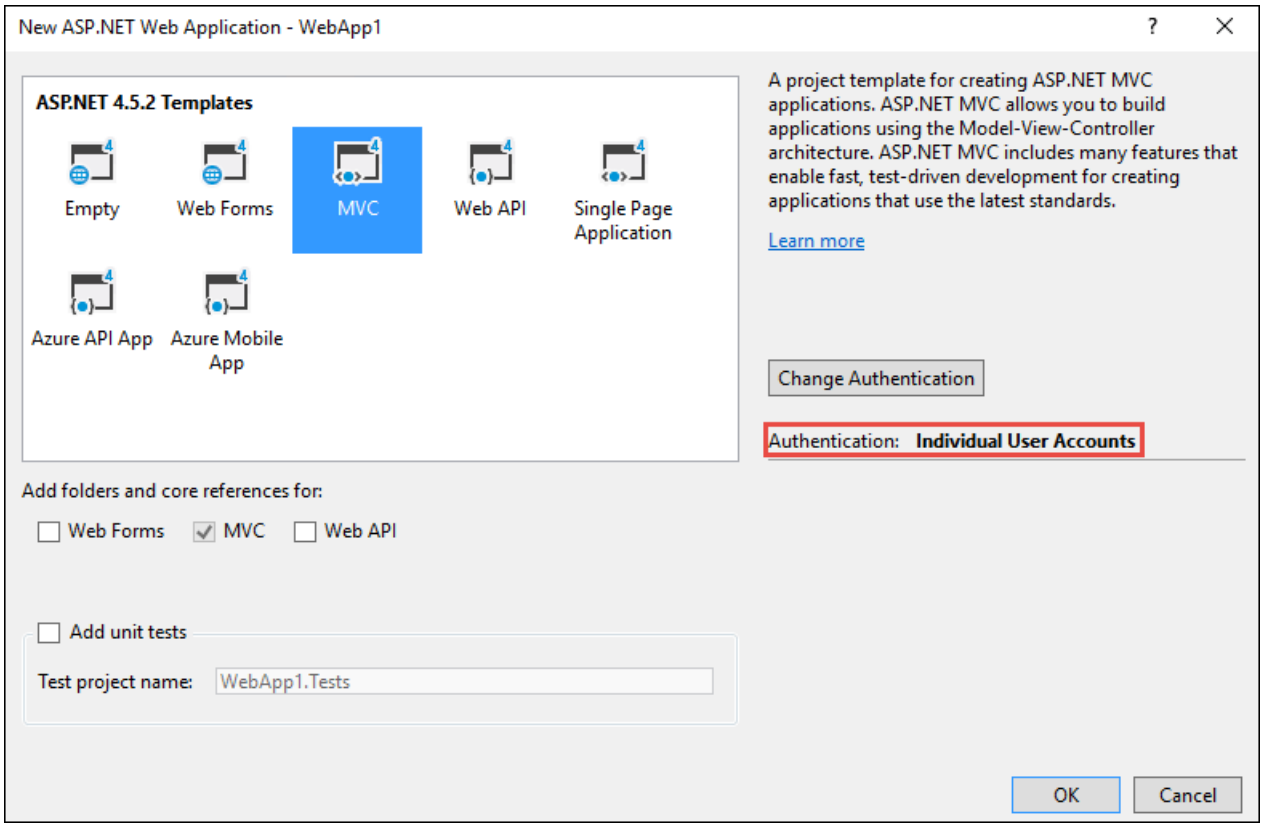
For migrating configuration and Identity code, see Migrate configuration to ASP.NET Core and Migrate Authentication and Identity to ASP.NET Core.

> **NOTE**
> The version numbers in the samples might not be current, update the projects accordingly.

Create the starter ASP.NET MVC project

To demonstrate the upgrade, we'll start by creating a ASP.NET MVC app. Create it with the name *WebApp1* so the namespace matches the ASP.NET Core project created in the next step.

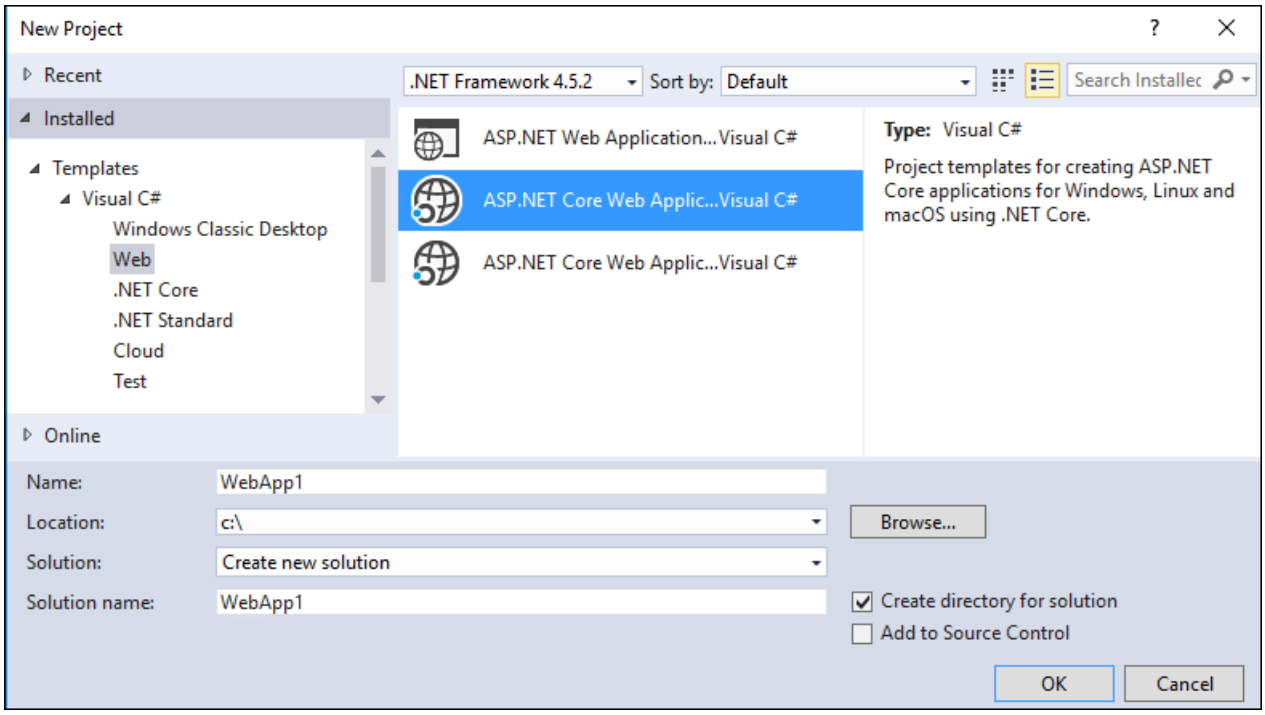


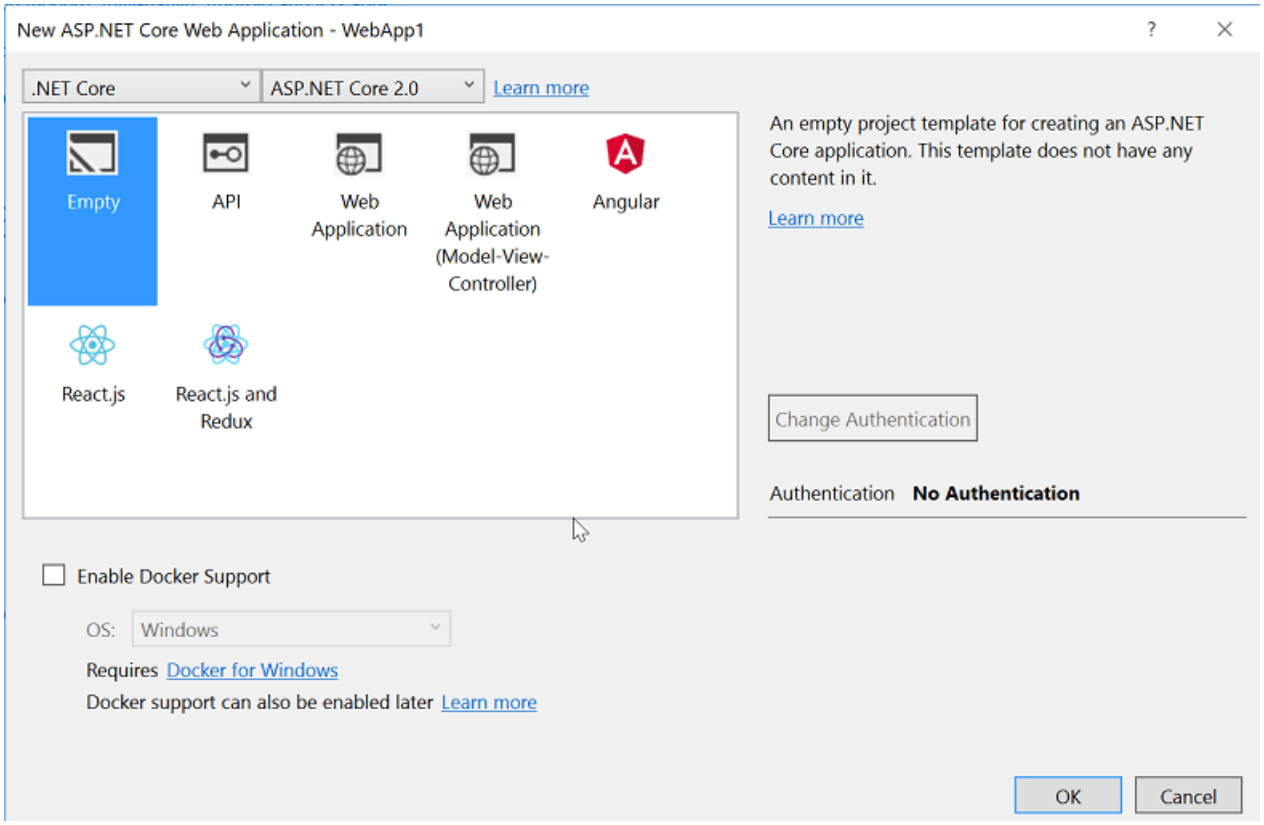


Optional: Change the name of the Solution from *WebApp1* to *Mvc5*. Visual Studio displays the new solution name (*Mvc5*), which makes it easier to tell this project from the next project.

Create the ASP.NET Core project

Create a new *empty* ASP.NET Core web app with the same name as the previous project (*WebApp1*) so the namespaces in the two projects match. Having the same namespace makes it easier to copy code between the two projects. Create this project in a different directory than the previous project to use the same name.





- *Optional:* Create a new ASP.NET Core app using the *Web Application* project template. Name the project *WebApp1*, and select an authentication option of **Individual User Accounts**. Rename this app to *FullAspNetCore*. Creating this project saves time in the conversion. The end result can be viewed in the template-generated code, code can be copied to the conversion project, or compared with the template-generated project.

Configure the site to use MVC

- When targeting .NET Core, the Microsoft.AspNetCore.App metapackage is referenced by default. This package contains packages commonly used by MVC apps. If targeting .NET Framework, package references must be listed individually in the project file.

`Microsoft.AspNetCore.Mvc` is the ASP.NET Core MVC framework. `Microsoft.AspNetCore.StaticFiles` is the static file

handler. ASP.NET Core apps explicitly opt in for middleware, such as for serving static files. For more information, see Static files.

- Open the *Startup.cs* file and change the code to match the following:

```
public class Startup
{
    // This method gets called by the runtime. Use this method to add services to the container.
    // For more information on how to configure your application, visit https://go.microsoft.com/fwlink/?
LinkID=398940
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddMvc();
    }

    // This method gets called by the runtime. Use this method to configure the HTTP request pipeline.
    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        app.UseStaticFiles();

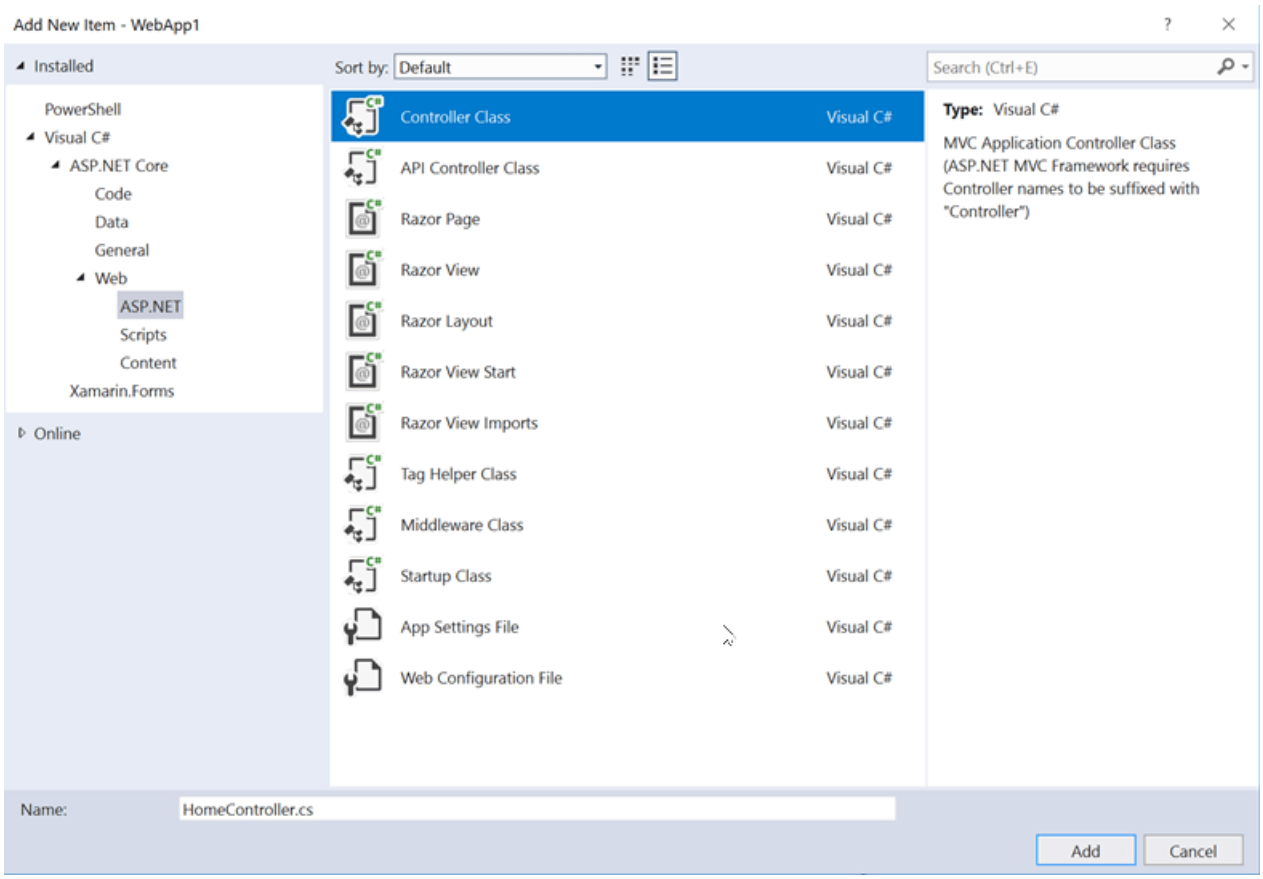
        app.UseMvc(routes =>
        {
            routes.MapRoute(
                name: "default",
                template: "{controller=Home}/{action=Index}/{id?}");
        });
    }
}
```

The UseStaticFiles extension method adds the static file handler. The `UseMvc` extension method adds routing. For more information, see Application Startup and Routing.

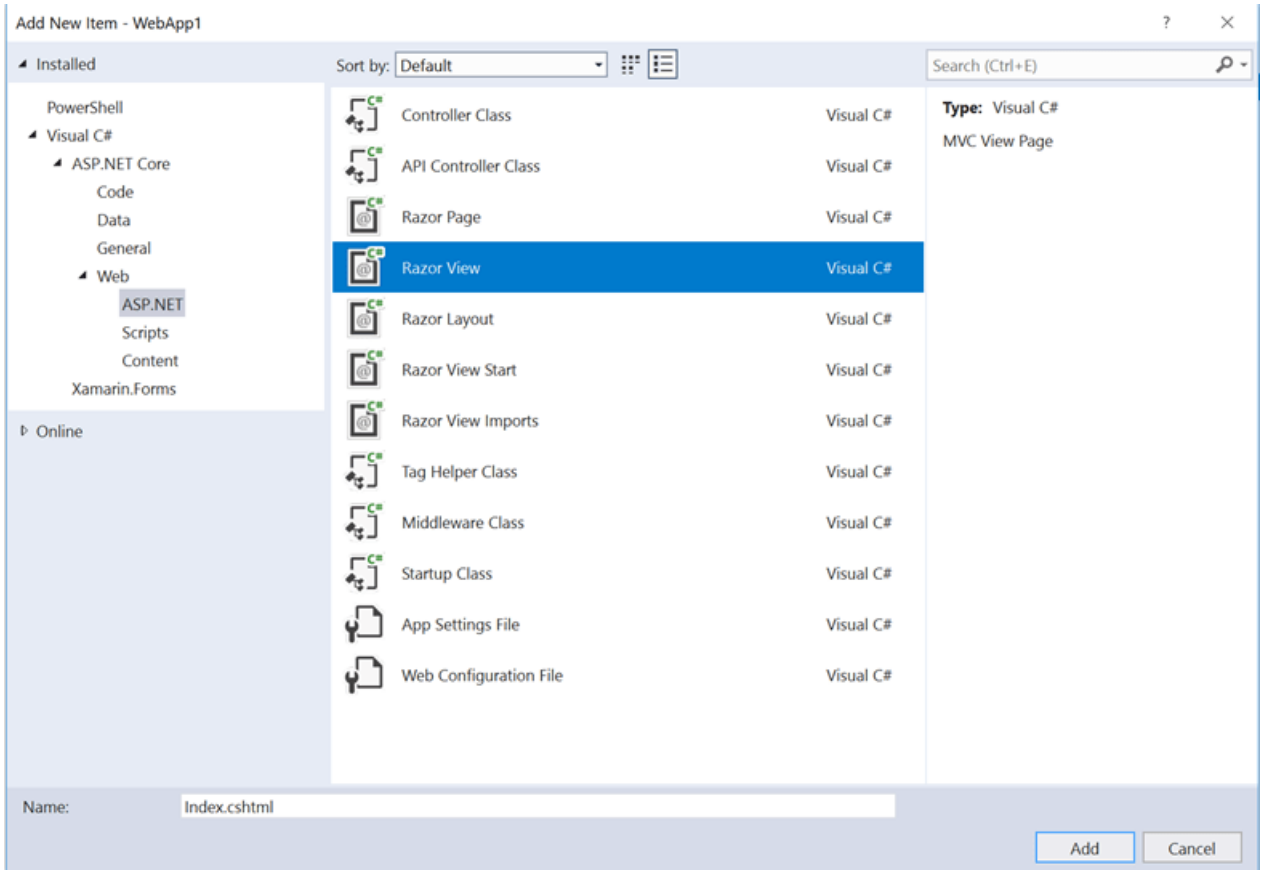
Add a controller and view

In this section, a minimal controller and view are added to serve as placeholders for the ASP.NET MVC controller and views migrated in the next section.

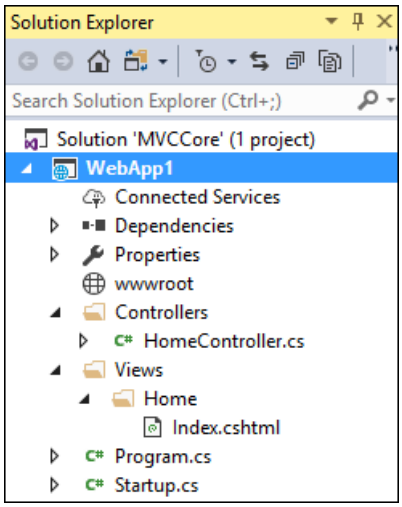
- Add a *Controllers* directory.
- Add a **Controller Class** named *HomeController.cs* to the *Controllers* directory.



- Add a *Views* directory.
- Add a *Views/Home* directory.
- Add a **Razor View** named *Index.cshtml* to the *Views/Home* directory.



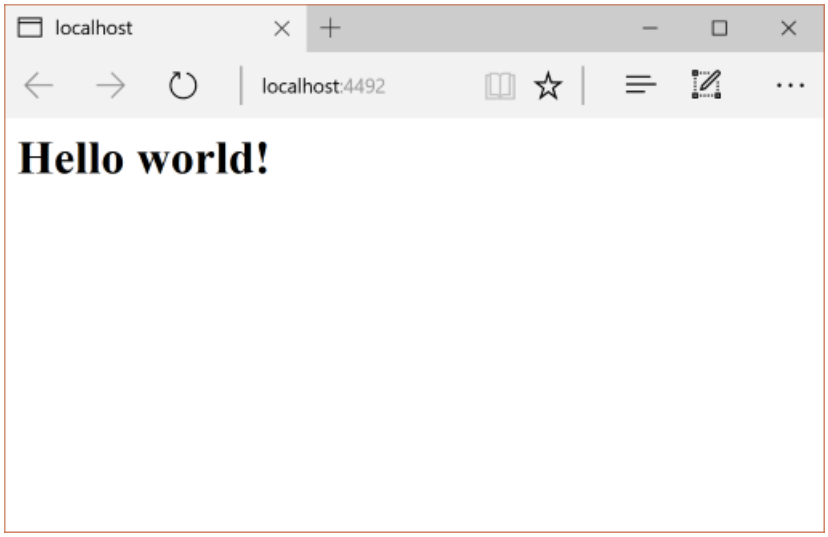
The project structure is shown below:



Replace the contents of the *Views/Home/Index.cshtml* file with the following markup:

```
<h1>Hello world!</h1>
```

Run the app.



For more information, see Controllers and Views.

The following functionality requires migration from the example ASP.NET MVC project to the ASP.NET Core project:

- client-side content (CSS, fonts, and scripts)
- controllers
- views
- models
- bundling
- filters
- Log in/out, Identity (This is done in the next tutorial.)

Controllers and views

- Copy each of the methods from the ASP.NET MVC `HomeController` to the new `HomeController`. In ASP.NET MVC, the built-in template's controller action method return type is

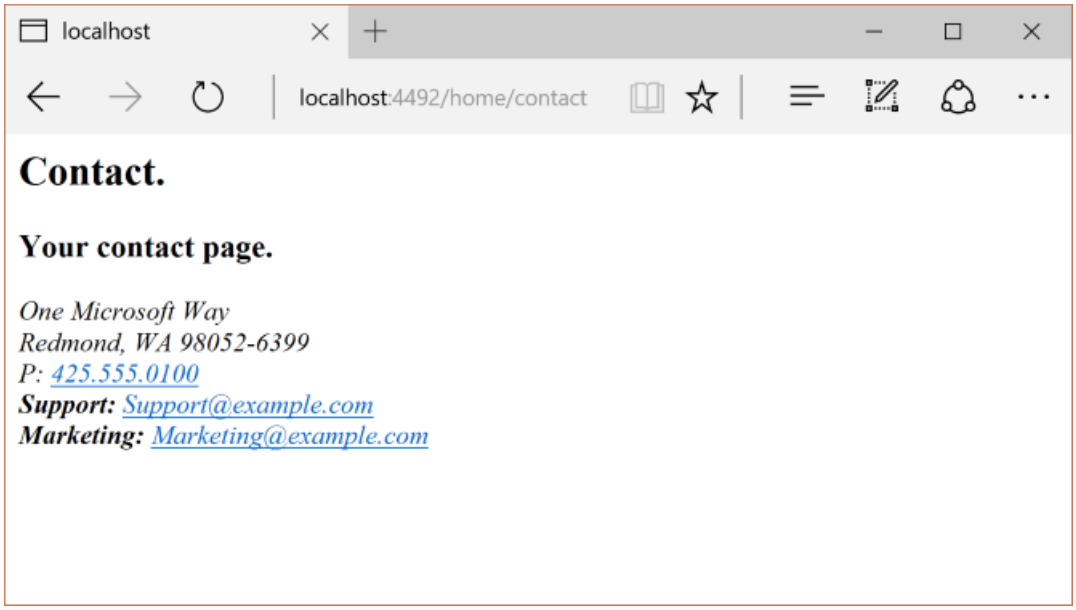
/dotnet/api/system.web.mvc.actionresult?view=aspnet-mvc-5.2; in ASP.NET Core MVC, the action methods return `IActionResult` instead. `ActionResult` implements `IActionResult`, so there's no need to change the return type of the action methods.

- Copy the *About.cshtml*, *Contact.cshtml*, and *Index.cshtml* Razor view files from the ASP.NET MVC project to the ASP.NET Core project.

Test each method

The layout file and styles have not been migrated yet, so the rendered views only contain the content in the view files. The layout file generated links for the `About` and `Contact` views will not be available yet.

- Invoke the rendered views from the browser on the running ASP.NET core app by replacing the current port number with the port number used in the ASP.NET core project. For example: `https://localhost:44375/home/about`.



Note the lack of styling and menu items. The styling will be fixed in the next section.

Static content

In ASP.NET MVC 5 and earlier, static content was hosted from the root of the web project and was intermixed with server-side files. In ASP.NET Core, static content is hosted in the *wwwroot* directory. Copy the static content from the ASP.NET MVC app to the *wwwroot* directory in the ASP.NET Core project. In this sample conversion:

- Copy the *favicon.ico* file from the ASP.NET MVC project to the *wwwroot* directory in the ASP.NET Core project.

The ASP.NET MVC project uses Bootstrap for its styling and stores the Bootstrap files in the *Content* and *Scripts* directories. The template, which generated the ASP.NET MVC project, references Bootstrap in the layout file (*Views/Shared/_Layout.cshtml*). The *bootstrap.js* and *bootstrap.css* files could be copied from the ASP.NET MVC project to the *wwwroot* directory in the new project. Instead, this document adds support for Bootstrap (and other client-side libraries) using CDNs, in the next section.

Migrate the layout file

- Copy the *_ViewStart.cshtml* file from the ASP.NET MVC project's *Views* directory into the ASP.NET Core project's *Views* directory. The *_ViewStart.cshtml* file has not changed in ASP.NET Core MVC.
- Create a *Views/Shared* directory.
- *Optional:* Copy *_ViewImports.cshtml* from the *FullAspNetCore* MVC project's *Views* directory into the

ASP.NET Core project's *Views* directory. Remove any namespace declaration in the *_ViewImports.cshtml* file. The *_ViewImports.cshtml* file provides namespaces for all the view files and brings in Tag Helpers. Tag Helpers are used in the new layout file. The *_ViewImports.cshtml* file is new for ASP.NET Core.

- Copy the *_Layout.cshtml* file from the ASP.NET MVC project's *Views/Shared* directory into the ASP.NET Core project's *Views/Shared* directory.

Open *_Layout.cshtml* file and make the following changes (the completed code is shown below):

- Replace `@Styles.Render("~/Content/css")` with a `<link>` element to load *bootstrap.css* (see below).
- Remove `@Scripts.Render("~/bundles/modernizr")`.
- Comment out the `@Html.Partial("_LoginPartial")` line (surround the line with `@*...*@`). For more information, see Migrate Authentication and Identity to ASP.NET Core
- Replace `@Scripts.Render("~/bundles/jquery")` with a `<script>` element (see below).
- Replace `@Scripts.Render("~/bundles/bootstrap")` with a `<script>` element (see below).

The replacement markup for Bootstrap CSS inclusion:

```
<link rel="stylesheet"
    href="https://maxcdn.bootstrapcdn.com/bootstrap/3.3.7/css/bootstrap.min.css"
    integrity="sha384-BVYiiSIFeK1dGmJRAkycuHAHRg32OmUcww7on3RYdg4Va+PmSTsz/K68vbdEjh4u"
    crossorigin="anonymous">
```

The replacement markup for jQuery and Bootstrap JavaScript inclusion:

```
<script src="https://code.jquery.com/jquery-3.3.1.min.js"></script>
<script src="https://maxcdn.bootstrapcdn.com/bootstrap/3.3.7/js/bootstrap.min.js"
    integrity="sha384-Tc5IQib027qvyjSMfHjOMaLkfuWVxZxUPnCJA7l2mCWNIpG9mGCD8wGNIcPD7Txa"
crossorigin="anonymous"></script>
```

The updated *_Layout.cshtml* file is shown below:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0">
    <title>@ViewBag.Title - My ASP.NET Application</title>
    <link rel="stylesheet"
          href="https://maxcdn.bootstrapcdn.com/bootstrap/3.3.7/css/bootstrap.min.css"
          integrity="sha384-BVYiiSIFeK1dGmJRAkycuHAHRg32OmUcww7on3RYdg4Va+PmSTsz/K68vbdEjh4u"
          crossorigin="anonymous">
</head>
<body>
    <div class="navbar navbar-inverse navbar-fixed-top">
        <div class="container">
            <div class="navbar-header">
                <button type="button" class="navbar-toggle" data-toggle="collapse" data-target=".navbar-
collapse">
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                </button>
                @Html.ActionLink("Application name", "Index", "Home", new { area = "" }, new { @class =
"navbar-brand" })
            </div>
            <div class="navbar-collapse collapse">
                <ul class="nav navbar-nav">
                    <li>@Html.ActionLink("Home", "Index", "Home")</li>
                    <li>@Html.ActionLink("About", "About", "Home")</li>
                    <li>@Html.ActionLink("Contact", "Contact", "Home")</li>
                </ul>
                @*@Html.Partial("_LoginPartial")*@
            </div>
        </div>
    </div>
    <div class="container body-content">
        @RenderBody()
        <hr />
        <footer>
            <p>&copy; @DateTime.Now.Year - My ASP.NET Application</p>
        </footer>
    </div>

    <script src="https://code.jquery.com/jquery-3.3.1.min.js"></script>
    <script src="https://maxcdn.bootstrapcdn.com/bootstrap/3.3.7/js/bootstrap.min.js"
            integrity="sha384-Tc5IQib027qvyjSMfHjOMaLkfuWVxZxUPnCJA7l2mCWNIpG9mGCD8wGNIcPD7Txa"
            crossorigin="anonymous"></script>
    @RenderSection("scripts", required: false)
</body>
</html>
```

View the site in the browser. It should now load correctly, with the expected styles in place.

- *Optional:* Try using the new layout file. Copy the layout file from the *FullAspNetCore* project. The new layout file uses Tag Helpers and has other improvements.

Configure bundling and minification

For information about how to configure bundling and minification, see Bundling and Minification.

Solve HTTP 500 errors

There are many problems that can cause an HTTP 500 error messages that contain no information on the source of the problem. For example, if the *Views/_ViewImports.cshtml* file contains a namespace that doesn't exist in the

project, a HTTP 500 error is generated. By default in ASP.NET Core apps, the `UseDeveloperExceptionPage` extension is added to the `IApplicationBuilder` and executed when the configuration is *Development*. See an example in the following code:

```
public class Startup
{
    // This method gets called by the runtime. Use this method to add services to the container.
    // For more information on how to configure your application, visit https://go.microsoft.com/fwlink/?
LinkID=398940
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddMvc();
    }

    // This method gets called by the runtime. Use this method to configure the HTTP request pipeline.
    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        app.UseStaticFiles();

        app.UseMvc(routes =>
        {
            routes.MapRoute(
                name: "default",
                template: "{controller=Home}/{action=Index}/{id?}");
        });
    }
}
```

ASP.NET Core converts unhandled exceptions into HTTP 500 error responses. Normally, error details aren't included in these responses to prevent disclosure of potentially sensitive information about the server. For more information, see Developer Exception Page.

Migrate from ASP.NET Web API to ASP.NET Core

9/22/2020 • 10 minutes to read • Edit Online

By Scott Addie and Steve Smith

An ASP.NET 4.x Web API is an HTTP service that reaches a broad range of clients, including browsers and mobile devices. ASP.NET Core combines ASP.NET 4.x's MVC and Web API app models into a single programming model known as ASP.NET Core MVC. This article demonstrates the steps required to migrate from ASP.NET 4.x Web API to ASP.NET Core MVC.

View or download sample code (how to download)

Prerequisites

- Visual Studio 2019 16.4 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

Review ASP.NET 4.x Web API project

This article uses the *ProductsApp* project created in Getting Started with ASP.NET Web API 2. In that project, a basic ASP.NET 4.x Web API project is configured as follows.

In *Global.asax.cs*, a call is made to `WebApiConfig.Register`:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Http;
using System.Web.Routing;

namespace ProductsApp
{
    public class WebApiApplication : System.Web.HttpApplication
    {
        protected void Application_Start()
        {
            GlobalConfiguration.Configure(WebApiConfig.Register);
        }
    }
}
```

The `WebApiConfig` class is found in the *App_Start* folder and has a static `Register` method:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web.Http;

namespace ProductsApp
{
    public static class WebApiConfig
    {
        public static void Register(HttpConfiguration config)
        {
            // Web API configuration and services

            // Web API routes
            config.MapHttpAttributeRoutes();

            config.Routes.MapHttpRoute(
                name: "DefaultApi",
                routeTemplate: "api/{controller}/{id}",
                defaults: new { id = RouteParameter.Optional }
            );
        }
    }
}
```

The preceding class:

- Configures attribute routing, although it's not actually being used.
- Configures the routing table. The sample code expects URLs to match the format `/api/{controller}/{id}`, with `{id}` being optional.

The following sections demonstrate migration of the Web API project to ASP.NET Core MVC.

Create the destination project

Create a new blank solution in Visual Studio and add the ASP.NET 4.x Web API project to migrate:

1. From the **File** menu, select **New** > **Project**.
2. Select the **Blank Solution** template and select **Next**.
3. Name the solution *WebAPIMigration*. Select **Create**.
4. Add the existing *ProductsApp* project to the solution.

Add a new API project to migrate to:

1. Add a new **ASP.NET Core Web Application** project to the solution.
2. In the **Configure your new project** dialog, Name the project *ProductsCore*, and select **Create**.
3. In the **Create a new ASP.NET Core Web Application** dialog, confirm that **.NET Core** and **ASP.NET Core 3.1** are selected. Select the **API** project template, and select **Create**.
4. Remove the *WeatherForecast.cs* and *Controllers/WeatherForecastController.cs* example files from the new *ProductsCore* project.

The solution now contains two projects. The following sections explain migrating the *ProductsApp* project's contents to the *ProductsCore* project.

Migrate configuration

ASP.NET Core doesn't use the *App_Start* folder or the *Global.asax* file. Additionally, the *web.config* file is added at publish time.

The `Startup` class:

- Replaces *Global.asax*.
- Handles all app startup tasks.

For more information, see App startup in ASP.NET Core.

Migrate models and controllers

The following code shows the `ProductsController` to be updated for ASP.NET Core:

```
using ProductsApp.Models;
using System;
using System.Collections.Generic;
using System.Linq;
using System.Net;
using System.Web.Http;

namespace ProductsApp.Controllers
{
    public class ProductsController : ApiController
    {
        Product[] products = new Product[]
        {
            new Product
            {
                Id = 1, Name = "Tomato Soup", Category = "Groceries", Price = 1
            },
            new Product
            {
                Id = 2, Name = "Yo-yo", Category = "Toys", Price = 3.75M
            },
            new Product
            {
                Id = 3, Name = "Hammer", Category = "Hardware", Price = 16.99M
            }
        };

        public IEnumerable<Product> GetAllProducts()
        {
            return products;
        }

        public IHttpActionResult GetProduct(int id)
        {
            var product = products.FirstOrDefault((p) => p.Id == id);
            if (product == null)
            {
                return NotFound();
            }
            return Ok(product);
        }
    }
}
```

Update the `ProductsController` for ASP.NET Core:

1. Copy *Controllers/ProductsController.cs* and the *Models* folder from the original project to the new one.
2. Change the copied files' root namespace to `ProductsCore`.
3. Update the `using ProductsApp.Models;` statement to `using ProductsCore.Models;`.

The following components don't exist in ASP.NET Core:

- `ApiController` class
- `System.Web.Http` namespace
- `IHttpActionResult` interface

Make the following changes:

1. Change `ApiController` to ControllerBase. Add `using Microsoft.AspNetCore.Mvc;` to resolve the `ControllerBase` reference.
2. Delete `using System.Web.Http;`.
3. Change the `GetProduct` action's return type from `IHttpActionResult` to `ActionResult<Product>`.
4. Simplify the `GetProduct` action's `return` statement to the following:

```
return product;
```

Configure routing

The ASP.NET Core *API* project template includes endpoint routing configuration in the generated code.

The following UseRouting and UseEndpoints calls:

- Register route matching and endpoint execution in the middleware pipeline.
- Replace the *ProductsApp* project's *App_Start/WebApiConfig.cs* file.

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    app.UseHttpsRedirection();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
    });
}
```

Configure routing as follows:

1. Mark the `ProductsController` class with the following attributes:

   ```
   [Route("api/[controller]")]
   [ApiController]
   ```

   The preceding `[Route]` attribute configures the controller's attribute routing pattern. The `[ApiController]` attribute makes attribute routing a requirement for all actions in this controller.

   Attribute routing supports tokens, such as `[controller]` and `[action]`. At runtime, each token is replaced with the name of the controller or action, respectively, to which the attribute has been applied. The tokens:

- Reduce the number of magic strings in the project.
- Ensure routes remain synchronized with the corresponding controllers and actions when automatic rename refactorings are applied.

2. Enable HTTP Get requests to the `ProductController` actions:

   - Apply the `[HttpGet]` attribute to the `GetAllProducts` action.
   - Apply the `[HttpGet("{id}")]` attribute to the `GetProduct` action.

Run the migrated project, and browse to `/api/products`. A full list of three products appears. Browse to `/api/products/1`. The first product appears.

Additional resources

- Create web APIs with ASP.NET Core
- Controller action return types in ASP.NET Core web API
- Compatibility version for ASP.NET Core MVC

Prerequisites

- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core SDK 2.2 or later

> **WARNING**
> If you use Visual Studio 2017, see dotnet/sdk issue #3124 for information about .NET Core SDK versions that don't work with Visual Studio.

Review ASP.NET 4.x Web API project

This article uses the *ProductsApp* project created in Getting Started with ASP.NET Web API 2. In that project, a basic ASP.NET 4.x Web API project is configured as follows.

In *Global.asax.cs*, a call is made to `WebApiConfig.Register`:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Http;
using System.Web.Routing;

namespace ProductsApp
{
    public class WebApiApplication : System.Web.HttpApplication
    {
        protected void Application_Start()
        {
            GlobalConfiguration.Configure(WebApiConfig.Register);
        }
    }
}
```

The `WebApiConfig` class is found in the *App_Start* folder and has a static `Register` method:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web.Http;

namespace ProductsApp
{
    public static class WebApiConfig
    {
        public static void Register(HttpConfiguration config)
        {
            // Web API configuration and services

            // Web API routes
            config.MapHttpAttributeRoutes();

            config.Routes.MapHttpRoute(
                name: "DefaultApi",
                routeTemplate: "api/{controller}/{id}",
                defaults: new { id = RouteParameter.Optional }
            );
        }
    }
}
```

This class configures attribute routing, although it's not actually being used in the project. It also configures the routing table, which is used by ASP.NET Web API. In this case, ASP.NET 4.x Web API expects URLs to match the format `/api/{controller}/{id}`, with `{id}` being optional.

The following sections demonstrate migration of the Web API project to ASP.NET Core MVC.

Create the destination project

Complete the following steps in Visual Studio:

- Go to **File** > **New** > **Project** > **Other Project Types** > **Visual Studio Solutions**. Select **Blank Solution**, and name the solution *WebAPIMigration*. Click the **OK** button.
- Add the existing *ProductsApp* project to the solution.
- Add a new **ASP.NET Core Web Application** project to the solution. Select the **.NET Core** target framework from the drop-down, and select the **API** project template. Name the project *ProductsCore*, and click the **OK** button.

The solution now contains two projects. The following sections explain migrating the *ProductsApp* project's contents to the *ProductsCore* project.

Migrate configuration

ASP.NET Core doesn't use:

- *App_Start* folder or the *Global.asax* file
- *web.config* file is added at publish time.

The `Startup` class:

- Replaces *Global.asax*.
- Handles all app startup tasks.

For more information, see App startup in ASP.NET Core.

In ASP.NET Core MVC, attribute routing is included by default when UseMvc is called in `Startup.Configure`. The

following `UseMvc` call replaces the *ProductsApp* project's *App_Start/WebApiConfig.cs* file:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseMvc();
}
```

Migrate models and controllers

The following code shows the `ProductsController` update for ASP.NET Core:

```
using ProductsApp.Models;
using System;
using System.Collections.Generic;
using System.Linq;
using System.Net;
using System.Web.Http;

namespace ProductsApp.Controllers
{
    public class ProductsController : ApiController
    {
        Product[] products = new Product[]
        {
            new Product
            {
                Id = 1, Name = "Tomato Soup", Category = "Groceries", Price = 1
            },
            new Product
            {
                Id = 2, Name = "Yo-yo", Category = "Toys", Price = 3.75M
            },
            new Product
            {
                Id = 3, Name = "Hammer", Category = "Hardware", Price = 16.99M
            }
        };

        public IEnumerable<Product> GetAllProducts()
        {
            return products;
        }

        public IHttpActionResult GetProduct(int id)
        {
            var product = products.FirstOrDefault((p) => p.Id == id);
            if (product == null)
            {
                return NotFound();
            }
            return Ok(product);
        }
    }
}
```

Update the `ProductsController` for ASP.NET Core:

1. Copy *Controllers/ProductsController.cs* from the original project to the new one.
2. Copy the *Models* folder from the original project to the new one.
3. Change the copied files' root namespace to `ProductsCore`.
4. Update the `using ProductsApp.Models;` statement to `using ProductsCore.Models;`.

The following components don't exist in ASP.NET Core:

- `ApiController` class
- `System.Web.Http` namespace
- `IHttpActionResult` interface

Make the following changes:

1. Change `ApiController` to ControllerBase. Add `using Microsoft.AspNetCore.Mvc;` to resolve the `ControllerBase` reference.
2. Delete `using System.Web.Http;`.

3. Change the `GetProduct` action's return type from `IHttpActionResult` to `ActionResult<Product>`.
4. Simplify the `GetProduct` action's `return` statement to the following:

```
return product;
```

Configure routing

Configure routing as follows:

1. Mark the `ProductsController` class with the following attributes:

```
[Route("api/[controller]")]
[ApiController]
```

   The preceding `[Route]` attribute configures the controller's attribute routing pattern. The `[ApiController]` attribute makes attribute routing a requirement for all actions in this controller.

   Attribute routing supports tokens, such as `[controller]` and `[action]`. At runtime, each token is replaced with the name of the controller or action, respectively, to which the attribute has been applied. The tokens reduce the number of magic strings in the project. The tokens also ensure routes remain synchronized with the corresponding controllers and actions when automatic rename refactorings are applied.

2. Set the project's compatibility mode to ASP.NET Core 2.2:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

   The preceding change:

   - Is required to use the `[ApiController]` attribute at the controller level.
   - Opts in to potentially breaking behaviors introduced in ASP.NET Core 2.2.

3. Enable HTTP Get requests to the `ProductController` actions:

   - Apply the `[HttpGet]` attribute to the `GetAllProducts` action.
   - Apply the `[HttpGet("{id}")]` attribute to the `GetProduct` action.

Run the migrated project, and browse to `/api/products`. A full list of three products appears. Browse to `/api/products/1`. The first product appears.

Compatibility shim

The Microsoft.AspNetCore.Mvc.WebApiCompatShim library provides a compatibility shim to move ASP.NET 4.x Web API projects to ASP.NET Core. The compatibility shim extends ASP.NET Core to support a number of conventions from ASP.NET 4.x Web API 2. The sample ported previously in this document is basic enough that the compatibility shim was unnecessary. For larger projects, using the compatibility shim can be useful for temporarily bridging the API gap between ASP.NET Core and ASP.NET 4.x Web API 2.

The Web API compatibility shim is meant to be used as a temporary measure to support migrating large ASP.NET 4.x Web API projects to ASP.NET Core. Over time, projects should be updated to use ASP.NET Core patterns instead of relying on the compatibility shim.

Compatibility features included in `Microsoft.AspNetCore.Mvc.WebApiCompatShim` include:

- Adds an `ApiController` type so that controllers' base types don't need to be updated.
- Enables Web API-style model binding. ASP.NET Core MVC model binding functions similarly to that of ASP.NET 4.x MVC 5, by default. The compatibility shim changes model binding to be more similar to ASP.NET 4.x Web API 2 model binding conventions. For example, complex types are automatically bound from the request body.
- Extends model binding so that controller actions can take parameters of type `HttpRequestMessage`.
- Adds message formatters allowing actions to return results of type `HttpResponseMessage`.
- Adds additional response methods that Web API 2 actions may have used to serve responses:
  - `HttpResponseMessage` generators:
    - `CreateResponse<T>`
    - `CreateErrorResponse`
  - Action result methods:
    - `BadRequestErrorMessageResult`
    - `ExceptionResult`
    - `InternalServerErrorResult`
    - `InvalidModelStateResult`
    - `NegotiatedContentResult`
    - `ResponseMessageResult`
- Adds an instance of `IContentNegotiator` to the app's dependency injection (DI) container and makes available the content negotiation-related types from Microsoft.AspNet.WebApi.Client. Examples of such types include `DefaultContentNegotiator` and `MediaTypeFormatter`.

To use the compatibility shim:

1. Install the Microsoft.AspNetCore.Mvc.WebApiCompatShim NuGet package.
2. Register the compatibility shim's services with the app's DI container by calling `services.AddMvc().AddWebApiConventions()` in `Startup.ConfigureServices`.
3. Define web API-specific routes using `MapWebApiRoute` on the `IRouteBuilder` in the app's `IApplicationBuilder.UseMvc` call.

Migrate configuration to ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

By Steve Smith and Scott Addie

In the previous article, we began to migrate an ASP.NET MVC project to ASP.NET Core MVC. In this article, we migrate configuration.

View or download sample code (how to download)

Setup configuration

ASP.NET Core no longer uses the *Global.asax* and *web.config* files that previous versions of ASP.NET utilized. In the earlier versions of ASP.NET, application startup logic was placed in an `Application_StartUp` method within *Global.asax*. Later, in ASP.NET MVC, a *Startup.cs* file was included in the root of the project; and, it was called when the application started. ASP.NET Core has adopted this approach completely by placing all startup logic in the *Startup.cs* file.

The *web.config* file has also been replaced in ASP.NET Core. Configuration itself can now be configured, as part of the application startup procedure described in *Startup.cs*. Configuration can still utilize XML files, but typically ASP.NET Core projects will place configuration values in a JSON-formatted file, such as *appsettings.json*. ASP.NET Core's configuration system can also easily access environment variables, which can provide a more secure and robust location for environment-specific values. This is especially true for secrets like connection strings and API keys that shouldn't be checked into source control. See Configuration to learn more about configuration in ASP.NET Core.

For this article, we are starting with the partially migrated ASP.NET Core project from the previous article. To setup configuration, add the following constructor and property to the *Startup.cs* file located in the root of the project:

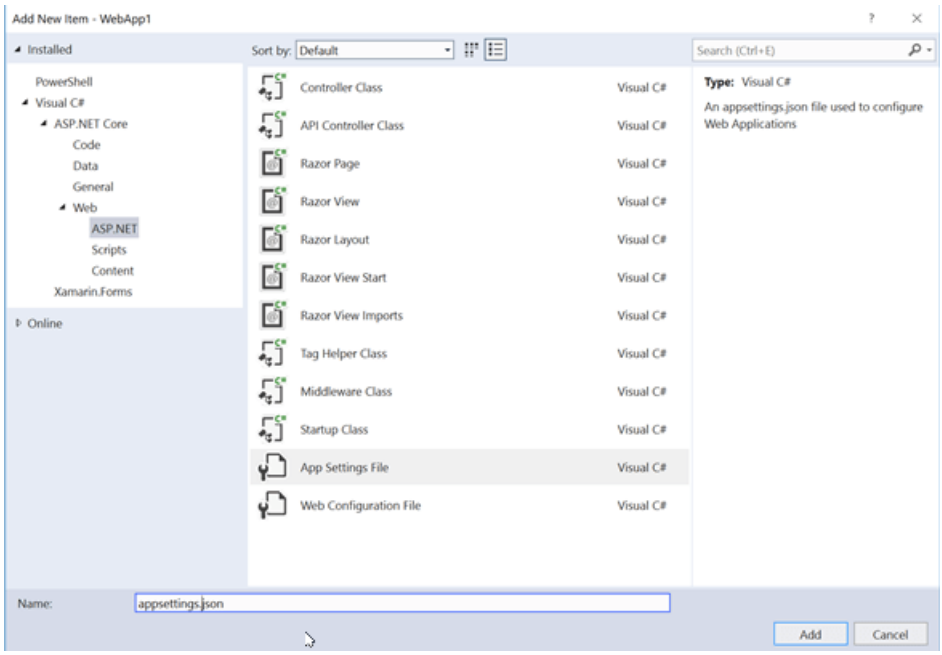
```
public Startup(IConfiguration configuration)
{
    Configuration = configuration;
}

public IConfiguration Configuration { get; }
```

Note that at this point, the *Startup.cs* file won't compile, as we still need to add the following `using` statement:

```
using Microsoft.Extensions.Configuration;
```

Add an *appsettings.json* file to the root of the project using the appropriate item template:



Migrate configuration settings from web.config

Our ASP.NET MVC project included the required database connection string in *web.config*, in the `<connectionStrings>` element. In our ASP.NET Core project, we are going to store this information in the *appsettings.json* file. Open *appsettings.json*, and note that it already includes the following:

```
{
    "Data": {
        "DefaultConnection": {
            "ConnectionString": "Server=(localdb)\\MSSQLLocalDB;Database=_CHANGE_ME;Trusted_Connection=True;"
        }
    }
}
```

In the highlighted line depicted above, change the name of the database from **_CHANGE_ME** to the name of your database.

Summary

ASP.NET Core places all startup logic for the application in a single file, in which the necessary services and dependencies can be defined and configured. It replaces the *web.config* file with a flexible configuration feature that can leverage a variety of file formats, such as JSON, as well as environment variables.

Migrate Authentication and Identity to ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

By Steve Smith

In the previous article, we migrated configuration from an ASP.NET MVC project to ASP.NET Core MVC. In this article, we migrate the registration, login, and user management features.

Configure Identity and Membership

In ASP.NET MVC, authentication and identity features are configured using ASP.NET Identity in *Startup.Auth.cs* and *IdentityConfig.cs*, located in the *App_Start* folder. In ASP.NET Core MVC, these features are configured in *Startup.cs*.

Install the following NuGet packages:

- `Microsoft.AspNetCore.Identity.EntityFrameworkCore`
- `Microsoft.AspNetCore.Authentication.Cookies`
- `Microsoft.EntityFrameworkCore.SqlServer`

In *Startup.cs*, update the `Startup.ConfigureServices` method to use Entity Framework and Identity services:

```
public void ConfigureServices(IServiceCollection services)
{
    // Add EF services to the services container.
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(Configuration.GetConnectionString("DefaultConnection")));

    services.AddIdentity<ApplicationUser, IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultTokenProviders();

     services.AddMvc();
}
```

At this point, there are two types referenced in the above code that we haven't yet migrated from the ASP.NET MVC project: `ApplicationDbContext` and `ApplicationUser`. Create a new *Models* folder in the ASP.NET Core project, and add two classes to it corresponding to these types. You will find the ASP.NET MVC versions of these classes in */Models/IdentityModels.cs*, but we will use one file per class in the migrated project since that's more clear.

ApplicationUser.cs:

```
using Microsoft.AspNetCore.Identity.EntityFrameworkCore;

namespace NewMvcProject.Models
{
  public class ApplicationUser : IdentityUser
  {
  }
}
```

ApplicationDbContext.cs:

```
using Microsoft.AspNetCore.Identity.EntityFrameworkCore;
using Microsoft.Data.Entity;

namespace NewMvcProject.Models
{
    public class ApplicationDbContext : IdentityDbContext<ApplicationUser>
    {
        public ApplicationDbContext(DbContextOptions<ApplicationDbContext> options)
            : base(options)
        {
        }

        protected override void OnModelCreating(ModelBuilder builder)
        {
            base.OnModelCreating(builder);
            // Customize the ASP.NET Core Identity model and override the defaults if needed.
            // For example, you can rename the ASP.NET Core Identity table names and more.
            // Add your customizations after calling base.OnModelCreating(builder);
        }
    }
}
```

The ASP.NET Core MVC Starter Web project doesn't include much customization of users, or the `ApplicationDbContext`. When migrating a real app, you also need to migrate all of the custom properties and methods of your app's user and `DbContext` classes, as well as any other Model classes your app utilizes. For example, if your `DbContext` has a `DbSet<Album>`, you need to migrate the `Album` class.

With these files in place, the *Startup.cs* file can be made to compile by updating its `using` statements:

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Hosting;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
```

Our app is now ready to support authentication and Identity services. It just needs to have these features exposed to users.

Migrate registration and login logic

With Identity services configured for the app and data access configured using Entity Framework and SQL Server, we're ready to add support for registration and login to the app. Recall that earlier in the migration process we commented out a reference to *_LoginPartial* in *_Layout.cshtml*. Now it's time to return to that code, uncomment it, and add in the necessary controllers and views to support login functionality.

Uncomment the `@Html.Partial` line in *_Layout.cshtml*:

```
      <li>@Html.ActionLink("Contact", "Contact", "Home")</li>
    </ul>
    @*@Html.Partial("_LoginPartial")*@
  </div>
</div>
```

Now, add a new Razor view called *_LoginPartial* to the *Views/Shared* folder:

Update *_LoginPartial.cshtml* with the following code (replace all of its contents):

```
@inject SignInManager<ApplicationUser> SignInManager
@inject UserManager<ApplicationUser> UserManager

@if (SignInManager.IsSignedIn(User))
{
    <form asp-area="" asp-controller="Account" asp-action="Logout" method="post" id="logoutForm"
class="navbar-right">
        <ul class="nav navbar-nav navbar-right">
            <li>
                <a asp-area="" asp-controller="Manage" asp-action="Index" title="Manage">Hello
@UserManager.GetUserName(User)!</a>
            </li>
            <li>
                <button type="submit" class="btn btn-link navbar-btn navbar-link">Log out</button>
            </li>
        </ul>
    </form>
}
else
{
    <ul class="nav navbar-nav navbar-right">
        <li><a asp-area="" asp-controller="Account" asp-action="Register">Register</a></li>
        <li><a asp-area="" asp-controller="Account" asp-action="Login">Log in</a></li>
    </ul>
}
```

At this point, you should be able to refresh the site in your browser.

Summary

ASP.NET Core introduces changes to the ASP.NET Identity features. In this article, you have seen how to migrate the authentication and user management features of ASP.NET Identity to ASP.NET Core.

Migrate from ClaimsPrincipal.Current

9/22/2020 • 2 minutes to read • Edit Online

In ASP.NET 4.x projects, it was common to use ClaimsPrincipal.Current to retrieve the current authenticated user's identity and claims. In ASP.NET Core, this property is no longer set. Code that was depending on it needs to be updated to get the current authenticated user's identity through a different means.

Context-specific state instead of static state

When using ASP.NET Core, the values of both `ClaimsPrincipal.Current` and `Thread.CurrentPrincipal` aren't set. These properties both represent static state, which ASP.NET Core generally avoids. Instead, ASP.NET Core uses dependency injection (DI) to provide dependencies such as the current user's identity. Getting the current user's identity from DI is more testable, too, since test identities can be easily injected.

Retrieve the current user in an ASP.NET Core app

There are several options for retrieving the current authenticated user's `ClaimsPrincipal` in ASP.NET Core in place of `ClaimsPrincipal.Current`:

- **ControllerBase.User**. MVC controllers can access the current authenticated user with their User property.
- **HttpContext.User**. Components with access to the current `HttpContext` (middleware, for example) can get the current user's `ClaimsPrincipal` from HttpContext.User.
- **Passed in from caller**. Libraries without access to the current `HttpContext` are often called from controllers or middleware components and can have the current user's identity passed as an argument.
- **IHttpContextAccessor**. The project being migrated to ASP.NET Core may be too large to easily pass the current user's identity to all necessary locations. In such cases, IHttpContextAccessor can be used as a workaround. `IHttpContextAccessor` is able to access the current `HttpContext` (if one exists). If DI is being used, see Access HttpContext in ASP.NET Core. A short-term solution to getting the current user's identity in code that hasn't yet been updated to work with ASP.NET Core's DI-driven architecture would be:
  - Make `IHttpContextAccessor` available in the DI container by calling AddHttpContextAccessor in `Startup.ConfigureServices`.
  - Get an instance of `IHttpContextAccessor` during startup and store it in a static variable. The instance is made available to code that was previously retrieving the current user from a static property.
  - Retrieve the current user's `ClaimsPrincipal` using `HttpContextAccessor.HttpContext?.User`. If this code is used outside of the context of an HTTP request, the `HttpContext` is null.

The final option, using an `IHttpContextAccessor` instance stored in a static variable, is contrary to the ASP.NET Core principle of preferring injected dependencies to static dependencies. Plan to eventually retrieve `IHttpContextAccessor` instances from DI instead. A static helper can be a useful bridge, though, when migrating large existing ASP.NET apps that use `ClaimsPrincipal.Current`.

Migrate from ASP.NET Membership authentication to ASP.NET Core 2.0 Identity

9/22/2020 • 6 minutes to read • Edit Online

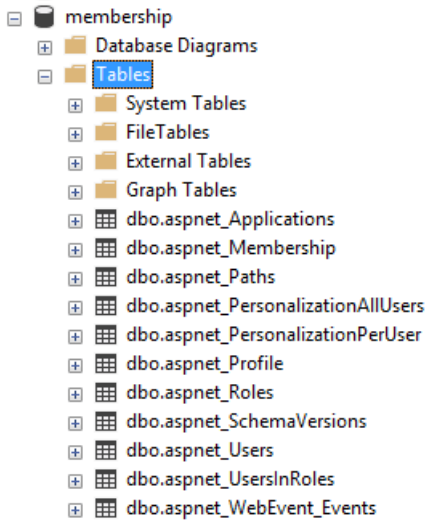
By Isaac Levin

This article demonstrates migrating the database schema for ASP.NET apps using Membership authentication to ASP.NET Core 2.0 Identity.

> **NOTE**
> This document provides the steps needed to migrate the database schema for ASP.NET Membership-based apps to the database schema used for ASP.NET Core Identity. For more information about migrating from ASP.NET Membership-based authentication to ASP.NET Identity, see Migrate an existing app from SQL Membership to ASP.NET Identity. For more information about ASP.NET Core Identity, see Introduction to Identity on ASP.NET Core.

Review of Membership schema

Prior to ASP.NET 2.0, developers were tasked with creating the entire authentication and authorization process for their apps. With ASP.NET 2.0, Membership was introduced, providing a boilerplate solution to handling security within ASP.NET apps. Developers were now able to bootstrap a schema into a SQL Server database with the /previous-versions/ms229862(v=vs.140) command. After running this command, the following tables were created in the database.



To migrate existing apps to ASP.NET Core 2.0 Identity, the data in these tables needs to be migrated to the tables used by the new Identity schema.

ASP.NET Core Identity 2.0 schema

ASP.NET Core 2.0 follows the Identity principle introduced in ASP.NET 4.5. Though the principle is shared, the implementation between the frameworks is different, even between versions of ASP.NET Core (see Migrate authentication and Identity to ASP.NET Core 2.0).

The fastest way to view the schema for ASP.NET Core 2.0 Identity is to create a new ASP.NET Core 2.0 app. Follow these steps in Visual Studio 2017:

1. Select **File** > **New** > **Project**.
2. Create a new **ASP.NET Core Web Application** project named *CoreIdentitySample*.
3. Select **ASP.NET Core 2.0** in the dropdown and then select **Web Application**. This template produces a Razor Pages app. Before clicking **OK**, click **Change Authentication**.
4. Choose **Individual User Accounts** for the Identity templates. Finally, click **OK**, then **OK**. Visual Studio creates a project using the ASP.NET Core Identity template.
5. Select **Tools** > **NuGet Package Manager** > **Package Manager Console** to open the **Package Manager Console** (PMC) window.
6. Navigate to the project root in PMC, and run the Entity Framework (EF) Core `Update-Database` command.

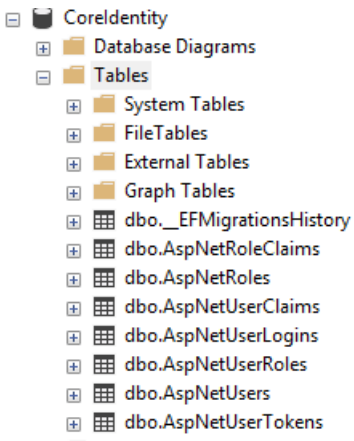
   ASP.NET Core 2.0 Identity uses EF Core to interact with the database storing the authentication data. In order for the newly created app to work, there needs to be a database to store this data. After creating a new app, the fastest way to inspect the schema in a database environment is to create the database using EF Core Migrations. This process creates a database, either locally or elsewhere, which mimics that schema. Review the preceding documentation for more information.

   EF Core commands use the connection string for the database specified in *appsettings.json*. The following connection string targets a database on *localhost* named *asp-net-core-identity*. In this setting, EF Core is configured to use the `DefaultConnection` connection string.

   ```
   {
     "ConnectionStrings": {
       "DefaultConnection": "Server=localhost;Database=aspnet-core-
   identity;Trusted_Connection=True;MultipleActiveResultSets=true"
     }
   }
   ```

7. Select **View** > **SQL Server Object Explorer**. Expand the node corresponding to the database name specified in the `ConnectionStrings:DefaultConnection` property of *appsettings.json*.

   The `Update-Database` command created the database specified with the schema and any data needed for app initialization. The following image depicts the table structure that's created with the preceding steps.



Migrate the schema

There are subtle differences in the table structures and fields for both Membership and ASP.NET Core Identity. The pattern has changed substantially for authentication/authorization with ASP.NET and ASP.NET Core apps. The key objects that are still used with Identity are *Users* and *Roles*. Here are mapping tables for *Users*, *Roles*, and *UserRoles*.

Users

IDENTITY (`dbo.AspNetUsers`) COLUMN	TYPE	MEMBERSHIP (`dbo.aspnet_Users` / `dbo.aspnet_Membership`) COLUMN	TYPE
`Id`	`string`	`aspnet_Users.UserId`	`string`
`UserName`	`string`	`aspnet_Users.UserName`	`string`
`Email`	`string`	`aspnet_Membership.Email`	`string`
`NormalizedUserName`	`string`	`aspnet_Users.LoweredUserName`	`string`
`NormalizedEmail`	`string`	`aspnet_Membership.LoweredEmai`	`string`
`PhoneNumber`	`string`	`aspnet_Users.MobileAlias`	`string`
`LockoutEnabled`	`bit`	`aspnet_Membership.IsLockedOut`	`bit`

> **NOTE**
>
> Not all the field mappings resemble one-to-one relationships from Membership to ASP.NET Core Identity. The preceding table takes the default Membership User schema and maps it to the ASP.NET Core Identity schema. Any other custom fields that were used for Membership need to be mapped manually. In this mapping, there's no map for passwords, as both password criteria and password salts don't migrate between the two. **It's recommended to leave the password as null and to ask users to reset their passwords.** In ASP.NET Core Identity, `LockoutEnd` should be set to some date in the future if the user is locked out. This is shown in the migration script.

Roles

IDENTITY (`dbo.AspNetRoles`) COLUMN	TYPE	MEMBERSHIP (`dbo.aspnet_Roles`) COLUMN	TYPE
`Id`	`string`	`RoleId`	`string`
`Name`	`string`	`RoleName`	`string`
`NormalizedName`	`string`	`LoweredRoleName`	`string`

User Roles

IDENTITY (`dbo.AspNetUserRoles`) COLUMN	TYPE	MEMBERSHIP (`dbo.aspnet_UsersInRoles`) COLUMN	TYPE
`RoleId`	`string`	`RoleId`	`string`
`UserId`	`string`	`UserId`	`string`

Reference the preceding mapping tables when creating a migration script for *Users* and *Roles*. The following example assumes you have two databases on a database server. One database contains the existing ASP.NET Membership schema and data. The other *CoreIdentitySample* database was created using steps described earlier.

Comments are included inline for more details.

```
-- THIS SCRIPT NEEDS TO RUN FROM THE CONTEXT OF THE MEMBERSHIP DB
BEGIN TRANSACTION MigrateUsersAndRoles
USE aspnetdb

-- INSERT USERS
INSERT INTO CoreIdentitySample.dbo.AspNetUsers
            (Id,
             UserName,
             NormalizedUserName,
             PasswordHash,
             SecurityStamp,
             EmailConfirmed,
             PhoneNumber,
             PhoneNumberConfirmed,
             TwoFactorEnabled,
             LockoutEnd,
             LockoutEnabled,
             AccessFailedCount,
             Email,
             NormalizedEmail)
SELECT aspnet_Users.UserId,
       aspnet_Users.UserName,
       -- The NormalizedUserName value is upper case in ASP.NET Core Identity
       UPPER(aspnet_Users.UserName),
       -- Creates an empty password since passwords don't map between the 2 schemas
       '',
       /*
        The SecurityStamp token is used to verify the state of an account and
        is subject to change at any time. It should be initialized as a new ID.
       */
       NewID(),
       /*
        EmailConfirmed is set when a new user is created and confirmed via email.
        Users must have this set during migration to reset passwords.
       */
       1,
       aspnet_Users.MobileAlias,
       CASE
         WHEN aspnet_Users.MobileAlias IS NULL THEN 0
         ELSE 1
       END,
       -- 2FA likely wasn't setup in Membership for users, so setting as false.
       0,
       CASE
         -- Setting lockout date to time in the future (1,000 years)
         WHEN aspnet_Membership.IsLockedOut = 1 THEN Dateadd(year, 1000,
                                                     Sysutcdatetime())
         ELSE NULL
       END,
       aspnet_Membership.IsLockedOut,
       /*
        AccessFailedAccount is used to track failed logins. This is stored in
        Membership in multiple columns. Setting to 0 arbitrarily.
       */
       0,
       aspnet_Membership.Email,
       -- The NormalizedEmail value is upper case in ASP.NET Core Identity
       UPPER(aspnet_Membership.Email)
FROM   aspnet_Users
       LEFT OUTER JOIN aspnet_Membership
                    ON aspnet_Membership.ApplicationId =
                       aspnet_Users.ApplicationId
                       AND aspnet_Users.UserId = aspnet_Membership.UserId
       LEFT OUTER JOIN CoreIdentitySample.dbo.AspNetUsers
                    ON aspnet_Membership.UserId = AspNetUsers.Id
WHERE  AspNetUsers.Id IS NULL
```

```
-- INSERT ROLES
INSERT INTO CoreIdentitySample.dbo.AspNetRoles(Id, Name)
SELECT RoleId, RoleName
FROM aspnet_Roles;

-- INSERT USER ROLES
INSERT INTO CoreIdentitySample.dbo.AspNetUserRoles(UserId, RoleId)
SELECT UserId, RoleId
FROM aspnet_UsersInRoles;

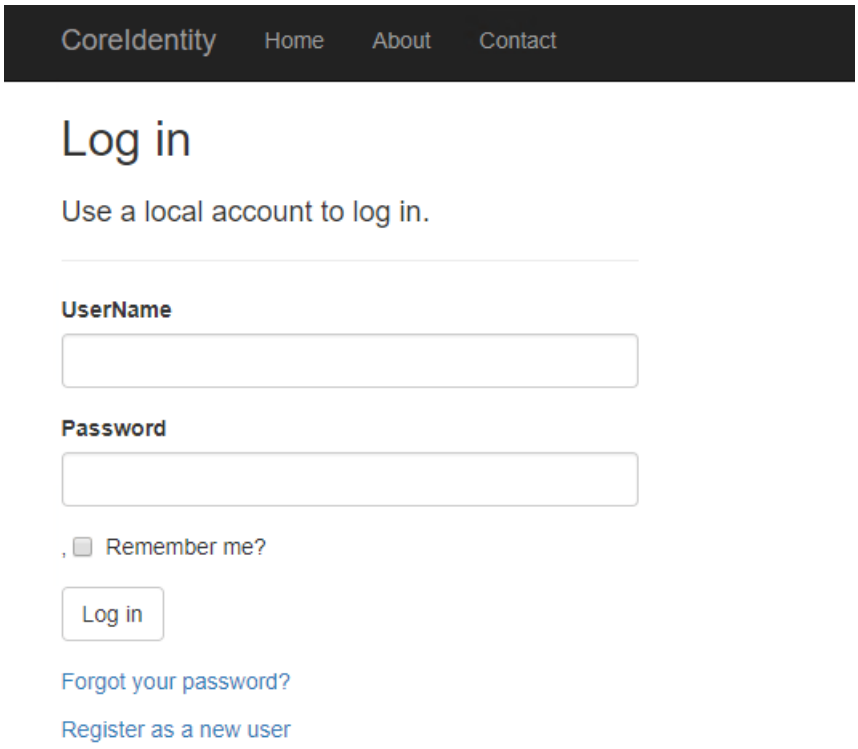
IF @@ERROR <> 0
  BEGIN
    ROLLBACK TRANSACTION MigrateUsersAndRoles
    RETURN
  END

COMMIT TRANSACTION MigrateUsersAndRoles
```

After completion of the preceding script, the ASP.NET Core Identity app created earlier is populated with Membership users. Users need to change their passwords before logging in.

> **NOTE**
> If the Membership system had users with user names that didn't match their email address, changes are required to the app created earlier to accommodate this. The default template expects `UserName` and `Email` to be the same. For situations in which they're different, the login process needs to be modified to use `UserName` instead of `Email`.

In the `PageModel` of the Login Page, located at *Pages\Account\Login.cshtml.cs*, remove the `[EmailAddress]` attribute from the *Email* property. Rename it to *UserName*. This requires a change wherever `EmailAddress` is mentioned, in the *View* and *PageModel*. The result looks like the following:



Next steps

In this tutorial, you learned how to port users from SQL membership to ASP.NET Core 2.0 Identity. For more

information regarding ASP.NET Core Identity, see Introduction to Identity.

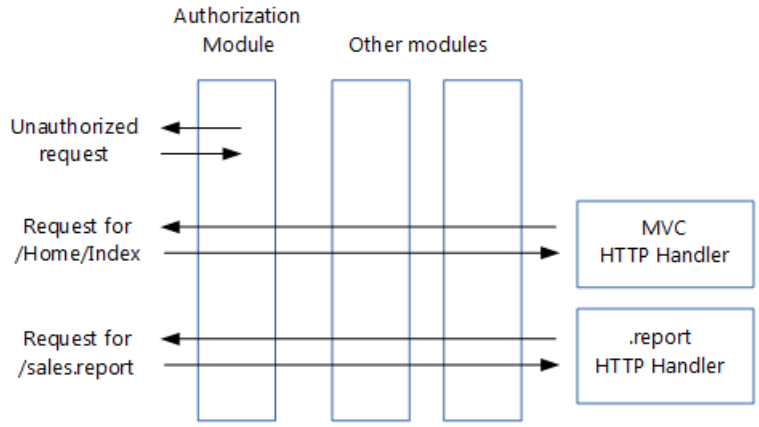
Migrate HTTP handlers and modules to ASP.NET Core middleware

9/22/2020 • 16 minutes to read • Edit Online

This article shows how to migrate existing ASP.NET HTTP modules and handlers from system.webserver to ASP.NET Core middleware.

Modules and handlers revisited

Before proceeding to ASP.NET Core middleware, let's first recap how HTTP modules and handlers work:



Handlers are:

- Classes that implement IHttpHandler
- Used to handle requests with a given file name or extension, such as *.report*
- Configured in *Web.config*

Modules are:

- Classes that implement IHttpModule
- Invoked for every request
- Able to short-circuit (stop further processing of a request)
- Able to add to the HTTP response, or create their own
- Configured in *Web.config*

The order in which modules process incoming requests is determined by:

1. The /previous-versions/ms227673(v=vs.140), which is a series events fired by ASP.NET: BeginRequest, AuthenticateRequest, etc. Each module can create a handler for one or more events.
2. For the same event, the order in which they're configured in *Web.config*.

In addition to modules, you can add handlers for the life cycle events to your *Global.asax.cs* file. These handlers run after the handlers in the configured modules.

From handlers and modules to middleware

Middleware are simpler than HTTP modules and handlers:

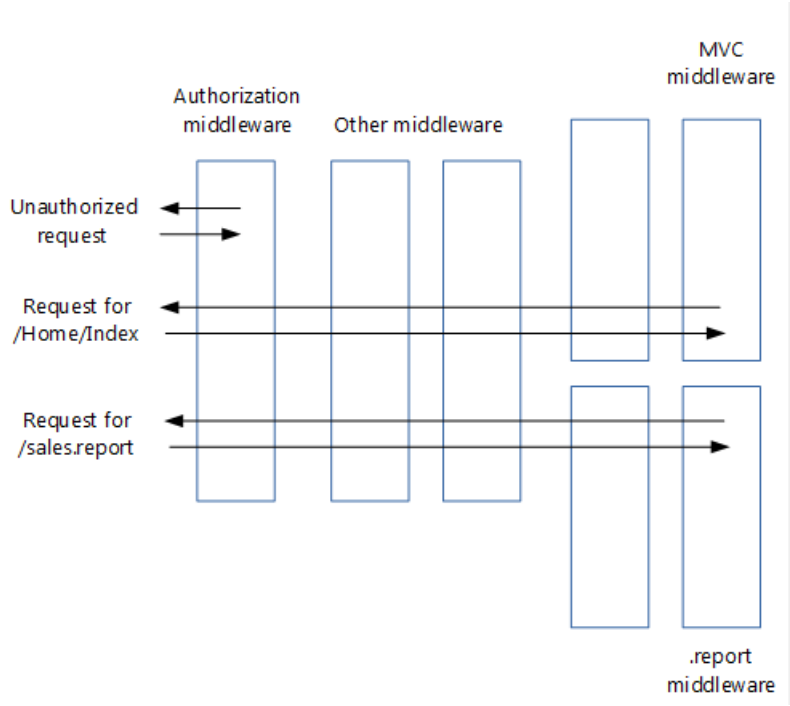
- Modules, handlers, *Global.asax.cs*, *Web.config* (except for IIS configuration) and the application life cycle are gone
- The roles of both modules and handlers have been taken over by middleware
- Middleware are configured using code rather than in *Web.config*
- Pipeline branching lets you send requests to specific middleware, based on not only the URL but also on request headers, query strings, etc.
- Pipeline branching lets you send requests to specific middleware, based on not only the URL but also on request headers, query strings, etc.

Middleware are very similar to modules:

- Invoked in principle for every request
- Able to short-circuit a request, by not passing the request to the next middleware
- Able to create their own HTTP response

Middleware and modules are processed in a different order:

- Order of middleware is based on the order in which they're inserted into the request pipeline, while order of modules is mainly based on /previous-versions/ms227673(v=vs.140) events
- Order of middleware for responses is the reverse from that for requests, while order of modules is the same for requests and responses
- See Create a middleware pipeline with IApplicationBuilder



Note how in the image above, the authentication middleware short-circuited the request.

Migrating module code to middleware

An existing HTTP module will look similar to this:

```
// ASP.NET 4 module

using System;
using System.Web;

namespace MyApp.Modules
{
    public class MyModule : IHttpModule
    {
        public void Dispose()
        {
        }

        public void Init(HttpApplication application)
        {
            application.BeginRequest += (new EventHandler(this.Application_BeginRequest));
            application.EndRequest += (new EventHandler(this.Application_EndRequest));
        }

        private void Application_BeginRequest(Object source, EventArgs e)
        {
            HttpContext context = ((HttpApplication)source).Context;

            // Do something with context near the beginning of request processing.
        }

        private void Application_EndRequest(Object source, EventArgs e)
        {
            HttpContext context = ((HttpApplication)source).Context;

            // Do something with context near the end of request processing.
        }
    }
}
```

As shown in the Middleware page, an ASP.NET Core middleware is a class that exposes an `Invoke` method taking an `HttpContext` and returning a `Task`. Your new middleware will look like this:

```
// ASP.NET Core middleware

using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Http;
using System.Threading.Tasks;

namespace MyApp.Middleware
{
    public class MyMiddleware
    {
        private readonly RequestDelegate _next;

        public MyMiddleware(RequestDelegate next)
        {
            _next = next;
        }

        public async Task Invoke(HttpContext context)
        {
            // Do something with context near the beginning of request processing.

            await _next.Invoke(context);

            // Clean up.
        }
    }

    public static class MyMiddlewareExtensions
    {
        public static IApplicationBuilder UseMyMiddleware(this IApplicationBuilder builder)
        {
            return builder.UseMiddleware<MyMiddleware>();
        }
    }
}
```

The preceding middleware template was taken from the section on writing middleware.

The *MyMiddlewareExtensions* helper class makes it easier to configure your middleware in your `Startup` class. The `UseMyMiddleware` method adds your middleware class to the request pipeline. Services required by the middleware get injected in the middleware's constructor.

Your module might terminate a request, for example if the user isn't authorized:

```
// ASP.NET 4 module that may terminate the request

private void Application_BeginRequest(Object source, EventArgs e)
{
    HttpContext context = ((HttpApplication)source).Context;

    // Do something with context near the beginning of request processing.

    if (TerminateRequest())
    {
        context.Response.End();
        return;
    }
}
```

A middleware handles this by not calling `Invoke` on the next middleware in the pipeline. Keep in mind that this doesn't fully terminate the request, because previous middlewares will still be invoked when the response makes its way back through the pipeline.

```
// ASP.NET Core middleware that may terminate the request

public async Task Invoke(HttpContext context)
{
    // Do something with context near the beginning of request processing.

    if (!TerminateRequest())
        await _next.Invoke(context);

    // Clean up.
}
```

When you migrate your module's functionality to your new middleware, you may find that your code doesn't compile because the `HttpContext` class has significantly changed in ASP.NET Core. Later on, you'll see how to migrate to the new ASP.NET Core HttpContext.

Migrating module insertion into the request pipeline

HTTP modules are typically added to the request pipeline using *Web.config*.

```
<?xml version="1.0" encoding="utf-8"?>
<!--ASP.NET 4 web.config-->
<configuration>
  <system.webServer>
    <modules>
      <add name="MyModule" type="MyApp.Modules.MyModule"/>
    </modules>
  </system.webServer>
</configuration>
```

Convert this by adding your new middleware to the request pipeline in your `Startup` class:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env, ILoggerFactory loggerFactory)
{
    loggerFactory.AddConsole(Configuration.GetSection("Logging"));
    loggerFactory.AddDebug();

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseBrowserLink();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
    }

    app.UseMyMiddleware();

    app.UseMyMiddlewareWithParams();

    var myMiddlewareOptions = Configuration.GetSection("MyMiddlewareOptionsSection").Get<MyMiddlewareOptions>
();
    var myMiddlewareOptions2 =
Configuration.GetSection("MyMiddlewareOptionsSection2").Get<MyMiddlewareOptions>();
    app.UseMyMiddlewareWithParams(myMiddlewareOptions);
    app.UseMyMiddlewareWithParams(myMiddlewareOptions2);

    app.UseMyTerminatingMiddleware();

    // Create branch to the MyHandlerMiddleware.
    // All requests ending in .report will follow this branch.
    app.MapWhen(
        context => context.Request.Path.ToString().EndsWith(".report"),
        appBranch => {
            // ... optionally add more middleware to this branch
            appBranch.UseMyHandler();
        });

    app.MapWhen(
        context => context.Request.Path.ToString().EndsWith(".context"),
        appBranch => {
            appBranch.UseHttpContextDemoMiddleware();
        });

    app.UseStaticFiles();

    app.UseMvc(routes =>
    {
        routes.MapRoute(
            name: "default",
            template: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

The exact spot in the pipeline where you insert your new middleware depends on the event that it handled as a module (`BeginRequest` , `EndRequest` , etc.) and its order in your list of modules in *Web.config*.

As previously stated, there's no application life cycle in ASP.NET Core and the order in which responses are processed by middleware differs from the order used by modules. This could make your ordering decision more challenging.

If ordering becomes a problem, you could split your module into multiple middleware components that can be ordered independently.

Migrating handler code to middleware

An HTTP handler looks something like this:

```
// ASP.NET 4 handler

using System.Web;

namespace MyApp.HttpHandlers
{
    public class MyHandler : IHttpHandler
    {
        public bool IsReusable { get { return true; } }

        public void ProcessRequest(HttpContext context)
        {
            string response = GenerateResponse(context);

            context.Response.ContentType = GetContentType();
            context.Response.Output.Write(response);
        }

        // ...

        private string GenerateResponse(HttpContext context)
        {
            string title = context.Request.QueryString["title"];
            return string.Format("Title of the report: {0}", title);
        }

        private string GetContentType()
        {
            return "text/plain";
        }
    }
}
```

In your ASP.NET Core project, you would translate this to a middleware similar to this:

```
// ASP.NET Core middleware migrated from a handler

using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Http;
using System.Threading.Tasks;

namespace MyApp.Middleware
{
    public class MyHandlerMiddleware
    {

        // Must have constructor with this signature, otherwise exception at run time
        public MyHandlerMiddleware(RequestDelegate next)
        {
            // This is an HTTP Handler, so no need to store next
        }

        public async Task Invoke(HttpContext context)
        {
            string response = GenerateResponse(context);

            context.Response.ContentType = GetContentType();
            await context.Response.WriteAsync(response);
        }

        // ...

        private string GenerateResponse(HttpContext context)
        {
            string title = context.Request.Query["title"];
            return string.Format("Title of the report: {0}", title);
        }

        private string GetContentType()
        {
            return "text/plain";
        }
    }

    public static class MyHandlerExtensions
    {
        public static IApplicationBuilder UseMyHandler(this IApplicationBuilder builder)
        {
            return builder.UseMiddleware<MyHandlerMiddleware>();
        }
    }
}
```

This middleware is very similar to the middleware corresponding to modules. The only real difference is that here there's no call to `_next.Invoke(context)`. That makes sense, because the handler is at the end of the request pipeline, so there will be no next middleware to invoke.

Migrating handler insertion into the request pipeline

Configuring an HTTP handler is done in *Web.config* and looks something like this:

```
<?xml version="1.0" encoding="utf-8"?>
<!--ASP.NET 4 web.config-->
<configuration>
  <system.webServer>
    <handlers>
      <add name="MyHandler" verb="*" path="*.report" type="MyApp.HttpHandlers.MyHandler"
resourceType="Unspecified" preCondition="integratedMode"/>
    </handlers>
  </system.webServer>
</configuration>
```

You could convert this by adding your new handler middleware to the request pipeline in your `Startup` class, similar to middleware converted from modules. The problem with that approach is that it would send all requests to your new handler middleware. However, you only want requests with a given extension to reach your middleware. That would give you the same functionality you had with your HTTP handler.

One solution is to branch the pipeline for requests with a given extension, using the `MapWhen` extension method. You do this in the same `Configure` method where you add the other middleware:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env, ILoggerFactory loggerFactory)
{
    loggerFactory.AddConsole(Configuration.GetSection("Logging"));
    loggerFactory.AddDebug();

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseBrowserLink();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
    }

    app.UseMyMiddleware();

    app.UseMyMiddlewareWithParams();

    var myMiddlewareOptions = Configuration.GetSection("MyMiddlewareOptionsSection").Get<MyMiddlewareOptions>
();
    var myMiddlewareOptions2 =
Configuration.GetSection("MyMiddlewareOptionsSection2").Get<MyMiddlewareOptions>();
    app.UseMyMiddlewareWithParams(myMiddlewareOptions);
    app.UseMyMiddlewareWithParams(myMiddlewareOptions2);

    app.UseMyTerminatingMiddleware();

    // Create branch to the MyHandlerMiddleware.
    // All requests ending in .report will follow this branch.
    app.MapWhen(
        context => context.Request.Path.ToString().EndsWith(".report"),
        appBranch => {
            // ... optionally add more middleware to this branch
            appBranch.UseMyHandler();
        });

    app.MapWhen(
        context => context.Request.Path.ToString().EndsWith(".context"),
        appBranch => {
            appBranch.UseHttpContextDemoMiddleware();
        });

    app.UseStaticFiles();

    app.UseMvc(routes =>
    {
        routes.MapRoute(
            name: "default",
            template: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

`MapWhen` takes these parameters:

1. A lambda that takes the `HttpContext` and returns `true` if the request should go down the branch. This means you can branch requests not just based on their extension, but also on request headers, query string parameters, etc.
2. A lambda that takes an `IApplicationBuilder` and adds all the middleware for the branch. This means you can add additional middleware to the branch in front of your handler middleware.

Middleware added to the pipeline before the branch will be invoked on all requests; the branch will have no impact on them.

Loading middleware options using the options pattern

Some modules and handlers have configuration options that are stored in *Web.config*. However, in ASP.NET Core a new configuration model is used in place of *Web.config*.

The new configuration system gives you these options to solve this:

- Directly inject the options into the middleware, as shown in the next section.
- Use the options pattern:

1. Create a class to hold your middleware options, for example:

```
public class MyMiddlewareOptions
{
    public string Param1 { get; set; }
    public string Param2 { get; set; }
}
```

2. Store the option values

   The configuration system allows you to store option values anywhere you want. However, most sites use *appsettings.json*, so we'll take that approach:

```
{
  "MyMiddlewareOptionsSection": {
    "Param1": "Param1Value",
    "Param2": "Param2Value"
  }
}
```

   MyMiddlewareOptionsSection here is a section name. It doesn't have to be the same as the name of your options class.

3. Associate the option values with the options class

   The options pattern uses ASP.NET Core's dependency injection framework to associate the options type (such as `MyMiddlewareOptions`) with a `MyMiddlewareOptions` object that has the actual options.

   Update your `Startup` class:

   a. If you're using *appsettings.json*, add it to the configuration builder in the `Startup` constructor:

```
public Startup(IHostingEnvironment env)
{
    var builder = new ConfigurationBuilder()
        .SetBasePath(env.ContentRootPath)
        .AddJsonFile("appsettings.json", optional: true, reloadOnChange: true)
        .AddJsonFile($"appsettings.{env.EnvironmentName}.json", optional: true)
        .AddEnvironmentVariables();
    Configuration = builder.Build();
}
```

   b. Configure the options service:

```
public void ConfigureServices(IServiceCollection services)
{
    // Setup options service
    services.AddOptions();

    // Load options from section "MyMiddlewareOptionsSection"
    services.Configure<MyMiddlewareOptions>(
        Configuration.GetSection("MyMiddlewareOptionsSection"));

    // Add framework services.
    services.AddMvc();
}
```

c. Associate your options with your options class:

```
public void ConfigureServices(IServiceCollection services)
{
    // Setup options service
    services.AddOptions();

    // Load options from section "MyMiddlewareOptionsSection"
    services.Configure<MyMiddlewareOptions>(
        Configuration.GetSection("MyMiddlewareOptionsSection"));

    // Add framework services.
    services.AddMvc();
}
```

4. Inject the options into your middleware constructor. This is similar to injecting options into a controller.

```
public class MyMiddlewareWithParams
{
    private readonly RequestDelegate _next;
    private readonly MyMiddlewareOptions _myMiddlewareOptions;

    public MyMiddlewareWithParams(RequestDelegate next,
        IOptions<MyMiddlewareOptions> optionsAccessor)
    {
        _next = next;
        _myMiddlewareOptions = optionsAccessor.Value;
    }

    public async Task Invoke(HttpContext context)
    {
        // Do something with context near the beginning of request processing
        // using configuration in _myMiddlewareOptions

        await _next.Invoke(context);

        // Do something with context near the end of request processing
        // using configuration in _myMiddlewareOptions
    }
}
```

The UseMiddleware extension method that adds your middleware to the `IApplicationBuilder` takes care of dependency injection.

This isn't limited to `IOptions` objects. Any other object that your middleware requires can be injected this way.

Loading middleware options through direct injection

The options pattern has the advantage that it creates loose coupling between options values and their consumers. Once you've associated an options class with the actual options values, any other class can get access to the options through the dependency injection framework. There's no need to pass around options values.

This breaks down though if you want to use the same middleware twice, with different options. For example an authorization middleware used in different branches allowing different roles. You can't associate two different options objects with the one options class.

The solution is to get the options objects with the actual options values in your `Startup` class and pass those directly to each instance of your middleware.

1. Add a second key to *appsettings.json*

   To add a second set of options to the *appsettings.json* file, use a new key to uniquely identify it:

   ```
   {
     "MyMiddlewareOptionsSection2": {
       "Param1": "Param1Value2",
       "Param2": "Param2Value2"
     },
     "MyMiddlewareOptionsSection": {
       "Param1": "Param1Value",
       "Param2": "Param2Value"
     }
   }
   ```

2. Retrieve options values and pass them to middleware. The `Use...` extension method (which adds your middleware to the pipeline) is a logical place to pass in the option values:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env, ILoggerFactory loggerFactory)
{
    loggerFactory.AddConsole(Configuration.GetSection("Logging"));
    loggerFactory.AddDebug();

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseBrowserLink();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
    }

    app.UseMyMiddleware();

    app.UseMyMiddlewareWithParams();

    var myMiddlewareOptions =
Configuration.GetSection("MyMiddlewareOptionsSection").Get<MyMiddlewareOptions>();
    var myMiddlewareOptions2 =
Configuration.GetSection("MyMiddlewareOptionsSection2").Get<MyMiddlewareOptions>();
    app.UseMyMiddlewareWithParams(myMiddlewareOptions);
    app.UseMyMiddlewareWithParams(myMiddlewareOptions2);

    app.UseMyTerminatingMiddleware();

    // Create branch to the MyHandlerMiddleware.
    // All requests ending in .report will follow this branch.
    app.MapWhen(
        context => context.Request.Path.ToString().EndsWith(".report"),
        appBranch => {
            // ... optionally add more middleware to this branch
            appBranch.UseMyHandler();
        });

    app.MapWhen(
        context => context.Request.Path.ToString().EndsWith(".context"),
        appBranch => {
            appBranch.UseHttpContextDemoMiddleware();
        });

    app.UseStaticFiles();

    app.UseMvc(routes =>
    {
        routes.MapRoute(
            name: "default",
            template: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

3. Enable middleware to take an options parameter. Provide an overload of the `Use...` extension method (that takes the options parameter and passes it to `UseMiddleware`). When `UseMiddleware` is called with parameters, it passes the parameters to your middleware constructor when it instantiates the middleware object.

```
public static class MyMiddlewareWithParamsExtensions
{
    public static IApplicationBuilder UseMyMiddlewareWithParams(
        this IApplicationBuilder builder)
    {
        return builder.UseMiddleware<MyMiddlewareWithParams>();
    }

    public static IApplicationBuilder UseMyMiddlewareWithParams(
        this IApplicationBuilder builder, MyMiddlewareOptions myMiddlewareOptions)
    {
        return builder.UseMiddleware<MyMiddlewareWithParams>(
            new OptionsWrapper<MyMiddlewareOptions>(myMiddlewareOptions));
    }
}
```

Note how this wraps the options object in an `OptionsWrapper` object. This implements `IOptions`, as expected by the middleware constructor.

Migrating to the new HttpContext

You saw earlier that the `Invoke` method in your middleware takes a parameter of type `HttpContext`:

```
public async Task Invoke(HttpContext context)
```

`HttpContext` has significantly changed in ASP.NET Core. This section shows how to translate the most commonly used properties of System.Web.HttpContext to the new `Microsoft.AspNetCore.Http.HttpContext`.

HttpContext

HttpContext.Items translates to:

```
IDictionary<object, object> items = httpContext.Items;
```

Unique request ID (no System.Web.HttpContext counterpart)

Gives you a unique id for each request. Very useful to include in your logs.

```
string requestId = httpContext.TraceIdentifier;
```

HttpContext.Request

HttpContext.Request.HttpMethod translates to:

```
string httpMethod = httpContext.Request.Method;
```

HttpContext.Request.QueryString translates to:

```
IQueryCollection queryParameters = httpContext.Request.Query;

// If no query parameter "key" used, values will have 0 items
// If single value used for a key (...?key=v1), values will have 1 item ("v1")
// If key has multiple values (...?key=v1&key=v2), values will have 2 items ("v1" and "v2")
IList<string> values = queryParameters["key"];

// If no query parameter "key" used, value will be ""
// If single value used for a key (...?key=v1), value will be "v1"
// If key has multiple values (...?key=v1&key=v2), value will be "v1,v2"
string value = queryParameters["key"].ToString();
```

HttpContext.Request.Url and **HttpContext.Request.RawUrl** translate to:

```
// using Microsoft.AspNetCore.Http.Extensions;
var url = httpContext.Request.GetDisplayUrl();
```

HttpContext.Request.IsSecureConnection translates to:

```
var isSecureConnection = httpContext.Request.IsHttps;
```

HttpContext.Request.UserHostAddress translates to:

```
var userHostAddress = httpContext.Connection.RemoteIpAddress?.ToString();
```

HttpContext.Request.Cookies translates to:

```
IRequestCookieCollection cookies = httpContext.Request.Cookies;
string unknownCookieValue = cookies["unknownCookie"]; // will be null (no exception)
string knownCookieValue = cookies["cookie1name"];     // will be actual value
```

HttpContext.Request.RequestContext.RouteData translates to:

```
var routeValue = httpContext.GetRouteValue("key");
```

HttpContext.Request.Headers translates to:

```
// using Microsoft.AspNetCore.Http.Headers;
// using Microsoft.Net.Http.Headers;

IHeaderDictionary headersDictionary = httpContext.Request.Headers;

// GetTypedHeaders extension method provides strongly typed access to many headers
var requestHeaders = httpContext.Request.GetTypedHeaders();
CacheControlHeaderValue cacheControlHeaderValue = requestHeaders.CacheControl;

// For unknown header, unknownheaderValues has zero items and unknownheaderValue is ""
IList<string> unknownheaderValues = headersDictionary["unknownheader"];
string unknownheaderValue = headersDictionary["unknownheader"].ToString();

// For known header, knownheaderValues has 1 item and knownheaderValue is the value
IList<string> knownheaderValues = headersDictionary[HeaderNames.AcceptLanguage];
string knownheaderValue = headersDictionary[HeaderNames.AcceptLanguage].ToString();
```

HttpContext.Request.UserAgent translates to:

```
string userAgent = headersDictionary[HeaderNames.UserAgent].ToString();
```

HttpContext.Request.UrlReferrer translates to:

```
string urlReferrer = headersDictionary[HeaderNames.Referer].ToString();
```

HttpContext.Request.ContentType translates to:

```
// using Microsoft.Net.Http.Headers;

MediaTypeHeaderValue mediaHeaderValue = requestHeaders.ContentType;
string contentType = mediaHeaderValue?.MediaType.ToString();   // ex. application/x-www-form-urlencoded
string contentMainType = mediaHeaderValue?.Type.ToString();    // ex. application
string contentSubType = mediaHeaderValue?.SubType.ToString();  // ex. x-www-form-urlencoded

System.Text.Encoding requestEncoding = mediaHeaderValue?.Encoding;
```

HttpContext.Request.Form translates to:

```
if (httpContext.Request.HasFormContentType)
{
    IFormCollection form;

    form = httpContext.Request.Form; // sync
    // Or
    form = await httpContext.Request.ReadFormAsync(); // async

    string firstName = form["firstname"];
    string lastName = form["lastname"];
}
```

WARNING

Read form values only if the content sub type is *x-www-form-urlencoded* or *form-data*.

HttpContext.Request.InputStream translates to:

```
string inputBody;
using (var reader = new System.IO.StreamReader(
    httpContext.Request.Body, System.Text.Encoding.UTF8))
{
    inputBody = reader.ReadToEnd();
}
```

WARNING

Use this code only in a handler type middleware, at the end of a pipeline.

You can read the raw body as shown above only once per request. Middleware trying to read the body after the first read will read an empty body.

This doesn't apply to reading a form as shown earlier, because that's done from a buffer.

HttpContext.Response

HttpContext.Response.Status and **HttpContext.Response.StatusDescription** translate to:

```
// using Microsoft.AspNetCore.Http;
httpContext.Response.StatusCode = StatusCodes.Status200OK;
```

HttpContext.Response.ContentEncoding and **HttpContext.Response.ContentType** translate to:

```
// using Microsoft.Net.Http.Headers;
var mediaType = new MediaTypeHeaderValue("application/json");
mediaType.Encoding = System.Text.Encoding.UTF8;
httpContext.Response.ContentType = mediaType.ToString();
```

HttpContext.Response.ContentType on its own also translates to:

```
httpContext.Response.ContentType = "text/html";
```

HttpContext.Response.Output translates to:

```
string responseContent = GetResponseContent();
await httpContext.Response.WriteAsync(responseContent);
```

HttpContext.Response.TransmitFile

Serving up a file is discussed here.

HttpContext.Response.Headers

Sending response headers is complicated by the fact that if you set them after anything has been written to the response body, they will not be sent.

The solution is to set a callback method that will be called right before writing to the response starts. This is best done at the start of the `Invoke` method in your middleware. It's this callback method that sets your response headers.

The following code sets a callback method called `SetHeaders`:

```
public async Task Invoke(HttpContext httpContext)
{
    // ...
    httpContext.Response.OnStarting(SetHeaders, state: httpContext);
```

The `SetHeaders` callback method would look like this:

```
// using Microsoft.AspNet.Http.Headers;
// using Microsoft.Net.Http.Headers;

private Task SetHeaders(object context)
{
    var httpContext = (HttpContext)context;

    // Set header with single value
    httpContext.Response.Headers["ResponseHeaderName"] = "headerValue";

    // Set header with multiple values
    string[] responseHeaderValues = new string[] { "headerValue1", "headerValue1" };
    httpContext.Response.Headers["ResponseHeaderName"] = responseHeaderValues;

    // Translating ASP.NET 4's HttpContext.Response.RedirectLocation
    httpContext.Response.Headers[HeaderNames.Location] = "http://www.example.com";
    // Or
    httpContext.Response.Redirect("http://www.example.com");

    // GetTypedHeaders extension method provides strongly typed access to many headers
    var responseHeaders = httpContext.Response.GetTypedHeaders();

    // Translating ASP.NET 4's HttpContext.Response.CacheControl
    responseHeaders.CacheControl = new CacheControlHeaderValue
    {
        MaxAge = new System.TimeSpan(365, 0, 0, 0)
        // Many more properties available
    };

    // If you use .NET Framework 4.6+, Task.CompletedTask will be a bit faster
    return Task.FromResult(0);
}
```

HttpContext.Response.Cookies

Cookies travel to the browser in a *Set-Cookie* response header. As a result, sending cookies requires the same callback as used for sending response headers:

```
public async Task Invoke(HttpContext httpContext)
{
    // ...
    httpContext.Response.OnStarting(SetCookies, state: httpContext);
    httpContext.Response.OnStarting(SetHeaders, state: httpContext);
```

The `SetCookies` callback method would look like the following:

```
private Task SetCookies(object context)
{
    var httpContext = (HttpContext)context;

    IResponseCookies responseCookies = httpContext.Response.Cookies;

    responseCookies.Append("cookie1name", "cookie1value");
    responseCookies.Append("cookie2name", "cookie2value",
        new CookieOptions { Expires = System.DateTime.Now.AddDays(5), HttpOnly = true });

    // If you use .NET Framework 4.6+, Task.CompletedTask will be a bit faster
    return Task.FromResult(0);
}
```

Migrate from Microsoft.Extensions.Logging 2.1 to 2.2 or 3.0

9/22/2020 • 2 minutes to read • Edit Online

This article outlines the common steps for migrating a non-ASP.NET Core application that uses `Microsoft.Extensions.Logging` from 2.1 to 2.2 or 3.0.

2.1 to 2.2

Manually create `ServiceCollection` and call `AddLogging`.

2.1 example:

```
using (var loggerFactory = new LoggerFactory())
{
    loggerFactory.AddConsole();

    // use loggerFactory
}
```

2.2 example:

```
var serviceCollection = new ServiceCollection();
serviceCollection.AddLogging(builder => builder.AddConsole());

using (var serviceProvider = serviceCollection.BuildServiceProvider())
using (var loggerFactory = serviceProvider.GetService<ILoggerFactory>())
{
    // use loggerFactory
}
```

2.1 to 3.0

In 3.0, use `LoggingFactory.Create`.

2.1 example:

```
using (var loggerFactory = new LoggerFactory())
{
    loggerFactory.AddConsole();

    // use loggerFactory
}
```

3.0 example:

```
using (var loggerFactory = LoggerFactory.Create(builder => builder.AddConsole()))
{
    // use loggerFactory
}
```
