- Apply an authorization policy before UseEndpoints dispatches to the endpoint.

Endpoint metadata

In the preceding example, there are two endpoints, but only the health check endpoint has an authorization policy attached. If the request matches the health check endpoint, `/healthz`, an authorization check is performed. This demonstrates that endpoints can have extra data attached to them. This extra data is called endpoint **metadata**:

- The metadata can be processed by routing-aware middleware.
- The metadata can be of any .NET type.

Routing concepts

The routing system builds on top of the middleware pipeline by adding the powerful **endpoint** concept. Endpoints represent units of the app's functionality that are distinct from each other in terms of routing, authorization, and any number of ASP.NET Core's systems.

ASP.NET Core endpoint definition

An ASP.NET Core endpoint is:

- Executable: Has a RequestDelegate.
- Extensible: Has a Metadata collection.
- Selectable: Optionally, has routing information.
- Enumerable: The collection of endpoints can be listed by retrieving the EndpointDataSource from DI.

The following code shows how to retrieve and inspect the endpoint matching the current request:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    app.UseRouting();

    app.Use(next => context =>
    {
        var endpoint = context.GetEndpoint();
        if (endpoint is null)
        {
            return Task.CompletedTask;
        }

        Console.WriteLine($"Endpoint: {endpoint.DisplayName}");

        if (endpoint is RouteEndpoint routeEndpoint)
        {
            Console.WriteLine("Endpoint has route pattern: " +
                routeEndpoint.RoutePattern.RawText);
        }

        foreach (var metadata in endpoint.Metadata)
        {
            Console.WriteLine($"Endpoint has metadata: {metadata}");
        }

        return Task.CompletedTask;
    });

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapGet("/", async context =>
        {
            await context.Response.WriteAsync("Hello World!");
        });
    });
}
```

The endpoint, if selected, can be retrieved from the `HttpContext`. Its properties can be inspected. Endpoint objects are immutable and cannot be modified after creation. The most common type of endpoint is a RouteEndpoint. `RouteEndpoint` includes information that allows it to be to selected by the routing system.

In the preceding code, app.Use configures an in-line middleware.

The following code shows that, depending on where `app.Use` is called in the pipeline, there may not be an endpoint:

```
// Location 1: before routing runs, endpoint is always null here
app.Use(next => context =>
{
    Console.WriteLine($"1. Endpoint: {context.GetEndpoint()?.DisplayName ?? "(null)"}");
    return next(context);
});

app.UseRouting();

// Location 2: after routing runs, endpoint will be non-null if routing found a match
app.Use(next => context =>
{
    Console.WriteLine($"2. Endpoint: {context.GetEndpoint()?.DisplayName ?? "(null)"}");
    return next(context);
});

app.UseEndpoints(endpoints =>
{
    // Location 3: runs when this endpoint matches
    endpoints.MapGet("/", context =>
    {
        Console.WriteLine(
            $"3. Endpoint: {context.GetEndpoint()?.DisplayName ?? "(null)"}");
        return Task.CompletedTask;
    }).WithDisplayName("Hello");
});

// Location 4: runs after UseEndpoints - will only run if there was no match
app.Use(next => context =>
{
    Console.WriteLine($"4. Endpoint: {context.GetEndpoint()?.DisplayName ?? "(null)"}");
    return next(context);
});
```

This preceding sample adds `Console.WriteLine` statements that display whether or not an endpoint has been selected. For clarity, the sample assigns a display name to the provided `/` endpoint.

Running this code with a URL of `/` displays:

```
1. Endpoint: (null)
2. Endpoint: Hello
3. Endpoint: Hello
```

Running this code with any other URL displays:

```
1. Endpoint: (null)
2. Endpoint: (null)
4. Endpoint: (null)
```

This output demonstrates that:

- The endpoint is always null before `UseRouting` is called.
- If a match is found, the endpoint is non-null between `UseRouting` and UseEndpoints.
- The `UseEndpoints` middleware is **terminal** when a match is found. Terminal middleware is defined later in this document.
- The middleware after `UseEndpoints` execute only when no match is found.

The `UseRouting` middleware uses the SetEndpoint method to attach the endpoint to the current context. It's possible to replace the `UseRouting` middleware with custom logic and still get the benefits of using

endpoints. Endpoints are a low-level primitive like middleware, and aren't coupled to the routing implementation. Most apps don't need to replace `UseRouting` with custom logic.

The `UseEndpoints` middleware is designed to be used in tandem with the `UseRouting` middleware. The core logic to execute an endpoint isn't complicated. Use GetEndpoint to retrieve the endpoint, and then invoke its RequestDelegate property.

The following code demonstrates how middleware can influence or react to routing:

```
public class IntegratedMiddlewareStartup
{
    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        // Location 1: Before routing runs. Can influence request before routing runs.
        app.UseHttpMethodOverride();

        app.UseRouting();

        // Location 2: After routing runs. Middleware can match based on metadata.
        app.Use(next => context =>
        {
            var endpoint = context.GetEndpoint();
            if (endpoint?.Metadata.GetMetadata<AuditPolicyAttribute>()?.NeedsAudit
                                                                        == true)
            {
                Console.WriteLine($"ACCESS TO SENSITIVE DATA AT: {DateTime.UtcNow}");
            }

            return next(context);
        });

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapGet("/", async context =>
            {
                await context.Response.WriteAsync("Hello world!");
            });

            // Using metadata to configure the audit policy.
            endpoints.MapGet("/sensitive", async context =>
            {
                await context.Response.WriteAsync("sensitive data");
            })
            .WithMetadata(new AuditPolicyAttribute(needsAudit: true));
        });

    }
}

public class AuditPolicyAttribute : Attribute
{
    public AuditPolicyAttribute(bool needsAudit)
    {
        NeedsAudit = needsAudit;
    }

    public bool NeedsAudit { get; }
}
```

The preceding example demonstrates two important concepts:

- Middleware can run before `UseRouting` to modify the data that routing operates upon.
  - Usually middleware that appears before routing modifies some property of the request, such as UseRewriter, UseHttpMethodOverride, or UsePathBase.
- Middleware can run between `UseRouting` and UseEndpoints to process the results of routing before the endpoint is executed.
  - Middleware that runs between `UseRouting` and `UseEndpoints`:
    - Usually inspects metadata to understand the endpoints.
    - Often makes security decisions, as done by `UseAuthorization` and `UseCors`.
  - The combination of middleware and metadata allows configuring policies per-endpoint.

The preceding code shows an example of a custom middleware that supports per-endpoint policies. The middleware writes an *audit log* of access to sensitive data to the console. The middleware can be configured to *audit* an endpoint with the `AuditPolicyAttribute` metadata. This sample demonstrates an *opt-in* pattern where only endpoints that are marked as sensitive are audited. It's possible to define this logic in reverse, auditing everything that isn't marked as safe, for example. The endpoint metadata system is flexible. This logic could be designed in whatever way suits the use case.

The preceding sample code is intended to demonstrate the basic concepts of endpoints. **The sample is not intended for production use**. A more complete version of an *audit log* middleware would:

- Log to a file or database.
- Include details such as the user, IP address, name of the sensitive endpoint, and more.

The audit policy metadata `AuditPolicyAttribute` is defined as an `Attribute` for easier use with class-based frameworks such as controllers and SignalR. When using *route to code*:

- Metadata is attached with a builder API.
- Class-based frameworks include all attributes on the corresponding method and class when creating endpoints.

The best practices for metadata types are to define them either as interfaces or attributes. Interfaces and attributes allow code reuse. The metadata system is flexible and doesn't impose any limitations.

Comparing a terminal middleware and routing

The following code sample contrasts using middleware with using routing:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    // Approach 1: Writing a terminal middleware.
    app.Use(next => async context =>
    {
        if (context.Request.Path == "/")
        {
            await context.Response.WriteAsync("Hello terminal middleware!");
            return;
        }

        await next(context);
    });

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        // Approach 2: Using routing.
        endpoints.MapGet("/Movie", async context =>
        {
            await context.Response.WriteAsync("Hello routing!");
        });
    });
}
```

The style of middleware shown with `Approach 1:` is **terminal middleware**. It's called terminal middleware because it does a matching operation:

- The matching operation in the preceding sample is `Path == "/"` for the middleware and `Path == "/Movie"` for routing.
- When a match is successful, it executes some functionality and returns, rather than invoking the `next` middleware.

It's called terminal middleware because it terminates the search, executes some functionality, and then returns.

Comparing a terminal middleware and routing:

- Both approaches allow terminating the processing pipeline:
  - Middleware terminates the pipeline by returning rather than invoking `next`.
  - Endpoints are always terminal.
- Terminal middleware allows positioning the middleware at an arbitrary place in the pipeline:
  - Endpoints execute at the position of UseEndpoints.
- Terminal middleware allows arbitrary code to determine when the middleware matches:
  - Custom route matching code can be verbose and difficult to write correctly.
  - Routing provides straightforward solutions for typical apps. Most apps don't require custom route matching code.
- Endpoints interface with middleware such as `UseAuthorization` and `UseCors`.
  - Using a terminal middleware with `UseAuthorization` or `UseCors` requires manual interfacing with the authorization system.

An endpoint defines both:

- A delegate to process requests.
- A collection of arbitrary metadata. The metadata is used to implement cross-cutting concerns based on policies and configuration attached to each endpoint.

Terminal middleware can be an effective tool, but can require:

- A significant amount of coding and testing.
- Manual integration with other systems to achieve the desired level of flexibility.

Consider integrating with routing before writing a terminal middleware.

Existing terminal middleware that integrates with Map or MapWhen can usually be turned into a routing aware endpoint. MapHealthChecks demonstrates the pattern for router-ware:

- Write an extension method on IEndpointRouteBuilder.
- Create a nested middleware pipeline using CreateApplicationBuilder.
- Attach the middleware to the new pipeline. In this case, UseHealthChecks.
- Build the middleware pipeline into a RequestDelegate.
- Call `Map` and provide the new middleware pipeline.
- Return the builder object provided by `Map` from the extension method.

The following code shows use of MapHealthChecks:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    // Matches request to an endpoint.
    app.UseRouting();

    // Endpoint aware middleware.
    // Middleware can use metadata from the matched endpoint.
    app.UseAuthentication();
    app.UseAuthorization();

    // Execute the matched endpoint.
    app.UseEndpoints(endpoints =>
    {
        // Configure the Health Check endpoint and require an authorized user.
        endpoints.MapHealthChecks("/healthz").RequireAuthorization();

        // Configure another endpoint, no authorization requirements.
        endpoints.MapGet("/", async context =>
        {
            await context.Response.WriteAsync("Hello World!");
        });
    });
}
```

The preceding sample shows why returning the builder object is important. Returning the builder object allows the app developer to configure policies such as authorization for the endpoint. In this example, the health checks middleware has no direct integration with the authorization system.

The metadata system was created in response to the problems encountered by extensibility authors using terminal middleware. It's problematic for each middleware to implement its own integration with the authorization system.

URL matching

- Is the process by which routing matches an incoming request to an endpoint.
- Is based on data in the URL path and headers.
- Can be extended to consider any data in the request.

When a routing middleware executes, it sets an `Endpoint` and route values to a request feature on the HttpContext from the current request:

- Calling HttpContext.GetEndpoint gets the endpoint.
- `HttpRequest.RouteValues` gets the collection of route values.

Middleware running after the routing middleware can inspect the endpoint and take action. For example, an authorization middleware can interrogate the endpoint's metadata collection for an authorization policy. After all of the middleware in the request processing pipeline is executed, the selected endpoint's delegate is invoked.

The routing system in endpoint routing is responsible for all dispatching decisions. Because the middleware applies policies based on the selected endpoint, it's important that:

- Any decision that can affect dispatching or the application of security policies is made inside the routing system.

> **WARNING**
> For backwards-compatibility, when a Controller or Razor Pages endpoint delegate is executed, the properties of RouteContext.RouteData are set to appropriate values based on the request processing performed thus far.
>
> The `RouteContext` type will be marked obsolete in a future release:
>
> - Migrate `RouteData.Values` to `HttpRequest.RouteValues`.
> - Migrate `RouteData.DataTokens` to retrieve IDataTokensMetadata from the endpoint metadata.

URL matching operates in a configurable set of phases. In each phase, the output is a set of matches. The set of matches can be narrowed down further by the next phase. The routing implementation does not guarantee a processing order for matching endpoints. **All** possible matches are processed at once. The URL matching phases occur in the following order. ASP.NET Core:

1. Processes the URL path against the set of endpoints and their route templates, collecting **all** of the matches.
2. Takes the preceding list and removes matches that fail with route constraints applied.
3. Takes the preceding list and removes matches that fail the set of MatcherPolicy instances.
4. Uses the EndpointSelector to make a final decision from the preceding list.

The list of endpoints is prioritized according to:

- The RouteEndpoint.Order
- The route template precedence

All matching endpoints are processed in each phase until the EndpointSelector is reached. The `EndpointSelector` is the final phase. It chooses the highest priority endpoint from the matches as the best match. If there are other matches with the same priority as the best match, an ambiguous match exception is thrown.

The route precedence is computed based on a **more specific** route template being given a higher priority. For example, consider the templates `/hello` and `/{message}`:

- Both match the URL path `/hello`.
- `/hello` is more specific and therefore higher priority.

In general, route precedence does a good job of choosing the best match for the kinds of URL schemes used in practice. Use Order only when necessary to avoid an ambiguity.

Due to the kinds of extensibility provided by routing, it isn't possible for the routing system to compute ahead of time the ambiguous routes. Consider an example such as the route templates `/{message:alpha}` and `/{message:int}`:

- The `alpha` constraint matches only alphabetic characters.
- The `int` constraint matches only numbers.
- These templates have the same route precedence, but there's no single URL they both match.
- If the routing system reported an ambiguity error at startup, it would block this valid use case.

> **WARNING**
>
> The order of operations inside UseEndpoints doesn't influence the behavior of routing, with one exception. MapControllerRoute and MapAreaRoute automatically assign an order value to their endpoints based on the order they are invoked. This simulates long-time behavior of controllers without the routing system providing the same guarantees as older routing implementations.
>
> In the legacy implementation of routing, it's possible to implement routing extensibility that has a dependency on the order in which routes are processed. Endpoint routing in ASP.NET Core 3.0 and later:
>
> - Doesn't have a concept of routes.
> - Doesn't provide ordering guarantees. All endpoints are processed at once.
>
> If this means you're stuck using the legacy routing system, open a GitHub issue for assistance.

Route template precedence and endpoint selection order

Route template precedence is a system that assigns each route template a value based on how specific it is. Route template precedence:

- Avoids the need to adjust the order of endpoints in common cases.
- Attempts to match the common-sense expectations of routing behavior.

For example, consider templates `/Products/List` and `/Products/{id}`. It would be reasonable to assume that `/Products/List` is a better match than `/Products/{id}` for the URL path `/Products/List`. The works because the literal segment `/List` is considered to have better precedence than the parameter segment `/{id}`.

The details of how precedence works are coupled to how route templates are defined:

- Templates with more segments are considered more specific.
- A segment with literal text is considered more specific than a parameter segment.
- A parameter segment with a constraint is considered more specific than one without.
- A complex segment is considered as specific as a parameter segment with a constraint.
- Catch-all parameters are the least specific. See **catch-all** in the Route template reference for important information on catch-all routes.

See the source code on GitHub for a reference of exact values.

URL generation concepts

URL generation:

- Is the process by which routing can create a URL path based on a set of route values.

- Allows for a logical separation between endpoints and the URLs that access them.

Endpoint routing includes the LinkGenerator API. `LinkGenerator` is a singleton service available from DI. The `LinkGenerator` API can be used outside of the context of an executing request. Mvc.IUrlHelper and scenarios that rely on IUrlHelper, such as Tag Helpers, HTML Helpers, and Action Results, use the `LinkGenerator` API internally to provide link generating capabilities.

The link generator is backed by the concept of an **address** and **address schemes**. An address scheme is a way of determining the endpoints that should be considered for link generation. For example, the route name and route values scenarios many users are familiar with from controllers and Razor Pages are implemented as an address scheme.

The link generator can link to controllers and Razor Pages via the following extension methods:

- GetPathByAction
- GetUriByAction
- GetPathByPage
- GetUriByPage

Overloads of these methods accept arguments that include the `HttpContext`. These methods are functionally equivalent to Url.Action and Url.Page, but offer additional flexibility and options.

The `GetPath*` methods are most similar to `Url.Action` and `Url.Page`, in that they generate a URI containing an absolute path. The `GetUri*` methods always generate an absolute URI containing a scheme and host. The methods that accept an `HttpContext` generate a URI in the context of the executing request. The ambient route values, URL base path, scheme, and host from the executing request are used unless overridden.

LinkGenerator is called with an address. Generating a URI occurs in two steps:

1. An address is bound to a list of endpoints that match the address.
2. Each endpoint's RoutePattern is evaluated until a route pattern that matches the supplied values is found. The resulting output is combined with the other URI parts supplied to the link generator and returned.

The methods provided by LinkGenerator support standard link generation capabilities for any type of address. The most convenient way to use the link generator is through extension methods that perform operations for a specific address type:

EXTENSION METHOD	DESCRIPTION
GetPathByAddress	Generates a URI with an absolute path based on the provided values.
GetUriByAddress	Generates an absolute URI based on the provided values.

WARNING

Pay attention to the following implications of calling LinkGenerator methods:

- Use `GetUri*` extension methods with caution in an app configuration that doesn't validate the `Host` header of incoming requests. If the `Host` header of incoming requests isn't validated, untrusted request input can be sent back to the client in URIs in a view or page. We recommend that all production apps configure their server to validate the `Host` header against known valid values.
- Use LinkGenerator with caution in middleware in combination with `Map` or `MapWhen`. `Map*` changes the base path of the executing request, which affects the output of link generation. All of the LinkGenerator APIs allow specifying a base path. Specify an empty base path to undo the `Map*` affect on link generation.

Middleware example

In the following example, a middleware uses the LinkGenerator API to create a link to an action method that lists store products. Using the link generator by injecting it into a class and calling `GenerateLink` is available to any class in an app:

```
public class ProductsLinkMiddleware
{
    private readonly LinkGenerator _linkGenerator;

    public ProductsLinkMiddleware(RequestDelegate next, LinkGenerator linkGenerator)
    {
        _linkGenerator = linkGenerator;
    }

    public async Task InvokeAsync(HttpContext httpContext)
    {
        var url = _linkGenerator.GetPathByAction("ListProducts", "Store");

        httpContext.Response.ContentType = "text/plain";

        await httpContext.Response.WriteAsync($"Go to {url} to see our products.");
    }
}
```

Route template reference

Tokens within `{}` define route parameters that are bound if the route is matched. More than one route parameter can be defined in a route segment, but route parameters must be separated by a literal value. For example, `{controller=Home}{action=Index}` isn't a valid route, since there's no literal value between `{controller}` and `{action}`. Route parameters must have a name and may have additional attributes specified.

Literal text other than route parameters (for example, `{id}`) and the path separator `/` must match the text in the URL. Text matching is case-insensitive and based on the decoded representation of the URL's path. To match a literal route parameter delimiter `{` or `}`, escape the delimiter by repeating the character. For example `{{` or `}}`.

Asterisk `*` or double asterisk `**`:

- Can be used as a prefix to a route parameter to bind to the rest of the URI.
- Are called a **catch-all** parameters. For example, `blog/{**slug}`:
  - Matches any URI that starts with `/blog` and has any value following it.
  - The value following `/blog` is assigned to the slug route value.

WARNING

A **catch-all** parameter may match routes incorrectly due to a bug in routing. Apps impacted by this bug have the following characteristics:

- A catch-all route, for example, `{**slug}"`
- The catch-all route fails to match requests it should match.
- Removing other routes makes catch-all route start working.

See GitHub bugs 18677 and 16579 for example cases that hit this bug.

An opt-in fix for this bug is contained in .NET Core 3.1.301 SDK and later. The following code sets an internal switch that fixes this bug:

```
public static void Main(string[] args)
{
   AppContext.SetSwitch("Microsoft.AspNetCore.Routing.UseCorrectCatchAllBehavior",
                        true);
   CreateHostBuilder(args).Build().Run();
}
// Remaining code removed for brevity.
```

Catch-all parameters can also match the empty string.

The catch-all parameter escapes the appropriate characters when the route is used to generate a URL, including path separator `/` characters. For example, the route `foo/{*path}` with route values `{ path = "my/path" }` generates `foo/my%2Fpath`. Note the escaped forward slash. To round-trip path separator characters, use the `**` route parameter prefix. The route `foo/{**path}` with `{ path = "my/path" }` generates `foo/my/path`.

URL patterns that attempt to capture a file name with an optional file extension have additional considerations. For example, consider the template `files/{filename}.{ext?}`. When values for both `filename` and `ext` exist, both values are populated. If only a value for `filename` exists in the URL, the route matches because the trailing `.` is optional. The following URLs match this route:

- `/files/myFile.txt`
- `/files/myFile`

Route parameters may have **default values** designated by specifying the default value after the parameter name separated by an equals sign (`=`). For example, `{controller=Home}` defines `Home` as the default value for `controller`. The default value is used if no value is present in the URL for the parameter. Route parameters are made optional by appending a question mark (`?`) to the end of the parameter name. For example, `id?`. The difference between optional values and default route parameters is:

- A route parameter with a default value always produces a value.
- An optional parameter has a value only when a value is provided by the request URL.

Route parameters may have constraints that must match the route value bound from the URL. Adding `:` and constraint name after the route parameter name specifies an inline constraint on a route parameter. If the constraint requires arguments, they're enclosed in parentheses `(...)` after the constraint name. Multiple *inline constraints* can be specified by appending another `:` and constraint name.

The constraint name and arguments are passed to the IInlineConstraintResolver service to create an instance of IRouteConstraint to use in URL processing. For example, the route template `blog/{article:minlength(10)}` specifies a `minlength` constraint with the argument `10`. For more information on route constraints and a list of the constraints provided by the framework, see the Route constraint reference section.

Route parameters may also have parameter transformers. Parameter transformers transform a parameter's value when generating links and matching actions and pages to URLs. Like constraints, parameter transformers can be added inline to a route parameter by adding a `:` and transformer name after the route parameter name. For example, the route template `blog/{article:slugify}` specifies a `slugify` transformer. For more information on parameter transformers, see the Parameter transformer reference section.

The following table demonstrates example route templates and their behavior:

ROUTE TEMPLATE	EXAMPLE MATCHING URI	THE REQUEST URI...
`hello`	`/hello`	Only matches the single path `/hello`.
`{Page=Home}`	`/`	Matches and sets `Page` to `Home`.
`{Page=Home}`	`/Contact`	Matches and sets `Page` to `Contact`.
`{controller}/{action}/{id?}`	`/Products/List`	Maps to the `Products` controller and `List` action.
`{controller}/{action}/{id?}`	`/Products/Details/123`	Maps to the `Products` controller and `Details` action with `id` set to 123.
`{controller=Home}/{action=Index}/{id?}`	`/`	Maps to the `Home` controller and `Index` method. `id` is ignored.
`{controller=Home}/{action=Index}/{id?}`	`/Products`	Maps to the `Products` controller and `Index` method. `id` is ignored.

Using a template is generally the simplest approach to routing. Constraints and defaults can also be specified outside the route template.

Complex segments

Complex segments are processed by matching up literal delimiters from right to left in a non-greedy way. For example, `[Route("/a{b}c{d}")]` is a complex segment. Complex segments work in a particular way that must be understood to use them successfully. The example in this section demonstrates why complex segments only really work well when the delimiter text doesn't appear inside the parameter values. Using a regex and then manually extracting the values is needed for more complex cases.

> **WARNING**
>
> When using System.Text.RegularExpressions to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions` causing a Denial-of-Service attack. ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

This is a summary of the steps that routing performs with the template `/a{b}c{d}` and the URL path `/abcd`. The `|` is used to help visualize how the algorithm works:

- The first literal, right to left, is `c`. So `/abcd` is searched from right and finds `/ab|c|d`.
- Everything to the right (`d`) is now matched to the route parameter `{d}`.
- The next literal, right to left, is `a`. So `/ab|c|d` is searched starting where we left off, then `a` is found

`/|a|b|c|d`.

- The value to the right (`b`) is now matched to the route parameter `{b}`.
- There is no remaining text and no remaining route template, so this is a match.

Here's an example of a negative case using the same template `/a{b}c{d}` and the URL path `/aabcd`. The `|` is used to help visualize how the algorithm works. This case isn't a match, which is explained by the same algorithm:

- The first literal, right to left, is `c`. So `/aabcd` is searched from right and finds `/aab|c|d`.
- Everything to the right (`d`) is now matched to the route parameter `{d}`.
- The next literal, right to left, is `a`. So `/aab|c|d` is searched starting where we left off, then `a` is found `/a|a|b|c|d`.
- The value to the right (`b`) is now matched to the route parameter `{b}`.
- At this point there is remaining text `a`, but the algorithm has run out of route template to parse, so this is not a match.

Since the matching algorithm is non-greedy:

- It matches the smallest amount of text possible in each step.
- Any case where the delimiter value appears inside the parameter values results in not matching.

Regular expressions provide much more control over their matching behavior.

Greedy matching, also know as lazy matching, matches the largest possible string. Non-greedy matches the smallest possible string.

Route constraint reference

Route constraints execute when a match has occurred to the incoming URL and the URL path is tokenized into route values. Route constraints generally inspect the route value associated via the route template and make a true or false decision about whether the value is acceptable. Some route constraints use data outside the route value to consider whether the request can be routed. For example, the HttpMethodRouteConstraint can accept or reject a request based on its HTTP verb. Constraints are used in routing requests and link generation.

> **WARNING**
> Don't use constraints for input validation. If constraints are used for input validation, invalid input results in a `404` Not Found response. Invalid input should produce a `400` Bad Request with an appropriate error message. Route constraints are used to disambiguate similar routes, not to validate the inputs for a particular route.

The following table demonstrates example route constraints and their expected behavior:

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	NOTES
`int`	`{id:int}`	`123456789`, `-123456789`	Matches any integer
`bool`	`{active:bool}`	`true`, `FALSE`	Matches `true` or `false`. Case-insensitive
`datetime`	`{dob:datetime}`	`2016-12-31`, `2016-12-31 7:32pm`	Matches a valid `DateTime` value in the invariant culture. See preceding warning.

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	NOTES
`decimal`	`{price:decimal}`	`49.99`, `-1,000.01`	Matches a valid `decimal` value in the invariant culture. See preceding warning.
`double`	`{weight:double}`	`1.234`, `-1,001.01e8`	Matches a valid `double` value in the invariant culture. See preceding warning.
`float`	`{weight:float}`	`1.234`, `-1,001.01e8`	Matches a valid `float` value in the invariant culture. See preceding warning.
`guid`	`{id:guid}`	`CD2C1638-1638-72D5-1638-DEADBEEF1638`	Matches a valid `Guid` value
`long`	`{ticks:long}`	`123456789`, `-123456789`	Matches a valid `long` value
`minlength(value)`	`{username:minlength(4)}`	`Rick`	String must be at least 4 characters
`maxlength(value)`	`{filename:maxlength(8)}`	`MyFile`	String must be no more than 8 characters
`length(length)`	`{filename:length(12)}`	`somefile.txt`	String must be exactly 12 characters long
`length(min,max)`	`{filename:length(8,16)}`	`somefile.txt`	String must be at least 8 and no more than 16 characters long
`min(value)`	`{age:min(18)}`	`19`	Integer value must be at least 18
`max(value)`	`{age:max(120)}`	`91`	Integer value must be no more than 120
`range(min,max)`	`{age:range(18,120)}`	`91`	Integer value must be at least 18 but no more than 120
`alpha`	`{name:alpha}`	`Rick`	String must consist of one or more alphabetical characters, `a`-`z` and case-insensitive.
`regex(expression)`	`{ssn:regex(^\\d{{3}}-\\d{{2}}-\\d{{4}}$)}`	`123-45-6789`	String must match the regular expression. See tips about defining a regular expression.

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	NOTES
`required`	`{name:required}`	`Rick`	Used to enforce that a non-parameter value is present during URL generation

> **WARNING**
> When using System.Text.RegularExpressions to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions` causing a Denial-of-Service attack. ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

Multiple, colon delimited constraints can be applied to a single parameter. For example, the following constraint restricts a parameter to an integer value of 1 or greater:

```
[Route("users/{id:int:min(1)}")]
public User GetUserById(int id) { }
```

> **WARNING**
> Route constraints that verify the URL and are converted to a CLR type always use the invariant culture. For example, conversion to the CLR type `int` or `DateTime`. These constraints assume that the URL is not localizable. The framework-provided route constraints don't modify the values stored in route values. All route values parsed from the URL are stored as strings. For example, the `float` constraint attempts to convert the route value to a float, but the converted value is used only to verify it can be converted to a float.

Regular expressions in constraints

> **WARNING**
> When using System.Text.RegularExpressions to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions` causing a Denial-of-Service attack. ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

Regular expressions can be specified as inline constraints using the `regex(...)` route constraint. Methods in the MapControllerRoute family also accept an object literal of constraints. If that form is used, string values are interpreted as regular expressions.

The following code uses an inline regex constraint:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapGet("{message:regex(^\\d{{3}}-\\d{{2}}-\\d{{4}}$)}",
        context =>
        {
            return context.Response.WriteAsync("inline-constraint match");
        });
 });
```

The following code uses an object literal to specify a regex constraint:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(
        name: "people",
        pattern: "People/{ssn}",
        constraints: new { ssn = "^\\d{3}-\\d{2}-\\d{4}$", },
        defaults: new { controller = "People", action = "List", });
});
```

The ASP.NET Core framework adds `RegexOptions.IgnoreCase | RegexOptions.Compiled | RegexOptions.CultureInvariant` to the regular expression constructor. See RegexOptions for a description of these members.

Regular expressions use delimiters and tokens similar to those used by routing and the C# language. Regular expression tokens must be escaped. To use the regular expression `^\d{3}-\d{2}-\d{4}$` in an inline constraint, use one of the following:

- Replace `\` characters provided in the string as `\\` characters in the C# source file in order to escape the `\` string escape character.
- Verbatim string literals.

To escape routing parameter delimiter characters `{`, `}`, `[`, `]`, double the characters in the expression, for example, `{{`, `}}`, `[[`, `]]`. The following table shows a regular expression and its escaped version:

REGULAR EXPRESSION	ESCAPED REGULAR EXPRESSION
`^\d{3}-\d{2}-\d{4}$`	`^\\d{{3}}-\\d{{2}}-\\d{{4}}$`
`^[a-z]{2}$`	`^[[a-z]]{{2}}$`

Regular expressions used in routing often start with the `^` character and match the starting position of the string. The expressions often end with the `$` character and match the end of the string. The `^` and `$` characters ensure that the regular expression matches the entire route parameter value. Without the `^` and `$` characters, the regular expression matches any substring within the string, which is often undesirable. The following table provides examples and explains why they match or fail to match:

EXPRESSION	STRING	MATCH	COMMENT
`[a-z]{2}`	hello	Yes	Substring matches
`[a-z]{2}`	123abc456	Yes	Substring matches
`[a-z]{2}`	mz	Yes	Matches expression
`[a-z]{2}`	MZ	Yes	Not case sensitive
`^[a-z]{2}$`	hello	No	See `^` and `$` above
`^[a-z]{2}$`	123abc456	No	See `^` and `$` above

For more information on regular expression syntax, see .NET Framework Regular Expressions.

To constrain a parameter to a known set of possible values, use a regular expression. For example, `{action:regex(^(list|get|create)$)}` only matches the `action` route value to `list`, `get`, or `create`. If

passed into the constraints dictionary, the string `^(list|get|create)$` is equivalent. Constraints that are passed in the constraints dictionary that don't match one of the known constraints are also treated as regular expressions. Constraints that are passed within a template that don't match one of the known constraints are not treated as regular expressions.

Custom route constraints

Custom route constraints can be created by implementing the IRouteConstraint interface. The `IRouteConstraint` interface contains Match, which returns `true` if the constraint is satisfied and `false` otherwise.

Custom route constraints are rarely needed. Before implementing a custom route constraint, consider alternatives, such as model binding.

The ASP.NET Core Constraints folder provides good examples of creating a constraints. For example, GuidRouteConstraint.

To use a custom `IRouteConstraint`, the route constraint type must be registered with the app's ConstraintMap in the service container. A `ConstraintMap` is a dictionary that maps route constraint keys to `IRouteConstraint` implementations that validate those constraints. An app's `ConstraintMap` can be updated in `Startup.ConfigureServices` either as part of a services.AddRouting call or by configuring RouteOptions directly with `services.Configure<RouteOptions>`. For example:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllers();

    services.AddRouting(options =>
    {
        options.ConstraintMap.Add("customName", typeof(MyCustomConstraint));
    });
}
```

The preceding constraint is applied in the following code:

```
[Route("api/[controller]")]
[ApiController]
public class TestController : ControllerBase
{
    // GET /api/test/3
    [HttpGet("{id:customName}")]
    public IActionResult Get(string id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }

    // GET /api/test/my/3
    [HttpGet("my/{id:customName}")]
    public IActionResult Get(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

MyDisplayRouteInfo is provided by the Rick.Docs.Samples.RouteInfo NuGet package and displays route information.

The implementation of `MyCustomConstraint` prevents `0` being applied to a route parameter:

```
class MyCustomConstraint : IRouteConstraint
{
    private Regex _regex;

    public MyCustomConstraint()
    {
        _regex = new Regex(@"^[1-9]*$",
                           RegexOptions.CultureInvariant | RegexOptions.IgnoreCase,
                           TimeSpan.FromMilliseconds(100));
    }
    public bool Match(HttpContext httpContext, IRouter route, string routeKey,
                      RouteValueDictionary values, RouteDirection routeDirection)
    {
        if (values.TryGetValue(routeKey, out object value))
        {
            var parameterValueString = Convert.ToString(value,
                                                        CultureInfo.InvariantCulture);
            if (parameterValueString == null)
            {
                return false;
            }

            return _regex.IsMatch(parameterValueString);
        }

        return false;
    }
}
```

WARNING

When using System.Text.RegularExpressions to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions` causing a Denial-of-Service attack. ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

The preceding code:

- Prevents `0` in the `{id}` segment of the route.
- Is shown to provide a basic example of implementing a custom constraint. It should not be used in a production app.

The following code is a better approach to preventing an `id` containing a `0` from being processed:

```
[HttpGet("{id}")]
public IActionResult Get(string id)
{
    if (id.Contains('0'))
    {
        return StatusCode(StatusCodes.Status406NotAcceptable);
    }

    return ControllerContext.MyDisplayRouteInfo(id);
}
```

The preceding code has the following advantages over the `MyCustomConstraint` approach:

- It doesn't require a custom constraint.
- It returns a more descriptive error when the route parameter includes `0`.

Parameter transformer reference

Parameter transformers:

- Execute when generating a link using LinkGenerator.
- Implement Microsoft.AspNetCore.Routing.IOutboundParameterTransformer.
- Are configured using ConstraintMap.
- Take the parameter's route value and transform it to a new string value.
- Result in using the transformed value in the generated link.

For example, a custom `slugify` parameter transformer in route pattern `blog\{article:slugify}` with `Url.Action(new { article = "MyTestArticle" })` generates `blog\my-test-article`.

Consider the following `IOutboundParameterTransformer` implementation:

```
public class SlugifyParameterTransformer : IOutboundParameterTransformer
{
    public string TransformOutbound(object value)
    {
        if (value == null) { return null; }

        return Regex.Replace(value.ToString(),
                             "([a-z])([A-Z])",
                             "$1-$2",
                             RegexOptions.CultureInvariant,
                             TimeSpan.FromMilliseconds(100)).ToLowerInvariant();
    }
}
```

To use a parameter transformer in a route pattern, configure it using ConstraintMap in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllers();

    services.AddRouting(options =>
    {
        options.ConstraintMap["slugify"] = typeof(SlugifyParameterTransformer);
    });
}
```

The ASP.NET Core framework uses parameter transformers to transform the URI where an endpoint resolves. For example, parameter transformers transform the route values used to match an `area`, `controller`, `action`, and `page`.

```
routes.MapControllerRoute(
    name: "default",
    template: "{controller:slugify=Home}/{action:slugify=Index}/{id?}");
```

With the preceding route template, the action `SubscriptionManagementController.GetAll` is matched with the URI `/subscription-management/get-all`. A parameter transformer doesn't change the route values used to generate a link. For example, `Url.Action("GetAll", "SubscriptionManagement")` outputs `/subscription-management/get-all`.

ASP.NET Core provides API conventions for using parameter transformers with generated routes:

- The Microsoft.AspNetCore.Mvc.ApplicationModels.RouteTokenTransformerConvention MVC convention applies a specified parameter transformer to all attribute routes in the app. The parameter transformer transforms attribute route tokens as they are replaced. For more information, see Use a parameter transformer to customize token replacement.
- Razor Pages uses the PageRouteTransformerConvention API convention. This convention applies a specified parameter transformer to all automatically discovered Razor Pages. The parameter transformer transforms the folder and file name segments of Razor Pages routes. For more information, see Use a parameter transformer to customize page routes.

URL generation reference

This section contains a reference for the algorithm implemented by URL generation. In practice, most complex examples of URL generation use controllers or Razor Pages. See routing in controllers for additional information.

The URL generation process begins with a call to LinkGenerator.GetPathByAddress or a similar method. The method is provided with an address, a set of route values, and optionally information about the current request from `HttpContext`.

The first step is to use the address to resolve a set of candidate endpoints using an `IEndpointAddressScheme<TAddress>` that matches the address's type.

Once of set of candidates is found by the address scheme, the endpoints are ordered and processed iteratively until a URL generation operation succeeds. URL generation does **not** check for ambiguities, the first result returned is the final result.

Troubleshooting URL generation with logging

The first step in troubleshooting URL generation is setting the logging level of `Microsoft.AspNetCore.Routing` to `TRACE`. `LinkGenerator` logs many details about its processing which can be useful to troubleshoot problems.

See URL generation reference for details on URL generation.

Addresses

Addresses are the concept in URL generation used to bind a call into the link generator to a set of candidate endpoints.

Addresses are an extensible concept that come with two implementations by default:

- Using *endpoint name* (`string`) as the address:
  - Provides similar functionality to MVC's route name.
  - Uses the IEndpointNameMetadata metadata type.
  - Resolves the provided string against the metadata of all registered endpoints.
  - Throws an exception on startup if multiple endpoints use the same name.
  - Recommended for general-purpose use outside of controllers and Razor Pages.
- Using *route values* (RouteValuesAddress) as the address:
  - Provides similar functionality to controllers and Razor Pages legacy URL generation.
  - Very complex to extend and debug.
  - Provides the implementation used by `IUrlHelper`, Tag Helpers, HTML Helpers, Action Results, etc.

The role of the address scheme is to make the association between the address and matching endpoints by arbitrary criteria:

- The endpoint name scheme performs a basic dictionary lookup.

- The route values scheme has a complex best subset of set algorithm.

Ambient values and explicit values

From the current request, routing accesses the route values of the current request `HttpContext.Request.RouteValues`. The values associated with the current request are referred to as the **ambient values**. For the purpose of clarity, the documentation refers to the route values passed in to methods as **explicit values**.

The following example shows ambient values and explicit values. It provides ambient values from the current request and explicit values: `{ id = 17, }`:

```
public class WidgetController : Controller
{
    private readonly LinkGenerator _linkGenerator;

    public WidgetController(LinkGenerator linkGenerator)
    {
        _linkGenerator = linkGenerator;
    }

    public IActionResult Index()
    {
        var url = _linkGenerator.GetPathByAction(HttpContext,
                                                 null, null,
                                                 new { id = 17, });
        return Content(url);
    }
```

The preceding code:

- Returns `/Widget/Index/17`
- Gets LinkGenerator via DI.

The following code provides no ambient values and explicit values:
`{ controller = "Home", action = "Subscribe", id = 17, }`:

```
public IActionResult Index2()
{
    var url = _linkGenerator.GetPathByAction("Subscribe", "Home",
                                             new { id = 17, });
    return Content(url);
}
```

The preceding method returns `/Home/Subscribe/17`

The following code in the `WidgetController` returns `/Widget/Subscribe/17`:

```
var url = _linkGenerator.GetPathByAction("Subscribe", null,
                                         new { id = 17, });
```

The following code provides the controller from ambient values in the current request and explicit values:
`{ action = "Edit", id = 17, }`:

```
public class GadgetController : Controller
{
    public IActionResult Index()
    {
        var url = Url.Action("Edit", new { id = 17, });
        return Content(url);
    }
```

In the preceding code:

- `/Gadget/Edit/17` is returned.
- Url gets the IUrlHelper.
- Action generates a URL with an absolute path for an action method. The URL contains the specified `action` name and `route` values.

The following code provides ambient values from the current request and explicit values: `{ page = "./Edit, id = 17, }`:

```
public class IndexModel : PageModel
{
    public void OnGet()
    {
        var url = Url.Page("./Edit", new { id = 17, });
        ViewData["URL"] = url;
    }
}
```

The preceding code sets `url` to `/Edit/17` when the Edit Razor Page contains the following page directive:

`@page "{id:int}"`

If the Edit page doesn't contain the `"{id:int}"` route template, `url` is `/Edit?id=17`.

The behavior of MVC's IUrlHelper adds a layer of complexity in addition to the rules described here:

- `IUrlHelper` always provides the route values from the current request as ambient values.
- IUrlHelper.Action always copies the current `action` and `controller` route values as explicit values unless overridden by the developer.
- IUrlHelper.Page always copies the current `page` route value as an explicit value unless overridden.
- `IUrlHelper.Page` always overrides the current `handler` route value with `null` as an explicit values unless overridden.

Users are often surprised by the behavioral details of ambient values, because MVC doesn't seem to follow its own rules. For historical and compatibility reasons, certain route values such as `action`, `controller`, `page`, and `handler` have their own special-case behavior.

The equivalent functionality provided by `LinkGenerator.GetPathByAction` and `LinkGenerator.GetPathByPage` duplicates these anomalies of `IUrlHelper` for compatibility.

URL generation process

Once the set of candidate endpoints are found, the URL generation algorithm:

- Processes the endpoints iteratively.
- Returns the first successful result.

The first step in this process is called **route value invalidation**. Route value invalidation is the process by which routing decides which route values from the ambient values should be used and which should be

ignored. Each ambient value is considered and either combined with the explicit values, or ignored.

The best way to think about the role of ambient values is that they attempt to save application developers typing, in some common cases. Traditionally, the scenarios where ambient values are helpful are related to MVC:

- When linking to another action in the same controller, the controller name doesn't need to be specified.
- When linking to another controller in the same area, the area name doesn't need to be specified.
- When linking to the same action method, route values don't need to be specified.
- When linking to another part of the app, you don't want to carry over route values that have no meaning in that part of the app.

Calls to `LinkGenerator` or `IUrlHelper` that return `null` are usually caused by not understanding route value invalidation. Troubleshoot route value invalidation by explicitly specifying more of the route values to see if that solves the problem.

Route value invalidation works on the assumption that the app's URL scheme is hierarchical, with a hierarchy formed from left-to-right. Consider the basic controller route template `{controller}/{action}/{id?}` to get an intuitive sense of how this works in practice. A **change** to a value **invalidates** all of the route values that appear to the right. This reflects the assumption about hierarchy. If the app has an ambient value for `id`, and the operation specifies a different value for the `controller`:

- `id` won't be reused because `{controller}` is to the left of `{id?}`.

Some examples demonstrating this principle:

- If the explicit values contain a value for `id`, the ambient value for `id` is ignored. The ambient values for `controller` and `action` can be used.
- If the explicit values contain a value for `action`, any ambient value for `action` is ignored. The ambient values for `controller` can be used. If the explicit value for `action` is different from the ambient value for `action`, the `id` value won't be used. If the explicit value for `action` is the same as the ambient value for `action`, the `id` value can be used.
- If the explicit values contain a value for `controller`, any ambient value for `controller` is ignored. If the explicit value for `controller` is different from the ambient value for `controller`, the `action` and `id` values won't be used. If the explicit value for `controller` is the same as the ambient value for `controller`, the `action` and `id` values can be used.

This process is further complicated by the existence of attribute routes and dedicated conventional routes. Controller conventional routes such as `{controller}/{action}/{id?}` specify a hierarchy using route parameters. For dedicated conventional routes and attribute routes to controllers and Razor Pages:

- There is a hierarchy of route values.
- They don't appear in the template.

For these cases, URL generation defines the **required values** concept. Endpoints created by controllers and Razor Pages have required values specified that allow route value invalidation to work.

The route value invalidation algorithm in detail:

- The required value names are combined with the route parameters, then processed from left-to-right.
- For each parameter, the ambient value and explicit value are compared:
  - If the ambient value and explicit value are the same, the process continues.
  - If the ambient value is present and the explicit value isn't, the ambient value is used when generating the URL.
  - If the ambient value isn't present and the explicit value is, reject the ambient value and all

subsequent ambient values.
    - If the ambient value and the explicit value are present, and the two values are different, reject the ambient value and all subsequent ambient values.

At this point, the URL generation operation is ready to evaluate route constraints. The set of accepted values is combined with the parameter default values, which is provided to constraints. If the constraints all pass, the operation continues.

Next, the **accepted values** can be used to expand the route template. The route template is processed:

- From left-to-right.
- Each parameter has its accepted value substituted.
- With the following special cases:
    - If the accepted values is missing a value and the parameter has a default value, the default value is used.
    - If the accepted values is missing a value and the parameter is optional, processing continues.
    - If any route parameter to the right of a missing optional parameter has a value, the operation fails.
    - Contiguous default-valued parameters and optional parameters are collapsed where possible.

Values explicitly provided that don't match a segment of the route are added to the query string. The following table shows the result when using the route template `{controller}/{action}/{id?}`.

AMBIENT VALUES	EXPLICIT VALUES	RESULT
controller = "Home"	action = "About"	`/Home/About`
controller = "Home"	controller = "Order", action = "About"	`/Order/About`
controller = "Home", color = "Red"	action = "About"	`/Home/About`
controller = "Home"	action = "About", color = "Red"	`/Home/About?color=Red`

Problems with route value invalidation

As of ASP.NET Core 3.0, some URL generation schemes used in earlier ASP.NET Core versions don't work well with URL generation. The ASP.NET Core team plans to add features to address these needs in a future release. For now the best solution is to use legacy routing.

The following code shows an example of a URL generation scheme that's not supported by routing.

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute("default",
                                 "{culture}/{controller=Home}/{action=Index}/{id?}");
    endpoints.MapControllerRoute("blog", "{culture}/{**slug}",
                                  new { controller = "Blog", action = "ReadPost", });
});
```

In the preceding code, the `culture` route parameter is used for localization. The desire is to have the `culture` parameter always accepted as an ambient value. However, the `culture` parameter is not accepted as an ambient value because of the way required values work:

- In the `"default"` route template, the `culture` route parameter is to the left of `controller`, so changes to `controller` won't invalidate `culture`.

- In the `"blog"` route template, the `culture` route parameter is considered to be to the right of `controller`, which appears in the required values.

Configuring endpoint metadata

The following links provide information on configuring endpoint metadata:

- Enable Cors with endpoint routing
- IAuthorizationPolicyProvider sample using a custom `[MinimumAgeAuthorize]` attribute
- Test authentication with the [Authorize] attribute
- RequireAuthorization
- Selecting the scheme with the [Authorize] attribute
- Apply policies using the [Authorize] attribute
- Role-based authorization in ASP.NET Core

Host matching in routes with RequireHost

RequireHost applies a constraint to the route which requires the specified host. The `RequireHost` or [Host] parameter can be:

- Host: `www.domain.com`, matches `www.domain.com` with any port.
- Host with wildcard: `*.domain.com`, matches `www.domain.com`, `subdomain.domain.com`, or `www.subdomain.domain.com` on any port.
- Port: `*:5000`, matches port 5000 with any host.
- Host and port: `www.domain.com:5000` or `*.domain.com:5000`, matches host and port.

Multiple parameters can be specified using `RequireHost` or `[Host]`. The constraint matches hosts valid for any of the parameters. For example, `[Host("domain.com", "*.domain.com")]` matches `domain.com`, `www.domain.com`, and `subdomain.domain.com`.

The following code uses `RequireHost` to require the specified host on the route:

```
public void Configure(IApplicationBuilder app)
{
    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapGet("/", context => context.Response.WriteAsync("Hi Contoso!"))
            .RequireHost("contoso.com");
        endpoints.MapGet("/", context => context.Response.WriteAsync("AdventureWorks!"))
            .RequireHost("adventure-works.com");
        endpoints.MapHealthChecks("/healthz").RequireHost("*:8080");
    });
}
```

The following code uses the `[Host]` attribute on the controller to require any of the specified hosts:

```
[Host("contoso.com", "adventure-works.com")]
public class ProductController : Controller
{
    public IActionResult Index()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [Host("example.com:8080")]
    public IActionResult Privacy()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

When the `[Host]` attribute is applied to both the controller and action method:

- The attribute on the action is used.
- The controller attribute is ignored.

Performance guidance for routing

Most of routing was updated in ASP.NET Core 3.0 to increase performance.

When an app has performance problems, routing is often suspected as the problem. The reason routing is suspected is that frameworks like controllers and Razor Pages report the amount of time spent inside the framework in their logging messages. When there's a significant difference between the time reported by controllers and the total time of the request:

- Developers eliminate their app code as the source of the problem.
- It's common to assume routing is the cause.

Routing is performance tested using thousands of endpoints. It's unlikely that a typical app will encounter a performance problem just by being too large. The most common root cause of slow routing performance is usually a badly-behaving custom middleware.

This following code sample demonstrates a basic technique for narrowing down the source of delay:

```
public void Configure(IApplicationBuilder app, ILogger<Startup> logger)
{
    app.Use(next => async context =>
    {
        var sw = Stopwatch.StartNew();
        await next(context);
        sw.Stop();

        logger.LogInformation("Time 1: {ElapsedMilliseconds}ms", sw.ElapsedMilliseconds);
    });

    app.UseRouting();

    app.Use(next => async context =>
    {
        var sw = Stopwatch.StartNew();
        await next(context);
        sw.Stop();

        logger.LogInformation("Time 2: {ElapsedMilliseconds}ms", sw.ElapsedMilliseconds);
    });

    app.UseAuthorization();

    app.Use(next => async context =>
    {
        var sw = Stopwatch.StartNew();
        await next(context);
        sw.Stop();

        logger.LogInformation("Time 3: {ElapsedMilliseconds}ms", sw.ElapsedMilliseconds);
    });

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapGet("/", async context =>
        {
            await context.Response.WriteAsync("Timing test.");
        });
    });
}
```

To time routing:

- Interleave each middleware with a copy of the timing middleware shown in the preceding code.
- Add a unique identifier to correlate the timing data with the code.

This is a basic way to narrow down the delay when it's significant, for example, more than `10ms`. Subtracting `Time 2` from `Time 1` reports the time spent inside the `UseRouting` middleware.

The following code uses a more compact approach to the preceding timing code:

```
public sealed class MyStopwatch : IDisposable
{
    ILogger<Startup> _logger;
    string _message;
    Stopwatch _sw;

    public MyStopwatch(ILogger<Startup> logger, string message)
    {
        _logger = logger;
        _message = message;
        _sw = Stopwatch.StartNew();
    }

    private bool disposed = false;

    public void Dispose()
    {
        if (!disposed)
        {
            _logger.LogInformation("{Message }: {ElapsedMilliseconds}ms",
                                   _message, _sw.ElapsedMilliseconds);

            disposed = true;
        }
    }
}
```

```
public void Configure(IApplicationBuilder app, ILogger<Startup> logger)
{
    int count = 0;
    app.Use(next => async context =>
    {
        using (new MyStopwatch(logger, $"Time {++count}"))
        {
            await next(context);
        }

    });

    app.UseRouting();

    app.Use(next => async context =>
    {
        using (new MyStopwatch(logger, $"Time {++count}"))
        {
            await next(context);
        }
    });

    app.UseAuthorization();

    app.Use(next => async context =>
    {
        using (new MyStopwatch(logger, $"Time {++count}"))
        {
            await next(context);
        }
    });

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapGet("/", async context =>
        {
            await context.Response.WriteAsync("Timing test.");
        });
    });
}
```

Potentially expensive routing features

The following list provides some insight into routing features that are relatively expensive compared with basic route templates:

- Regular expressions: It's possible to write regular expressions that are complex, or have long running time with a small amount of input.
- Complex segments (`{x}-{y}-{z}`):
  - Are significantly more expensive than parsing a regular URL path segment.
  - Result in many more substrings being allocated.
  - The complex segment logic was not updated in ASP.NET Core 3.0 routing performance update.
- Synchronous data access: Many complex apps have database access as part of their routing. ASP.NET Core 2.2 and earlier routing might not provide the right extensibility points to support database access routing. For example, IRouteConstraint, and IActionConstraint are synchronous. Extensibility points such as MatcherPolicy and EndpointSelectorContext are asynchronous.

Guidance for library authors

This section contains guidance for library authors building on top of routing. These details are intended to

ensure that app developers have a good experience using libraries and frameworks that extend routing.

Define endpoints

To create a framework that uses routing for URL matching, start by defining a user experience that builds on top of UseEndpoints.

DO build on top of IEndpointRouteBuilder. This allows users to compose your framework with other ASP.NET Core features without confusion. Every ASP.NET Core template includes routing. Assume routing is present and familiar for users.

```
app.UseEndpoints(endpoints =>
{
    // Your framework
    endpoints.MapMyFramework(...);

    endpoints.MapHealthChecks("/healthz");
});
```

DO return a sealed concrete type from a call to `MapMyFramework(...)` that implements IEndpointConventionBuilder. Most framework `Map...` methods follow this pattern. The `IEndpointConventionBuilder` interface:

- Allows composability of metadata.
- Is targeted by a variety of extension methods.

Declaring your own type allows you to add your own framework-specific functionality to the builder. It's ok to wrap a framework-declared builder and forward calls to it.

```
app.UseEndpoints(endpoints =>
{
    // Your framework
    endpoints.MapMyFramework(...).RequireAuthorization()
                                 .WithMyFrameworkFeature(awesome: true);

    endpoints.MapHealthChecks("/healthz");
});
```

CONSIDER writing your own EndpointDataSource. `EndpointDataSource` is the low-level primitive for declaring and updating a collection of endpoints. `EndpointDataSource` is a powerful API used by controllers and Razor Pages.

The routing tests have a basic example of a non-updating data source.

DO NOT attempt to register an `EndpointDataSource` by default. Require users to register your framework in UseEndpoints. The philosophy of routing is that nothing is included by default, and that `UseEndpoints` is the place to register endpoints.

Creating routing-integrated middleware

CONSIDER defining metadata types as an interface.

DO make it possible to use metadata types as an attribute on classes and methods.

```
public interface ICoolMetadata
{
    bool IsCool { get; }
}

[AttributeUsage(AttributeTargets.Class | AttributeTargets.Method)]
public class CoolMetadataAttribute : Attribute, ICoolMetadata
{
    public bool IsCool => true;
}
```

Frameworks like controllers and Razor Pages support applying metadata attributes to types and methods. If you declare metadata types:

- Make them accessible as attributes.
- Most users are familiar with applying attributes.

Declaring a metadata type as an interface adds another layer of flexibility:

- Interfaces are composable.
- Developers can declare their own types that combine multiple policies.

DO make it possible to override metadata, as shown in the following example:

```
public interface ICoolMetadata
{
    bool IsCool { get; }
}

[AttributeUsage(AttributeTargets.Class | AttributeTargets.Method)]
public class CoolMetadataAttribute : Attribute, ICoolMetadata
{
    public bool IsCool => true;
}

[AttributeUsage(AttributeTargets.Class | AttributeTargets.Method)]
public class SuppressCoolMetadataAttribute : Attribute, ICoolMetadata
{
    public bool IsCool => false;
}

[CoolMetadata]
public class MyController : Controller
{
    public void MyCool() { }

    [SuppressCoolMetadata]
    public void Uncool() { }
}
```

The best way to follow these guidelines is to avoid defining **marker metadata**:

- Don't just look for the presence of a metadata type.
- Define a property on the metadata and check the property.

The metadata collection is ordered and supports overriding by priority. In the case of controllers, metadata on the action method is most specific.

DO make middleware useful with and without routing.

```
app.UseRouting();

app.UseAuthorization(new AuthorizationPolicy() { ... });

app.UseEndpoints(endpoints =>
{
    // Your framework
    endpoints.MapMyFramework(...).RequireAuthorization();
});
```

As an example of this guideline, consider the `UseAuthorization` middleware. The authorization middleware allows you to pass in a fallback policy. The fallback policy, if specified, applies to both:

- Endpoints without a specified policy.
- Requests that don't match an endpoint.

This makes the authorization middleware useful outside of the context of routing. The authorization middleware can be used for traditional middleware programming.

Debug diagnostics

For detailed routing diagnostic output, set `Logging:LogLevel:Microsoft` to `Debug`. In the development environment, set the log level in *appsettings.Development.json*:

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Debug",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  }
}
```

Routing is responsible for mapping request URIs to endpoints and dispatching incoming requests to those endpoints. Routes are defined in the app and configured when the app starts. A route can optionally extract values from the URL contained in the request, and these values can then be used for request processing. Using route information from the app, routing is also able to generate URLs that map to endpoints.

To use the latest routing scenarios in ASP.NET Core 2.2, specify the compatibility version to the MVC services registration in `Startup.ConfigureServices`:

```
services.AddMvc()
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

The EnableEndpointRouting option determines if routing should internally use endpoint-based logic or the IRouter-based logic of ASP.NET Core 2.1 or earlier. When the compatibility version is set to 2.2 or later, the default value is `true`. Set the value to `false` to use the prior routing logic:

```
// Use the routing logic of ASP.NET Core 2.1 or earlier:
services.AddMvc(options => options.EnableEndpointRouting = false)
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

For more information on IRouter-based routing, see the .

> **IMPORTANT**
>
> This document covers low-level ASP.NET Core routing. For information on ASP.NET Core MVC routing, see Routing to controller actions in ASP.NET Core. For information on routing conventions in Razor Pages, see Razor Pages route and app conventions in ASP.NET Core.

View or download sample code (how to download)

Routing basics

Most apps should choose a basic and descriptive routing scheme so that URLs are readable and meaningful. The default conventional route `{controller=Home}/{action=Index}/{id?}`:

- Supports a basic and descriptive routing scheme.
- Is a useful starting point for UI-based apps.

Developers commonly add additional terse routes to high-traffic areas of an app in specialized situations using attribute routing or dedicated conventional routes. Specialized situations examples include, blog and ecommerce endpoints.

Web APIs should use attribute routing to model the app's functionality as a set of resources where operations are represented by HTTP verbs. This means that many operations, for example, GET, and POST, on the same logical resource use the same URL. Attribute routing provides a level of control that's needed to carefully design an API's public endpoint layout.

Razor Pages apps use default conventional routing to serve named resources in the *Pages* folder of an app. Additional conventions are available that allow you to customize Razor Pages routing behavior. For more information, see Introduction to Razor Pages in ASP.NET Core and Razor Pages route and app conventions in ASP.NET Core.

URL generation support allows the app to be developed without hard-coding URLs to link the app together. This support allows for starting with a basic routing configuration and modifying the routes after the app's resource layout is determined.

Routing uses *endpoints* (`Endpoint`) to represent logical endpoints in an app.

An endpoint defines a delegate to process requests and a collection of arbitrary metadata. The metadata is used implement cross-cutting concerns based on policies and configuration attached to each endpoint.

The routing system has the following characteristics:

- Route template syntax is used to define routes with tokenized route parameters.
- Conventional-style and attribute-style endpoint configuration is permitted.
- IRouteConstraint is used to determine whether a URL parameter contains a valid value for a given endpoint constraint.
- App models, such as MVC/Razor Pages, register all of their endpoints, which have a predictable implementation of routing scenarios.
- The routing implementation makes routing decisions wherever desired in the middleware pipeline.
- Middleware that appears after a Routing Middleware can inspect the result of the Routing Middleware's endpoint decision for a given request URI.
- It's possible to enumerate all of the endpoints in the app anywhere in the middleware pipeline.

- An app can use routing to generate URLs (for example, for redirection or links) based on endpoint information and thus avoid hard-coded URLs, which helps maintainability.
- URL generation is based on addresses, which support arbitrary extensibility:
  - The Link Generator API (LinkGenerator) can be resolved anywhere using dependency injection (DI) to generate URLs.
  - Where the Link Generator API isn't available via DI, IUrlHelper offers methods to build URLs.

> **NOTE**
> With the release of endpoint routing in ASP.NET Core 2.2, endpoint linking is limited to MVC/Razor Pages actions and pages. The expansions of endpoint-linking capabilities is planned for future releases.

Routing is connected to the middleware pipeline by the RouterMiddleware class. ASP.NET Core MVC adds routing to the middleware pipeline as part of its configuration and handles routing in MVC and Razor Pages apps. To learn how to use routing as a standalone component, see the Use Routing Middleware section.

URL matching

URL matching is the process by which routing dispatches an incoming request to an *endpoint*. This process is based on data in the URL path but can be extended to consider any data in the request. The ability to dispatch requests to separate handlers is key to scaling the size and complexity of an app.

The routing system in endpoint routing is responsible for all dispatching decisions. Since the middleware applies policies based on the selected endpoint, it's important that any decision that can affect dispatching or the application of security policies is made inside the routing system.

When the endpoint delegate is executed, the properties of RouteContext.RouteData are set to appropriate values based on the request processing performed thus far.

RouteData.Values is a dictionary of *route values* produced from the route. These values are usually determined by tokenizing the URL and can be used to accept user input or to make further dispatching decisions inside the app.

RouteData.DataTokens is a property bag of additional data related to the matched route. DataTokens are provided to support associating state data with each route so that the app can make decisions based on which route matched. These values are developer-defined and do **not** affect the behavior of routing in any way. Additionally, values stashed in RouteData.DataTokens can be of any type, in contrast to RouteData.Values, which must be convertible to and from strings.

RouteData.Routers is a list of the routes that took part in successfully matching the request. Routes can be nested inside of one another. The Routers property reflects the path through the logical tree of routes that resulted in a match. Generally, the first item in Routers is the route collection and should be used for URL generation. The last item in Routers is the route handler that matched.

URL generation with LinkGenerator

URL generation is the process by which routing can create a URL path based on a set of route values. This allows for a logical separation between your endpoints and the URLs that access them.

Endpoint routing includes the Link Generator API (LinkGenerator). LinkGenerator is a singleton service that can be retrieved from DI. The API can be used outside of the context of an executing request. MVC's IUrlHelper and scenarios that rely on IUrlHelper, such as Tag Helpers, HTML Helpers, and Action Results, use the link generator to provide link generating capabilities.

The link generator is backed by the concept of an *address* and *address schemes*. An address scheme is a way of determining the endpoints that should be considered for link generation. For example, the route name and

route values scenarios many users are familiar with from MVC/Razor Pages are implemented as an address scheme.

The link generator can link to MVC/Razor Pages actions and pages via the following extension methods:

- GetPathByAction
- GetUriByAction
- GetPathByPage
- GetUriByPage

An overload of these methods accepts arguments that include the `HttpContext`. These methods are functionally equivalent to `Url.Action` and `Url.Page` but offer additional flexibility and options.

The `GetPath*` methods are most similar to `Url.Action` and `Url.Page` in that they generate a URI containing an absolute path. The `GetUri*` methods always generate an absolute URI containing a scheme and host. The methods that accept an `HttpContext` generate a URI in the context of the executing request. The ambient route values, URL base path, scheme, and host from the executing request are used unless overridden.

LinkGenerator is called with an address. Generating a URI occurs in two steps:

1. An address is bound to a list of endpoints that match the address.
2. Each endpoint's `RoutePattern` is evaluated until a route pattern that matches the supplied values is found. The resulting output is combined with the other URI parts supplied to the link generator and returned.

The methods provided by LinkGenerator support standard link generation capabilities for any type of address. The most convenient way to use the link generator is through extension methods that perform operations for a specific address type.

EXTENSION METHOD	DESCRIPTION
GetPathByAddress	Generates a URI with an absolute path based on the provided values.
GetUriByAddress	Generates an absolute URI based on the provided values.

WARNING

Pay attention to the following implications of calling LinkGenerator methods:

- Use `GetUri*` extension methods with caution in an app configuration that doesn't validate the `Host` header of incoming requests. If the `Host` header of incoming requests isn't validated, untrusted request input can be sent back to the client in URIs in a view/page. We recommend that all production apps configure their server to validate the `Host` header against known valid values.
- Use LinkGenerator with caution in middleware in combination with `Map` or `MapWhen`. `Map*` changes the base path of the executing request, which affects the output of link generation. All of the LinkGenerator APIs allow specifying a base path. Always specify an empty base path to undo `Map*`'s affect on link generation.

Differences from earlier versions of routing

A few differences exist between endpoint routing in ASP.NET Core 2.2 or later and earlier versions of routing in ASP.NET Core:

- The endpoint routing system doesn't support IRouter-based extensibility, including inheriting from Route.

- Endpoint routing doesn't support WebApiCompatShim. Use the 2.1 compatibility version (`.SetCompatibilityVersion(CompatibilityVersion.Version_2_1)`) to continue using the compatibility shim.

- Endpoint Routing has different behavior for the casing of generated URIs when using conventional routes.

  Consider the following default route template:

  ```
  app.UseMvc(routes =>
  {
      routes.MapRoute("default", "{controller=Home}/{action=Index}/{id?}");
  });
  ```

  Suppose you generate a link to an action using the following route:

  ```
  var link = Url.Action("ReadPost", "blog", new { id = 17, });
  ```

  With IRouter-based routing, this code generates a URI of `/blog/ReadPost/17`, which respects the casing of the provided route value. Endpoint routing in ASP.NET Core 2.2 or later produces `/Blog/ReadPost/17` ("Blog" is capitalized). Endpoint routing provides the `IOutboundParameterTransformer` interface that can be used to customize this behavior globally or to apply different conventions for mapping URLs.

  For more information, see the Parameter transformer reference section.

- Link Generation used by MVC/Razor Pages with conventional routes behaves differently when attempting to link to an controller/action or page that doesn't exist.

  Consider the following default route template:

  ```
  app.UseMvc(routes =>
  {
      routes.MapRoute("default", "{controller=Home}/{action=Index}/{id?}");
  });
  ```

  Suppose you generate a link to an action using the default template with the following:

  ```
  var link = Url.Action("ReadPost", "Blog", new { id = 17, });
  ```

  With `IRouter`-based routing, the result is always `/Blog/ReadPost/17`, even if the `BlogController` doesn't exist or doesn't have a `ReadPost` action method. As expected, endpoint routing in ASP.NET Core 2.2 or later produces `/Blog/ReadPost/17` if the action method exists. *However, endpoint routing produces an empty string if the action doesn't exist.* Conceptually, endpoint routing doesn't assume that the endpoint exists if the action doesn't exist.

- The link generation *ambient value invalidation algorithm* behaves differently when used with endpoint routing.

  Ambient value invalidation is the algorithm that decides which route values from the currently executing request (the ambient values) can be used in link generation operations. Conventional routing always invalidated extra route values when linking to a different action. Attribute routing didn't have this behavior prior to the release of ASP.NET Core 2.2. In earlier versions of ASP.NET Core, links to another action that use the same route parameter names resulted in link generation errors. In ASP.NET Core 2.2 or later, both forms of routing invalidate values when linking to another action.

Consider the following example in ASP.NET Core 2.1 or earlier. When linking to another action (or another page), route values can be reused in undesirable ways.

In */Pages/Store/Product.cshtml*:

```
@page "{id}"
@Url.Page("/Login")
```

In */Pages/Login.cshtml*:

```
@page "{id?}"
```

If the URI is `/Store/Product/18` in ASP.NET Core 2.1 or earlier, the link generated on the Store/Info page by `@Url.Page("/Login")` is `/Login/18`. The `id` value of 18 is reused, even though the link destination is different part of the app entirely. The `id` route value in the context of the `/Login` page is probably a user ID value, not a store product ID value.

In endpoint routing with ASP.NET Core 2.2 or later, the result is `/Login`. Ambient values aren't reused when the linked destination is a different action or page.

- Round-tripping route parameter syntax: Forward slashes aren't encoded when using a double-asterisk (`**`) catch-all parameter syntax.

  During link generation, the routing system encodes the value captured in a double-asterisk (`**`) catch-all parameter (for example, `{**myparametername}`) except the forward slashes. The double-asterisk catch-all is supported with `IRouter`-based routing in ASP.NET Core 2.2 or later.

  The single asterisk catch-all parameter syntax in prior versions of ASP.NET Core (`{*myparametername}`) remains supported, and forward slashes are encoded.

ROUTE	LINK GENERATED WITH `URL.ACTION(NEW { CATEGORY = "ADMIN/PRODUCTS" })`...
`/search/{*page}`	`/search/admin%2Fproducts` (the forward slash is encoded)
`/search/{**page}`	`/search/admin/products`

Middleware example

In the following example, a middleware uses the LinkGenerator API to create link to an action method that lists store products. Using the link generator by injecting it into a class and calling `GenerateLink` is available to any class in an app.

```
using Microsoft.AspNetCore.Routing;

public class ProductsLinkMiddleware
{
    private readonly LinkGenerator _linkGenerator;

    public ProductsLinkMiddleware(RequestDelegate next, LinkGenerator linkGenerator)
    {
        _linkGenerator = linkGenerator;
    }

    public async Task InvokeAsync(HttpContext httpContext)
    {
        var url = _linkGenerator.GetPathByAction("ListProducts", "Store");

        httpContext.Response.ContentType = "text/plain";

        await httpContext.Response.WriteAsync($"Go to {url} to see our products.");
    }
}
```

Create routes

Most apps create routes by calling MapRoute or one of the similar extension methods defined on IRouteBuilder. Any of the IRouteBuilder extension methods create an instance of Route and add it to the route collection.

MapRoute doesn't accept a route handler parameter. MapRoute only adds routes that are handled by the DefaultHandler. To learn more about routing in MVC, see Routing to controller actions in ASP.NET Core.

The following code example is an example of a MapRoute call used by a typical ASP.NET Core MVC route definition:

```
routes.MapRoute(
    name: "default",
    template: "{controller=Home}/{action=Index}/{id?}");
```

This template matches a URL path and extracts the route values. For example, the path `/Products/Details/17` generates the following route values: `{ controller = Products, action = Details, id = 17 }`.

Route values are determined by splitting the URL path into segments and matching each segment with the *route parameter* name in the route template. Route parameters are named. The parameters defined by enclosing the parameter name in braces `{ ... }`.

The preceding template could also match the URL path `/` and produce the values `{ controller = Home, action = Index }`. This occurs because the `{controller}` and `{action}` route parameters have default values and the `id` route parameter is optional. An equals sign (`=`) followed by a value after the route parameter name defines a default value for the parameter. A question mark (`?`) after the route parameter name defines an optional parameter.

Route parameters with a default value *always* produce a route value when the route matches. Optional parameters don't produce a route value if there is no corresponding URL path segment. See the Route template reference section for a thorough description of route template scenarios and syntax.

In the following example, the route parameter definition `{id:int}` defines a route constraint for the `id` route parameter:

```
routes.MapRoute(
    name: "default",
    template: "{controller=Home}/{action=Index}/{id:int}");
```

This template matches a URL path like `/Products/Details/17` but not `/Products/Details/Apples`. Route constraints implement IRouteConstraint and inspect route values to verify them. In this example, the route value `id` must be convertible to an integer. See route-constraint-reference for an explanation of route constraints provided by the framework.

Additional overloads of MapRoute accept values for `constraints`, `dataTokens`, and `defaults`. The typical usage of these parameters is to pass an anonymously typed object, where the property names of the anonymous type match route parameter names.

The following MapRoute examples create equivalent routes:

```
routes.MapRoute(
    name: "default_route",
    template: "{controller}/{action}/{id?}",
    defaults: new { controller = "Home", action = "Index" });

routes.MapRoute(
    name: "default_route",
    template: "{controller=Home}/{action=Index}/{id?}");
```

TIP

The inline syntax for defining constraints and defaults can be convenient for simple routes. However, there are scenarios, such as data tokens, that aren't supported by inline syntax.

The following example demonstrates a few additional scenarios:

```
routes.MapRoute(
    name: "blog",
    template: "Blog/{**article}",
    defaults: new { controller = "Blog", action = "ReadArticle" });
```

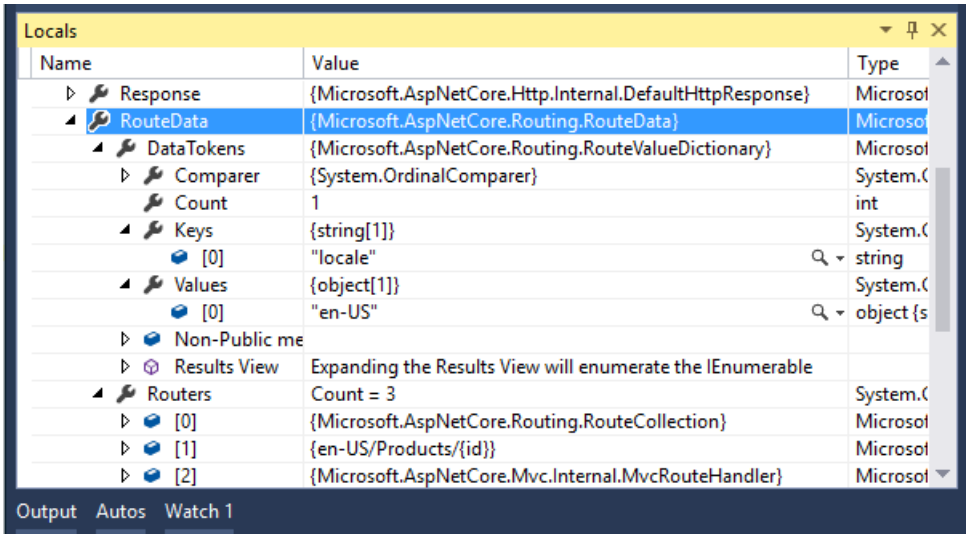
The preceding template matches a URL path like `/Blog/All-About-Routing/Introduction` and extracts the values `{ controller = Blog, action = ReadArticle, article = All-About-Routing/Introduction }`. The default route values for `controller` and `action` are produced by the route even though there are no corresponding route parameters in the template. Default values can be specified in the route template. The `article` route parameter is defined as a *catch-all* by the appearance of an double asterisk (`**`) before the route parameter name. Catch-all route parameters capture the remainder of the URL path and can also match the empty string.

The following example adds route constraints and data tokens:

```
routes.MapRoute(
    name: "us_english_products",
    template: "en-US/Products/{id}",
    defaults: new { controller = "Products", action = "Details" },
    constraints: new { id = new IntRouteConstraint() },
    dataTokens: new { locale = "en-US" });
```

The preceding template matches a URL path like `/en-US/Products/5` and extracts the values

`{ controller = Products, action = Details, id = 5 }` and the data tokens `{ locale = en-US }`.



Route class URL generation

The Route class can also perform URL generation by combining a set of route values with its route template. This is logically the reverse process of matching the URL path.

> **TIP**
>
> To better understand URL generation, imagine what URL you want to generate and then think about how a route template would match that URL. What values would be produced? This is the rough equivalent of how URL generation works in the Route class.

The following example uses a general ASP.NET Core MVC default route:

```
routes.MapRoute(
    name: "default",
    template: "{controller=Home}/{action=Index}/{id?}");
```

With the route values `{ controller = Products, action = List }`, the URL `/Products/List` is generated. The route values are substituted for the corresponding route parameters to form the URL path. Since `id` is an optional route parameter, the URL is successfully generated without a value for `id`.

With the route values `{ controller = Home, action = Index }`, the URL `/` is generated. The provided route values match the default values, and the segments corresponding to the default values are safely omitted.

Both URLs generated round-trip with the following route definition (`/Home/Index` and `/`) produce the same route values that were used to generate the URL.

> **NOTE**
>
> An app using ASP.NET Core MVC should use UrlHelper to generate URLs instead of calling into routing directly.

For more information on URL generation, see the Url generation reference section.

Use Routing Middleware

Reference the Microsoft.AspNetCore.App metapackage in the app's project file.

Add routing to the service container in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRouting();
}
```

Routes must be configured in the `Startup.Configure` method. The sample app uses the following APIs:

- RouteBuilder
- MapGet: Matches only HTTP GET requests.
- UseRouter

```
var trackPackageRouteHandler = new RouteHandler(context =>
{
    var routeValues = context.GetRouteData().Values;
    return context.Response.WriteAsync(
        $"Hello! Route values: {string.Join(", ", routeValues)}");
});

var routeBuilder = new RouteBuilder(app, trackPackageRouteHandler);

routeBuilder.MapRoute(
    "Track Package Route",
    "package/{operation:regex(^track|create$)}/{id:int}");

routeBuilder.MapGet("hello/{name}", context =>
{
    var name = context.GetRouteValue("name");
    // The route handler when HTTP GET "hello/<anything>" matches
    // To match HTTP GET "hello/<anything>/<anything>,
    // use routeBuilder.MapGet("hello/{*name}"
    return context.Response.WriteAsync($"Hi, {name}!");
});

var routes = routeBuilder.Build();
app.UseRouter(routes);
```

The following table shows the responses with the given URIs.

URI	RESPONSE
`/package/create/3`	Hello! Route values: [operation, create], [id, 3]
`/package/track/-3`	Hello! Route values: [operation, track], [id, -3]
`/package/track/-3/`	Hello! Route values: [operation, track], [id, -3]
`/package/track/`	The request falls through, no match.
`GET /hello/Joe`	Hi, Joe!
`POST /hello/Joe`	The request falls through, matches HTTP GET only.
`GET /hello/Joe/Smith`	The request falls through, no match.

The framework provides a set of extension methods for creating routes (RequestDelegateRouteBuilderExtensions):

- MapDelete
- MapGet
- MapMiddlewareDelete
- MapMiddlewareGet
- MapMiddlewarePost
- MapMiddlewarePut
- MapMiddlewareRoute
- MapMiddlewareVerb
- MapPost
- MapPut
- MapRoute
- MapVerb

The `Map[Verb]` methods use constraints to limit the route to the HTTP Verb in the method name. For example, see MapGet and MapVerb.

Route template reference

Tokens within curly braces (`{ ... }`) define *route parameters* that are bound if the route is matched. You can define more than one route parameter in a route segment, but they must be separated by a literal value. For example, `{controller=Home}{action=Index}` isn't a valid route, since there's no literal value between `{controller}` and `{action}`. These route parameters must have a name and may have additional attributes specified.

Literal text other than route parameters (for example, `{id}`) and the path separator `/` must match the text in the URL. Text matching is case-insensitive and based on the decoded representation of the URLs path. To match a literal route parameter delimiter (`{` or `}`), escape the delimiter by repeating the character (`{{` or `}}`).

URL patterns that attempt to capture a file name with an optional file extension have additional considerations. For example, consider the template `files/{filename}.{ext?}` . When values for both `filename` and `ext` exist, both values are populated. If only a value for `filename` exists in the URL, the route matches because the trailing period (`.`) is optional. The following URLs match this route:

- `/files/myFile.txt`
- `/files/myFile`

You can use an asterisk (`*`) or double asterisk (`**`) as a prefix to a route parameter to bind to the rest of the URI. These are called a *catch-all* parameters. For example, `blog/{**slug}` matches any URI that starts with `/blog` and has any value following it, which is assigned to the `slug` route value. Catch-all parameters can also match the empty string.

The catch-all parameter escapes the appropriate characters when the route is used to generate a URL, including path separator (`/`) characters. For example, the route `foo/{*path}` with route values `{ path = "my/path" }` generates `foo/my%2Fpath` . Note the escaped forward slash. To round-trip path separator characters, use the `**` route parameter prefix. The route `foo/{**path}` with `{ path = "my/path" }` generates `foo/my/path` .

Route parameters may have *default values* designated by specifying the default value after the parameter name separated by an equals sign (`=`). For example, `{controller=Home}` defines `Home` as the default value for `controller` . The default value is used if no value is present in the URL for the parameter. Route parameters are made optional by appending a question mark (`?`) to the end of the parameter name, as in `id?` . The difference between optional values and default route parameters is that a route parameter with a

default value always produces a value—an optional parameter has a value only when a value is provided by the request URL.

Route parameters may have constraints that must match the route value bound from the URL. Adding a colon (`:`) and constraint name after the route parameter name specifies an *inline constraint* on a route parameter. If the constraint requires arguments, they're enclosed in parentheses (`(...)`) after the constraint name. Multiple inline constraints can be specified by appending another colon (`:`) and constraint name.

The constraint name and arguments are passed to the IInlineConstraintResolver service to create an instance of IRouteConstraint to use in URL processing. For example, the route template `blog/{article:minlength(10)}` specifies a `minlength` constraint with the argument `10`. For more information on route constraints and a list of the constraints provided by the framework, see the Route constraint reference section.

Route parameters may also have parameter transformers, which transform a parameter's value when generating links and matching actions and pages to URLs. Like constraints, parameter transformers can be added inline to a route parameter by adding a colon (`:`) and transformer name after the route parameter name. For example, the route template `blog/{article:slugify}` specifies a `slugify` transformer. For more information on parameter transformers, see the Parameter transformer reference section.

The following table demonstrates example route templates and their behavior.

ROUTE TEMPLATE	EXAMPLE MATCHING URI	THE REQUEST URI...
`hello`	`/hello`	Only matches the single path `/hello`.
`{Page=Home}`	`/`	Matches and sets `Page` to `Home`.
`{Page=Home}`	`/Contact`	Matches and sets `Page` to `Contact`.
`{controller}/{action}/{id?}`	`/Products/List`	Maps to the `Products` controller and `List` action.
`{controller}/{action}/{id?}`	`/Products/Details/123`	Maps to the `Products` controller and `Details` action (`id` set to 123).
`{controller=Home}/{action=Index}/{id?}`	`/`	Maps to the `Home` controller and `Index` method (`id` is ignored).

Using a template is generally the simplest approach to routing. Constraints and defaults can also be specified outside the route template.

> **TIP**
> Enable Logging to see how the built-in routing implementations, such as Route, match requests.

Reserved routing names

The following keywords are reserved names and can't be used as route names or parameters:

- `action`
- `area`

- `controller`
- `handler`
- `page`

Route constraint reference

Route constraints execute when a match has occurred to the incoming URL and the URL path is tokenized into route values. Route constraints generally inspect the route value associated via the route template and make a yes/no decision about whether or not the value is acceptable. Some route constraints use data outside the route value to consider whether the request can be routed. For example, the HttpMethodRouteConstraint can accept or reject a request based on its HTTP verb. Constraints are used in routing requests and link generation.

> **WARNING**
> Don't use constraints for **input validation**. If constraints are used for **input validation**, invalid input results in a *404 - Not Found* response instead of a *400 - Bad Request* with an appropriate error message. Route constraints are used to **disambiguate** similar routes, not to validate the inputs for a particular route.

The following table demonstrates example route constraints and their expected behavior.

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	NOTES
`int`	`{id:int}`	`123456789`, `-123456789`	Matches any integer.
`bool`	`{active:bool}`	`true`, `FALSE`	Matches `true` or `false`. Case-insensitive.
`datetime`	`{dob:datetime}`	`2016-12-31`, `2016-12-31 7:32pm`	Matches a valid `DateTime` value in the invariant culture. See preceding warning.
`decimal`	`{price:decimal}`	`49.99`, `-1,000.01`	Matches a valid `decimal` value in the invariant culture. See preceding warning.
`double`	`{weight:double}`	`1.234`, `-1,001.01e8`	Matches a valid `double` value in the invariant culture. See preceding warning.
`float`	`{weight:float}`	`1.234`, `-1,001.01e8`	Matches a valid `float` value in the invariant culture. See preceding warning.
`guid`	`{id:guid}`	`CD2C1638-1638-72D5-1638-DEADBEEF1638`, `{CD2C1638-1638-72D5-1638-DEADBEEF1638}`	Matches a valid `Guid` value.

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	NOTES
`long`	`{ticks:long}`	`123456789`, `-123456789`	Matches a valid `long` value.
`minlength(value)`	`{username:minlength(4)}`	`Rick`	String must be at least 4 characters.
`maxlength(value)`	`{filename:maxlength(8)}`	`MyFile`	String has maximum of 8 characters.
`length(length)`	`{filename:length(12)}`	`somefile.txt`	String must be exactly 12 characters long.
`length(min,max)`	`{filename:length(8,16)}`	`somefile.txt`	String must be at least 8 and has maximum of 16 characters.
`min(value)`	`{age:min(18)}`	`19`	Integer value must be at least 18.
`max(value)`	`{age:max(120)}`	`91`	Integer value maximum of 120.
`range(min,max)`	`{age:range(18,120)}`	`91`	Integer value must be at least 18 and maximum of 120.
`alpha`	`{name:alpha}`	`Rick`	String must consist of one or more alphabetical characters `a`-`z`. Case-insensitive.
`regex(expression)`	`{ssn:regex(^\\d{{3}}-\\d{{2}}-\\d{{4}}$)}`	`123-45-6789`	String must match the regular expression. See tips about defining a regular expression.
`required`	`{name:required}`	`Rick`	Used to enforce that a non-parameter value is present during URL generation.

Multiple, colon-delimited constraints can be applied to a single parameter. For example, the following constraint restricts a parameter to an integer value of 1 or greater:

```
[Route("users/{id:int:min(1)}")]
public User GetUserById(int id) { }
```

WARNING

Route constraints that verify the URL and are converted to a CLR type (such as `int` or `DateTime`) always use the invariant culture. These constraints assume that the URL is non-localizable. The framework-provided route constraints don't modify the values stored in route values. All route values parsed from the URL are stored as strings. For example, the `float` constraint attempts to convert the route value to a float, but the converted value is used only to verify it can be converted to a float.

Regular expressions

The ASP.NET Core framework adds `RegexOptions.IgnoreCase | RegexOptions.Compiled | RegexOptions.CultureInvariant` to the regular expression constructor. See RegexOptions for a description of these members.

Regular expressions use delimiters and tokens similar to those used by routing and the C# language. Regular expression tokens must be escaped. To use the regular expression `^\d{3}-\d{2}-\d{4}$` in routing:

- The expression must have the single backslash `\` characters provided in the string as double backslash `\\` characters in the source code.
- The regular expression must us `\\` in order to escape the `\` string escape character.
- The regular expression doesn't require `\\` when using verbatim string literals.

To escape routing parameter delimiter characters `{`, `}`, `[`, `]`, double the characters in the expression `{{`, `}}`, `[[`, `]]`. The following table shows a regular expression and the escaped version:

REGULAR EXPRESSION	ESCAPED REGULAR EXPRESSION
`^\d{3}-\d{2}-\d{4}$`	`^\\d{{3}}-\\d{{2}}-\\d{{4}}$`
`^[a-z]{2}$`	`^[[a-z]]{{2}}$`

Regular expressions used in routing often start with the caret `^` character and match starting position of the string. The expressions often end with the dollar sign `$` character and match end of the string. The `^` and `$` characters ensure that the regular expression match the entire route parameter value. Without the `^` and `$` characters, the regular expression match any substring within the string, which is often undesirable. The following table provides examples and explains why they match or fail to match.

EXPRESSION	STRING	MATCH	COMMENT
`[a-z]{2}`	hello	Yes	Substring matches
`[a-z]{2}`	123abc456	Yes	Substring matches
`[a-z]{2}`	mz	Yes	Matches expression
`[a-z]{2}`	MZ	Yes	Not case sensitive
`^[a-z]{2}$`	hello	No	See `^` and `$` above
`^[a-z]{2}$`	123abc456	No	See `^` and `$` above

For more information on regular expression syntax, see .NET Framework Regular Expressions.

To constrain a parameter to a known set of possible values, use a regular expression. For example, `{action:regex(^(list|get|create)$)}` only matches the `action` route value to `list`, `get`, or `create`. If passed into the constraints dictionary, the string `^(list|get|create)$` is equivalent. Constraints that are passed in the constraints dictionary (not inline within a template) that don't match one of the known constraints are also treated as regular expressions.

Custom route constraints

In addition to the built-in route constraints, custom route constraints can be created by implementing the IRouteConstraint interface. The IRouteConstraint interface contains a single method, `Match`, which returns `true` if the constraint is satisfied and `false` otherwise.

To use a custom IRouteConstraint, the route constraint type must be registered with the app's ConstraintMap in the app's service container. A ConstraintMap is a dictionary that maps route constraint keys to IRouteConstraint implementations that validate those constraints. An app's ConstraintMap can be updated in `Startup.ConfigureServices` either as part of a services.AddRouting call or by configuring RouteOptions directly with `services.Configure<RouteOptions>`. For example:

```
services.AddRouting(options =>
{
    options.ConstraintMap.Add("customName", typeof(MyCustomConstraint));
});
```

The constraint can then be applied to routes in the usual manner, using the name specified when registering the constraint type. For example:

```
[HttpGet("{id:customName}")]
public ActionResult<string> Get(string id)
```

Parameter transformer reference

Parameter transformers:

- Execute when generating a link for a Route.
- Implement `Microsoft.AspNetCore.Routing.IOutboundParameterTransformer`.
- Are configured using ConstraintMap.
- Take the parameter's route value and transform it to a new string value.
- Result in using the transformed value in the generated link.

For example, a custom `slugify` parameter transformer in route pattern `blog\{article:slugify}` with `Url.Action(new { article = "MyTestArticle" })` generates `blog\my-test-article`.

To use a parameter transformer in a route pattern, configure it first using ConstraintMap in `Startup.ConfigureServices`:

```
services.AddRouting(options =>
{
    // Replace the type and the name used to refer to it with your own
    // IOutboundParameterTransformer implementation
    options.ConstraintMap["slugify"] = typeof(SlugifyParameterTransformer);
});
```

Parameter transformers are used by the framework to transform the URI where an endpoint resolves. For example, ASP.NET Core MVC uses parameter transformers to transform the route value used to match an

`area`, `controller`, `action`, and `page`.

```
routes.MapRoute(
    name: "default",
    template: "{controller:slugify=Home}/{action:slugify=Index}/{id?}");
```

With the preceding route, the action `SubscriptionManagementController.GetAll` is matched with the URI `/subscription-management/get-all`. A parameter transformer doesn't change the route values used to generate a link. For example, `Url.Action("GetAll", "SubscriptionManagement")` outputs `/subscription-management/get-all`.

ASP.NET Core provides API conventions for using a parameter transformers with generated routes:

- ASP.NET Core MVC has the `Microsoft.AspNetCore.Mvc.ApplicationModels.RouteTokenTransformerConvention` API convention. This convention applies a specified parameter transformer to all attribute routes in the app. The parameter transformer transforms attribute route tokens as they are replaced. For more information, see Use a parameter transformer to customize token replacement.
- Razor Pages has the `Microsoft.AspNetCore.Mvc.ApplicationModels.PageRouteTransformerConvention` API convention. This convention applies a specified parameter transformer to all automatically discovered Razor Pages. The parameter transformer transforms the folder and file name segments of Razor Pages routes. For more information, see Use a parameter transformer to customize page routes.

URL generation reference

The following example shows how to generate a link to a route given a dictionary of route values and a RouteCollection.

```
app.Run(async (context) =>
{
    var dictionary = new RouteValueDictionary
    {
        { "operation", "create" },
        { "id", 123}
    };

    var vpc = new VirtualPathContext(context, null, dictionary,
        "Track Package Route");
    var path = routes.GetVirtualPath(vpc).VirtualPath;

    context.Response.ContentType = "text/html";
    await context.Response.WriteAsync("Menu<hr/>");
    await context.Response.WriteAsync(
        $"<a href='{path}'>Create Package 123</a><br/>");
});
```

The VirtualPath generated at the end of the preceding sample is `/package/create/123`. The dictionary supplies the `operation` and `id` route values of the "Track Package Route" template, `package/{operation}/{id}`. For details, see the sample code in the Use Routing Middleware section or the sample app.

The second parameter to the VirtualPathContext constructor is a collection of *ambient values*. Ambient values are convenient to use because they limit the number of values a developer must specify within a request context. The current route values of the current request are considered ambient values for link generation. In an ASP.NET Core MVC app's `About` action of the `HomeController`, you don't need to specify the controller route value to link to the `Index` action—the ambient value of `Home` is used.

Ambient values that don't match a parameter are ignored. Ambient values are also ignored when an explicitly

provided value overrides the ambient value. Matching occurs from left to right in the URL.

Values explicitly provided but that don't match a segment of the route are added to the query string. The following table shows the result when using the route template `{controller}/{action}/{id?}`.

AMBIENT VALUES	EXPLICIT VALUES	RESULT
controller = "Home"	action = "About"	`/Home/About`
controller = "Home"	controller = "Order", action = "About"	`/Order/About`
controller = "Home", color = "Red"	action = "About"	`/Home/About`
controller = "Home"	action = "About", color = "Red"	`/Home/About?color=Red`

If a route has a default value that doesn't correspond to a parameter and that value is explicitly provided, it must match the default value:

```
routes.MapRoute("blog_route", "blog/{*slug}",
    defaults: new { controller = "Blog", action = "ReadPost" });
```

Link generation only generates a link for this route when the matching values for `controller` and `action` are provided.

Complex segments

Complex segments (for example `[Route("/x{token}y")]`) are processed by matching up literals from right to left in a non-greedy way. See this code for a detailed explanation of how complex segments are matched. The code sample is not used by ASP.NET Core, but it provides a good explanation of complex segments.

Routing is responsible for mapping request URIs to route handlers and dispatching an incoming requests. Routes are defined in the app and configured when the app starts. A route can optionally extract values from the URL contained in the request, and these values can then be used for request processing. Using configured routes from the app, routing is able to generate URLs that map to route handlers.

To use the latest routing scenarios in ASP.NET Core 2.1, specify the compatibility version to the MVC services registration in `Startup.ConfigureServices`:

```
services.AddMvc()
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
```

IMPORTANT

This document covers low-level ASP.NET Core routing. For information on ASP.NET Core MVC routing, see Routing to controller actions in ASP.NET Core. For information on routing conventions in Razor Pages, see Razor Pages route and app conventions in ASP.NET Core.

View or download sample code (how to download)

Routing basics

Most apps should choose a basic and descriptive routing scheme so that URLs are readable and meaningful.

The default conventional route `{controller=Home}/{action=Index}/{id?}`:

- Supports a basic and descriptive routing scheme.
- Is a useful starting point for UI-based apps.

Developers commonly add additional terse routes to high-traffic areas of an app in specialized situations (for example, blog and ecommerce endpoints) using attribute routing or dedicated conventional routes.

Web APIs should use attribute routing to model the app's functionality as a set of resources where operations are represented by HTTP verbs. This means that many operations (for example, GET, POST) on the same logical resource will use the same URL. Attribute routing provides a level of control that's needed to carefully design an API's public endpoint layout.

Razor Pages apps use default conventional routing to serve named resources in the *Pages* folder of an app. Additional conventions are available that allow you to customize Razor Pages routing behavior. For more information, see Introduction to Razor Pages in ASP.NET Core and Razor Pages route and app conventions in ASP.NET Core.

URL generation support allows the app to be developed without hard-coding URLs to link the app together. This support allows for starting with a basic routing configuration and modifying the routes after the app's resource layout is determined.

Routing uses routes implementations of IRouter to:

- Map incoming requests to *route handlers*.
- Generate the URLs used in responses.

By default, an app has a single collection of routes. When a request arrives, the routes in the collection are processed in the order that they exist in the collection. The framework attempts to match an incoming request URL to a route in the collection by calling the RouteAsync method on each route in the collection. A response can use routing to generate URLs (for example, for redirection or links) based on route information and thus avoid hard-coded URLs, which helps maintainability.

The routing system has the following characteristics:

- Route template syntax is used to define routes with tokenized route parameters.
- Conventional-style and attribute-style endpoint configuration is permitted.
- IRouteConstraint is used to determine whether a URL parameter contains a valid value for a given endpoint constraint.
- App models, such as MVC/Razor Pages, register all of their routes, which have a predictable implementation of routing scenarios.
- A response can use routing to generate URLs (for example, for redirection or links) based on route information and thus avoid hard-coded URLs, which helps maintainability.
- URL generation is based on routes, which support arbitrary extensibility. IUrlHelper offers methods to build URLs.

Routing is connected to the middleware pipeline by the RouterMiddleware class. ASP.NET Core MVC adds routing to the middleware pipeline as part of its configuration and handles routing in MVC and Razor Pages apps. To learn how to use routing as a standalone component, see the Use Routing Middleware section.

URL matching

URL matching is the process by which routing dispatches an incoming request to a *handler*. This process is based on data in the URL path but can be extended to consider any data in the request. The ability to dispatch requests to separate handlers is key to scaling the size and complexity of an app.

Incoming requests enter the RouterMiddleware, which calls the RouteAsync method on each route in

sequence. The IRouter instance chooses whether to *handle* the request by setting the RouteContext.Handler to a non-null RequestDelegate. If a route sets a handler for the request, route processing stops, and the handler is invoked to process the request. If no route handler is found to process the request, the middleware hands the request off to the next middleware in the request pipeline.

The primary input to RouteAsync is the RouteContext.HttpContext associated with the current request. The RouteContext.Handler and RouteContext.RouteData are outputs set after a route is matched.

A match that calls RouteAsync also sets the properties of the RouteContext.RouteData to appropriate values based on the request processing performed thus far.

RouteData.Values is a dictionary of *route values* produced from the route. These values are usually determined by tokenizing the URL and can be used to accept user input or to make further dispatching decisions inside the app.

RouteData.DataTokens is a property bag of additional data related to the matched route. DataTokens are provided to support associating state data with each route so that the app can make decisions based on which route matched. These values are developer-defined and do **not** affect the behavior of routing in any way. Additionally, values stashed in RouteData.DataTokens can be of any type, in contrast to RouteData.Values, which must be convertible to and from strings.

RouteData.Routers is a list of the routes that took part in successfully matching the request. Routes can be nested inside of one another. The Routers property reflects the path through the logical tree of routes that resulted in a match. Generally, the first item in Routers is the route collection and should be used for URL generation. The last item in Routers is the route handler that matched.

URL generation

URL generation is the process by which routing can create a URL path based on a set of route values. This allows for a logical separation between route handlers and the URLs that access them.

URL generation follows a similar iterative process, but it starts with user or framework code calling into the GetVirtualPath method of the route collection. Each *route* has its GetVirtualPath method called in sequence until a non-null VirtualPathData is returned.

The primary inputs to GetVirtualPath are:

- VirtualPathContext.HttpContext
- VirtualPathContext.Values
- VirtualPathContext.AmbientValues

Routes primarily use the route values provided by Values and AmbientValues to decide whether it's possible to generate a URL and what values to include. The AmbientValues are the set of route values that were produced from matching the current request. In contrast, Values are the route values that specify how to generate the desired URL for the current operation. The HttpContext is provided in case a route should obtain services or additional data associated with the current context.

> **TIP**
>
> Think of VirtualPathContext.Values as a set of overrides for the VirtualPathContext.AmbientValues. URL generation attempts to reuse route values from the current request to generate URLs for links using the same route or route values.

The output of GetVirtualPath is a VirtualPathData. VirtualPathData is a parallel of RouteData. VirtualPathData contains the VirtualPath for the output URL and some additional properties that should be set by the route.

The VirtualPathData.VirtualPath property contains the *virtual path* produced by the route. Depending on

your needs, you may need to process the path further. If you want to render the generated URL in HTML, prepend the base path of the app.

The VirtualPathData.Router is a reference to the route that successfully generated the URL.

The VirtualPathData.DataTokens properties is a dictionary of additional data related to the route that generated the URL. This is the parallel of RouteData.DataTokens.

Create routes

Routing provides the Route class as the standard implementation of IRouter. Route uses the *route template* syntax to define patterns to match against the URL path when RouteAsync is called. Route uses the same route template to generate a URL when GetVirtualPath is called.

Most apps create routes by calling MapRoute or one of the similar extension methods defined on IRouteBuilder. Any of the IRouteBuilder extension methods create an instance of Route and add it to the route collection.

MapRoute doesn't accept a route handler parameter. MapRoute only adds routes that are handled by the DefaultHandler. The default handler is an `IRouter`, and the handler might not handle the request. For example, ASP.NET Core MVC is typically configured as a default handler that only handles requests that match an available controller and action. To learn more about routing in MVC, see Routing to controller actions in ASP.NET Core.

The following code example is an example of a MapRoute call used by a typical ASP.NET Core MVC route definition:

```
routes.MapRoute(
    name: "default",
    template: "{controller=Home}/{action=Index}/{id?}");
```

This template matches a URL path and extracts the route values. For example, the path `/Products/Details/17` generates the following route values: `{ controller = Products, action = Details, id = 17 }`.

Route values are determined by splitting the URL path into segments and matching each segment with the *route parameter* name in the route template. Route parameters are named. The parameters defined by enclosing the parameter name in braces `{ ... }`.

The preceding template could also match the URL path `/` and produce the values `{ controller = Home, action = Index }`. This occurs because the `{controller}` and `{action}` route parameters have default values and the `id` route parameter is optional. An equals sign (`=`) followed by a value after the route parameter name defines a default value for the parameter. A question mark (`?`) after the route parameter name defines an optional parameter.

Route parameters with a default value *always* produce a route value when the route matches. Optional parameters don't produce a route value if there is no corresponding URL path segment. See the Route template reference section for a thorough description of route template scenarios and syntax.

In the following example, the route parameter definition `{id:int}` defines a route constraint for the `id` route parameter:

```
routes.MapRoute(
    name: "default",
    template: "{controller=Home}/{action=Index}/{id:int}");
```

This template matches a URL path like `/Products/Details/17` but not `/Products/Details/Apples`. Route constraints implement IRouteConstraint and inspect route values to verify them. In this example, the route

value `id` must be convertible to an integer. See route-constraint-reference for an explanation of route constraints provided by the framework.

Additional overloads of MapRoute accept values for `constraints`, `dataTokens`, and `defaults`. The typical usage of these parameters is to pass an anonymously typed object, where the property names of the anonymous type match route parameter names.

The following MapRoute examples create equivalent routes:

```
routes.MapRoute(
    name: "default_route",
    template: "{controller}/{action}/{id?}",
    defaults: new { controller = "Home", action = "Index" });

routes.MapRoute(
    name: "default_route",
    template: "{controller=Home}/{action=Index}/{id?}");
```

TIP

The inline syntax for defining constraints and defaults can be convenient for simple routes. However, there are scenarios, such as data tokens, that aren't supported by inline syntax.

The following example demonstrates a few additional scenarios:

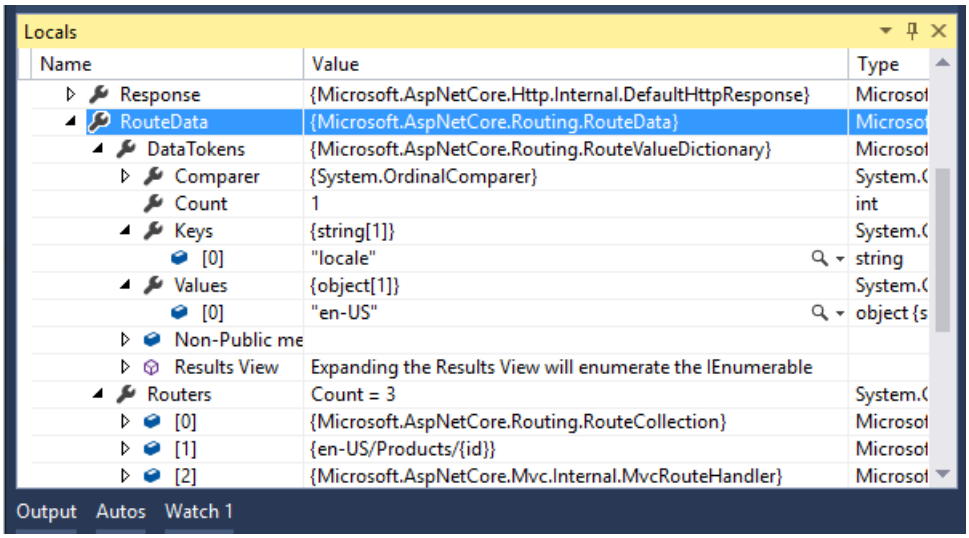
```
routes.MapRoute(
    name: "blog",
    template: "Blog/{*article}",
    defaults: new { controller = "Blog", action = "ReadArticle" });
```

The preceding template matches a URL path like `/Blog/All-About-Routing/Introduction` and extracts the values `{ controller = Blog, action = ReadArticle, article = All-About-Routing/Introduction }`. The default route values for `controller` and `action` are produced by the route even though there are no corresponding route parameters in the template. Default values can be specified in the route template. The `article` route parameter is defined as a *catch-all* by the appearance of an asterisk (`*`) before the route parameter name. Catch-all route parameters capture the remainder of the URL path and can also match the empty string.

The following example adds route constraints and data tokens:

```
routes.MapRoute(
    name: "us_english_products",
    template: "en-US/Products/{id}",
    defaults: new { controller = "Products", action = "Details" },
    constraints: new { id = new IntRouteConstraint() },
    dataTokens: new { locale = "en-US" });
```

The preceding template matches a URL path like `/en-US/Products/5` and extracts the values `{ controller = Products, action = Details, id = 5 }` and the data tokens `{ locale = en-US }`.



Route class URL generation

The Route class can also perform URL generation by combining a set of route values with its route template. This is logically the reverse process of matching the URL path.

> **TIP**
>
> To better understand URL generation, imagine what URL you want to generate and then think about how a route template would match that URL. What values would be produced? This is the rough equivalent of how URL generation works in the Route class.

The following example uses a general ASP.NET Core MVC default route:

```
routes.MapRoute(
    name: "default",
    template: "{controller=Home}/{action=Index}/{id?}");
```

With the route values `{ controller = Products, action = List }`, the URL `/Products/List` is generated. The route values are substituted for the corresponding route parameters to form the URL path. Since `id` is an optional route parameter, the URL is successfully generated without a value for `id`.

With the route values `{ controller = Home, action = Index }`, the URL `/` is generated. The provided route values match the default values, and the segments corresponding to the default values are safely omitted.

Both URLs generated round-trip with the following route definition (`/Home/Index` and `/`) produce the same route values that were used to generate the URL.

> **NOTE**
>
> An app using ASP.NET Core MVC should use UrlHelper to generate URLs instead of calling into routing directly.

For more information on URL generation, see the Url generation reference section.

Use routing middleware

Reference the Microsoft.AspNetCore.App metapackage in the app's project file.

Add routing to the service container in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRouting();
}
```

Routes must be configured in the `Startup.Configure` method. The sample app uses the following APIs:

- RouteBuilder
- MapGet: Matches only HTTP GET requests.
- UseRouter

```
var trackPackageRouteHandler = new RouteHandler(context =>
{
    var routeValues = context.GetRouteData().Values;
    return context.Response.WriteAsync(
        $"Hello! Route values: {string.Join(", ", routeValues)}");
});

var routeBuilder = new RouteBuilder(app, trackPackageRouteHandler);

routeBuilder.MapRoute(
    "Track Package Route",
    "package/{operation:regex(^track|create$)}/{id:int}");

routeBuilder.MapGet("hello/{name}", context =>
{
    var name = context.GetRouteValue("name");
    // The route handler when HTTP GET "hello/<anything>" matches
    // To match HTTP GET "hello/<anything>/<anything>,
    // use routeBuilder.MapGet("hello/{*name}"
    return context.Response.WriteAsync($"Hi, {name}!");
});

var routes = routeBuilder.Build();
app.UseRouter(routes);
```

The following table shows the responses with the given URIs.

URI	RESPONSE
`/package/create/3`	Hello! Route values: [operation, create], [id, 3]
`/package/track/-3`	Hello! Route values: [operation, track], [id, -3]
`/package/track/-3/`	Hello! Route values: [operation, track], [id, -3]
`/package/track/`	The request falls through, no match.
`GET /hello/Joe`	Hi, Joe!
`POST /hello/Joe`	The request falls through, matches HTTP GET only.
`GET /hello/Joe/Smith`	The request falls through, no match.

If you're configuring a single route, call UseRouter passing in an `IRouter` instance. You won't need to use RouteBuilder.

The framework provides a set of extension methods for creating routes (RequestDelegateRouteBuilderExtensions):

- MapDelete
- MapGet
- MapMiddlewareDelete
- MapMiddlewareGet
- MapMiddlewarePost
- MapMiddlewarePut
- MapMiddlewareRoute
- MapMiddlewareVerb
- MapPost
- MapPut
- MapRoute
- MapVerb

Some of listed methods, such as MapGet, require a RequestDelegate. The RequestDelegate is used as the *route handler* when the route matches. Other methods in this family allow configuring a middleware pipeline for use as the route handler. If the `Map*` method doesn't accept a handler, such as MapRoute, it uses the DefaultHandler.

The `Map[Verb]` methods use constraints to limit the route to the HTTP Verb in the method name. For example, see MapGet and MapVerb.

Route template reference

Tokens within curly braces (`{ ... }`) define *route parameters* that are bound if the route is matched. You can define more than one route parameter in a route segment, but they must be separated by a literal value. For example, `{controller=Home}{action=Index}` isn't a valid route, since there's no literal value between `{controller}` and `{action}`. These route parameters must have a name and may have additional attributes specified.

Literal text other than route parameters (for example, `{id}`) and the path separator `/` must match the text in the URL. Text matching is case-insensitive and based on the decoded representation of the URLs path. To match a literal route parameter delimiter (`{` or `}`), escape the delimiter by repeating the character (`{{` or `}}`).

URL patterns that attempt to capture a file name with an optional file extension have additional considerations. For example, consider the template `files/{filename}.{ext?}`. When values for both `filename` and `ext` exist, both values are populated. If only a value for `filename` exists in the URL, the route matches because the trailing period (`.`) is optional. The following URLs match this route:

- `/files/myFile.txt`
- `/files/myFile`

You can use the asterisk (`*`) as a prefix to a route parameter to bind to the rest of the URI. This is called a *catch-all* parameter. For example, `blog/{*slug}` matches any URI that starts with `/blog` and has any value following it, which is assigned to the `slug` route value. Catch-all parameters can also match the empty string.

The catch-all parameter escapes the appropriate characters when the route is used to generate a URL, including path separator (`/`) characters. For example, the route `foo/{*path}` with route values `{ path = "my/path" }` generates `foo/my%2Fpath`. Note the escaped forward slash.

Route parameters may have *default values* designated by specifying the default value after the parameter name separated by an equals sign (`=`). For example, `{controller=Home}` defines `Home` as the default value for `controller`. The default value is used if no value is present in the URL for the parameter. Route parameters are made optional by appending a question mark (`?`) to the end of the parameter name, as in `id?`. The difference between optional values and default route parameters is that a route parameter with a default value always produces a value—an optional parameter has a value only when a value is provided by the request URL.

Route parameters may have constraints that must match the route value bound from the URL. Adding a colon (`:`) and constraint name after the route parameter name specifies an *inline constraint* on a route parameter. If the constraint requires arguments, they're enclosed in parentheses (`(...)`) after the constraint name. Multiple inline constraints can be specified by appending another colon (`:`) and constraint name.

The constraint name and arguments are passed to the IInlineConstraintResolver service to create an instance of IRouteConstraint to use in URL processing. For example, the route template `blog/{article:minlength(10)}` specifies a `minlength` constraint with the argument `10`. For more information on route constraints and a list of the constraints provided by the framework, see the Route constraint reference section.

The following table demonstrates example route templates and their behavior.

ROUTE TEMPLATE	EXAMPLE MATCHING URI	THE REQUEST URI...
`hello`	`/hello`	Only matches the single path `/hello`.
`{Page=Home}`	`/`	Matches and sets `Page` to `Home`.
`{Page=Home}`	`/Contact`	Matches and sets `Page` to `Contact`.
`{controller}/{action}/{id?}`	`/Products/List`	Maps to the `Products` controller and `List` action.
`{controller}/{action}/{id?}`	`/Products/Details/123`	Maps to the `Products` controller and `Details` action (`id` set to 123).
`{controller=Home}/{action=Index}/{id?}`	`/`	Maps to the `Home` controller and `Index` method (`id` is ignored).

Using a template is generally the simplest approach to routing. Constraints and defaults can also be specified outside the route template.

> **TIP**
> Enable Logging to see how the built-in routing implementations, such as Route, match requests.

Route constraint reference

Route constraints execute when a match has occurred to the incoming URL and the URL path is tokenized into route values. Route constraints generally inspect the route value associated via the route template and make a yes/no decision about whether or not the value is acceptable. Some route constraints use data outside the route value to consider whether the request can be routed. For example, the

HttpMethodRouteConstraint can accept or reject a request based on its HTTP verb. Constraints are used in routing requests and link generation.

> **WARNING**
> Don't use constraints for **input validation**. If constraints are used for **input validation**, invalid input results in a *404 - Not Found* response instead of a *400 - Bad Request* with an appropriate error message. Route constraints are used to **disambiguate** similar routes, not to validate the inputs for a particular route.

The following table demonstrates example route constraints and their expected behavior.

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	NOTES
`int`	`{id:int}`	`123456789`, `-123456789`	Matches any integer
`bool`	`{active:bool}`	`true`, `FALSE`	Matches `true` or `false` (case-insensitive)
`datetime`	`{dob:datetime}`	`2016-12-31`, `2016-12-31 7:32pm`	Matches a valid `DateTime` value in the invariant culture. See preceding warning.
`decimal`	`{price:decimal}`	`49.99`, `-1,000.01`	Matches a valid `decimal` value in the invariant culture. See preceding warning.
`double`	`{weight:double}`	`1.234`, `-1,001.01e8`	Matches a valid `double` value in the invariant culture. See preceding warning.
`float`	`{weight:float}`	`1.234`, `-1,001.01e8`	Matches a valid `float` value in the invariant culture. See preceding warning.
`guid`	`{id:guid}`	`CD2C1638-1638-72D5-1638-DEADBEEF1638`, `{CD2C1638-1638-72D5-1638-DEADBEEF1638}`	Matches a valid `Guid` value
`long`	`{ticks:long}`	`123456789`, `-123456789`	Matches a valid `long` value
`minlength(value)`	`{username:minlength(4)}`	`Rick`	String must be at least 4 characters
`maxlength(value)`	`{filename:maxlength(8)}`	`Richard`	String must be no more than 8 characters
`length(length)`	`{filename:length(12)}`	`somefile.txt`	String must be exactly 12 characters long

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	NOTES
`length(min,max)`	`{filename:length(8,16)}`	`somefile.txt`	String must be at least 8 and no more than 16 characters long
`min(value)`	`{age:min(18)}`	`19`	Integer value must be at least 18
`max(value)`	`{age:max(120)}`	`91`	Integer value must be no more than 120
`range(min,max)`	`{age:range(18,120)}`	`91`	Integer value must be at least 18 but no more than 120
`alpha`	`{name:alpha}`	`Rick`	String must consist of one or more alphabetical characters (`a`-`z`, case-insensitive)
`regex(expression)`	`{ssn:regex(^\\d{{3}}-\\d{{2}}-\\d{{4}}$)}`	`123-45-6789`	String must match the regular expression (see tips about defining a regular expression)
`required`	`{name:required}`	`Rick`	Used to enforce that a non-parameter value is present during URL generation

Multiple, colon-delimited constraints can be applied to a single parameter. For example, the following constraint restricts a parameter to an integer value of 1 or greater:

```
[Route("users/{id:int:min(1)}")]
public User GetUserById(int id) { }
```

WARNING

Route constraints that verify the URL and are converted to a CLR type (such as `int` or `DateTime`) always use the invariant culture. These constraints assume that the URL is non-localizable. The framework-provided route constraints don't modify the values stored in route values. All route values parsed from the URL are stored as strings. For example, the `float` constraint attempts to convert the route value to a float, but the converted value is used only to verify it can be converted to a float.

Regular expressions

The ASP.NET Core framework adds `RegexOptions.IgnoreCase | RegexOptions.Compiled | RegexOptions.CultureInvariant` to the regular expression constructor. See RegexOptions for a description of these members.

Regular expressions use delimiters and tokens similar to those used by Routing and the C# language. Regular expression tokens must be escaped. To use the regular expression `^\d{3}-\d{2}-\d{4}$` in routing, the expression must have the `\` (single backslash) characters provided in the string as `\\` (double backslash)

characters in the C# source file in order to escape the `\` string escape character (unless using verbatim string literals). To escape routing parameter delimiter characters (`{`, `}`, `[`, `]`), double the characters in the expression (`{{`, `}`, `[[`, `]]`). The following table shows a regular expression and the escaped version.

REGULAR EXPRESSION	ESCAPED REGULAR EXPRESSION
`^\d{3}-\d{2}-\d{4}$`	`^\\d{{3}}-\\d{{2}}-\\d{{4}}$`
`^[a-z]{2}$`	`^[[a-z]]{{2}}$`

Regular expressions used in routing often start with the caret (`^`) character and match starting position of the string. The expressions often end with the dollar sign (`$`) character and match end of the string. The `^` and `$` characters ensure that the regular expression match the entire route parameter value. Without the `^` and `$` characters, the regular expression match any substring within the string, which is often undesirable. The following table provides examples and explains why they match or fail to match.

EXPRESSION	STRING	MATCH	COMMENT
`[a-z]{2}`	hello	Yes	Substring matches
`[a-z]{2}`	123abc456	Yes	Substring matches
`[a-z]{2}`	mz	Yes	Matches expression
`[a-z]{2}`	MZ	Yes	Not case sensitive
`^[a-z]{2}$`	hello	No	See `^` and `$` above
`^[a-z]{2}$`	123abc456	No	See `^` and `$` above

For more information on regular expression syntax, see .NET Framework Regular Expressions.

To constrain a parameter to a known set of possible values, use a regular expression. For example, `{action:regex(^(list|get|create)$)}` only matches the `action` route value to `list`, `get`, or `create`. If passed into the constraints dictionary, the string `^(list|get|create)$` is equivalent. Constraints that are passed in the constraints dictionary (not inline within a template) that don't match one of the known constraints are also treated as regular expressions.

Custom Route Constraints

In addition to the built-in route constraints, custom route constraints can be created by implementing the IRouteConstraint interface. The IRouteConstraint interface contains a single method, `Match`, which returns `true` if the constraint is satisfied and `false` otherwise.

To use a custom IRouteConstraint, the route constraint type must be registered with the app's ConstraintMap in the app's service container. A ConstraintMap is a dictionary that maps route constraint keys to IRouteConstraint implementations that validate those constraints. An app's ConstraintMap can be updated in `Startup.ConfigureServices` either as part of a services.AddRouting call or by configuring RouteOptions directly with `services.Configure<RouteOptions>`. For example:

```
services.AddRouting(options =>
{
    options.ConstraintMap.Add("customName", typeof(MyCustomConstraint));
});
```

The constraint can then be applied to routes in the usual manner, using the name specified when registering the constraint type. For example:

```
[HttpGet("{id:customName}")]
public ActionResult<string> Get(string id)
```

URL generation reference

The following example shows how to generate a link to a route given a dictionary of route values and a RouteCollection.

```
app.Run(async (context) =>
{
    var dictionary = new RouteValueDictionary
    {
        { "operation", "create" },
        { "id", 123}
    };

    var vpc = new VirtualPathContext(context, null, dictionary,
        "Track Package Route");
    var path = routes.GetVirtualPath(vpc).VirtualPath;

    context.Response.ContentType = "text/html";
    await context.Response.WriteAsync("Menu<hr/>");
    await context.Response.WriteAsync(
        $"<a href='{path}'>Create Package 123</a><br/>");
});
```

The VirtualPath generated at the end of the preceding sample is `/package/create/123`. The dictionary supplies the `operation` and `id` route values of the "Track Package Route" template, `package/{operation}/{id}`. For details, see the sample code in the Use Routing Middleware section or the sample app.

The second parameter to the VirtualPathContext constructor is a collection of *ambient values*. Ambient values are convenient to use because they limit the number of values a developer must specify within a request context. The current route values of the current request are considered ambient values for link generation. In an ASP.NET Core MVC app's `About` action of the `HomeController`, you don't need to specify the controller route value to link to the `Index` action—the ambient value of `Home` is used.

Ambient values that don't match a parameter are ignored. Ambient values are also ignored when an explicitly provided value overrides the ambient value. Matching occurs from left to right in the URL.

Values explicitly provided but that don't match a segment of the route are added to the query string. The following table shows the result when using the route template `{controller}/{action}/{id?}`.

AMBIENT VALUES	EXPLICIT VALUES	RESULT
controller = "Home"	action = "About"	`/Home/About`

AMBIENT VALUES	EXPLICIT VALUES	RESULT
controller = "Home"	controller = "Order", action = "About"	`/Order/About`
controller = "Home", color = "Red"	action = "About"	`/Home/About`
controller = "Home"	action = "About", color = "Red"	`/Home/About?color=Red`

If a route has a default value that doesn't correspond to a parameter and that value is explicitly provided, it must match the default value:

```
routes.MapRoute("blog_route", "blog/{*slug}",
    defaults: new { controller = "Blog", action = "ReadPost" });
```

Link generation only generates a link for this route when the matching values for `controller` and `action` are provided.

Complex segments

Complex segments (for example `[Route("/x{token}y")]`) are processed by matching up literals from right to left in a non-greedy way. See this code for a detailed explanation of how complex segments are matched. The code sample is not used by ASP.NET Core, but it provides a good explanation of complex segments.

Handle errors in ASP.NET Core

9/22/2020 • 19 minutes to read • Edit Online

By Kirk Larkin, Tom Dykstra, and Steve Smith

This article covers common approaches to handling errors in ASP.NET Core web apps. See Handle errors in ASP.NET Core web APIs for web APIs.

View or download sample code. (How to download.) The network tab on the F12 browser developer tools is useful when testing the sample app.

Developer Exception Page

The *Developer Exception Page* displays detailed information about request exceptions. The ASP.NET Core templates generate the following code:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

The preceding highlighted code enables the developer exception page when the app is running in the Development environment.

The templates place UseDeveloperExceptionPage early in the middleware pipeline so that it can catch exceptions thrown in middleware that follows.

The preceding code enables the Developer Exception Page ***only*** when the app runs in the Development environment. Detailed exception information should not be displayed publicly when the app runs in the Production environment. For more information on configuring environments, see Use multiple environments in ASP.NET Core.

The Developer Exception Page includes the following information about the exception and the request:

- Stack trace
- Query string parameters if any

- Cookies if any
- Headers

Exception handler page

To configure a custom error handling page for the Production environment, call UseExceptionHandler. This exception handling middleware:

- Catches and logs exceptions.
- Re-executes the request in an alternate pipeline using the path indicated. The request isn't re-executed if the response has started. The template generated code re-executes the request using the `/Error` path.

In the following example, UseExceptionHandler adds the exception handling middleware in non-Development environments:

```
if (env.IsDevelopment())
{
    app.UseDeveloperExceptionPage();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}
```

The Razor Pages app template provides an Error page (*.cshtml*) and PageModel class (`ErrorModel`) in the *Pages* folder. For an MVC app, the project template includes an `Error` action method and an Error view for the Home controller.

Don't mark the error handler action method with HTTP method attributes, such as `HttpGet`. Explicit verbs prevent some requests from reaching the action method. Allow anonymous access to the method if unauthenticated users should see the error view.

Access the exception

Use IExceptionHandlerPathFeature to access the exception and the original request path in an error handler. The following code adds `ExceptionMessage` to the default *Pages/Error.cshtml.cs* generated by the ASP.NET Core templates:

```
[ResponseCache(Duration=0, Location=ResponseCacheLocation.None, NoStore=true)]
[IgnoreAntiforgeryToken]
public class ErrorModel : PageModel
{
    public string RequestId { get; set; }
    public bool ShowRequestId => !string.IsNullOrEmpty(RequestId);
    public string ExceptionMessage { get; set; }
    private readonly ILogger<ErrorModel> _logger;

    public ErrorModel(ILogger<ErrorModel> logger)
    {
        _logger = logger;
    }

    public void OnGet()
    {
        RequestId = Activity.Current?.Id ?? HttpContext.TraceIdentifier;

        var exceptionHandlerPathFeature =
        HttpContext.Features.Get<IExceptionHandlerPathFeature>();
        if (exceptionHandlerPathFeature?.Error is FileNotFoundException)
        {
            ExceptionMessage = "File error thrown";
            _logger.LogError(ExceptionMessage);
        }
        if (exceptionHandlerPathFeature?.Path == "/index")
        {
            ExceptionMessage += " from home page";
        }
    }
}
```

WARNING

Do **not** serve sensitive error information to clients. Serving errors is a security risk.

To test the exception in the sample app:

- Set the environment to production.
- Remove the comments from `webBuilder.UseStartup<Startup>();` in *Program.cs*.
- Select **Trigger an exception** on the home page.

Exception handler lambda

An alternative to a custom exception handler page is to provide a lambda to UseExceptionHandler. Using a lambda allows access to the error before returning the response.

The following code uses a lambda for exception handling:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler(errorApp =>
        {
            errorApp.Run(async context =>
            {
                context.Response.StatusCode = 500;
                context.Response.ContentType = "text/html";

                await context.Response.WriteAsync("<html lang=\"en\"><body>\r\n");
                await context.Response.WriteAsync("ERROR!<br><br>\r\n");

                var exceptionHandlerPathFeature =
                    context.Features.Get<IExceptionHandlerPathFeature>();

                if (exceptionHandlerPathFeature?.Error is FileNotFoundException)
                {
                    await context.Response.WriteAsync(
                                            "File error thrown!<br><br>\r\n");
                }

                await context.Response.WriteAsync(
                                            "<a href=\"/\">Home</a><br>\r\n");
                await context.Response.WriteAsync("</body></html>\r\n");
                await context.Response.WriteAsync(new string(' ', 512));
            });
        });
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

WARNING

Do **not** serve sensitive error information from IExceptionHandlerFeature or IExceptionHandlerPathFeature to clients. Serving errors is a security risk.

To test the exception handling lambda in the sample app:

- Set the environment to production.
- Remove the comments from `webBuilder.UseStartup<StartupLambda>();` in *Program.cs*.
- Select **Trigger an exception** on the home page.

UseStatusCodePages

By default, an ASP.NET Core app doesn't provide a status code page for HTTP error status codes, such as *404 - Not Found*. When the app encounters an HTTP 400-499 error condition that doesn't have a body, it returns the status code and an empty response body. To provide status code pages, use the status code pages middleware. To enable default text-only handlers for common error status codes, call UseStatusCodePages in the `Startup.Configure` method:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseStatusCodePages();

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

Call `UseStatusCodePages` before request handling middleware. For example, call `UseStatusCodePages` before the Static File Middleware and the Endpoints Middleware.

When `UseStatusCodePages` isn't used, navigating to a URL without an endpoint returns a browser dependent error message indicating the endpoint can't be found. For example, navigating to `Home/Privacy2`. When `UseStatusCodePages` is called, the browser returns:

```
Status Code: 404; Not Found
```

`UseStatusCodePages` isn't typically used in production because it returns a message that isn't useful to users.

To test `UseStatusCodePages` in the sample app:

- Set the environment to production.
- Remove the comments from `webBuilder.UseStartup<StartupUseStatusCodePages>();` in *Program.cs*.
- Select the links on the home page on the home page.

UseStatusCodePages with format string

To customize the response content type and text, use the overload of UseStatusCodePages that takes a content type and format string:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseStatusCodePages(
        "text/plain", "Status code page, status code: {0}");

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

In the preceding code, `{0}` is a placeholder for the error code.

`UseStatusCodePages` with a format string isn't typically used in production because it returns a message that isn't useful to users.

To test `UseStatusCodePages` in the sample app, remove the comments from `webBuilder.UseStartup<StartupFormat>();` in *Program.cs*.

UseStatusCodePages with lambda

To specify custom error-handling and response-writing code, use the overload of UseStatusCodePages that takes a lambda expression:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseStatusCodePages(async context =>
    {
        context.HttpContext.Response.ContentType = "text/plain";

        await context.HttpContext.Response.WriteAsync(
            "Status code page, status code: " +
            context.HttpContext.Response.StatusCode);
    });

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

`UseStatusCodePages` with a lambda isn't typically used in production because it returns a message that isn't useful to users.

To test `UseStatusCodePages` in the sample app, remove the comments from `webBuilder.UseStartup<StartupStatusLambda>();` in *Program.cs*.

UseStatusCodePagesWithRedirects

The UseStatusCodePagesWithRedirects extension method:

- Sends a 302 - Found status code to the client.
- Redirects the client to the error handling endpoint provided in the URL template. The error handling endpoint typically displays error information and returns HTTP 200.

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseStatusCodePagesWithRedirects("/MyStatusCode?code={0}");

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

The URL template can include a `{0}` placeholder for the status code, as shown in the preceding code. If the URL template starts with `~` (tilde), the `~` is replaced by the app's `PathBase`. When specifying an endpoint in the app, create an MVC view or Razor page for the endpoint. For a Razor Pages example, see Pages/MyStatusCode.cshtml in the sample app.

This method is commonly used when the app:

- Should redirect the client to a different endpoint, usually in cases where a different app processes the error. For web apps, the client's browser address bar reflects the redirected endpoint.
- Shouldn't preserve and return the original status code with the initial redirect response.

To test `UseStatusCodePages` in the sample app, remove the comments from `webBuilder.UseStartup<StartupSCredirect>();` in *Program.cs*.

UseStatusCodePagesWithReExecute

The UseStatusCodePagesWithReExecute extension method:

- Returns the original status code to the client.
- Generates the response body by re-executing the request pipeline using an alternate path.

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseStatusCodePagesWithReExecute("/MyStatusCode2", "?code={0}");

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

If an endpoint within the app is specified, create an MVC view or Razor page for the endpoint. Ensure `UseStatusCodePagesWithReExecute` is placed before `UseRouting` so the request can be rerouted to the status page. For a Razor Pages example, see Pages/MyStatusCode2.cshtml in the sample app.

This method is commonly used when the app should:

- Process the request without redirecting to a different endpoint. For web apps, the client's browser address bar reflects the originally requested endpoint.
- Preserve and return the original status code with the response.

The URL and query string templates may include a placeholder `{0}` for the status code. The URL template must start with `/`.

The endpoint that processes the error can get the original URL that generated the error, as shown in the following example:

```
[ResponseCache(Duration = 0, Location = ResponseCacheLocation.None, NoStore = true)]
public class MyStatusCode2Model : PageModel
{
    public string RequestId { get; set; }
    public bool ShowRequestId => !string.IsNullOrEmpty(RequestId);

    public string ErrorStatusCode { get; set; }

    public string OriginalURL { get; set; }
    public bool ShowOriginalURL => !string.IsNullOrEmpty(OriginalURL);

    public void OnGet(string code)
    {
        RequestId = Activity.Current?.Id ?? HttpContext.TraceIdentifier;
        ErrorStatusCode = code;

        var statusCodeReExecuteFeature = HttpContext.Features.Get<
                                            IStatusCodeReExecuteFeature>();
        if (statusCodeReExecuteFeature != null)
        {
            OriginalURL =
                statusCodeReExecuteFeature.OriginalPathBase
                + statusCodeReExecuteFeature.OriginalPath
                + statusCodeReExecuteFeature.OriginalQueryString;
        }
    }
}
```

For a Razor Pages example, see Pages/MyStatusCode2.cshtml in the sample app.

To test `UseStatusCodePages` in the sample app, remove the comments from `webBuilder.UseStartup<StartupSCreX>();` in *Program.cs*.

Disable status code pages

To disable status code pages for an MVC controller or action method, use the [SkipStatusCodePages] attribute.

To disable status code pages for specific requests in a Razor Pages handler method or in an MVC controller, use IStatusCodePagesFeature:

```
public void OnGet()
{
    // using Microsoft.AspNetCore.Diagnostics;
    var statusCodePagesFeature = HttpContext.Features.Get<IStatusCodePagesFeature>();

    if (statusCodePagesFeature != null)
    {
        statusCodePagesFeature.Enabled = false;
    }
}
```

Exception-handling code

Code in exception handling pages can also throw exceptions. Production error pages should be tested thoroughly and take extra care to avoid throwing exceptions of their own.

Response headers

Once the headers for a response are sent:

- The app can't change the response's status code.

- Any exception pages or handlers can't run. The response must be completed or the connection aborted.

Server exception handling

In addition to the exception handling logic in an app, the HTTP server implementation can handle some exceptions. If the server catches an exception before response headers are sent, the server sends a `500 - Internal Server Error` response without a response body. If the server catches an exception after response headers are sent, the server closes the connection. Requests that aren't handled by the app are handled by the server. Any exception that occurs when the server is handling the request is handled by the server's exception handling. The app's custom error pages, exception handling middleware, and filters don't affect this behavior.

Startup exception handling

Only the hosting layer can handle exceptions that take place during app startup. The host can be configured to capture startup errors and capture detailed errors.

The hosting layer can show an error page for a captured startup error only if the error occurs after host address/port binding. If binding fails:

- The hosting layer logs a critical exception.
- The dotnet process crashes.
- No error page is displayed when the HTTP server is Kestrel.

When running on IIS (or Azure App Service) or IIS Express, a *502.5 - Process Failure* is returned by the ASP.NET Core Module if the process can't start. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

Database error page

The Database developer page exception filter `AddDatabaseDeveloperPageExceptionFilter` captures database-related exceptions that can be resolved by using Entity Framework Core migrations. When these exceptions occur, an HTML response is generated with details of possible actions to resolve the issue. This page is enabled only in the Development environment. The following code was generated by the ASP.NET Core Razor Pages templates when individual user accounts were specified:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDatabaseDeveloperPageExceptionFilter();
    services.AddDefaultIdentity<IdentityUser>(options => options.SignIn.RequireConfirmedAccount = true)
        .AddEntityFrameworkStores<ApplicationDbContext>();
    services.AddRazorPages();
}
```

Exception filters

In MVC apps, exception filters can be configured globally or on a per-controller or per-action basis. In Razor Pages apps, they can be configured globally or per page model. These filters handle any unhandled exceptions that occur during the execution of a controller action or another filter. For more information, see Filters in ASP.NET Core.

Exception filters are useful for trapping exceptions that occur within MVC actions, but they're not as flexible as

the built-in exception handling middleware, `UseExceptionHandler`. We recommend using `UseExceptionHandler`, unless you need to perform error handling differently based on which MVC action is chosen.

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

Model state errors

For information about how to handle model state errors, see Model binding and Model validation.

By Tom Dykstra, and Steve Smith

This article covers common approaches to handling errors in ASP.NET Core web apps. See Handle errors in ASP.NET Core web APIs for web APIs.

View or download sample code. (How to download.)

Developer Exception Page

The *Developer Exception Page* displays detailed information about request exceptions. The ASP.NET Core templates generate the following code:

```
if (env.IsDevelopment())
{
    app.UseDeveloperExceptionPage();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}
```

The preceding code enables the developer exception page when the app is running in the Development

environment.

The templates place UseDeveloperExceptionPage before any middleware so exceptions are caught in the middleware that follows.

The preceding code enables the Developer Exception Page **only when the app is running in the Development environment**. Detailed exception information should not be displayed publicly when the app runs in production. For more information on configuring environments, see Use multiple environments in ASP.NET Core.

The Developer Exception Page includes the following information about the exception and the request:

- Stack trace
- Query string parameters if any
- Cookies if any
- Headers

Exception handler page

To configure a custom error handling page for the Production environment, use the Exception Handling Middleware. The middleware:

- Catches and logs exceptions.
- Re-executes the request in an alternate pipeline for the page or controller indicated. The request isn't re-executed if the response has started. The template generated code re-executes the request to `/Error`.

In the following example, UseExceptionHandler adds the Exception Handling Middleware in non-Development environments:

```
if (env.IsDevelopment())
{
    app.UseDeveloperExceptionPage();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}
```

The Razor Pages app template provides an Error page (*.cshtml*) and PageModel class (`ErrorModel`) in the *Pages* folder. For an MVC app, the project template includes an Error action method and an Error view in the Home controller.

Don't mark the error handler action method with HTTP method attributes, such as `HttpGet`. Explicit verbs prevent some requests from reaching the method. Allow anonymous access to the method if unauthenticated users should see the error view.

Access the exception

Use IExceptionHandlerPathFeature to access the exception and the original request path in an error handler controller or page:

```
[ResponseCache(Duration = 0, Location = ResponseCacheLocation.None, NoStore = true)]
public class ErrorModel : PageModel
{
    public string RequestId { get; set; }
    public bool ShowRequestId => !string.IsNullOrEmpty(RequestId);
    public string ExceptionMessage { get; set; }

    public void OnGet()
    {
        RequestId = Activity.Current?.Id ?? HttpContext.TraceIdentifier;

        var exceptionHandlerPathFeature =
            HttpContext.Features.Get<IExceptionHandlerPathFeature>();
        if (exceptionHandlerPathFeature?.Error is FileNotFoundException)
        {
            ExceptionMessage = "File error thrown";
        }
        if (exceptionHandlerPathFeature?.Path == "/index")
        {
            ExceptionMessage += " from home page";
        }
    }
}
```

WARNING

Do **not** serve sensitive error information to clients. Serving errors is a security risk.

To trigger the preceding exception handling page, set the environment to productions and force an exception.

Exception handler lambda

An alternative to a custom exception handler page is to provide a lambda to UseExceptionHandler. Using a lambda allows access to the error before returning the response.

Here's an example of using a lambda for exception handling:

```
if (env.IsDevelopment())
{
    app.UseDeveloperExceptionPage();
}
else
{
   app.UseExceptionHandler(errorApp =>
   {
        errorApp.Run(async context =>
        {
            context.Response.StatusCode = 500;
            context.Response.ContentType = "text/html";

            await context.Response.WriteAsync("<html lang=\"en\"><body>\r\n");
            await context.Response.WriteAsync("ERROR!<br><br>\r\n");

            var exceptionHandlerPathFeature =
                context.Features.Get<IExceptionHandlerPathFeature>();

            if (exceptionHandlerPathFeature?.Error is FileNotFoundException)
            {
                await context.Response.WriteAsync("File error thrown!<br><br>\r\n");
            }

            await context.Response.WriteAsync("<a href=\"/\">Home</a><br>\r\n");
            await context.Response.WriteAsync("</body></html>\r\n");
            await context.Response.WriteAsync(new string(' ', 512)); // IE padding
        });
    });
    app.UseHsts();
}
```

In the preceding code, `await context.Response.WriteAsync(new string(' ', 512));` is added so the Internet Explorer browser displays the error message rather than an IE error message. For more information, see this GitHub issue.

> **WARNING**
>
> Do **not** serve sensitive error information from IExceptionHandlerFeature or IExceptionHandlerPathFeature to clients. Serving errors is a security risk.

To see the result of the exception handling lambda in the sample app, use the `ProdEnvironment` and `ErrorHandlerLambda` preprocessor directives, and select **Trigger an exception** on the home page.

UseStatusCodePages

By default, an ASP.NET Core app doesn't provide a status code page for HTTP status codes, such as *404 - Not Found*. The app returns a status code and an empty response body. To provide status code pages, use Status Code Pages middleware.

The middleware is made available by the Microsoft.AspNetCore.Diagnostics package.

To enable default text-only handlers for common error status codes, call UseStatusCodePages in the `Startup.Configure` method:

```
app.UseStatusCodePages();
```

Call `UseStatusCodePages` before request handling middleware (for example, Static File Middleware and MVC Middleware).

When `UseStatusCodePages` isn't used, navigating to a URL without an endpoint returns a browser dependent error message indicating the endpoint can't be found. For example, navigating to `Home/Privacy2`. When `UseStatusCodePages` is called, the browser returns:

```
Status Code: 404; Not Found
```

UseStatusCodePages with format string

To customize the response content type and text, use the overload of UseStatusCodePages that takes a content type and format string:

```
app.UseStatusCodePages(
    "text/plain", "Status code page, status code: {0}");
```

UseStatusCodePages with lambda

To specify custom error-handling and response-writing code, use the overload of UseStatusCodePages that takes a lambda expression:

```
app.UseStatusCodePages(async context =>
{
    context.HttpContext.Response.ContentType = "text/plain";

    await context.HttpContext.Response.WriteAsync(
        "Status code page, status code: " +
        context.HttpContext.Response.StatusCode);
});
```

UseStatusCodePagesWithRedirects

The UseStatusCodePagesWithRedirects extension method:

- Sends a *302 - Found* status code to the client.
- Redirects the client to the location provided in the URL template.

```
app.UseStatusCodePagesWithRedirects("/StatusCode?code={0}");
```

The URL template can include a `{0}` placeholder for the status code, as shown in the example. If the URL template starts with `~` (tilde), the `~` is replaced by the app's `PathBase`. If you point to an endpoint within the app, create an MVC view or Razor page for the endpoint. For a Razor Pages example, see *Pages/StatusCode.cshtml* in the sample app.

This method is commonly used when the app:

- Should redirect the client to a different endpoint, usually in cases where a different app processes the error. For web apps, the client's browser address bar reflects the redirected endpoint.
- Shouldn't preserve and return the original status code with the initial redirect response.

UseStatusCodePagesWithReExecute

The UseStatusCodePagesWithReExecute extension method:

- Returns the original status code to the client.
- Generates the response body by re-executing the request pipeline using an alternate path.

```
app.UseStatusCodePagesWithReExecute("/StatusCode","?code={0}");
```

If you point to an endpoint within the app, create an MVC view or Razor page for the endpoint. Ensure `UseStatusCodePagesWithReExecute` is placed before `UseRouting` so the request can be rerouted to the status page. For a Razor Pages example, see *Pages/StatusCode.cshtml* in the sample app.

This method is commonly used when the app should:

- Process the request without redirecting to a different endpoint. For web apps, the client's browser address bar reflects the originally requested endpoint.
- Preserve and return the original status code with the response.

The URL and query string templates may include a placeholder (`{0}`) for the status code. The URL template must start with a slash (`/`). When using a placeholder in the path, confirm that the endpoint (page or controller) can process the path segment. For example, a Razor Page for errors should accept the optional path segment value with the `@page` directive:

```
@page "{code?}"
```

The endpoint that processes the error can get the original URL that generated the error, as shown in the following example:

```
var statusCodeReExecuteFeature = HttpContext.Features.Get<IStatusCodeReExecuteFeature>();
if (statusCodeReExecuteFeature != null)
{
    OriginalURL =
        statusCodeReExecuteFeature.OriginalPathBase
        + statusCodeReExecuteFeature.OriginalPath
        + statusCodeReExecuteFeature.OriginalQueryString;
}
```

Disable status code pages

To disable status code pages for an MVC controller or action method, use the `[SkipStatusCodePages]` attribute.

To disable status code pages for specific requests in a Razor Pages handler method or in an MVC controller, use IStatusCodePagesFeature:

```
var statusCodePagesFeature = HttpContext.Features.Get<IStatusCodePagesFeature>();

if (statusCodePagesFeature != null)
{
    statusCodePagesFeature.Enabled = false;
}
```

Exception-handling code

Code in exception handling pages can throw exceptions. It's often a good idea for production error pages to consist of purely static content.

Response headers

Once the headers for a response are sent:

- The app can't change the response's status code.
- Any exception pages or handlers can't run. The response must be completed or the connection aborted.

Server exception handling

In addition to the exception handling logic in your app, the HTTP server implementation can handle some exceptions. If the server catches an exception before response headers are sent, the server sends a *500 - Internal Server Error* response without a response body. If the server catches an exception after response headers are sent, the server closes the connection. Requests that aren't handled by your app are handled by the server. Any exception that occurs when the server is handling the request is handled by the server's exception handling. The app's custom error pages, exception handling middleware, and filters don't affect this behavior.

Startup exception handling

Only the hosting layer can handle exceptions that take place during app startup. The host can be configured to capture startup errors and capture detailed errors.

The hosting layer can show an error page for a captured startup error only if the error occurs after host address/port binding. If binding fails:

- The hosting layer logs a critical exception.
- The dotnet process crashes.
- No error page is displayed when the HTTP server is Kestrel.

When running on IIS (or Azure App Service) or IIS Express, a *502.5 - Process Failure* is returned by the ASP.NET Core Module if the process can't start. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

Database error page

Database Error Page Middleware captures database-related exceptions that can be resolved by using Entity Framework migrations. When these exceptions occur, an HTML response with details of possible actions to resolve the issue is generated. This page should be enabled only in the Development environment. Enable the page by adding code to `Startup.Configure`:

```
if (env.IsDevelopment())
{
    app.UseDatabaseErrorPage();
}
```

UseDatabaseErrorPage requires the Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore NuGet package.

Exception filters

In MVC apps, exception filters can be configured globally or on a per-controller or per-action basis. In Razor Pages apps, they can be configured globally or per page model. These filters handle any unhandled exception that occurs during the execution of a controller action or another filter. For more information, see Filters in ASP.NET Core.

> **TIP**
>
> Exception filters are useful for trapping exceptions that occur within MVC actions, but they're not as flexible as the Exception Handling Middleware. We recommend using the middleware. Use filters only where you need to perform error handling differently based on which MVC action is chosen.

Model state errors

For information about how to handle model state errors, see Model binding and Model validation.

Make HTTP requests using IHttpClientFactory in ASP.NET Core

9/22/2020 • 47 minutes to read • Edit Online

By Glenn Condron, Ryan Nowak, Steve Gordon, Rick Anderson, and Kirk Larkin

An IHttpClientFactory can be registered and used to configure and create HttpClient instances in an app. `IHttpClientFactory` offers the following benefits:

- Provides a central location for naming and configuring logical `HttpClient` instances. For example, a client named *github* could be registered and configured to access GitHub. A default client can be registered for general access.
- Codifies the concept of outgoing middleware via delegating handlers in `HttpClient`. Provides extensions for Polly-based middleware to take advantage of delegating handlers in `HttpClient`.
- Manages the pooling and lifetime of underlying `HttpClientMessageHandler` instances. Automatic management avoids common DNS (Domain Name System) problems that occur when manually managing `HttpClient` lifetimes.
- Adds a configurable logging experience (via `ILogger`) for all requests sent through clients created by the factory.

View or download sample code (how to download).

The sample code in this topic version uses System.Text.Json to deserialize JSON content returned in HTTP responses. For samples that use `Json.NET` and `ReadAsAsync<T>`, use the version selector to select a 2.x version of this topic.

Consumption patterns

There are several ways `IHttpClientFactory` can be used in an app:

- Basic usage
- Named clients
- Typed clients
- Generated clients

The best approach depends upon the app's requirements.

Basic usage

`IHttpClientFactory` can be registered by calling `AddHttpClient`:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddHttpClient();
        // Remaining code deleted for brevity.
```

An `IHttpClientFactory` can be requested using dependency injection (DI). The following code uses `IHttpClientFactory` to create an `HttpClient` instance:

```
public class BasicUsageModel : PageModel
{
    private readonly IHttpClientFactory _clientFactory;

    public IEnumerable<GitHubBranch> Branches { get; private set; }

    public bool GetBranchesError { get; private set; }

    public BasicUsageModel(IHttpClientFactory clientFactory)
    {
        _clientFactory = clientFactory;
    }

    public async Task OnGet()
    {
        var request = new HttpRequestMessage(HttpMethod.Get,
            "https://api.github.com/repos/aspnet/AspNetCore.Docs/branches");
        request.Headers.Add("Accept", "application/vnd.github.v3+json");
        request.Headers.Add("User-Agent", "HttpClientFactory-Sample");

        var client = _clientFactory.CreateClient();

        var response = await client.SendAsync(request);

        if (response.IsSuccessStatusCode)
        {
            using var responseStream = await response.Content.ReadAsStreamAsync();
            Branches = await JsonSerializer.DeserializeAsync
                <IEnumerable<GitHubBranch>>(responseStream);
        }
        else
        {
            GetBranchesError = true;
            Branches = Array.Empty<GitHubBranch>();
        }
    }
}
```

Using `IHttpClientFactory` like in the preceding example is a good way to refactor an existing app. It has no impact on how `HttpClient` is used. In places where `HttpClient` instances are created in an existing app, replace those occurrences with calls to CreateClient.

Named clients

Named clients are a good choice when:

- The app requires many distinct uses of `HttpClient`.

- Many `HttpClient`s have different configuration.

Configuration for a named `HttpClient` can be specified during registration in `Startup.ConfigureServices`:

```
services.AddHttpClient("github", c =>
{
    c.BaseAddress = new Uri("https://api.github.com/");
    // Github API versioning
    c.DefaultRequestHeaders.Add("Accept", "application/vnd.github.v3+json");
    // Github requires a user-agent
    c.DefaultRequestHeaders.Add("User-Agent", "HttpClientFactory-Sample");
});
```

In the preceding code the client is configured with:

- The base address `https://api.github.com/`.
- Two headers required to work with the GitHub API.

CreateClient

Each time CreateClient is called:

- A new instance of `HttpClient` is created.
- The configuration action is called.

To create a named client, pass its name into `CreateClient`:

```
public class NamedClientModel : PageModel
{
    private readonly IHttpClientFactory _clientFactory;

    public IEnumerable<GitHubPullRequest> PullRequests { get; private set; }

    public bool GetPullRequestsError { get; private set; }

    public bool HasPullRequests => PullRequests.Any();

    public NamedClientModel(IHttpClientFactory clientFactory)
    {
        _clientFactory = clientFactory;
    }

    public async Task OnGet()
    {
        var request = new HttpRequestMessage(HttpMethod.Get,
            "repos/aspnet/AspNetCore.Docs/pulls");

        var client = _clientFactory.CreateClient("github");

        var response = await client.SendAsync(request);

        if (response.IsSuccessStatusCode)
        {
            using var responseStream = await response.Content.ReadAsStreamAsync();
            PullRequests = await JsonSerializer.DeserializeAsync
                    <IEnumerable<GitHubPullRequest>>(responseStream);
        }
        else
        {
            GetPullRequestsError = true;
            PullRequests = Array.Empty<GitHubPullRequest>();
        }
    }
}
```

In the preceding code, the request doesn't need to specify a hostname. The code can pass just the path, since the base address configured for the client is used.

Typed clients

Typed clients:

- Provide the same capabilities as named clients without the need to use strings as keys.
- Provides IntelliSense and compiler help when consuming clients.
- Provide a single location to configure and interact with a particular `HttpClient`. For example, a single typed client might be used:
  - For a single backend endpoint.
  - To encapsulate all logic dealing with the endpoint.
- Work with DI and can be injected where required in the app.

A typed client accepts an `HttpClient` parameter in its constructor:

```
public class GitHubService
{
    public HttpClient Client { get; }

    public GitHubService(HttpClient client)
    {
        client.BaseAddress = new Uri("https://api.github.com/");
        // GitHub API versioning
        client.DefaultRequestHeaders.Add("Accept",
            "application/vnd.github.v3+json");
        // GitHub requires a user-agent
        client.DefaultRequestHeaders.Add("User-Agent",
            "HttpClientFactory-Sample");

        Client = client;
    }

    public async Task<IEnumerable<GitHubIssue>> GetAspNetDocsIssues()
    {
        var response = await Client.GetAsync(
            "/repos/aspnet/AspNetCore.Docs/issues?state=open&sort=created&direction=desc");

        response.EnsureSuccessStatusCode();

        using var responseStream = await response.Content.ReadAsStreamAsync();
        return await JsonSerializer.DeserializeAsync
            <IEnumerable<GitHubIssue>>(responseStream);
    }
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

In the preceding code:

- The configuration is moved into the typed client.
- The `HttpClient` object is exposed as a public property.

API-specific methods can be created that expose `HttpClient` functionality. For example, the `GetAspNetDocsIssues` method encapsulates code to retrieve open issues.

The following code calls AddHttpClient in `Startup.ConfigureServices` to register a typed client class:

```
services.AddHttpClient<GitHubService>();
```

The typed client is registered as transient with DI. In the preceding code, `AddHttpClient` registers `GitHubService` as a transient service. This registration uses a factory method to:

1. Create an instance of `HttpClient`.
2. Create an instance of `GitHubService`, passing in the instance of `HttpClient` to its constructor.

The typed client can be injected and consumed directly:

```
public class TypedClientModel : PageModel
{
    private readonly GitHubService _gitHubService;

    public IEnumerable<GitHubIssue> LatestIssues { get; private set; }

    public bool HasIssue => LatestIssues.Any();

    public bool GetIssuesError { get; private set; }

    public TypedClientModel(GitHubService gitHubService)
    {
        _gitHubService = gitHubService;
    }

    public async Task OnGet()
    {
        try
        {
            LatestIssues = await _gitHubService.GetAspNetDocsIssues();
        }
        catch(HttpRequestException)
        {
            GetIssuesError = true;
            LatestIssues = Array.Empty<GitHubIssue>();
        }
    }
}
```

The configuration for a typed client can be specified during registration in `Startup.ConfigureServices`, rather than in the typed client's constructor:

```
services.AddHttpClient<RepoService>(c =>
{
    c.BaseAddress = new Uri("https://api.github.com/");
    c.DefaultRequestHeaders.Add("Accept", "application/vnd.github.v3+json");
    c.DefaultRequestHeaders.Add("User-Agent", "HttpClientFactory-Sample");
});
```

The `HttpClient` can be encapsulated within a typed client. Rather than exposing it as a property, define a method which calls the `HttpClient` instance internally:

```
public class RepoService
{
    // _httpClient isn't exposed publicly
    private readonly HttpClient _httpClient;

    public RepoService(HttpClient client)
    {
        _httpClient = client;
    }

    public async Task<IEnumerable<string>> GetRepos()
    {
        var response = await _httpClient.GetAsync("aspnet/repos");

        response.EnsureSuccessStatusCode();

        using var responseStream = await response.Content.ReadAsStreamAsync();
        return await JsonSerializer.DeserializeAsync
            <IEnumerable<string>>(responseStream);
    }
}
```

In the preceding code, the `HttpClient` is stored in a private field. Access to the `HttpClient` is by the public `GetRepos` method.

Generated clients

`IHttpClientFactory` can be used in combination with third-party libraries such as Refit. Refit is a REST library for .NET. It converts REST APIs into live interfaces. An implementation of the interface is generated dynamically by the `RestService`, using `HttpClient` to make the external HTTP calls.

An interface and a reply are defined to represent the external API and its response:

```
public interface IHelloClient
{
    [Get("/helloworld")]
    Task<Reply> GetMessageAsync();
}

public class Reply
{
    public string Message { get; set; }
}
```

A typed client can be added, using Refit to generate the implementation:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddHttpClient("hello", c =>
    {
        c.BaseAddress = new Uri("http://localhost:5000");
    })
    .AddTypedClient(c => Refit.RestService.For<IHelloClient>(c));

    services.AddControllers();
}
```

The defined interface can be consumed where necessary, with the implementation provided by DI and Refit:

```
[ApiController]
public class ValuesController : ControllerBase
{
    private readonly IHelloClient _client;

    public ValuesController(IHelloClient client)
    {
        _client = client;
    }

    [HttpGet("/")]
    public async Task<ActionResult<Reply>> Index()
    {
        return await _client.GetMessageAsync();
    }
}
```

Make POST, PUT, and DELETE requests

In the preceding examples, all HTTP requests use the GET HTTP verb. `HttpClient` also supports other HTTP verbs, including:

- POST
- PUT
- DELETE
- PATCH

For a complete list of supported HTTP verbs, see HttpMethod.

The following example shows how to make an HTTP POST request:

```
public async Task CreateItemAsync(TodoItem todoItem)
{
    var todoItemJson = new StringContent(
        JsonSerializer.Serialize(todoItem, _jsonSerializerOptions),
        Encoding.UTF8,
        "application/json");

    using var httpResponse =
        await _httpClient.PostAsync("/api/TodoItems", todoItemJson);

    httpResponse.EnsureSuccessStatusCode();
}
```

In the preceding code, the `CreateItemAsync` method:

- Serializes the `TodoItem` parameter to JSON using `System.Text.Json`. This uses an instance of JsonSerializerOptions to configure the serialization process.
- Creates an instance of StringContent to package the serialized JSON for sending in the HTTP request's body.
- Calls PostAsync to send the JSON content to the specified URL. This is a relative URL that gets added to the HttpClient.BaseAddress.
- Calls EnsureSuccessStatusCode to throw an exception if the response status code does not indicate success.

`HttpClient` also supports other types of content. For example, MultipartContent and StreamContent. For a complete list of supported content, see HttpContent.

The following example shows an HTTP PUT request:

```
public async Task SaveItemAsync(TodoItem todoItem)
{
    var todoItemJson = new StringContent(
        JsonSerializer.Serialize(todoItem),
        Encoding.UTF8,
        "application/json");

    using var httpResponse =
        await _httpClient.PutAsync($"/api/TodoItems/{todoItem.Id}", todoItemJson);

    httpResponse.EnsureSuccessStatusCode();
}
```

The preceding code is very similar to the POST example. The `SaveItemAsync` method calls PutAsync instead of `PostAsync`.

The following example shows an HTTP DELETE request:

```
public async Task DeleteItemAsync(long itemId)
{
    using var httpResponse =
        await _httpClient.DeleteAsync($"/api/TodoItems/{itemId}");

    httpResponse.EnsureSuccessStatusCode();
}
```

In the preceding code, the `DeleteItemAsync` method calls DeleteAsync. Because HTTP DELETE requests typically contain no body, the `DeleteAsync` method doesn't provide an overload that accepts an instance of `HttpContent`.

To learn more about using different HTTP verbs with `HttpClient`, see HttpClient.

Outgoing request middleware

`HttpClient` has the concept of delegating handlers that can be linked together for outgoing HTTP requests. `IHttpClientFactory`:

- Simplifies defining the handlers to apply for each named client.
- Supports registration and chaining of multiple handlers to build an outgoing request middleware pipeline. Each of these handlers is able to perform work before and after the outgoing request. This pattern:
  - Is similar to the inbound middleware pipeline in ASP.NET Core.
  - Provides a mechanism to manage cross-cutting concerns around HTTP requests, such as:
    - caching
    - error handling
    - serialization
    - logging

To create a delegating handler:

- Derive from DelegatingHandler.
- Override SendAsync. Execute code before passing the request to the next handler in the pipeline:

```
public class ValidateHeaderHandler : DelegatingHandler
{
    protected override async Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request,
        CancellationToken cancellationToken)
    {
        if (!request.Headers.Contains("X-API-KEY"))
        {
            return new HttpResponseMessage(HttpStatusCode.BadRequest)
            {
                Content = new StringContent(
                    "You must supply an API key header called X-API-KEY")
            };
        }

        return await base.SendAsync(request, cancellationToken);
    }
}
```

The preceding code checks if the `X-API-KEY` header is in the request. If `X-API-KEY` is missing, BadRequest is returned.

More than one handler can be added to the configuration for an `HttpClient` with Microsoft.Extensions.DependencyInjection.HttpClientBuilderExtensions.AddHttpMessageHandler:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddTransient<ValidateHeaderHandler>();

    services.AddHttpClient("externalservice", c =>
    {
        // Assume this is an "external" service which requires an API KEY
        c.BaseAddress = new Uri("https://localhost:5001/");
    })
    .AddHttpMessageHandler<ValidateHeaderHandler>();

    // Remaining code deleted for brevity.
```

In the preceding code, the `ValidateHeaderHandler` is registered with DI. The `IHttpClientFactory` creates a separate DI scope for each handler. Handlers can depend upon services of any scope. Services that handlers depend upon are disposed when the handler is disposed.

Once registered, AddHttpMessageHandler can be called, passing in the type for the handler.

Multiple handlers can be registered in the order that they should execute. Each handler wraps the next handler until the final `HttpClientHandler` executes the request:

```
services.AddTransient<SecureRequestHandler>();
services.AddTransient<RequestDataHandler>();

services.AddHttpClient("clientwithhandlers")
    // This handler is on the outside and called first during the
    // request, last during the response.
    .AddHttpMessageHandler<SecureRequestHandler>()
    // This handler is on the inside, closest to the request being
    // sent.
    .AddHttpMessageHandler<RequestDataHandler>();
```

Use one of the following approaches to share per-request state with message handlers:

- Pass data into the handler using HttpRequestMessage.Properties.

- Use IHttpContextAccessor to access the current request.
- Create a custom AsyncLocal<T> storage object to pass the data.

Use Polly-based handlers

`IHttpClientFactory` integrates with the third-party library Polly. Polly is a comprehensive resilience and transient fault-handling library for .NET. It allows developers to express policies such as Retry, Circuit Breaker, Timeout, Bulkhead Isolation, and Fallback in a fluent and thread-safe manner.

Extension methods are provided to enable the use of Polly policies with configured `HttpClient` instances. The Polly extensions support adding Polly-based handlers to clients. Polly requires the Microsoft.Extensions.Http.Polly NuGet package.

Handle transient faults

Faults typically occur when external HTTP calls are transient. AddTransientHttpErrorPolicy allows a policy to be defined to handle transient errors. Policies configured with `AddTransientHttpErrorPolicy` handle the following responses:

- HttpRequestException
- HTTP 5xx
- HTTP 408

`AddTransientHttpErrorPolicy` provides access to a `PolicyBuilder` object configured to handle errors representing a possible transient fault:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddHttpClient<UnreliableEndpointCallerService>()
        .AddTransientHttpErrorPolicy(p =>
            p.WaitAndRetryAsync(3, _ => TimeSpan.FromMilliseconds(600)));

    // Remaining code deleted for brevity.
```

In the preceding code, a `WaitAndRetryAsync` policy is defined. Failed requests are retried up to three times with a delay of 600 ms between attempts.

Dynamically select policies

Extension methods are provided to add Polly-based handlers, for example, AddPolicyHandler. The following `AddPolicyHandler` overload inspects the request to decide which policy to apply:

```
var timeout = Policy.TimeoutAsync<HttpResponseMessage>(
    TimeSpan.FromSeconds(10));
var longTimeout = Policy.TimeoutAsync<HttpResponseMessage>(
    TimeSpan.FromSeconds(30));

services.AddHttpClient("conditionalpolicy")
// Run some code to select a policy based on the request
    .AddPolicyHandler(request =>
        request.Method == HttpMethod.Get ? timeout : longTimeout);
```

In the preceding code, if the outgoing request is an HTTP GET, a 10-second timeout is applied. For any other HTTP method, a 30-second timeout is used.

Add multiple Polly handlers

It's common to nest Polly policies:

```
services.AddHttpClient("multiplepolicies")
    .AddTransientHttpErrorPolicy(p => p.RetryAsync(3))
    .AddTransientHttpErrorPolicy(
        p => p.CircuitBreakerAsync(5, TimeSpan.FromSeconds(30)));
```

In the preceding example:

- Two handlers are added.
- The first handler uses AddTransientHttpErrorPolicy to add a retry policy. Failed requests are retried up to three times.
- The second `AddTransientHttpErrorPolicy` call adds a circuit breaker policy. Further external requests are blocked for 30 seconds if 5 failed attempts occur sequentially. Circuit breaker policies are stateful. All calls through this client share the same circuit state.

Add policies from the Polly registry

An approach to managing regularly used policies is to define them once and register them with a `PolicyRegistry`
.

In the following code:

- The "regular" and "long" policies are added.
- AddPolicyHandlerFromRegistry adds the "regular" and "long" policies from the registry.

```
public void ConfigureServices(IServiceCollection services)
{
    var timeout = Policy.TimeoutAsync<HttpResponseMessage>(
        TimeSpan.FromSeconds(10));
    var longTimeout = Policy.TimeoutAsync<HttpResponseMessage>(
        TimeSpan.FromSeconds(30));

    var registry = services.AddPolicyRegistry();

    registry.Add("regular", timeout);
    registry.Add("long", longTimeout);

    services.AddHttpClient("regularTimeoutHandler")
        .AddPolicyHandlerFromRegistry("regular");

    services.AddHttpClient("longTimeoutHandler")
       .AddPolicyHandlerFromRegistry("long");

    // Remaining code deleted for brevity.
```

For more information on `IHttpClientFactory` and Polly integrations, see the Polly wiki.

HttpClient and lifetime management

A new `HttpClient` instance is returned each time `CreateClient` is called on the `IHttpClientFactory`. An HttpMessageHandler is created per named client. The factory manages the lifetimes of the `HttpMessageHandler` instances.

`IHttpClientFactory` pools the `HttpMessageHandler` instances created by the factory to reduce resource consumption. An `HttpMessageHandler` instance may be reused from the pool when creating a new `HttpClient` instance if its lifetime hasn't expired.

Pooling of handlers is desirable as each handler typically manages its own underlying HTTP connections. Creating more handlers than necessary can result in connection delays. Some handlers also keep connections open indefinitely, which can prevent the handler from reacting to DNS (Domain Name System) changes.

The default handler lifetime is two minutes. The default value can be overridden on a per named client basis:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddHttpClient("extendedhandlerlifetime")
        .SetHandlerLifetime(TimeSpan.FromMinutes(5));

    // Remaining code deleted for brevity.
```

`HttpClient` instances can generally be treated as .NET objects **not** requiring disposal. Disposal cancels outgoing requests and guarantees the given `HttpClient` instance can't be used after calling Dispose. `IHttpClientFactory` tracks and disposes resources used by `HttpClient` instances.

Keeping a single `HttpClient` instance alive for a long duration is a common pattern used before the inception of `IHttpClientFactory`. This pattern becomes unnecessary after migrating to `IHttpClientFactory`.

Alternatives to IHttpClientFactory

Using `IHttpClientFactory` in a DI-enabled app avoids:

- Resource exhaustion problems by pooling `HttpMessageHandler` instances.
- Stale DNS problems by cycling `HttpMessageHandler` instances at regular intervals.

There are alternative ways to solve the preceding problems using a long-lived SocketsHttpHandler instance.

- Create an instance of `SocketsHttpHandler` when the app starts and use it for the life of the app.
- Configure PooledConnectionLifetime to an appropriate value based on DNS refresh times.
- Create `HttpClient` instances using `new HttpClient(handler, disposeHandler: false)` as needed.

The preceding approaches solve the resource management problems that `IHttpClientFactory` solves in a similar way.

- The `SocketsHttpHandler` shares connections across `HttpClient` instances. This sharing prevents socket exhaustion.
- The `SocketsHttpHandler` cycles connections according to `PooledConnectionLifetime` to avoid stale DNS problems.

Cookies

The pooled `HttpMessageHandler` instances results in `CookieContainer` objects being shared. Unanticipated `CookieContainer` object sharing often results in incorrect code. For apps that require cookies, consider either:

- Disabling automatic cookie handling
- Avoiding `IHttpClientFactory`

Call ConfigurePrimaryHttpMessageHandler to disable automatic cookie handling:

```
services.AddHttpClient("configured-disable-automatic-cookies")
    .ConfigurePrimaryHttpMessageHandler(() =>
    {
        return new SocketsHttpHandler()
        {
            UseCookies = false,
        };
    });
```

Logging

Clients created via `IHttpClientFactory` record log messages for all requests. Enable the appropriate information level in the logging configuration to see the default log messages. Additional logging, such as the logging of request headers, is only included at trace level.

The log category used for each client includes the name of the client. A client named *MyNamedClient*, for example, logs messages with a category of "System.Net.Http.HttpClient.**MyNamedClient**.LogicalHandler". Messages suffixed with *LogicalHandler* occur outside the request handler pipeline. On the request, messages are logged before any other handlers in the pipeline have processed it. On the response, messages are logged after any other pipeline handlers have received the response.

Logging also occurs inside the request handler pipeline. In the *MyNamedClient* example, those messages are logged with the log category "System.Net.Http.HttpClient.**MyNamedClient**.ClientHandler". For the request, this occurs after all other handlers have run and immediately before the request is sent. On the response, this logging includes the state of the response before it passes back through the handler pipeline.

Enabling logging outside and inside the pipeline enables inspection of the changes made by the other pipeline handlers. This may include changes to request headers or to the response status code.

Including the name of the client in the log category enables log filtering for specific named clients.

Configure the HttpMessageHandler

It may be necessary to control the configuration of the inner `HttpMessageHandler` used by a client.

An `IHttpClientBuilder` is returned when adding named or typed clients. The ConfigurePrimaryHttpMessageHandler extension method can be used to define a delegate. The delegate is used to create and configure the primary `HttpMessageHandler` used by that client:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddHttpClient("configured-inner-handler")
        .ConfigurePrimaryHttpMessageHandler(() =>
        {
            return new HttpClientHandler()
            {
                AllowAutoRedirect = false,
                UseDefaultCredentials = true
            };
        });

    // Remaining code deleted for brevity.
```

Use IHttpClientFactory in a console app

In a console app, add the following package references to the project:

- Microsoft.Extensions.Hosting
- Microsoft.Extensions.Http

In the following example:

- IHttpClientFactory is registered in the Generic Host's service container.
- `MyService` creates a client factory instance from the service, which is used to create an `HttpClient`. `HttpClient` is used to retrieve a webpage.
- `Main` creates a scope to execute the service's `GetPage` method and write the first 500 characters of the webpage content to the console.

```
using System;
using System.Net.Http;
using System.Threading.Tasks;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
class Program
{
    static async Task<int> Main(string[] args)
    {
        var builder = new HostBuilder()
            .ConfigureServices((hostContext, services) =>
            {
                services.AddHttpClient();
                services.AddTransient<IMyService, MyService>();
            }).UseConsoleLifetime();

        var host = builder.Build();

        using (var serviceScope = host.Services.CreateScope())
        {
            var services = serviceScope.ServiceProvider;

            try
            {
                var myService = services.GetRequiredService<IMyService>();
                var pageContent = await myService.GetPage();

                Console.WriteLine(pageContent.Substring(0, 500));
            }
            catch (Exception ex)
            {
                var logger = services.GetRequiredService<ILogger<Program>>();

                logger.LogError(ex, "An error occurred.");
            }
        }

        return 0;
    }

    public interface IMyService
    {
        Task<string> GetPage();
    }

    public class MyService : IMyService
    {
        private readonly IHttpClientFactory _clientFactory;

        public MyService(IHttpClientFactory clientFactory)
        {
            _clientFactory = clientFactory;
        }

        public async Task<string> GetPage()
        {
            // Content from BBC One: Dr. Who website (©BBC)
            var request = new HttpRequestMessage(HttpMethod.Get,
                "https://www.bbc.co.uk/programmes/b006q2x0");
            var client = _clientFactory.CreateClient();
            var response = await client.SendAsync(request);

            if (response.IsSuccessStatusCode)
            {
                return await response.Content.ReadAsStringAsync();
            }
            else
            {
```

```
                return $"StatusCode: {response.StatusCode}";
            }
        }
    }
}
```

Header propagation middleware

Header propagation is an ASP.NET Core middleware to propagate HTTP headers from the incoming request to the outgoing HTTP Client requests. To use header propagation:

- Reference the Microsoft.AspNetCore.HeaderPropagation package.
- Configure the middleware and `HttpClient` in `Startup`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllers();

    services.AddHttpClient("MyForwardingClient").AddHeaderPropagation();
    services.AddHeaderPropagation(options =>
    {
        options.Headers.Add("X-TraceId");
    });
}

public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    app.UseHttpsRedirection();

    app.UseHeaderPropagation();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
    });
}
```

- The client includes the configured headers on outbound requests:

```
var client = clientFactory.CreateClient("MyForwardingClient");
var response = client.GetAsync(...);
```

- Implement the Circuit Breaker pattern
- How to serialize and deserialize JSON in .NET

By Glenn Condron, Ryan Nowak, and Steve Gordon

An IHttpClientFactory can be registered and used to configure and create HttpClient instances in an app. It offers the following benefits:

- Provides a central location for naming and configuring logical `HttpClient` instances. For example, a *github* client can be registered and configured to access GitHub. A default client can be registered for other purposes.
- Codifies the concept of outgoing middleware via delegating handlers in `HttpClient` and provides extensions for Polly-based middleware to take advantage of that.
- Manages the pooling and lifetime of underlying `HttpClientMessageHandler` instances to avoid common DNS problems that occur when manually managing `HttpClient` lifetimes.
- Adds a configurable logging experience (via `ILogger`) for all requests sent through clients created by the factory.

View or download sample code (how to download)

Consumption patterns

There are several ways `IHttpClientFactory` can be used in an app:

- Basic usage
- Named clients
- Typed clients
- Generated clients

None of them are strictly superior to another. The best approach depends upon the app's constraints.

Basic usage

The `IHttpClientFactory` can be registered by calling the `AddHttpClient` extension method on the `IServiceCollection`, inside the `Startup.ConfigureServices` method.

```
services.AddHttpClient();
```

Once registered, code can accept an `IHttpClientFactory` anywhere services can be injected with dependency injection (DI). The `IHttpClientFactory` can be used to create an `HttpClient` instance:

```
public class BasicUsageModel : PageModel
{
    private readonly IHttpClientFactory _clientFactory;

    public IEnumerable<GitHubBranch> Branches { get; private set; }

    public bool GetBranchesError { get; private set; }

    public BasicUsageModel(IHttpClientFactory clientFactory)
    {
        _clientFactory = clientFactory;
    }

    public async Task OnGet()
    {
        var request = new HttpRequestMessage(HttpMethod.Get,
            "https://api.github.com/repos/aspnet/AspNetCore.Docs/branches");
        request.Headers.Add("Accept", "application/vnd.github.v3+json");
        request.Headers.Add("User-Agent", "HttpClientFactory-Sample");

        var client = _clientFactory.CreateClient();

        var response = await client.SendAsync(request);

        if (response.IsSuccessStatusCode)
        {
            Branches = await response.Content
                .ReadAsAsync<IEnumerable<GitHubBranch>>();
        }
        else
        {
            GetBranchesError = true;
            Branches = Array.Empty<GitHubBranch>();
        }
    }
}
```

Using `IHttpClientFactory` in this fashion is a good way to refactor an existing app. It has no impact on the way `HttpClient` is used. In places where `HttpClient` instances are currently created, replace those occurrences with a call to CreateClient.

Named clients

If an app requires many distinct uses of `HttpClient`, each with a different configuration, an option is to use **named clients**. Configuration for a named `HttpClient` can be specified during registration in `Startup.ConfigureServices`.

```
services.AddHttpClient("github", c =>
{
    c.BaseAddress = new Uri("https://api.github.com/");
    // Github API versioning
    c.DefaultRequestHeaders.Add("Accept", "application/vnd.github.v3+json");
    // Github requires a user-agent
    c.DefaultRequestHeaders.Add("User-Agent", "HttpClientFactory-Sample");
});
```

In the preceding code, `AddHttpClient` is called, providing the name *github*. This client has some default configuration applied—namely the base address and two headers required to work with the GitHub API.

Each time `CreateClient` is called, a new instance of `HttpClient` is created and the configuration action is called.

To consume a named client, a string parameter can be passed to `CreateClient`. Specify the name of the client to be created:

```
public class NamedClientModel : PageModel
{
    private readonly IHttpClientFactory _clientFactory;

    public IEnumerable<GitHubPullRequest> PullRequests { get; private set; }

    public bool GetPullRequestsError { get; private set; }

    public bool HasPullRequests => PullRequests.Any();

    public NamedClientModel(IHttpClientFactory clientFactory)
    {
        _clientFactory = clientFactory;
    }

    public async Task OnGet()
    {
        var request = new HttpRequestMessage(HttpMethod.Get,
            "repos/aspnet/AspNetCore.Docs/pulls");

        var client = _clientFactory.CreateClient("github");

        var response = await client.SendAsync(request);

        if (response.IsSuccessStatusCode)
        {
            PullRequests = await response.Content
                .ReadAsAsync<IEnumerable<GitHubPullRequest>>();
        }
        else
        {
            GetPullRequestsError = true;
            PullRequests = Array.Empty<GitHubPullRequest>();
        }
    }
}
```

In the preceding code, the request doesn't need to specify a hostname. It can pass just the path, since the base address configured for the client is used.

Typed clients

Typed clients:

- Provide the same capabilities as named clients without the need to use strings as keys.
- Provides IntelliSense and compiler help when consuming clients.
- Provide a single location to configure and interact with a particular `HttpClient`. For example, a single typed client might be used for a single backend endpoint and encapsulate all logic dealing with that endpoint.
- Work with DI and can be injected where required in your app.

A typed client accepts an `HttpClient` parameter in its constructor:

```
public class GitHubService
{
    public HttpClient Client { get; }

    public GitHubService(HttpClient client)
    {
        client.BaseAddress = new Uri("https://api.github.com/");
        // GitHub API versioning
        client.DefaultRequestHeaders.Add("Accept",
            "application/vnd.github.v3+json");
        // GitHub requires a user-agent
        client.DefaultRequestHeaders.Add("User-Agent",
            "HttpClientFactory-Sample");

        Client = client;
    }

    public async Task<IEnumerable<GitHubIssue>> GetAspNetDocsIssues()
    {
        var response = await Client.GetAsync(
            "/repos/aspnet/AspNetCore.Docs/issues?state=open&sort=created&direction=desc");

        response.EnsureSuccessStatusCode();

        var result = await response.Content
            .ReadAsAsync<IEnumerable<GitHubIssue>>();

        return result;
    }
}
```

In the preceding code, the configuration is moved into the typed client. The `HttpClient` object is exposed as a public property. It's possible to define API-specific methods that expose `HttpClient` functionality. The `GetAspNetDocsIssues` method encapsulates the code needed to query for and parse out the latest open issues from a GitHub repository.

To register a typed client, the generic AddHttpClient extension method can be used within `Startup.ConfigureServices`, specifying the typed client class:

```
services.AddHttpClient<GitHubService>();
```

The typed client is registered as transient with DI. The typed client can be injected and consumed directly:

```
public class TypedClientModel : PageModel
{
    private readonly GitHubService _gitHubService;

    public IEnumerable<GitHubIssue> LatestIssues { get; private set; }

    public bool HasIssue => LatestIssues.Any();

    public bool GetIssuesError { get; private set; }

    public TypedClientModel(GitHubService gitHubService)
    {
        _gitHubService = gitHubService;
    }

    public async Task OnGet()
    {
        try
        {
            LatestIssues = await _gitHubService.GetAspNetDocsIssues();
        }
        catch(HttpRequestException)
        {
            GetIssuesError = true;
            LatestIssues = Array.Empty<GitHubIssue>();
        }
    }
}
```

If preferred, the configuration for a typed client can be specified during registration in `Startup.ConfigureServices`, rather than in the typed client's constructor:

```
services.AddHttpClient<RepoService>(c =>
{
    c.BaseAddress = new Uri("https://api.github.com/");
    c.DefaultRequestHeaders.Add("Accept", "application/vnd.github.v3+json");
    c.DefaultRequestHeaders.Add("User-Agent", "HttpClientFactory-Sample");
});
```

It's possible to entirely encapsulate the `HttpClient` within a typed client. Rather than exposing it as a property, public methods can be provided which call the `HttpClient` instance internally.

```
public class RepoService
{
    // _httpClient isn't exposed publicly
    private readonly HttpClient _httpClient;

    public RepoService(HttpClient client)
    {
        _httpClient = client;
    }

    public async Task<IEnumerable<string>> GetRepos()
    {
        var response = await _httpClient.GetAsync("aspnet/repos");

        response.EnsureSuccessStatusCode();

        var result = await response.Content
            .ReadAsAsync<IEnumerable<string>>();

        return result;
    }
}
```

In the preceding code, the `HttpClient` is stored as a private field. All access to make external calls goes through the `GetRepos` method.

Generated clients

`IHttpClientFactory` can be used in combination with other third-party libraries such as Refit. Refit is a REST library for .NET. It converts REST APIs into live interfaces. An implementation of the interface is generated dynamically by the `RestService`, using `HttpClient` to make the external HTTP calls.

An interface and a reply are defined to represent the external API and its response:

```
public interface IHelloClient
{
    [Get("/helloworld")]
    Task<Reply> GetMessageAsync();
}

public class Reply
{
    public string Message { get; set; }
}
```

A typed client can be added, using Refit to generate the implementation:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddHttpClient("hello", c =>
    {
        c.BaseAddress = new Uri("https://localhost:5001");
    })
    .AddTypedClient(c => Refit.RestService.For<IHelloClient>(c));

    services.AddMvc();
}
```

The defined interface can be consumed where necessary, with the implementation provided by DI and Refit:

```
[ApiController]
public class ValuesController : ControllerBase
{
    private readonly IHelloClient _client;

    public ValuesController(IHelloClient client)
    {
        _client = client;
    }

    [HttpGet("/")]
    public async Task<ActionResult<Reply>> Index()
    {
        return await _client.GetMessageAsync();
    }
}
```

Outgoing request middleware

`HttpClient` already has the concept of delegating handlers that can be linked together for outgoing HTTP requests. The `IHttpClientFactory` makes it easy to define the handlers to apply for each named client. It supports registration and chaining of multiple handlers to build an outgoing request middleware pipeline. Each of these handlers is able to perform work before and after the outgoing request. This pattern is similar to the inbound middleware pipeline in ASP.NET Core. The pattern provides a mechanism to manage cross-cutting concerns around HTTP requests, including caching, error handling, serialization, and logging.

To create a handler, define a class deriving from DelegatingHandler. Override the `SendAsync` method to execute code before passing the request to the next handler in the pipeline:

```
public class ValidateHeaderHandler : DelegatingHandler
{
    protected override async Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request,
        CancellationToken cancellationToken)
    {
        if (!request.Headers.Contains("X-API-KEY"))
        {
            return new HttpResponseMessage(HttpStatusCode.BadRequest)
            {
                Content = new StringContent(
                    "You must supply an API key header called X-API-KEY")
            };
        }

        return await base.SendAsync(request, cancellationToken);
    }
}
```

The preceding code defines a basic handler. It checks to see if an `X-API-KEY` header has been included on the request. If the header is missing, it can avoid the HTTP call and return a suitable response.

During registration, one or more handlers can be added to the configuration for an `HttpClient`. This task is accomplished via extension methods on the IHttpClientBuilder.

```
services.AddTransient<ValidateHeaderHandler>();

services.AddHttpClient("externalservice", c =>
{
    // Assume this is an "external" service which requires an API KEY
    c.BaseAddress = new Uri("https://localhost:5000/");
})
.AddHttpMessageHandler<ValidateHeaderHandler>();
```

In the preceding code, the `ValidateHeaderHandler` is registered with DI. The `IHttpClientFactory` creates a separate DI scope for each handler. Handlers are free to depend upon services of any scope. Services that handlers depend upon are disposed when the handler is disposed.

Once registered, AddHttpMessageHandler can be called, passing in the type for the handler.

Multiple handlers can be registered in the order that they should execute. Each handler wraps the next handler until the final `HttpClientHandler` executes the request:

```
services.AddTransient<SecureRequestHandler>();
services.AddTransient<RequestDataHandler>();

services.AddHttpClient("clientwithhandlers")
    // This handler is on the outside and called first during the
    // request, last during the response.
    .AddHttpMessageHandler<SecureRequestHandler>()
    // This handler is on the inside, closest to the request being
    // sent.
    .AddHttpMessageHandler<RequestDataHandler>();
```

Use one of the following approaches to share per-request state with message handlers:

- Pass data into the handler using `HttpRequestMessage.Properties`.
- Use `IHttpContextAccessor` to access the current request.
- Create a custom `AsyncLocal` storage object to pass the data.

Use Polly-based handlers

`IHttpClientFactory` integrates with a popular third-party library called Polly. Polly is a comprehensive resilience and transient fault-handling library for .NET. It allows developers to express policies such as Retry, Circuit Breaker, Timeout, Bulkhead Isolation, and Fallback in a fluent and thread-safe manner.

Extension methods are provided to enable the use of Polly policies with configured `HttpClient` instances. The Polly extensions:

- Support adding Polly-based handlers to clients.
- Can be used after installing the Microsoft.Extensions.Http.Polly NuGet package. The package isn't included in the ASP.NET Core shared framework.

Handle transient faults

Most common faults occur when external HTTP calls are transient. A convenient extension method called `AddTransientHttpErrorPolicy` is included which allows a policy to be defined to handle transient errors. Policies configured with this extension method handle `HttpRequestException`, HTTP 5xx responses, and HTTP 408 responses.

The `AddTransientHttpErrorPolicy` extension can be used within `Startup.ConfigureServices`. The extension provides access to a `PolicyBuilder` object configured to handle errors representing a possible transient fault:

```
services.AddHttpClient<UnreliableEndpointCallerService>()
    .AddTransientHttpErrorPolicy(p =>
        p.WaitAndRetryAsync(3, _ => TimeSpan.FromMilliseconds(600)));
```

In the preceding code, a `WaitAndRetryAsync` policy is defined. Failed requests are retried up to three times with a delay of 600 ms between attempts.

Dynamically select policies

Additional extension methods exist which can be used to add Polly-based handlers. One such extension is `AddPolicyHandler`, which has multiple overloads. One overload allows the request to be inspected when defining which policy to apply:

```
var timeout = Policy.TimeoutAsync<HttpResponseMessage>(
    TimeSpan.FromSeconds(10));
var longTimeout = Policy.TimeoutAsync<HttpResponseMessage>(
    TimeSpan.FromSeconds(30));

services.AddHttpClient("conditionalpolicy")
// Run some code to select a policy based on the request
    .AddPolicyHandler(request =>
        request.Method == HttpMethod.Get ? timeout : longTimeout);
```

In the preceding code, if the outgoing request is an HTTP GET, a 10-second timeout is applied. For any other HTTP method, a 30-second timeout is used.

Add multiple Polly handlers

It's common to nest Polly policies to provide enhanced functionality:

```
services.AddHttpClient("multiplepolicies")
    .AddTransientHttpErrorPolicy(p => p.RetryAsync(3))
    .AddTransientHttpErrorPolicy(
        p => p.CircuitBreakerAsync(5, TimeSpan.FromSeconds(30)));
```

In the preceding example, two handlers are added. The first uses the `AddTransientHttpErrorPolicy` extension to add a retry policy. Failed requests are retried up to three times. The second call to `AddTransientHttpErrorPolicy` adds a circuit breaker policy. Further external requests are blocked for 30 seconds if five failed attempts occur sequentially. Circuit breaker policies are stateful. All calls through this client share the same circuit state.

Add policies from the Polly registry

An approach to managing regularly used policies is to define them once and register them with a `PolicyRegistry`. An extension method is provided which allows a handler to be added using a policy from the registry:

```
var registry = services.AddPolicyRegistry();

registry.Add("regular", timeout);
registry.Add("long", longTimeout);

services.AddHttpClient("regulartimeouthandler")
    .AddPolicyHandlerFromRegistry("regular");
```

In the preceding code, two policies are registered when the `PolicyRegistry` is added to the `ServiceCollection`. To use a policy from the registry, the `AddPolicyHandlerFromRegistry` method is used, passing the name of the policy to apply.

Further information about `IHttpClientFactory` and Polly integrations can be found on the Polly wiki.

HttpClient and lifetime management

A new `HttpClient` instance is returned each time `CreateClient` is called on the `IHttpClientFactory`. There's an HttpMessageHandler per named client. The factory manages the lifetimes of the `HttpMessageHandler` instances.

`IHttpClientFactory` pools the `HttpMessageHandler` instances created by the factory to reduce resource consumption. An `HttpMessageHandler` instance may be reused from the pool when creating a new `HttpClient` instance if its lifetime hasn't expired.

Pooling of handlers is desirable as each handler typically manages its own underlying HTTP connections. Creating more handlers than necessary can result in connection delays. Some handlers also keep connections open indefinitely, which can prevent the handler from reacting to DNS changes.

The default handler lifetime is two minutes. The default value can be overridden on a per named client basis. To override it, call SetHandlerLifetime on the `IHttpClientBuilder` that is returned when creating the client:

```
services.AddHttpClient("extendedhandlerlifetime")
    .SetHandlerLifetime(TimeSpan.FromMinutes(5));
```

Disposal of the client isn't required. Disposal cancels outgoing requests and guarantees the given `HttpClient` instance can't be used after calling Dispose. `IHttpClientFactory` tracks and disposes resources used by `HttpClient` instances. The `HttpClient` instances can generally be treated as .NET objects not requiring disposal.

Keeping a single `HttpClient` instance alive for a long duration is a common pattern used before the inception of `IHttpClientFactory`. This pattern becomes unnecessary after migrating to `IHttpClientFactory`.

Alternatives to IHttpClientFactory

Using `IHttpClientFactory` in a DI-enabled app avoids:

- Resource exhaustion problems by pooling `HttpMessageHandler` instances.
- Stale DNS problems by cycling `HttpMessageHandler` instances at regular intervals.

There are alternative ways to solve the preceding problems using a long-lived SocketsHttpHandler instance.

- Create an instance of `SocketsHttpHandler` when the app starts and use it for the life of the app.
- Configure PooledConnectionLifetime to an appropriate value based on DNS refresh times.
- Create `HttpClient` instances using `new HttpClient(handler, disposeHandler: false)` as needed.

The preceding approaches solve the resource management problems that `IHttpClientFactory` solves in a similar way.

- The `SocketsHttpHandler` shares connections across `HttpClient` instances. This sharing prevents socket exhaustion.
- The `SocketsHttpHandler` cycles connections according to `PooledConnectionLifetime` to avoid stale DNS problems.

Cookies

The pooled `HttpMessageHandler` instances results in `CookieContainer` objects being shared. Unanticipated `CookieContainer` object sharing often results in incorrect code. For apps that require cookies, consider either:

- Disabling automatic cookie handling
- Avoiding `IHttpClientFactory`

Call ConfigurePrimaryHttpMessageHandler to disable automatic cookie handling:

```
services.AddHttpClient("configured-disable-automatic-cookies")
    .ConfigurePrimaryHttpMessageHandler(() =>
    {
        return new SocketsHttpHandler()
        {
            UseCookies = false,
        };
    });
```

Logging

Clients created via `IHttpClientFactory` record log messages for all requests. Enable the appropriate information level in your logging configuration to see the default log messages. Additional logging, such as the logging of request headers, is only included at trace level.

The log category used for each client includes the name of the client. A client named *MyNamedClient*, for example, logs messages with a category of `System.Net.Http.HttpClient.MyNamedClient.LogicalHandler`. Messages suffixed with *LogicalHandler* occur outside the request handler pipeline. On the request, messages are logged before any other handlers in the pipeline have processed it. On the response, messages are logged after any other pipeline handlers have received the response.

Logging also occurs inside the request handler pipeline. In the *MyNamedClient* example, those messages are logged against the log category `System.Net.Http.HttpClient.MyNamedClient.ClientHandler`. For the request, this occurs after all other handlers have run and immediately before the request is sent out on the network. On the response, this logging includes the state of the response before it passes back through the handler pipeline.

Enabling logging outside and inside the pipeline enables inspection of the changes made by the other pipeline handlers. This may include changes to request headers, for example, or to the response status code.

Including the name of the client in the log category enables log filtering for specific named clients where necessary.

Configure the HttpMessageHandler

It may be necessary to control the configuration of the inner `HttpMessageHandler` used by a client.

An `IHttpClientBuilder` is returned when adding named or typed clients. The ConfigurePrimaryHttpMessageHandler extension method can be used to define a delegate. The delegate is used to create and configure the primary `HttpMessageHandler` used by that client:

```
services.AddHttpClient("configured-inner-handler")
    .ConfigurePrimaryHttpMessageHandler(() =>
    {
        return new HttpClientHandler()
        {
            AllowAutoRedirect = false,
            UseDefaultCredentials = true
        };
    });
```

Use IHttpClientFactory in a console app

In a console app, add the following package references to the project:

- Microsoft.Extensions.Hosting
- Microsoft.Extensions.Http

In the following example:

- IHttpClientFactory is registered in the Generic Host's service container.
- `MyService` creates a client factory instance from the service, which is used to create an `HttpClient`. `HttpClient` is used to retrieve a webpage.
- `Main` creates a scope to execute the service's `GetPage` method and write the first 500 characters of the webpage content to the console.

```
using System;
using System.Net.Http;
using System.Threading.Tasks;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
class Program
{
    static async Task<int> Main(string[] args)
    {
        var builder = new HostBuilder()
            .ConfigureServices((hostContext, services) =>
            {
                services.AddHttpClient();
                services.AddTransient<IMyService, MyService>();
            }).UseConsoleLifetime();

        var host = builder.Build();

        using (var serviceScope = host.Services.CreateScope())
        {
            var services = serviceScope.ServiceProvider;

            try
            {
                var myService = services.GetRequiredService<IMyService>();
                var pageContent = await myService.GetPage();

                Console.WriteLine(pageContent.Substring(0, 500));
            }
            catch (Exception ex)
            {
                var logger = services.GetRequiredService<ILogger<Program>>();

                logger.LogError(ex, "An error occurred.");
            }
        }

        return 0;
    }

    public interface IMyService
    {
        Task<string> GetPage();
    }

    public class MyService : IMyService
    {
        private readonly IHttpClientFactory _clientFactory;

        public MyService(IHttpClientFactory clientFactory)
        {
            _clientFactory = clientFactory;
        }

        public async Task<string> GetPage()
        {
            // Content from BBC One: Dr. Who website (©BBC)
```

```
            var request = new HttpRequestMessage(HttpMethod.Get,
                "https://www.bbc.co.uk/programmes/b006q2x0");
            var client = _clientFactory.CreateClient();
            var response = await client.SendAsync(request);

            if (response.IsSuccessStatusCode)
            {
                return await response.Content.ReadAsStringAsync();
            }
            else
            {
                return $"StatusCode: {response.StatusCode}";
            }
        }
    }
}
```

Additional resources

- Use HttpClientFactory to implement resilient HTTP requests
- Implement HTTP call retries with exponential backoff with HttpClientFactory and Polly policies
- Implement the Circuit Breaker pattern

By Glenn Condron, Ryan Nowak, and Steve Gordon

An IHttpClientFactory can be registered and used to configure and create HttpClient instances in an app. It offers the following benefits:

- Provides a central location for naming and configuring logical `HttpClient` instances. For example, a *github* client can be registered and configured to access GitHub. A default client can be registered for other purposes.
- Codifies the concept of outgoing middleware via delegating handlers in `HttpClient` and provides extensions for Polly-based middleware to take advantage of that.
- Manages the pooling and lifetime of underlying `HttpClientMessageHandler` instances to avoid common DNS problems that occur when manually managing `HttpClient` lifetimes.
- Adds a configurable logging experience (via `ILogger`) for all requests sent through clients created by the factory.

View or download sample code (how to download)

Prerequisites

Projects targeting .NET Framework require installation of the Microsoft.Extensions.Http NuGet package. Projects that target .NET Core and reference the Microsoft.AspNetCore.App metapackage already include the `Microsoft.Extensions.Http` package.

Consumption patterns

There are several ways `IHttpClientFactory` can be used in an app:

- Basic usage
- Named clients
- Typed clients
- Generated clients

None of them are strictly superior to another. The best approach depends upon the app's constraints.

Basic usage

The `IHttpClientFactory` can be registered by calling the `AddHttpClient` extension method on the `IServiceCollection`, inside the `Startup.ConfigureServices` method.

```
services.AddHttpClient();
```

Once registered, code can accept an `IHttpClientFactory` anywhere services can be injected with dependency injection (DI). The `IHttpClientFactory` can be used to create an `HttpClient` instance:

```
public class BasicUsageModel : PageModel
{
    private readonly IHttpClientFactory _clientFactory;

    public IEnumerable<GitHubBranch> Branches { get; private set; }

    public bool GetBranchesError { get; private set; }

    public BasicUsageModel(IHttpClientFactory clientFactory)
    {
        _clientFactory = clientFactory;
    }

    public async Task OnGet()
    {
        var request = new HttpRequestMessage(HttpMethod.Get,
            "https://api.github.com/repos/aspnet/AspNetCore.Docs/branches");
        request.Headers.Add("Accept", "application/vnd.github.v3+json");
        request.Headers.Add("User-Agent", "HttpClientFactory-Sample");

        var client = _clientFactory.CreateClient();

        var response = await client.SendAsync(request);

        if (response.IsSuccessStatusCode)
        {
            Branches = await response.Content
                .ReadAsAsync<IEnumerable<GitHubBranch>>();
        }
        else
        {
            GetBranchesError = true;
            Branches = Array.Empty<GitHubBranch>();
        }
    }
}
```

Using `IHttpClientFactory` in this fashion is a good way to refactor an existing app. It has no impact on the way `HttpClient` is used. In places where `HttpClient` instances are currently created, replace those occurrences with a call to CreateClient.

Named clients

If an app requires many distinct uses of `HttpClient`, each with a different configuration, an option is to use **named clients**. Configuration for a named `HttpClient` can be specified during registration in `Startup.ConfigureServices`.

```
services.AddHttpClient("github", c =>
{
    c.BaseAddress = new Uri("https://api.github.com/");
    // Github API versioning
    c.DefaultRequestHeaders.Add("Accept", "application/vnd.github.v3+json");
    // Github requires a user-agent
    c.DefaultRequestHeaders.Add("User-Agent", "HttpClientFactory-Sample");
});
```

In the preceding code, `AddHttpClient` is called, providing the name *github*. This client has some default configuration applied—namely the base address and two headers required to work with the GitHub API.

Each time `CreateClient` is called, a new instance of `HttpClient` is created and the configuration action is called.

To consume a named client, a string parameter can be passed to `CreateClient`. Specify the name of the client to be created:

```
public class NamedClientModel : PageModel
{
    private readonly IHttpClientFactory _clientFactory;

    public IEnumerable<GitHubPullRequest> PullRequests { get; private set; }

    public bool GetPullRequestsError { get; private set; }

    public bool HasPullRequests => PullRequests.Any();

    public NamedClientModel(IHttpClientFactory clientFactory)
    {
        _clientFactory = clientFactory;
    }

    public async Task OnGet()
    {
        var request = new HttpRequestMessage(HttpMethod.Get,
            "repos/aspnet/AspNetCore.Docs/pulls");

        var client = _clientFactory.CreateClient("github");

        var response = await client.SendAsync(request);

        if (response.IsSuccessStatusCode)
        {
            PullRequests = await response.Content
                .ReadAsAsync<IEnumerable<GitHubPullRequest>>();
        }
        else
        {
            GetPullRequestsError = true;
            PullRequests = Array.Empty<GitHubPullRequest>();
        }
    }
}
```

In the preceding code, the request doesn't need to specify a hostname. It can pass just the path, since the base address configured for the client is used.

Typed clients

Typed clients:

- Provide the same capabilities as named clients without the need to use strings as keys.
- Provides IntelliSense and compiler help when consuming clients.

- Provide a single location to configure and interact with a particular `HttpClient`. For example, a single typed client might be used for a single backend endpoint and encapsulate all logic dealing with that endpoint.
- Work with DI and can be injected where required in your app.

A typed client accepts an `HttpClient` parameter in its constructor:

```
public class GitHubService
{
    public HttpClient Client { get; }

    public GitHubService(HttpClient client)
    {
        client.BaseAddress = new Uri("https://api.github.com/");
        // GitHub API versioning
        client.DefaultRequestHeaders.Add("Accept",
            "application/vnd.github.v3+json");
        // GitHub requires a user-agent
        client.DefaultRequestHeaders.Add("User-Agent",
            "HttpClientFactory-Sample");

        Client = client;
    }

    public async Task<IEnumerable<GitHubIssue>> GetAspNetDocsIssues()
    {
        var response = await Client.GetAsync(
            "/repos/aspnet/AspNetCore.Docs/issues?state=open&sort=created&direction=desc");

        response.EnsureSuccessStatusCode();

        var result = await response.Content
            .ReadAsAsync<IEnumerable<GitHubIssue>>();

        return result;
    }
}
```

In the preceding code, the configuration is moved into the typed client. The `HttpClient` object is exposed as a public property. It's possible to define API-specific methods that expose `HttpClient` functionality. The `GetAspNetDocsIssues` method encapsulates the code needed to query for and parse out the latest open issues from a GitHub repository.

To register a typed client, the generic AddHttpClient extension method can be used within `Startup.ConfigureServices`, specifying the typed client class:

```
services.AddHttpClient<GitHubService>();
```

The typed client is registered as transient with DI. The typed client can be injected and consumed directly:

```
public class TypedClientModel : PageModel
{
    private readonly GitHubService _gitHubService;

    public IEnumerable<GitHubIssue> LatestIssues { get; private set; }

    public bool HasIssue => LatestIssues.Any();

    public bool GetIssuesError { get; private set; }

    public TypedClientModel(GitHubService gitHubService)
    {
        _gitHubService = gitHubService;
    }

    public async Task OnGet()
    {
        try
        {
            LatestIssues = await _gitHubService.GetAspNetDocsIssues();
        }
        catch(HttpRequestException)
        {
            GetIssuesError = true;
            LatestIssues = Array.Empty<GitHubIssue>();
        }
    }
}
```

If preferred, the configuration for a typed client can be specified during registration in `Startup.ConfigureServices`, rather than in the typed client's constructor:

```
services.AddHttpClient<RepoService>(c =>
{
    c.BaseAddress = new Uri("https://api.github.com/");
    c.DefaultRequestHeaders.Add("Accept", "application/vnd.github.v3+json");
    c.DefaultRequestHeaders.Add("User-Agent", "HttpClientFactory-Sample");
});
```

It's possible to entirely encapsulate the `HttpClient` within a typed client. Rather than exposing it as a property, public methods can be provided which call the `HttpClient` instance internally.

```
public class RepoService
{
    // _httpClient isn't exposed publicly
    private readonly HttpClient _httpClient;

    public RepoService(HttpClient client)
    {
        _httpClient = client;
    }

    public async Task<IEnumerable<string>> GetRepos()
    {
        var response = await _httpClient.GetAsync("aspnet/repos");

        response.EnsureSuccessStatusCode();

        var result = await response.Content
            .ReadAsAsync<IEnumerable<string>>();

        return result;
    }
}
```

In the preceding code, the `HttpClient` is stored as a private field. All access to make external calls goes through the `GetRepos` method.

Generated clients

`IHttpClientFactory` can be used in combination with other third-party libraries such as Refit. Refit is a REST library for .NET. It converts REST APIs into live interfaces. An implementation of the interface is generated dynamically by the `RestService`, using `HttpClient` to make the external HTTP calls.

An interface and a reply are defined to represent the external API and its response:

```
public interface IHelloClient
{
    [Get("/helloworld")]
    Task<Reply> GetMessageAsync();
}

public class Reply
{
    public string Message { get; set; }
}
```

A typed client can be added, using Refit to generate the implementation:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddHttpClient("hello", c =>
    {
        c.BaseAddress = new Uri("http://localhost:5000");
    })
    .AddTypedClient(c => Refit.RestService.For<IHelloClient>(c));

    services.AddMvc();
}
```

The defined interface can be consumed where necessary, with the implementation provided by DI and Refit:

```
[ApiController]
public class ValuesController : ControllerBase
{
    private readonly IHelloClient _client;

    public ValuesController(IHelloClient client)
    {
        _client = client;
    }

    [HttpGet("/")]
    public async Task<ActionResult<Reply>> Index()
    {
        return await _client.GetMessageAsync();
    }
}
```

Outgoing request middleware

`HttpClient` already has the concept of delegating handlers that can be linked together for outgoing HTTP requests. The `IHttpClientFactory` makes it easy to define the handlers to apply for each named client. It supports registration and chaining of multiple handlers to build an outgoing request middleware pipeline. Each of these handlers is able to perform work before and after the outgoing request. This pattern is similar to the inbound middleware pipeline in ASP.NET Core. The pattern provides a mechanism to manage cross-cutting concerns around HTTP requests, including caching, error handling, serialization, and logging.

To create a handler, define a class deriving from DelegatingHandler. Override the `SendAsync` method to execute code before passing the request to the next handler in the pipeline:

```
public class ValidateHeaderHandler : DelegatingHandler
{
    protected override async Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request,
        CancellationToken cancellationToken)
    {
        if (!request.Headers.Contains("X-API-KEY"))
        {
            return new HttpResponseMessage(HttpStatusCode.BadRequest)
            {
                Content = new StringContent(
                    "You must supply an API key header called X-API-KEY")
            };
        }

        return await base.SendAsync(request, cancellationToken);
    }
}
```

The preceding code defines a basic handler. It checks to see if an `X-API-KEY` header has been included on the request. If the header is missing, it can avoid the HTTP call and return a suitable response.

During registration, one or more handlers can be added to the configuration for an `HttpClient`. This task is accomplished via extension methods on the IHttpClientBuilder.

```
services.AddTransient<ValidateHeaderHandler>();

services.AddHttpClient("externalservice", c =>
{
    // Assume this is an "external" service which requires an API KEY
    c.BaseAddress = new Uri("https://localhost:5000/");
})
.AddHttpMessageHandler<ValidateHeaderHandler>();
```

In the preceding code, the `ValidateHeaderHandler` is registered with DI. The handler **must** be registered in DI as a transient service, never scoped. If the handler is registered as a scoped service and any services that the handler depends upon are disposable:

- The handler's services could be disposed before the handler goes out of scope.
- The disposed handler services causes the handler to fail.

Once registered, AddHttpMessageHandler can be called, passing in the handler type.

Multiple handlers can be registered in the order that they should execute. Each handler wraps the next handler until the final `HttpClientHandler` executes the request:

```
services.AddTransient<SecureRequestHandler>();
services.AddTransient<RequestDataHandler>();

services.AddHttpClient("clientwithhandlers")
    // This handler is on the outside and called first during the
    // request, last during the response.
    .AddHttpMessageHandler<SecureRequestHandler>()
    // This handler is on the inside, closest to the request being
    // sent.
    .AddHttpMessageHandler<RequestDataHandler>();
```

Use one of the following approaches to share per-request state with message handlers:

- Pass data into the handler using `HttpRequestMessage.Properties`.
- Use `IHttpContextAccessor` to access the current request.
- Create a custom `AsyncLocal` storage object to pass the data.

Use Polly-based handlers

`IHttpClientFactory` integrates with a popular third-party library called Polly. Polly is a comprehensive resilience and transient fault-handling library for .NET. It allows developers to express policies such as Retry, Circuit Breaker, Timeout, Bulkhead Isolation, and Fallback in a fluent and thread-safe manner.

Extension methods are provided to enable the use of Polly policies with configured `HttpClient` instances. The Polly extensions:

- Support adding Polly-based handlers to clients.
- Can be used after installing the Microsoft.Extensions.Http.Polly NuGet package. The package isn't included in the ASP.NET Core shared framework.

Handle transient faults

Most common faults occur when external HTTP calls are transient. A convenient extension method called `AddTransientHttpErrorPolicy` is included which allows a policy to be defined to handle transient errors. Policies configured with this extension method handle `HttpRequestException`, HTTP 5xx responses, and HTTP 408 responses.

The `AddTransientHttpErrorPolicy` extension can be used within `Startup.ConfigureServices`. The extension provides access to a `PolicyBuilder` object configured to handle errors representing a possible transient fault:

```
services.AddHttpClient<UnreliableEndpointCallerService>()
    .AddTransientHttpErrorPolicy(p =>
        p.WaitAndRetryAsync(3, _ => TimeSpan.FromMilliseconds(600)));
```

In the preceding code, a `WaitAndRetryAsync` policy is defined. Failed requests are retried up to three times with a delay of 600 ms between attempts.

Dynamically select policies

Additional extension methods exist which can be used to add Polly-based handlers. One such extension is `AddPolicyHandler`, which has multiple overloads. One overload allows the request to be inspected when defining which policy to apply:

```
var timeout = Policy.TimeoutAsync<HttpResponseMessage>(
    TimeSpan.FromSeconds(10));
var longTimeout = Policy.TimeoutAsync<HttpResponseMessage>(
    TimeSpan.FromSeconds(30));

services.AddHttpClient("conditionalpolicy")
// Run some code to select a policy based on the request
    .AddPolicyHandler(request =>
        request.Method == HttpMethod.Get ? timeout : longTimeout);
```

In the preceding code, if the outgoing request is an HTTP GET, a 10-second timeout is applied. For any other HTTP method, a 30-second timeout is used.

Add multiple Polly handlers

It's common to nest Polly policies to provide enhanced functionality:

```
services.AddHttpClient("multiplepolicies")
    .AddTransientHttpErrorPolicy(p => p.RetryAsync(3))
    .AddTransientHttpErrorPolicy(
        p => p.CircuitBreakerAsync(5, TimeSpan.FromSeconds(30)));
```

In the preceding example, two handlers are added. The first uses the `AddTransientHttpErrorPolicy` extension to add a retry policy. Failed requests are retried up to three times. The second call to `AddTransientHttpErrorPolicy` adds a circuit breaker policy. Further external requests are blocked for 30 seconds if five failed attempts occur sequentially. Circuit breaker policies are stateful. All calls through this client share the same circuit state.

Add policies from the Polly registry

An approach to managing regularly used policies is to define them once and register them with a `PolicyRegistry`. An extension method is provided which allows a handler to be added using a policy from the registry:

```
var registry = services.AddPolicyRegistry();

registry.Add("regular", timeout);
registry.Add("long", longTimeout);

services.AddHttpClient("regulartimeouthandler")
    .AddPolicyHandlerFromRegistry("regular");
```

In the preceding code, two policies are registered when the `PolicyRegistry` is added to the `ServiceCollection`. To use a policy from the registry, the `AddPolicyHandlerFromRegistry` method is used, passing the name of the policy

to apply.

Further information about `IHttpClientFactory` and Polly integrations can be found on the Polly wiki.

HttpClient and lifetime management

A new `HttpClient` instance is returned each time `CreateClient` is called on the `IHttpClientFactory`. There's an HttpMessageHandler per named client. The factory manages the lifetimes of the `HttpMessageHandler` instances.

`IHttpClientFactory` pools the `HttpMessageHandler` instances created by the factory to reduce resource consumption. An `HttpMessageHandler` instance may be reused from the pool when creating a new `HttpClient` instance if its lifetime hasn't expired.

Pooling of handlers is desirable as each handler typically manages its own underlying HTTP connections. Creating more handlers than necessary can result in connection delays. Some handlers also keep connections open indefinitely, which can prevent the handler from reacting to DNS changes.

The default handler lifetime is two minutes. The default value can be overridden on a per named client basis. To override it, call SetHandlerLifetime on the `IHttpClientBuilder` that is returned when creating the client:

```
services.AddHttpClient("extendedhandlerlifetime")
    .SetHandlerLifetime(TimeSpan.FromMinutes(5));
```

Disposal of the client isn't required. Disposal cancels outgoing requests and guarantees the given `HttpClient` instance can't be used after calling Dispose. `IHttpClientFactory` tracks and disposes resources used by `HttpClient` instances. The `HttpClient` instances can generally be treated as .NET objects not requiring disposal.

Keeping a single `HttpClient` instance alive for a long duration is a common pattern used before the inception of `IHttpClientFactory`. This pattern becomes unnecessary after migrating to `IHttpClientFactory`.

Alternatives to IHttpClientFactory

Using `IHttpClientFactory` in a DI-enabled app avoids:

- Resource exhaustion problems by pooling `HttpMessageHandler` instances.
- Stale DNS problems by cycling `HttpMessageHandler` instances at regular intervals.

There are alternative ways to solve the preceding problems using a long-lived SocketsHttpHandler instance.

- Create an instance of `SocketsHttpHandler` when the app starts and use it for the life of the app.
- Configure PooledConnectionLifetime to an appropriate value based on DNS refresh times.
- Create `HttpClient` instances using `new HttpClient(handler, disposeHandler: false)` as needed.

The preceding approaches solve the resource management problems that `IHttpClientFactory` solves in a similar way.

- The `SocketsHttpHandler` shares connections across `HttpClient` instances. This sharing prevents socket exhaustion.
- The `SocketsHttpHandler` cycles connections according to `PooledConnectionLifetime` to avoid stale DNS problems.

Cookies

The pooled `HttpMessageHandler` instances results in `CookieContainer` objects being shared. Unanticipated `CookieContainer` object sharing often results in incorrect code. For apps that require cookies, consider either:

- Disabling automatic cookie handling
- Avoiding `IHttpClientFactory`

Call ConfigurePrimaryHttpMessageHandler to disable automatic cookie handling:

```
services.AddHttpClient("configured-disable-automatic-cookies")
    .ConfigurePrimaryHttpMessageHandler(() =>
    {
        return new SocketsHttpHandler()
        {
            UseCookies = false,
        };
    });
```

Logging

Clients created via `IHttpClientFactory` record log messages for all requests. Enable the appropriate information level in your logging configuration to see the default log messages. Additional logging, such as the logging of request headers, is only included at trace level.

The log category used for each client includes the name of the client. A client named *MyNamedClient*, for example, logs messages with a category of `System.Net.Http.HttpClient.MyNamedClient.LogicalHandler`. Messages suffixed with *LogicalHandler* occur outside the request handler pipeline. On the request, messages are logged before any other handlers in the pipeline have processed it. On the response, messages are logged after any other pipeline handlers have received the response.

Logging also occurs inside the request handler pipeline. In the *MyNamedClient* example, those messages are logged against the log category `System.Net.Http.HttpClient.MyNamedClient.ClientHandler`. For the request, this occurs after all other handlers have run and immediately before the request is sent out on the network. On the response, this logging includes the state of the response before it passes back through the handler pipeline.

Enabling logging outside and inside the pipeline enables inspection of the changes made by the other pipeline handlers. This may include changes to request headers, for example, or to the response status code.

Including the name of the client in the log category enables log filtering for specific named clients where necessary.

Configure the HttpMessageHandler

It may be necessary to control the configuration of the inner `HttpMessageHandler` used by a client.

An `IHttpClientBuilder` is returned when adding named or typed clients. The ConfigurePrimaryHttpMessageHandler extension method can be used to define a delegate. The delegate is used to create and configure the primary `HttpMessageHandler` used by that client:

```
services.AddHttpClient("configured-inner-handler")
    .ConfigurePrimaryHttpMessageHandler(() =>
    {
        return new HttpClientHandler()
        {
            AllowAutoRedirect = false,
            UseDefaultCredentials = true
        };
    });
```

Use IHttpClientFactory in a console app

In a console app, add the following package references to the project:

- Microsoft.Extensions.Hosting

- Microsoft.Extensions.Http

In the following example:

- IHttpClientFactory is registered in the Generic Host's service container.
- `MyService` creates a client factory instance from the service, which is used to create an `HttpClient`. `HttpClient` is used to retrieve a webpage.
- `Main` creates a scope to execute the service's `GetPage` method and write the first 500 characters of the webpage content to the console.

```
using System;
using System.Net.Http;
using System.Threading.Tasks;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
class Program
{
    static async Task<int> Main(string[] args)
    {
        var builder = new HostBuilder()
            .ConfigureServices((hostContext, services) =>
            {
                services.AddHttpClient();
                services.AddTransient<IMyService, MyService>();
            }).UseConsoleLifetime();

        var host = builder.Build();

        using (var serviceScope = host.Services.CreateScope())
        {
            var services = serviceScope.ServiceProvider;

            try
            {
                var myService = services.GetRequiredService<IMyService>();
                var pageContent = await myService.GetPage();

                Console.WriteLine(pageContent.Substring(0, 500));
            }
            catch (Exception ex)
            {
                var logger = services.GetRequiredService<ILogger<Program>>();

                logger.LogError(ex, "An error occurred.");
            }
        }

        return 0;
    }

    public interface IMyService
    {
        Task<string> GetPage();
    }

    public class MyService : IMyService
    {
        private readonly IHttpClientFactory _clientFactory;

        public MyService(IHttpClientFactory clientFactory)
        {
            _clientFactory = clientFactory;
        }

        public async Task<string> GetPage()
```

```
        {
            // Content from BBC One: Dr. Who website (©BBC)
            var request = new HttpRequestMessage(HttpMethod.Get,
                "https://www.bbc.co.uk/programmes/b006q2x0");
            var client = _clientFactory.CreateClient();
            var response = await client.SendAsync(request);

            if (response.IsSuccessStatusCode)
            {
                return await response.Content.ReadAsStringAsync();
            }
            else
            {
                return $"StatusCode: {response.StatusCode}";
            }
        }
    }
}
```

Header propagation middleware

Header propagation is a community supported middleware to propagate HTTP headers from the incoming request to the outgoing HTTP Client requests. To use header propagation:

- Reference the community supported port of the package HeaderPropagation. ASP.NET Core 3.1 and later supports Microsoft.AspNetCore.HeaderPropagation.
- Configure the middleware and `HttpClient` in `Startup`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);

    services.AddHttpClient("MyForwardingClient").AddHeaderPropagation();
    services.AddHeaderPropagation(options =>
    {
        options.Headers.Add("X-TraceId");
    });
}

public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseHsts();
    }

    app.UseHttpsRedirection();

    app.UseHeaderPropagation();

    app.UseMvc();
}
```

- The client includes the configured headers on outbound requests:

```
var client = clientFactory.CreateClient("MyForwardingClient");
var response = client.GetAsync(...);
```

Additional resources

- Use HttpClientFactory to implement resilient HTTP requests
- Implement HTTP call retries with exponential backoff with HttpClientFactory and Polly policies
- Implement the Circuit Breaker pattern

Static files in ASP.NET Core

9/22/2020 • 18 minutes to read • Edit Online

By Rick Anderson and Kirk Larkin

Static files, such as HTML, CSS, images, and JavaScript, are assets an ASP.NET Core app serves directly to clients by default.

View or download sample code (how to download)

Serve static files

Static files are stored within the project's web root directory. The default directory is `{content root}/wwwroot`, but it can be changed with the UseWebRoot method. For more information, see Content root and Web root.

The CreateDefaultBuilder method sets the content root to the current directory:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The preceding code was created with the web app template.

Static files are accessible via a path relative to the web root. For example, the **Web Application** project templates contain several folders within the `wwwroot` folder:

- `wwwroot`
  - `css`
  - `js`
  - `lib`

Consider creating the *wwwroot/images* folder and adding the *wwwroot/images/MyImage.jpg* file. The URI format to access a file in the `images` folder is `https://<hostname>/images/<image_file_name>`. For example, `https://localhost:5001/images/MyImage.jpg`

Serve files in web root

The default web app templates call the UseStaticFiles method in `Startup.Configure`, which enables static files to be served:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();

    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}
```

The parameterless `UseStaticFiles` method overload marks the files in web root as servable. The following markup references *wwwroot/images/MyImage.jpg*:

```
<img src="~/images/MyImage.jpg" class="img" alt="My image" />
```

In the preceding code, the tilde character `~/` points to the web root.

Serve files outside of web root

Consider a directory hierarchy in which the static files to be served reside outside of the web root:

- `wwwroot`
  - `css`
  - `images`
  - `js`
- `MyStaticFiles`
  - `images`
    - `red-rose.jpg`

A request can access the `red-rose.jpg` file by configuring the Static File Middleware as follows:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();

    // using Microsoft.Extensions.FileProviders;
    // using System.IO;
    app.UseStaticFiles(new StaticFileOptions
    {
        FileProvider = new PhysicalFileProvider(
            Path.Combine(env.ContentRootPath, "MyStaticFiles")),
        RequestPath = "/StaticFiles"
    });

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}
```

In the preceding code, the *MyStaticFiles* directory hierarchy is exposed publicly via the *StaticFiles* URI segment. A request to `https://<hostname>/StaticFiles/images/red-rose.jpg` serves the *red-rose.jpg* file.

The following markup references *MyStaticFiles/images/red-rose.jpg*:

```
<img src="~/StaticFiles/images/red-rose.jpg" class="img" alt="A red rose" />
```

Set HTTP response headers

A StaticFileOptions object can be used to set HTTP response headers. In addition to configuring static file serving from the web root, the following code sets the `Cache-Control` header:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();

    const string cacheMaxAge = "604800";
    app.UseStaticFiles(new StaticFileOptions
    {
        OnPrepareResponse = ctx =>
        {
            // using Microsoft.AspNetCore.Http;
            ctx.Context.Response.Headers.Append(
                 "Cache-Control", $"public, max-age={cacheMaxAge}");
        }
    });

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}
```

Static files are publicly cacheable for 600 seconds:

Static file authorization

The Static File Middleware doesn't provide authorization checks. Any files served by it, including those under `wwwroot`, are publicly accessible. To serve files based on authorization:

- Store them outside of `wwwroot` and any directory accessible to the default Static File Middleware.
- Call `UseStaticFiles` after `UseAuthorization` and specify the path:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();

    // wwwroot css, JavaScrip, and images don't require authentication.
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseStaticFiles(new StaticFileOptions
    {
        FileProvider = new PhysicalFileProvider(
                    Path.Combine(env.ContentRootPath, "MyStaticFiles")),
        RequestPath = "/StaticFiles"
    });

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

The preceding approach requires users to be authenticated:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddDbContext<ApplicationDbContext>(options =>
            options.UseSqlServer(
                Configuration.GetConnectionString("DefaultConnection")));
        services.AddDefaultIdentity<IdentityUser>(options => options.SignIn.RequireConfirmedAccount
= true)
            .AddEntityFrameworkStores<ApplicationDbContext>();

        services.AddRazorPages();

        services.AddAuthorization(options =>
        {
            options.FallbackPolicy = new AuthorizationPolicyBuilder()
                .RequireAuthenticatedUser()
                .Build();
        });
    }

    // Remaining code ommitted for brevity.
```

For information on how to globally require all users to be authenticated, see Require authenticated users.

An alternative approach to serve files based on authorization:

- Store them outside of `wwwroot` and any directory accessible to the Static File Middleware.
- Serve them via an action method to which authorization is applied and return a FileResult object:

```
[Authorize]
public IActionResult BannerImage()
{
    var filePath = Path.Combine(
        _env.ContentRootPath, "MyStaticFiles", "images", "red-rose.jpg");

    return PhysicalFile(filePath, "image/jpeg");
}
```

Directory browsing

Directory browsing allows directory listing within specified directories.

Directory browsing is disabled by default for security reasons. For more information, see Considerations.

Enable directory browsing with:

- AddDirectoryBrowser in `Startup.ConfigureServices`.
- UseDirectoryBrowser in `Startup.Configure`.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();
    services.AddDirectoryBrowser();
}

public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();

    // using Microsoft.Extensions.FileProviders;
    // using System.IO;
    app.UseStaticFiles(new StaticFileOptions
    {
        FileProvider = new PhysicalFileProvider(
            Path.Combine(env.WebRootPath, "images")),
        RequestPath = "/MyImages"
    });

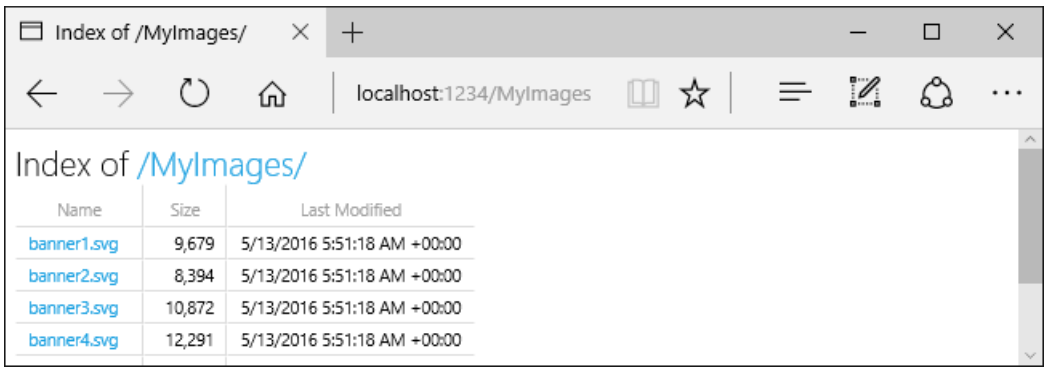
    app.UseDirectoryBrowser(new DirectoryBrowserOptions
    {
        FileProvider = new PhysicalFileProvider(
            Path.Combine(env.WebRootPath, "images")),
        RequestPath = "/MyImages"
    });

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}
```

The preceding code allows directory browsing of the *wwwroot/images* folder using the URL `https://<hostname>/MyImages`, with links to each file and folder:



Serve default documents

Setting a default page provides visitors a starting point on a site. To serve a default page from `wwwroot`

without a fully qualified URI, call the UseDefaultFiles method:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();

    app.UseDefaultFiles();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}
```

`UseDefaultFiles` must be called before `UseStaticFiles` to serve the default file. `UseDefaultFiles` is a URL rewriter that doesn't serve the file.

With `UseDefaultFiles`, requests to a folder in `wwwroot` search for:

- *default.htm*
- *default.html*
- *index.htm*
- *index.html*

The first file found from the list is served as though the request were the fully qualified URI. The browser URL continues to reflect the URI requested.

The following code changes the default file name to *mydefault.html*:

```
var options = new DefaultFilesOptions();
options.DefaultFileNames.Clear();
options.DefaultFileNames.Add("mydefault.html");
app.UseDefaultFiles(options);
app.UseStaticFiles();
```

The following code shows `Startup.Configure` with the preceding code:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();

    var options = new DefaultFilesOptions();
    options.DefaultFileNames.Clear();
    options.DefaultFileNames.Add("mydefault.html");
    app.UseDefaultFiles(options);
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}
```

UseFileServer for default documents

UseFileServer combines the functionality of `UseStaticFiles`, `UseDefaultFiles`, and optionally `UseDirectoryBrowser`.

Call `app.UseFileServer` to enable the serving of static files and the default file. Directory browsing isn't enabled. The following code shows `Startup.Configure` with `UseFileServer`:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();

    app.UseFileServer();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}
```

The following code enables the serving of static files, the default file, and directory browsing:

```
app.UseFileServer(enableDirectoryBrowsing: true);
```

The following code shows `Startup.Configure` with the preceding code:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();

    app.UseFileServer(enableDirectoryBrowsing: true);

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}
```

Consider the following directory hierarchy:

- `wwwroot`
  - `css`
  - `images`
  - `js`
- `MyStaticFiles`
  - `images`
    - `MyImage.jpg`
  - `default.html`

The following code enables the serving of static files, the default file, and directory browsing of `MyStaticFiles`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();
    services.AddDirectoryBrowser();
}

public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();

    app.UseStaticFiles(); // For the wwwroot folder.

    // using Microsoft.Extensions.FileProviders;
    // using System.IO;
    app.UseFileServer(new FileServerOptions
    {
        FileProvider = new PhysicalFileProvider(
            Path.Combine(env.ContentRootPath, "MyStaticFiles")),
        RequestPath = "/StaticFiles",
        EnableDirectoryBrowsing = true
    });

    app.UseRouting();

    app.UseAuthorization();

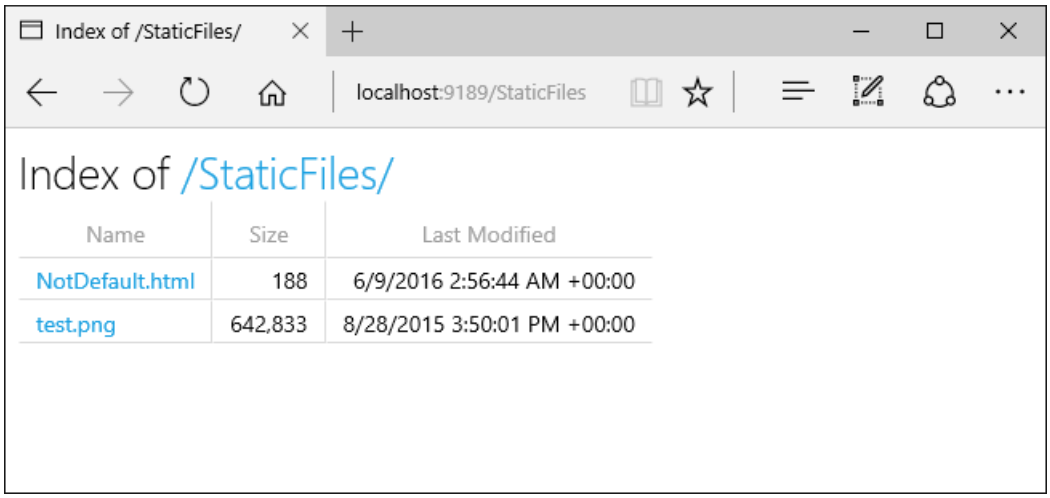
    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}
```

AddDirectoryBrowser must be called when the `EnableDirectoryBrowsing` property value is `true`.

Using the file hierarchy and preceding code, URLs resolve as follows:

URI	RESPONSE
`https://<hostname>/StaticFiles/images/MyImage.jpg`	*MyStaticFiles/images/MyImage.jpg*
`https://<hostname>/StaticFiles`	*MyStaticFiles/default.html*

If no default-named file exists in the *MyStaticFiles* directory, `https://<hostname>/StaticFiles` returns the directory listing with clickable links:



UseDefaultFiles and UseDirectoryBrowser perform a client-side redirect from the target URI without a trailing `/` to the target URI with a trailing `/`. For example, from `https://<hostname>/StaticFiles` to `https://<hostname>/StaticFiles/`. Relative URLs within the *StaticFiles* directory are invalid without a trailing slash (`/`).

FileExtensionContentTypeProvider

The FileExtensionContentTypeProvider class contains a `Mappings` property that serves as a mapping of file extensions to MIME content types. In the following sample, several file extensions are mapped to known MIME types. The *.rtf* extension is replaced, and *.mp4* is removed:

```
// using Microsoft.AspNetCore.StaticFiles;
// using Microsoft.Extensions.FileProviders;
// using System.IO;

// Set up custom content types - associating file extension to MIME type
var provider = new FileExtensionContentTypeProvider();
// Add new mappings
provider.Mappings[".myapp"] = "application/x-msdownload";
provider.Mappings[".htm3"] = "text/html";
provider.Mappings[".image"] = "image/png";
// Replace an existing mapping
provider.Mappings[".rtf"] = "application/x-msdownload";
// Remove MP4 videos.
provider.Mappings.Remove(".mp4");

app.UseStaticFiles(new StaticFileOptions
{
    FileProvider = new PhysicalFileProvider(
        Path.Combine(env.WebRootPath, "images")),
    RequestPath = "/MyImages",
    ContentTypeProvider = provider
});

app.UseDirectoryBrowser(new DirectoryBrowserOptions
{
    FileProvider = new PhysicalFileProvider(
        Path.Combine(env.WebRootPath, "images")),
    RequestPath = "/MyImages"
});
```

The following code shows `Startup.Configure` with the preceding code:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();

    // using Microsoft.AspNetCore.StaticFiles;
    // using Microsoft.Extensions.FileProviders;
    // using System.IO;

    // Set up custom content types - associating file extension to MIME type
    var provider = new FileExtensionContentTypeProvider();
    // Add new mappings
    provider.Mappings[".myapp"] = "application/x-msdownload";
    provider.Mappings[".htm3"] = "text/html";
    provider.Mappings[".image"] = "image/png";
    // Replace an existing mapping
    provider.Mappings[".rtf"] = "application/x-msdownload";
    // Remove MP4 videos.
    provider.Mappings.Remove(".mp4");

    app.UseStaticFiles(new StaticFileOptions
    {
        FileProvider = new PhysicalFileProvider(
            Path.Combine(env.WebRootPath, "images")),
        RequestPath = "/MyImages",
        ContentTypeProvider = provider
    });

    app.UseDirectoryBrowser(new DirectoryBrowserOptions
    {
        FileProvider = new PhysicalFileProvider(
            Path.Combine(env.WebRootPath, "images")),
        RequestPath = "/MyImages"
    });

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}
```

See MIME content types.

Non-standard content types

The Static File Middleware understands almost 400 known file content types. If the user requests a file with an unknown file type, the Static File Middleware passes the request to the next middleware in the pipeline. If no middleware handles the request, a *404 Not Found* response is returned. If directory browsing is enabled, a link to the file is displayed in a directory listing.

The following code enables serving unknown types and renders the unknown file as an image:

```
app.UseStaticFiles(new StaticFileOptions
{
    ServeUnknownFileTypes = true,
    DefaultContentType = "image/png"
});
```

The following code shows `Startup.Configure` with the preceding code:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();

    app.UseStaticFiles(new StaticFileOptions
    {
        ServeUnknownFileTypes = true,
        DefaultContentType = "image/png"
    });

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}
```

With the preceding code, a request for a file with an unknown content type is returned as an image.

> **WARNING**
>
> Enabling ServeUnknownFileTypes is a security risk. It's disabled by default, and its use is discouraged. FileExtensionContentTypeProvider provides a safer alternative to serving files with non-standard extensions.

Serve files from multiple locations

`UseStaticFiles` and `UseFileServer` default to the file provider pointing at `wwwroot`. Additional instances of `UseStaticFiles` and `UseFileServer` can be provided with other file providers to serve files from other locations. For more information, see this GitHub issue.

Security considerations for static files

> **WARNING**
>
> `UseDirectoryBrowser` and `UseStaticFiles` can leak secrets. Disabling directory browsing in production is highly recommended. Carefully review which directories are enabled via `UseStaticFiles` or `UseDirectoryBrowser`. The entire directory and its sub-directories become publicly accessible. Store files suitable for serving to the public in a dedicated directory, such as `<content_root>/wwwroot`. Separate these files from MVC views, Razor Pages, configuration files, etc.

- The URLs for content exposed with `UseDirectoryBrowser` and `UseStaticFiles` are subject to the case sensitivity and character restrictions of the underlying file system. For example, Windows is case insensitive, but macOS and Linux aren't.
- ASP.NET Core apps hosted in IIS use the ASP.NET Core Module to forward all requests to the app, including static file requests. The IIS static file handler isn't used and has no chance to handle requests.
- Complete the following steps in IIS Manager to remove the IIS static file handler at the server or website level:
  1. Navigate to the **Modules** feature.
  2. Select **StaticFileModule** in the list.
  3. Click **Remove** in the **Actions** sidebar.

> **WARNING**
>
> If the IIS static file handler is enabled **and** the ASP.NET Core Module is configured incorrectly, static files are served. This happens, for example, if the *web.config* file isn't deployed.

- Place code files, including *.cs* and *.cshtml*, outside of the app project's web root. A logical separation is therefore created between the app's client-side content and server-based code. This prevents server-side code from being leaked.

Additional resources

- Middleware
- Introduction to ASP.NET Core

By Rick Anderson and Scott Addie

Static files, such as HTML, CSS, images, and JavaScript, are assets an ASP.NET Core app serves directly to clients. Some configuration is required to enable serving of these files.

View or download sample code (how to download)

Serve static files

Static files are stored within the project's web root directory. The default directory is *{content root}/wwwroot*, but it can be changed via the UseWebRoot method. See Content root and Web root for more information.

The app's web host must be made aware of the content root directory.

The `WebHost.CreateDefaultBuilder` method sets the content root to the current directory:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

Static files are accessible via a path relative to the web root. For example, the **Web Application** project template contains several folders within the `wwwroot` folder:

- `wwwroot`
  - `css`
  - `images`
  - `js`

The URI format to access a file in the *images* subfolder is *http://<server_address>/images/<image_file_name>*. For example, *http://localhost:9189/images/banner3.svg*.

If targeting .NET Framework, add the Microsoft.AspNetCore.StaticFiles package to the project. If targeting .NET Core, the Microsoft.AspNetCore.App metapackage includes this package.

Configure the middleware, which enables the serving of static files.

Serve files inside of web root

Invoke the UseStaticFiles method within `Startup.Configure`:

```
public void Configure(IApplicationBuilder app)
{
    app.UseStaticFiles();
}
```

The parameterless `UseStaticFiles` method overload marks the files in web root as servable. The following markup references *wwwroot/images/banner1.svg*:

```
<img src="~/images/banner1.svg" alt="ASP.NET" class="img-responsive" />
```

In the preceding code, the tilde character `~/` points to the web root.

Serve files outside of web root

Consider a directory hierarchy in which the static files to be served reside outside of the web root:

- `wwwroot`
  - `css`
  - `images`
  - `js`
- `MyStaticFiles`
  - `images`
    - `banner1.svg`

A request can access the *banner1.svg* file by configuring the Static File Middleware as follows:

```
public void Configure(IApplicationBuilder app)
{
    app.UseStaticFiles(); // For the wwwroot folder

    app.UseStaticFiles(new StaticFileOptions
    {
        FileProvider = new PhysicalFileProvider(
            Path.Combine(Directory.GetCurrentDirectory(), "MyStaticFiles")),
        RequestPath = "/StaticFiles"
    });
}
```

In the preceding code, the *MyStaticFiles* directory hierarchy is exposed publicly via the *StaticFiles* URI segment. A request to *http://<server_address>/StaticFiles/images/banner1.svg* serves the *banner1.svg* file.

The following markup references *MyStaticFiles/images/banner1.svg*:

```
<img src="~/StaticFiles/images/banner1.svg" alt="ASP.NET" class="img-responsive" />
```

Set HTTP response headers

A StaticFileOptions object can be used to set HTTP response headers. In addition to configuring static file serving from the web root, the following code sets the `Cache-Control` header:

```
public void Configure(IApplicationBuilder app)
{
    var cachePeriod =  "604800";
    app.UseStaticFiles(new StaticFileOptions
    {
        OnPrepareResponse = ctx =>
        {
            // Requires the following import:
            // using Microsoft.AspNetCore.Http;
            ctx.Context.Response.Headers.Append("Cache-Control", $"public, max-age={cachePeriod}");
        }
    });
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

The HeaderDictionaryExtensions.Append method exists in the Microsoft.AspNetCore.Http package.

The files have been made publicly cacheable for 10 minutes (600 seconds) in the Development environment:

Static file authorization

The Static File Middleware doesn't provide authorization checks. Any files served by it, including those under *wwwroot*, are publicly accessible. To serve files based on authorization:

- Store them outside of *wwwroot* and any directory accessible to the Static File Middleware.
- Serve them via an action method to which authorization is applied. Return a FileResult object:

```
[Authorize]
public IActionResult BannerImage()
{
    var file = Path.Combine(Directory.GetCurrentDirectory(),
                            "MyStaticFiles", "images", "banner1.svg");

    return PhysicalFile(file, "image/svg+xml");
}
```

Enable directory browsing

Directory browsing allows users of your web app to see a directory listing and files within a specified directory. Directory browsing is disabled by default for security reasons (see Considerations). Enable directory browsing by invoking the UseDirectoryBrowser method in `Startup.Configure`:

```
public void Configure(IApplicationBuilder app)
{
    app.UseStaticFiles(); // For the wwwroot folder

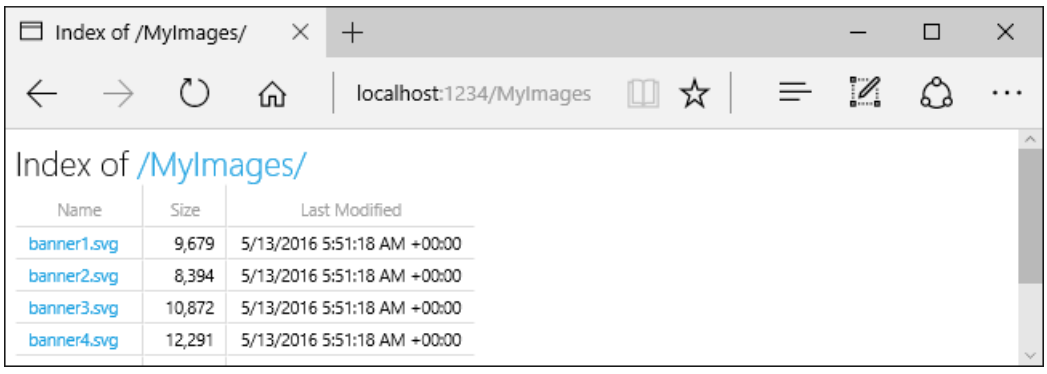
    app.UseStaticFiles(new StaticFileOptions
    {
        FileProvider = new PhysicalFileProvider(
            Path.Combine(Directory.GetCurrentDirectory(), "wwwroot", "images")),
        RequestPath = "/MyImages"
    });

    app.UseDirectoryBrowser(new DirectoryBrowserOptions
    {
        FileProvider = new PhysicalFileProvider(
            Path.Combine(Directory.GetCurrentDirectory(), "wwwroot", "images")),
        RequestPath = "/MyImages"
    });
}
```

Add required services by invoking the AddDirectoryBrowser method from `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDirectoryBrowser();
}
```

The preceding code allows directory browsing of the *wwwroot/images* folder using the URL *http://<server_address>/MyImages*, with links to each file and folder:



See Considerations on the security risks when enabling browsing.

Note the two `UseStaticFiles` calls in the following example. The first call enables the serving of static files in the *wwwroot* folder. The second call enables directory browsing of the *wwwroot/images* folder using the URL *http://<server_address>/MyImages*:

```
public void Configure(IApplicationBuilder app)
{
    app.UseStaticFiles(); // For the wwwroot folder

    app.UseStaticFiles(new StaticFileOptions
    {
        FileProvider = new PhysicalFileProvider(
            Path.Combine(Directory.GetCurrentDirectory(), "wwwroot", "images")),
        RequestPath = "/MyImages"
    });

    app.UseDirectoryBrowser(new DirectoryBrowserOptions
    {
        FileProvider = new PhysicalFileProvider(
            Path.Combine(Directory.GetCurrentDirectory(), "wwwroot", "images")),
        RequestPath = "/MyImages"
    });
}
```

Serve a default document

Setting a default home page provides visitors a logical starting point when visiting your site. To serve a default page without the user fully qualifying the URI, call the UseDefaultFiles method from `Startup.Configure`:

```
public void Configure(IApplicationBuilder app)
{
    app.UseDefaultFiles();
    app.UseStaticFiles();
}
```

IMPORTANT

`UseDefaultFiles` must be called before `UseStaticFiles` to serve the default file. `UseDefaultFiles` is a URL rewriter that doesn't actually serve the file. Enable Static File Middleware via `UseStaticFiles` to serve the file.

With `UseDefaultFiles`, requests to a folder search for:

- *default.htm*
- *default.html*
- *index.htm*
- *index.html*

The first file found from the list is served as though the request were the fully qualified URI. The browser URL continues to reflect the URI requested.

The following code changes the default file name to *mydefault.html*:

```
public void Configure(IApplicationBuilder app)
{
    // Serve my app-specific default file, if present.
    DefaultFilesOptions options = new DefaultFilesOptions();
    options.DefaultFileNames.Clear();
    options.DefaultFileNames.Add("mydefault.html");
    app.UseDefaultFiles(options);
    app.UseStaticFiles();
}
```

UseFileServer

UseFileServer combines the functionality of `UseStaticFiles`, `UseDefaultFiles`, and optionally `UseDirectoryBrowser`.

The following code enables the serving of static files and the default file. Directory browsing isn't enabled.

```
app.UseFileServer();
```

The following code builds upon the parameterless overload by enabling directory browsing:

```
app.UseFileServer(enableDirectoryBrowsing: true);
```

Consider the following directory hierarchy:

- **wwwroot**
  - **css**
  - **images**
  - **js**
- **MyStaticFiles**
  - **images**
    - *banner1.svg*
  - *default.html*

The following code enables static files, default files, and directory browsing of `MyStaticFiles`:

```
public void Configure(IApplicationBuilder app)
{
    app.UseStaticFiles(); // For the wwwroot folder

    app.UseFileServer(new FileServerOptions
    {
        FileProvider = new PhysicalFileProvider(
            Path.Combine(Directory.GetCurrentDirectory(), "MyStaticFiles")),
        RequestPath = "/StaticFiles",
        EnableDirectoryBrowsing = true
    });
}
```

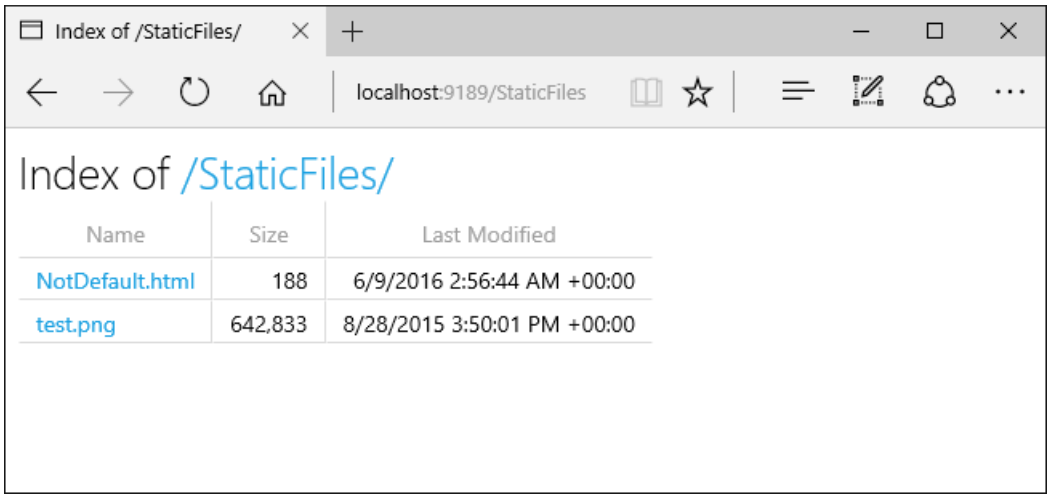
`AddDirectoryBrowser` must be called when the `EnableDirectoryBrowsing` property value is `true`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDirectoryBrowser();
}
```

Using the file hierarchy and preceding code, URLs resolve as follows:

URI	RESPONSE
http://<server_address>/StaticFiles/images/banner1.svg	MyStaticFiles/images/banner1.svg
http://<server_address>/StaticFiles	MyStaticFiles/default.html

If no default-named file exists in the *MyStaticFiles* directory, *http://<server_address>/StaticFiles* returns the directory listing with clickable links:



> **NOTE**
>
> UseDefaultFiles and UseDirectoryBrowser perform a client-side redirect from `http://{SERVER ADDRESS}/StaticFiles` (without a trailing slash) to `http://{SERVER ADDRESS}/StaticFiles/` (with a trailing slash). Relative URLs within the *StaticFiles* directory are invalid without a trailing slash.

FileExtensionContentTypeProvider

The FileExtensionContentTypeProvider class contains a `Mappings` property serving as a mapping of file extensions to MIME content types. In the following sample, several file extensions are registered to known MIME types. The *.rtf* extension is replaced, and *.mp4* is removed.

```
public void Configure(IApplicationBuilder app)
{
    // Set up custom content types - associating file extension to MIME type
    var provider = new FileExtensionContentTypeProvider();
    // Add new mappings
    provider.Mappings[".myapp"] = "application/x-msdownload";
    provider.Mappings[".htm3"] = "text/html";
    provider.Mappings[".image"] = "image/png";
    // Replace an existing mapping
    provider.Mappings[".rtf"] = "application/x-msdownload";
    // Remove MP4 videos.
    provider.Mappings.Remove(".mp4");

    app.UseStaticFiles(new StaticFileOptions
    {
        FileProvider = new PhysicalFileProvider(
            Path.Combine(Directory.GetCurrentDirectory(), "wwwroot", "images")),
        RequestPath = "/MyImages",
        ContentTypeProvider = provider
    });

    app.UseDirectoryBrowser(new DirectoryBrowserOptions
    {
        FileProvider = new PhysicalFileProvider(
            Path.Combine(Directory.GetCurrentDirectory(), "wwwroot", "images")),
        RequestPath = "/MyImages"
    });
}
```

See MIME content types.

For information on using a custom FileExtensionContentTypeProvider or to configure other StaticFileOptions in Blazor Server apps, see ASP.NET Core Blazor hosting model configuration.

Non-standard content types

Static File Middleware understands almost 400 known file content types. If the user requests a file with an unknown file type, Static File Middleware passes the request to the next middleware in the pipeline. If no middleware handles the request, a *404 Not Found* response is returned. If directory browsing is enabled, a link to the file is displayed in a directory listing.

The following code enables serving unknown types and renders the unknown file as an image:

```
public void Configure(IApplicationBuilder app)
{
    app.UseStaticFiles(new StaticFileOptions
    {
        ServeUnknownFileTypes = true,
        DefaultContentType = "image/png"
    });
}
```

With the preceding code, a request for a file with an unknown content type is returned as an image.

WARNING

Enabling ServeUnknownFileTypes is a security risk. It's disabled by default, and its use is discouraged. FileExtensionContentTypeProvider provides a safer alternative to serving files with non-standard extensions.

Serve files from multiple locations

`UseStaticFiles` and `UseFileServer` defaults to the file provider pointing at *wwwroot*. You can provide additional instances of `UseStaticFiles` and `UseFileServer` with other file providers to serve files from other locations. For more information, see this GitHub issue.

Considerations

> **WARNING**
>
> `UseDirectoryBrowser` and `UseStaticFiles` can leak secrets. Disabling directory browsing in production is highly recommended. Carefully review which directories are enabled via `UseStaticFiles` or `UseDirectoryBrowser`. The entire directory and its sub-directories become publicly accessible. Store files suitable for serving to the public in a dedicated directory, such as *<content_root>/wwwroot*. Separate these files from MVC views, Razor Pages (2.x only), configuration files, etc.

- The URLs for content exposed with `UseDirectoryBrowser` and `UseStaticFiles` are subject to the case sensitivity and character restrictions of the underlying file system. For example, Windows is case insensitive—macOS and Linux aren't.
- ASP.NET Core apps hosted in IIS use the ASP.NET Core Module to forward all requests to the app, including static file requests. The IIS static file handler isn't used. It has no chance to handle requests before they're handled by the module.
- Complete the following steps in IIS Manager to remove the IIS static file handler at the server or website level:
  1. Navigate to the **Modules** feature.
  2. Select **StaticFileModule** in the list.
  3. Click **Remove** in the **Actions** sidebar.

> **WARNING**
>
> If the IIS static file handler is enabled **and** the ASP.NET Core Module is configured incorrectly, static files are served. This happens, for example, if the *web.config* file isn't deployed.

- Place code files (including *.cs* and *.cshtml*) outside of the app project's web root. A logical separation is therefore created between the app's client-side content and server-based code. This prevents server-side code from being leaked.

Introduction to Razor Pages in ASP.NET Core

9/22/2020 • 43 minutes to read • Edit Online

By Rick Anderson and Ryan Nowak

Razor Pages can make coding page-focused scenarios easier and more productive than using controllers and views.

If you're looking for a tutorial that uses the Model-View-Controller approach, see Get started with ASP.NET Core MVC.

This document provides an introduction to Razor Pages. It's not a step by step tutorial. If you find some of the sections too advanced, see Get started with Razor Pages. For an overview of ASP.NET Core, see the Introduction to ASP.NET Core.

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core 3.0 SDK or later

Create a Razor Pages project

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

See Get started with Razor Pages for detailed instructions on how to create a Razor Pages project.

Razor Pages

Razor Pages is enabled in *Startup.cs*:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapRazorPages();
        });
    }
}
```

Consider a basic page:

```
@page

<h1>Hello, world!</h1>
<h2>The time on the server is @DateTime.Now</h2>
```

The preceding code looks a lot like a Razor view file used in an ASP.NET Core app with controllers and views. What makes it different is the `@page` directive. `@page` makes the file into an MVC action - which means that it handles requests directly, without going through a controller. `@page` must be the first Razor directive on a page. `@page` affects the behavior of other Razor constructs. Razor Pages file names have a *.cshtml* suffix.

A similar page, using a `PageModel` class, is shown in the following two files. The *Pages/Index2.cshtml* file:

```
@page
@using RazorPagesIntro.Pages
@model Index2Model

<h2>Separate page model</h2>
<p>
    @Model.Message
</p>
```

The *Pages/Index2.cshtml.cs* page model:

```
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.Extensions.Logging;
using System;

namespace RazorPagesIntro.Pages
{
    public class Index2Model : PageModel
    {
        public string Message { get; private set; } = "PageModel in C#";

        public void OnGet()
        {
            Message += $" Server time is { DateTime.Now }";
        }
    }
}
```

By convention, the `PageModel` class file has the same name as the Razor Page file with *.cs* appended. For example, the previous Razor Page is *Pages/Index2.cshtml*. The file containing the `PageModel` class is named *Pages/Index2.cshtml.cs*.

The associations of URL paths to pages are determined by the page's location in the file system. The following table shows a Razor Page path and the matching URL:

FILE NAME AND PATH	MATCHING URL
/Pages/Index.cshtml	`/` or `/Index`
/Pages/Contact.cshtml	`/Contact`
/Pages/Store/Contact.cshtml	`/Store/Contact`
/Pages/Store/Index.cshtml	`/Store` or `/Store/Index`

Notes:

- The runtime looks for Razor Pages files in the *Pages* folder by default.
- `Index` is the default page when a URL doesn't include a page.

Write a basic form

Razor Pages is designed to make common patterns used with web browsers easy to implement when building an app. Model binding, Tag Helpers, and HTML helpers all *just work* with the properties defined in a Razor Page class. Consider a page that implements a basic "contact us" form for the `Contact` model:

For the samples in this document, the `DbContext` is initialized in the Startup.cs file.

The in memory database requires the `Microsoft.EntityFrameworkCore.InMemory` NuGet package.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<CustomerDbContext>(options =>
                    options.UseInMemoryDatabase("name"));
    services.AddRazorPages();
}
```

The data model:

```
using System.ComponentModel.DataAnnotations;

namespace RazorPagesContacts.Models
{
    public class Customer
    {
        public int Id { get; set; }

        [Required, StringLength(10)]
        public string Name { get; set; }
    }
}
```

The db context:

```
using Microsoft.EntityFrameworkCore;
using RazorPagesContacts.Models;

namespace RazorPagesContacts.Data
{
    public class CustomerDbContext : DbContext
    {
        public CustomerDbContext(DbContextOptions options)
            : base(options)
        {
        }

        public DbSet<Customer> Customers { get; set; }
    }
}
```

The *Pages/Create.cshtml* view file:

```
@page
@model RazorPagesContacts.Pages.Customers.CreateModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<p>Enter a customer name:</p>

<form method="post">
    Name:
    <input asp-for="Customer.Name" />
    <input type="submit" />
</form>
```

The *Pages/Create.cshtml.cs* page model:

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using RazorPagesContacts.Data;
using RazorPagesContacts.Models;
using System.Threading.Tasks;

namespace RazorPagesContacts.Pages.Customers
{
    public class CreateModel : PageModel
    {
        private readonly CustomerDbContext _context;

        public CreateModel(CustomerDbContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            return Page();
        }

        [BindProperty]
        public Customer Customer { get; set; }

        public async Task<IActionResult> OnPostAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            _context.Customers.Add(Customer);
            await _context.SaveChangesAsync();

            return RedirectToPage("./Index");
        }
    }
}
```

By convention, the `PageModel` class is called `<PageName>Model` and is in the same namespace as the page.

The `PageModel` class allows separation of the logic of a page from its presentation. It defines page handlers for requests sent to the page and the data used to render the page. This separation allows:

- Managing of page dependencies through dependency injection.
- Unit testing

The page has an `OnPostAsync` *handler method*, which runs on `POST` requests (when a user posts the form). Handler methods for any HTTP verb can be added. The most common handlers are:

- `OnGet` to initialize state needed for the page. In the preceding code, the `OnGet` method displays the *CreateModel.cshtml* Razor Page.
- `OnPost` to handle form submissions.

The `Async` naming suffix is optional but is often used by convention for asynchronous functions. The preceding code is typical for Razor Pages.

If you're familiar with ASP.NET apps using controllers and views:

- The `OnPostAsync` code in the preceding example looks similar to typical controller code.
- Most of the MVC primitives like model binding, validation, and action results work the same with

Controllers and Razor Pages.

The previous `OnPostAsync` method:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Customers.Add(Customer);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

The basic flow of `OnPostAsync`:

Check for validation errors.

- If there are no errors, save the data and redirect.
- If there are errors, show the page again with validation messages. In many cases, validation errors would be detected on the client, and never submitted to the server.

The *Pages/Create.cshtml* view file:

```
@page
@model RazorPagesContacts.Pages.Customers.CreateModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<p>Enter a customer name:</p>

<form method="post">
    Name:
    <input asp-for="Customer.Name" />
    <input type="submit" />
</form>
```

The rendered HTML from *Pages/Create.cshtml*:

```
<p>Enter a customer name:</p>

<form method="post">
    Name:
    <input type="text" data-val="true"
           data-val-length="The field Name must be a string with a maximum length of 10."
           data-val-length-max="10" data-val-required="The Name field is required."
           id="Customer_Name" maxlength="10" name="Customer.Name" value="" />
    <input type="submit" />
    <input name="__RequestVerificationToken" type="hidden"
           value="<Antiforgery token here>" />
</form>
```

In the previous code, posting the form:

- With valid data:
  - The `OnPostAsync` handler method calls the RedirectToPage helper method. `RedirectToPage` returns an instance of RedirectToPageResult. `RedirectToPage`:

    - Is an action result.
    - Is similar to `RedirectToAction` or `RedirectToRoute` (used in controllers and views).
    - Is customized for pages. In the preceding sample, it redirects to the root Index page (`/Index`). `RedirectToPage` is detailed in the URL generation for Pages section.
- With validation errors that are passed to the server:
    - The `OnPostAsync` handler method calls the Page helper method. `Page` returns an instance of PageResult. Returning `Page` is similar to how actions in controllers return `View` . `PageResult` is the default return type for a handler method. A handler method that returns `void` renders the page.
    - In the preceding example, posting the form with no value results in ModelState.IsValid returning false. In this sample, no validation errors are displayed on the client. Validation error handing is covered later in this document.

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Customers.Add(Customer);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

- With validation errors detected by client side validation:
    - Data is **not** posted to the server.
    - Client-side validation is explained later in this document.

The `Customer` property uses `[BindProperty]` attribute to opt in to model binding:

```
public class CreateModel : PageModel
{
    private readonly CustomerDbContext _context;

    public CreateModel(CustomerDbContext context)
    {
        _context = context;
    }

    public IActionResult OnGet()
    {
        return Page();
    }

    [BindProperty]
    public Customer Customer { get; set; }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _context.Customers.Add(Customer);
        await _context.SaveChangesAsync();

        return RedirectToPage("./Index");
    }
}
```

`[BindProperty]` should **not** be used on models containing properties that should not be changed by the client. For more information, see Overposting.

Razor Pages, by default, bind properties only with non-`GET` verbs. Binding to properties removes the need to writing code to convert HTTP data to the model type. Binding reduces code by using the same property to render form fields (`<input asp-for="Customer.Name">`) and accept the input.

WARNING

For security reasons, you must opt in to binding `GET` request data to page model properties. Verify user input before mapping it to properties. Opting into `GET` binding is useful when addressing scenarios that rely on query string or route values.

To bind a property on `GET` requests, set the `[BindProperty]` attribute's `SupportsGet` property to `true` :

```
[BindProperty(SupportsGet = true)]
```

For more information, see ASP.NET Core Community Standup: Bind on GET discussion (YouTube).

Reviewing the *Pages/Create.cshtml* view file:

```
@page
@model RazorPagesContacts.Pages.Customers.CreateModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<p>Enter a customer name:</p>

<form method="post">
    Name:
    <input asp-for="Customer.Name" />
    <input type="submit" />
</form>
```

- In the preceding code, the input tag helper `<input asp-for="Customer.Name" />` binds the HTML `<input>` element to the `Customer.Name` model expression.
- `@addTagHelper` makes Tag Helpers available.

The home page

Index.cshtml is the home page:

```
@page
@model RazorPagesContacts.Pages.Customers.IndexModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<h1>Contacts home page</h1>
<form method="post">
    <table class="table">
        <thead>
            <tr>
                <th>ID</th>
                <th>Name</th>
            </tr>
        </thead>
        <tbody>
            @foreach (var contact in Model.Customer)
            {
                <tr>
                    <td> @contact.Id  </td>
                    <td>@contact.Name</td>
                    <td>
                        <a asp-page="./Edit" asp-route-id="@contact.Id">Edit</a> |
                        <button type="submit" asp-page-handler="delete"
                                asp-route-id="@contact.Id">delete
                        </button>
                    </td>
                </tr>
            }
        </tbody>
    </table>
    <a asp-page="Create">Create New</a>
</form>
```

The associated `PageModel` class (*Index.cshtml.cs*):

```
public class IndexModel : PageModel
{
    private readonly CustomerDbContext _context;

    public IndexModel(CustomerDbContext context)
    {
        _context = context;
    }

    public IList<Customer> Customer { get; set; }

    public async Task OnGetAsync()
    {
        Customer = await _context.Customers.ToListAsync();
    }

    public async Task<IActionResult> OnPostDeleteAsync(int id)
    {
        var contact = await _context.Customers.FindAsync(id);

        if (contact != null)
        {
            _context.Customers.Remove(contact);
            await _context.SaveChangesAsync();
        }

        return RedirectToPage();
    }
}
```

The *Index.cshtml* file contains the following markup:

```
<a asp-page="./Edit" asp-route-id="@contact.Id">Edit</a> |
```

The `<a /a>` Anchor Tag Helper used the `asp-route-{value}` attribute to generate a link to the Edit page. The link contains route data with the contact ID. For example, `https://localhost:5001/Edit/1`. Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files.

The *Index.cshtml* file contains markup to create a delete button for each customer contact:

```
<button type="submit" asp-page-handler="delete"
        asp-route-id="@contact.Id">delete
```

The rendered HTML:

```
<button type="submit" formaction="/Customers?id=1&amp;handler=delete">delete</button>
```

When the delete button is rendered in HTML, its formaction includes parameters for:

- The customer contact ID, specified by the `asp-route-id` attribute.
- The `handler`, specified by the `asp-page-handler` attribute.

When the button is selected, a form `POST` request is sent to the server. By convention, the name of the handler method is selected based on the value of the `handler` parameter according to the scheme `OnPost[handler]Async`.

Because the `handler` is `delete` in this example, the `OnPostDeleteAsync` handler method is used to process the `POST` request. If the `asp-page-handler` is set to a different value, such as `remove`, a handler

method with the name `OnPostRemoveAsync` is selected.

```
public async Task<IActionResult> OnPostDeleteAsync(int id)
{
    var contact = await _context.Customers.FindAsync(id);

    if (contact != null)
    {
        _context.Customers.Remove(contact);
        await _context.SaveChangesAsync();
    }

    return RedirectToPage();
}
```

The `OnPostDeleteAsync` method:

- Gets the `id` from the query string.
- Queries the database for the customer contact with `FindAsync`.
- If the customer contact is found, it's removed and the database is updated.
- Calls RedirectToPage to redirect to the root Index page (`/Index`).

The Edit.cshtml file

```
@page "{id:int}"
@model RazorPagesContacts.Pages.Customers.EditModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<h1>Edit Customer - @Model.Customer.Id</h1>
<form method="post">
    <div asp-validation-summary="All"></div>
    <input asp-for="Customer.Id" type="hidden" />
    <div>
        <label asp-for="Customer.Name"></label>
        <div>
            <input asp-for="Customer.Name" />
            <span asp-validation-for="Customer.Name"></span>
        </div>
    </div>

    <div>
        <button type="submit">Save</button>
    </div>
</form>
```

The first line contains the `@page "{id:int}"` directive. The routing constraint `"{id:int}"` tells the page to accept requests to the page that contain `int` route data. If a request to the page doesn't contain route data that can be converted to an `int`, the runtime returns an HTTP 404 (not found) error. To make the ID optional, append `?` to the route constraint:

```
@page "{id:int?}"
```

The *Edit.cshtml.cs* file:

```
public class EditModel : PageModel
{
    private readonly CustomerDbContext _context;

    public EditModel(CustomerDbContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Customer Customer { get; set; }

    public async Task<IActionResult> OnGetAsync(int id)
    {
        Customer = await _context.Customers.FindAsync(id);

        if (Customer == null)
        {
            return RedirectToPage("./Index");
        }

        return Page();
    }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _context.Attach(Customer).State = EntityState.Modified;

        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            throw new Exception($"Customer {Customer.Id} not found!");
        }

        return RedirectToPage("./Index");
    }

}
```

Validation

Validation rules:

- Are declaratively specified in the model class.
- Are enforced everywhere in the app.

The System.ComponentModel.DataAnnotations namespace provides a set of built-in validation attributes that are applied declaratively to a class or property. DataAnnotations also contains formatting attributes like `[DataType]` that help with formatting and don't provide any validation.

Consider the `Customer` model:

```
using System.ComponentModel.DataAnnotations;

namespace RazorPagesContacts.Models
{
    public class Customer
    {
        public int Id { get; set; }

        [Required, StringLength(10)]
        public string Name { get; set; }
    }
}
```

Using the following *Create.cshtml* view file:

```
@page
@model RazorPagesContacts.Pages.Customers.CreateModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<p>Validation: customer name:</p>

<form method="post">
    <div asp-validation-summary="ModelOnly"></div>
    <span asp-validation-for="Customer.Name"></span>
    Name:
    <input asp-for="Customer.Name" />
    <input type="submit" />
</form>

<script src="~/lib/jquery/dist/jquery.js"></script>
<script src="~/lib/jquery-validation/dist/jquery.validate.js"></script>
<script src="~/lib/jquery-validation-unobtrusive/jquery.validate.unobtrusive.js"></script>
```

The preceding code:

- Includes jQuery and jQuery validation scripts.
- Uses the `<div />` and `<span />` Tag Helpers to enable:
  - Client-side validation.
  - Validation error rendering.
- Generates the following HTML:

```
<p>Enter a customer name:</p>

<form method="post">
    Name:
    <input type="text" data-val="true"
           data-val-length="The field Name must be a string with a maximum length of 10."
           data-val-length-max="10" data-val-required="The Name field is required."
           id="Customer_Name" maxlength="10" name="Customer.Name" value="" />
    <input type="submit" />
    <input name="__RequestVerificationToken" type="hidden"
           value="<Antiforgery token here>" />
</form>

<script src="/lib/jquery/dist/jquery.js"></script>
<script src="/lib/jquery-validation/dist/jquery.validate.js"></script>
<script src="/lib/jquery-validation-unobtrusive/jquery.validate.unobtrusive.js"></script>
```

Posting the Create form without a name value displays the error message "The Name field is required." on

the form. If JavaScript is enabled on the client, the browser displays the error without posting to the server.

The `[StringLength(10)]` attribute generates `data-val-length-max="10"` on the rendered HTML. `data-val-length-max` prevents browsers from entering more than the maximum length specified. If a tool such as Fiddler is used to edit and replay the post:

- With the name longer than 10.
- The error message "The field Name must be a string with a maximum length of 10." is returned.

Consider the following `Movie` model:

```
public class Movie
{
    public int ID { get; set; }

    [StringLength(60, MinimumLength = 3)]
    [Required]
    public string Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [Range(1, 100)]
    [DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
    [Required]
    [StringLength(30)]
    public string Genre { get; set; }

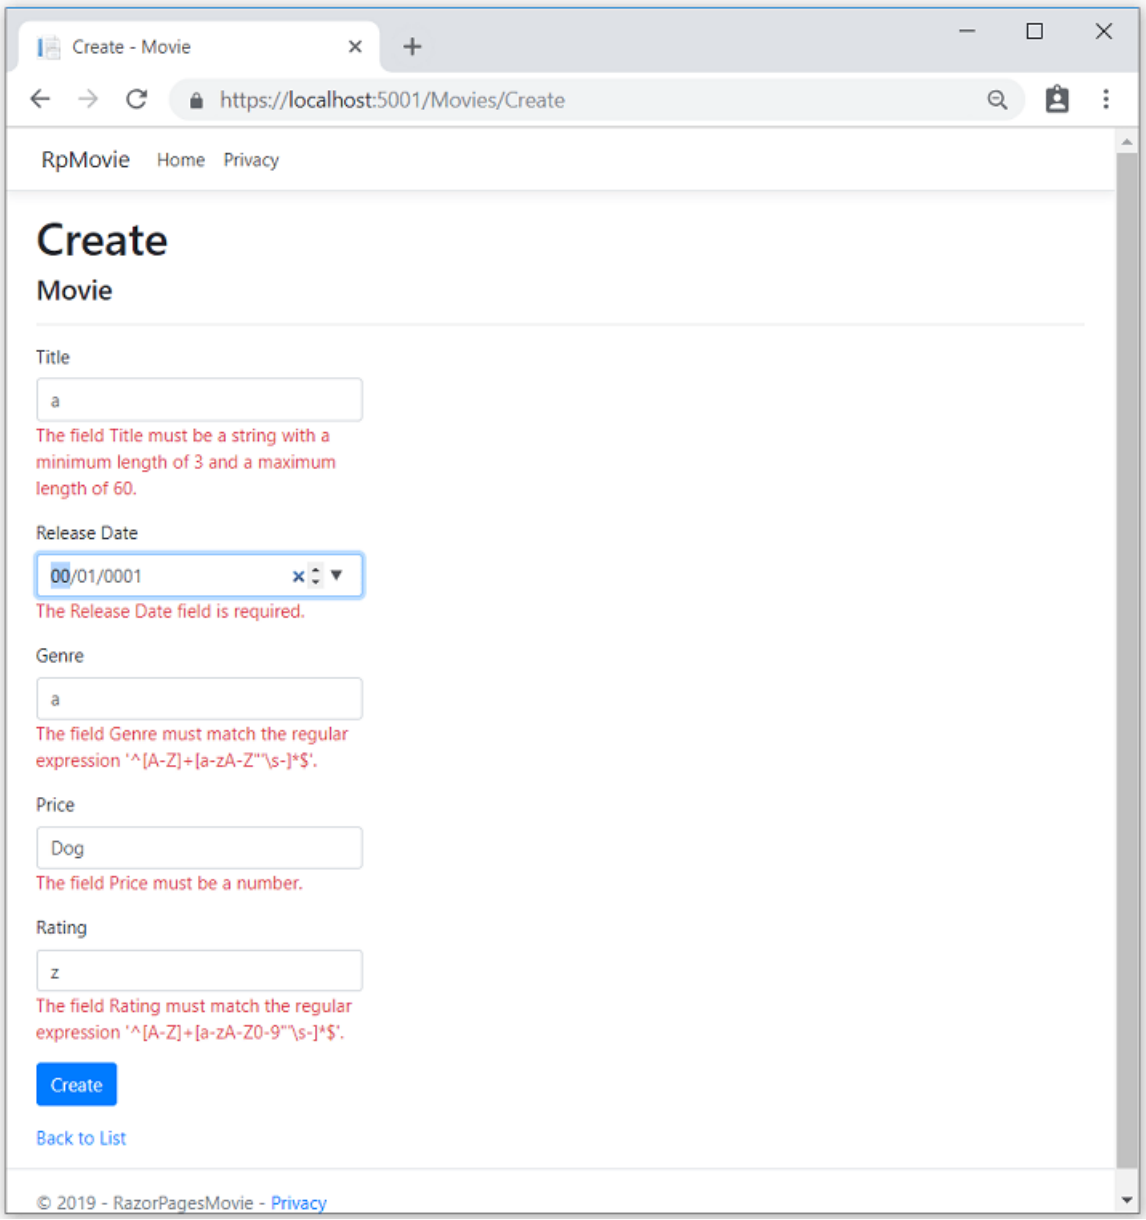
    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$")]
    [StringLength(5)]
    [Required]
    public string Rating { get; set; }
}
```

The validation attributes specify behavior to enforce on the model properties they're applied to:

- The `Required` and `MinimumLength` attributes indicate that a property must have a value, but nothing prevents a user from entering white space to satisfy this validation.
- The `RegularExpression` attribute is used to limit what characters can be input. In the preceding code, "Genre":
  - Must only use letters.
  - The first letter is required to be uppercase. White space, numbers, and special characters are not allowed.
- The `RegularExpression` "Rating":
  - Requires that the first character be an uppercase letter.
  - Allows special characters and numbers in subsequent spaces. "PG-13" is valid for a rating, but fails for a "Genre".
- The `Range` attribute constrains a value to within a specified range.
- The `StringLength` attribute sets the maximum length of a string property, and optionally its minimum length.

- Value types (such as `decimal`, `int`, `float`, `DateTime`) are inherently required and don't need the `[Required]` attribute.

The Create page for the `Movie` model shows displays errors with invalid values:



For more information, see:

- Add validation to the Movie app
- Model validation in ASP.NET Core.

Handle HEAD requests with an OnGet handler fallback

`HEAD` requests allow retrieving the headers for a specific resource. Unlike `GET` requests, `HEAD` requests don't return a response body.

Ordinarily, an `OnHead` handler is created and called for `HEAD` requests:

```
public void OnHead()
{
    HttpContext.Response.Headers.Add("Head Test", "Handled by OnHead!");
}
```

Razor Pages falls back to calling the `OnGet` handler if no `OnHead` handler is defined.

XSRF/CSRF and Razor Pages

Razor Pages are protected by Antiforgery validation. The FormTagHelper injects antiforgery tokens into HTML form elements.

Using Layouts, partials, templates, and Tag Helpers with Razor Pages

Pages work with all the capabilities of the Razor view engine. Layouts, partials, templates, Tag Helpers, *_ViewStart.cshtml*, and *_ViewImports.cshtml* work in the same way they do for conventional Razor views.

Let's declutter this page by taking advantage of some of those capabilities.

Add a layout page to *Pages/Shared/_Layout.cshtml*:

```
<!DOCTYPE html>
<html>
<head>
    <title>RP Sample</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
</head>
<body>
    <a asp-page="/Index">Home</a>
    <a asp-page="/Customers/Create">Create</a>
    <a asp-page="/Customers/Index">Customers</a> <br />

    @RenderBody()
    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/jquery-validation/dist/jquery.validate.js"></script>
    <script src="~/lib/jquery-validation-unobtrusive/jquery.validate.unobtrusive.js"></script>
</body>
</html>
```

The Layout:

- Controls the layout of each page (unless the page opts out of layout).
- Imports HTML structures such as JavaScript and stylesheets.
- The contents of the Razor page are rendered where `@RenderBody()` is called.

For more information, see layout page.

The Layout property is set in *Pages/_ViewStart.cshtml*:

```
@{
    Layout = "_Layout";
}
```

The layout is in the *Pages/Shared* folder. Pages look for other views (layouts, templates, partials) hierarchically, starting in the same folder as the current page. A layout in the *Pages/Shared* folder can be used from any Razor page under the *Pages* folder.

The layout file should go in the *Pages/Shared* folder.

We recommend you **not** put the layout file in the *Views/Shared* folder. *Views/Shared* is an MVC views pattern. Razor Pages are meant to rely on folder hierarchy, not path conventions.

View search from a Razor Page includes the *Pages* folder. The layouts, templates, and partials used with

MVC controllers and conventional Razor views *just work*.

Add a *Pages/_ViewImports.cshtml* file:

```
@namespace RazorPagesContacts.Pages
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
```

`@namespace` is explained later in the tutorial. The `@addTagHelper` directive brings in the built-in Tag Helpers to all the pages in the *Pages* folder.

The `@namespace` directive set on a page:

```
@page
@namespace RazorPagesIntro.Pages.Customers

@model NameSpaceModel

<h2>Name space</h2>
<p>
    @Model.Message
</p>
```

The `@namespace` directive sets the namespace for the page. The `@model` directive doesn't need to include the namespace.

When the `@namespace` directive is contained in *_ViewImports.cshtml*, the specified namespace supplies the prefix for the generated namespace in the Page that imports the `@namespace` directive. The rest of the generated namespace (the suffix portion) is the dot-separated relative path between the folder containing *_ViewImports.cshtml* and the folder containing the page.

For example, the `PageModel` class *Pages/Customers/Edit.cshtml.cs* explicitly sets the namespace:

```
namespace RazorPagesContacts.Pages
{
    public class EditModel : PageModel
    {
        private readonly AppDbContext _db;

        public EditModel(AppDbContext db)
        {
            _db = db;
        }

        // Code removed for brevity.
```

The *Pages/_ViewImports.cshtml* file sets the following namespace:

```
@namespace RazorPagesContacts.Pages
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
```

The generated namespace for the *Pages/Customers/Edit.cshtml* Razor Page is the same as the `PageModel` class.

`@namespace` *also works with conventional Razor views.*

Consider the *Pages/Create.cshtml* view file:

```
@page
@model RazorPagesContacts.Pages.Customers.CreateModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<p>Validation: customer name:</p>

<form method="post">
    <div asp-validation-summary="ModelOnly"></div>
    <span asp-validation-for="Customer.Name"></span>
    Name:
    <input asp-for="Customer.Name" />
    <input type="submit" />
</form>

<script src="~/lib/jquery/dist/jquery.js"></script>
<script src="~/lib/jquery-validation/dist/jquery.validate.js"></script>
<script src="~/lib/jquery-validation-unobtrusive/jquery.validate.unobtrusive.js"></script>
```

The updated *Pages/Create.cshtml* view file with *_ViewImports.cshtml* and the preceding layout file:

```
@page
@model CreateModel

<p>Enter a customer name:</p>

<form method="post">
    Name:
    <input asp-for="Customer.Name" />
    <input type="submit" />
</form>
```

In the preceding code, the *_ViewImports.cshtml* imported the namespace and Tag Helpers. The layout file imported the JavaScript files.

The Razor Pages starter project contains the *Pages/_ValidationScriptsPartial.cshtml*, which hooks up client-side validation.

For more information on partial views, see Partial views in ASP.NET Core.

URL generation for Pages

The `Create` page, shown previously, uses `RedirectToPage`:

```
public class CreateModel : PageModel
{
    private readonly CustomerDbContext _context;

    public CreateModel(CustomerDbContext context)
    {
        _context = context;
    }

    public IActionResult OnGet()
    {
        return Page();
    }

    [BindProperty]
    public Customer Customer { get; set; }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _context.Customers.Add(Customer);
        await _context.SaveChangesAsync();

        return RedirectToPage("./Index");
    }
}
```

The app has the following file/folder structure:

- */Pages*
  - *Index.cshtml*
  - *Privacy.cshtml*
  - */Customers*
    - *Create.cshtml*
    - *Edit.cshtml*
    - *Index.cshtml*

The *Pages/Customers/Create.cshtml* and *Pages/Customers/Edit.cshtml* pages redirect to *Pages/Customers/Index.cshtml* after success. The string `./Index` is a relative page name used to access the preceding page. It is used to generate URLs to the *Pages/Customers/Index.cshtml* page. For example:

- `Url.Page("./Index", ...)`
- `<a asp-page="./Index">Customers Index Page</a>`
- `RedirectToPage("./Index")`

The absolute page name `/Index` is used to generate URLs to the *Pages/Index.cshtml* page. For example:

- `Url.Page("/Index", ...)`
- `<a asp-page="/Index">Home Index Page</a>`
- `RedirectToPage("/Index")`

The page name is the path to the page from the root */Pages* folder including a leading `/` (for example, `/Index`). The preceding URL generation samples offer enhanced options and functional capabilities over

hard-coding a URL. URL generation uses routing and can generate and encode parameters according to how the route is defined in the destination path.

URL generation for pages supports relative names. The following table shows which Index page is selected using different `RedirectToPage` parameters in *Pages/Customers/Create.cshtml*.

REDIRECTTOPAGE(X)	PAGE
RedirectToPage("/Index")	*Pages/Index*
RedirectToPage("./Index");	*Pages/Customers/Index*
RedirectToPage("../Index")	*Pages/Index*
RedirectToPage("Index")	*Pages/Customers/Index*

`RedirectToPage("Index")`, `RedirectToPage("./Index")`, and `RedirectToPage("../Index")` are *relative names*. The `RedirectToPage` parameter is *combined* with the path of the current page to compute the name of the destination page.

Relative name linking is useful when building sites with a complex structure. When relative names are used to link between pages in a folder:

- Renaming a folder doesn't break the relative links.
- Links are not broken because they don't include the folder name.

To redirect to a page in a different Area, specify the area:

```
RedirectToPage("/Index", new { area = "Services" });
```

For more information, see Areas in ASP.NET Core and Razor Pages route and app conventions in ASP.NET Core.

ViewData attribute

Data can be passed to a page with ViewDataAttribute. Properties with the `[ViewData]` attribute have their values stored and loaded from the ViewDataDictionary.

In the following example, the `AboutModel` applies the `[ViewData]` attribute to the `Title` property:

```
public class AboutModel : PageModel
{
    [ViewData]
    public string Title { get; } = "About";

    public void OnGet()
    {
    }
}
```

In the About page, access the `Title` property as a model property:

```
<h1>@Model.Title</h1>
```

In the layout, the title is read from the ViewData dictionary:

```
<!DOCTYPE html>
<html lang="en">
<head>
    <title>@ViewData["Title"] - WebApplication</title>
    ...
```

TempData

ASP.NET Core exposes the TempData. This property stores data until it's read. The Keep and Peek methods can be used to examine the data without deletion. `TempData` is useful for redirection, when data is needed for more than a single request.

The following code sets the value of `Message` using `TempData`:

```
public class CreateDotModel : PageModel
{
    private readonly AppDbContext _db;

    public CreateDotModel(AppDbContext db)
    {
        _db = db;
    }

    [TempData]
    public string Message { get; set; }

    [BindProperty]
    public Customer Customer { get; set; }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _db.Customers.Add(Customer);
        await _db.SaveChangesAsync();
        Message = $"Customer {Customer.Name} added";
        return RedirectToPage("./Index");
    }
}
```

The following markup in the *Pages/Customers/Index.cshtml* file displays the value of `Message` using `TempData`.

```
<h3>Msg: @Model.Message</h3>
```

The *Pages/Customers/Index.cshtml.cs* page model applies the `[TempData]` attribute to the `Message` property.

```
[TempData]
public string Message { get; set; }
```

For more information, see TempData.

Multiple handlers per page

The following page generates markup for two handlers using the `asp-page-handler` Tag Helper:

```
@page
@model CreateFATHModel

<html>
<body>
    <p>
        Enter your name.
    </p>
    <div asp-validation-summary="All"></div>
    <form method="POST">
        <div>Name: <input asp-for="Customer.Name" /></div>
        <input type="submit" asp-page-handler="JoinList" value="Join" />
        <input type="submit" asp-page-handler="JoinListUC" value="JOIN UC" />
    </form>
</body>
</html>
```

The form in the preceding example has two submit buttons, each using the `FormActionTagHelper` to submit to a different URL. The `asp-page-handler` attribute is a companion to `asp-page`. `asp-page-handler` generates URLs that submit to each of the handler methods defined by a page. `asp-page` isn't specified because the sample is linking to the current page.

The page model:

```
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using RazorPagesContacts.Data;

namespace RazorPagesContacts.Pages.Customers
{
    public class CreateFATHModel : PageModel
    {
        private readonly AppDbContext _db;

        public CreateFATHModel(AppDbContext db)
        {
            _db = db;
        }

        [BindProperty]
        public Customer Customer { get; set; }

        public async Task<IActionResult> OnPostJoinListAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            _db.Customers.Add(Customer);
            await _db.SaveChangesAsync();
            return RedirectToPage("/Index");
        }

        public async Task<IActionResult> OnPostJoinListUCAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }
            Customer.Name = Customer.Name?.ToUpperInvariant();
            return await OnPostJoinListAsync();
        }
    }
}
```

The preceding code uses *named handler methods*. Named handler methods are created by taking the text in the name after `On<HTTP Verb>` and before `Async` (if present). In the preceding example, the page methods are OnPost**JoinList**Async and OnPost**JoinListUC**Async. With *OnPost* and *Async* removed, the handler names are `JoinList` and `JoinListUC`.

```
<input type="submit" asp-page-handler="JoinList" value="Join" />
<input type="submit" asp-page-handler="JoinListUC" value="JOIN UC" />
```

Using the preceding code, the URL path that submits to `OnPostJoinListAsync` is `https://localhost:5001/Customers/CreateFATH?handler=JoinList`. The URL path that submits to `OnPostJoinListUCAsync` is `https://localhost:5001/Customers/CreateFATH?handler=JoinListUC`.

Custom routes

Use the `@page` directive to:

- Specify a custom route to a page. For example, the route to the About page can be set to `/Some/Other/Path` with `@page "/Some/Other/Path"`.

- Append segments to a page's default route. For example, an "item" segment can be added to a page's default route with `@page "item"`.
- Append parameters to a page's default route. For example, an ID parameter, `id`, can be required for a page with `@page "{id}"`.

A root-relative path designated by a tilde (`~`) at the beginning of the path is supported. For example, `@page "~/Some/Other/Path"` is the same as `@page "/Some/Other/Path"`.

If you don't like the query string `?handler=JoinList` in the URL, change the route to put the handler name in the path portion of the URL. The route can be customized by adding a route template enclosed in double quotes after the `@page` directive.

```
@page "{handler?}"
@model CreateRouteModel

<html>
<body>
    <p>
        Enter your name.
    </p>
    <div asp-validation-summary="All"></div>
    <form method="POST">
        <div>Name: <input asp-for="Customer.Name" /></div>
        <input type="submit" asp-page-handler="JoinList" value="Join" />
        <input type="submit" asp-page-handler="JoinListUC" value="JOIN UC" />
    </form>
</body>
</html>
```

Using the preceding code, the URL path that submits to `OnPostJoinListAsync` is `https://localhost:5001/Customers/CreateFATH/JoinList`. The URL path that submits to `OnPostJoinListUCAsync` is `https://localhost:5001/Customers/CreateFATH/JoinListUC`.

The `?` following `handler` means the route parameter is optional.

Advanced configuration and settings

The configuration and settings in following sections is not required by most apps.

To configure advanced options, use the AddRazorPages overload that configures RazorPagesOptions:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages(options =>
    {
        options.RootDirectory = "/MyPages";
        options.Conventions.AuthorizeFolder("/MyPages/Admin");
    });
}
```

Use the RazorPagesOptions to set the root directory for pages, or add application model conventions for pages. For more information on conventions, see Razor Pages authorization conventions.

To precompile views, see Razor view compilation.

Specify that Razor Pages are at the content root

By default, Razor Pages are rooted in the */Pages* directory. Add WithRazorPagesAtContentRoot to specify that your Razor Pages are at the content root (ContentRootPath) of the app:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages(options =>
        {
            options.Conventions.AuthorizeFolder("/MyPages/Admin");
        })
        .WithRazorPagesAtContentRoot();
}
```

Specify that Razor Pages are at a custom root directory

Add WithRazorPagesRoot to specify that Razor Pages are at a custom root directory in the app (provide a relative path):

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages(options =>
        {
            options.Conventions.AuthorizeFolder("/MyPages/Admin");
        })
        .WithRazorPagesRoot("/path/to/razor/pages");
}
```

By Rick Anderson and Ryan Nowak

Razor Pages is a new aspect of ASP.NET Core MVC that makes coding page-focused scenarios easier and more productive.

If you're looking for a tutorial that uses the Model-View-Controller approach, see Get started with ASP.NET Core MVC.

This document provides an introduction to Razor Pages. It's not a step by step tutorial. If you find some of the sections too advanced, see Get started with Razor Pages. For an overview of ASP.NET Core, see the Introduction to ASP.NET Core.

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core SDK 2.2 or later

> **WARNING**
>
> If you use Visual Studio 2017, see dotnet/sdk issue #3124 for information about .NET Core SDK versions that don't work with Visual Studio.

Create a Razor Pages project

- Visual Studio
- Visual Studio for Mac
- Visual Studio Code

See Get started with Razor Pages for detailed instructions on how to create a Razor Pages project.

Razor Pages

Razor Pages is enabled in *Startup.cs*:

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        // Includes support for Razor Pages and controllers.
        services.AddMvc();
    }

    public void Configure(IApplicationBuilder app)
    {
        app.UseMvc();
    }
}
```

Consider a basic page:

```
@page

<h1>Hello, world!</h1>
<h2>The time on the server is @DateTime.Now</h2>
```

The preceding code looks a lot like a Razor view file used in an ASP.NET Core app with controllers and views. What makes it different is the `@page` directive. `@page` makes the file into an MVC action - which means that it handles requests directly, without going through a controller. `@page` must be the first Razor directive on a page. `@page` affects the behavior of other Razor constructs.

A similar page, using a `PageModel` class, is shown in the following two files. The *Pages/Index2.cshtml* file:

```
@page
@using RazorPagesIntro.Pages
@model IndexModel2

<h2>Separate page model</h2>
<p>
    @Model.Message
</p>
```

The *Pages/Index2.cshtml.cs* page model:

```
using Microsoft.AspNetCore.Mvc.RazorPages;
using System;

namespace RazorPagesIntro.Pages
{
    public class IndexModel2 : PageModel
    {
        public string Message { get; private set; } = "PageModel in C#";

        public void OnGet()
        {
            Message += $" Server time is { DateTime.Now }";
        }
    }
}
```

By convention, the `PageModel` class file has the same name as the Razor Page file with *.cs* appended. For example, the previous Razor Page is *Pages/Index2.cshtml*. The file containing the `PageModel` class is named *Pages/Index2.cshtml.cs*.

The associations of URL paths to pages are determined by the page's location in the file system. The following table shows a Razor Page path and the matching URL:

FILE NAME AND PATH	MATCHING URL
/Pages/Index.cshtml	`/` or `/Index`
/Pages/Contact.cshtml	`/Contact`
/Pages/Store/Contact.cshtml	`/Store/Contact`
/Pages/Store/Index.cshtml	`/Store` or `/Store/Index`

Notes:

- The runtime looks for Razor Pages files in the *Pages* folder by default.
- `Index` is the default page when a URL doesn't include a page.

Write a basic form

Razor Pages is designed to make common patterns used with web browsers easy to implement when building an app. Model binding, Tag Helpers, and HTML helpers all *just work* with the properties defined in a Razor Page class. Consider a page that implements a basic "contact us" form for the `Contact` model:

For the samples in this document, the `DbContext` is initialized in the Startup.cs file.

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using RazorPagesContacts.Data;

namespace RazorPagesContacts
{
    public class Startup
    {
        public IHostingEnvironment HostingEnvironment { get; }

        public void ConfigureServices(IServiceCollection services)
        {
            services.AddDbContext<AppDbContext>(options =>
                                options.UseInMemoryDatabase("name"));
            services.AddMvc();
        }

        public void Configure(IApplicationBuilder app)
        {
            app.UseMvc();
        }
    }
}
```

The data model:

```
using System.ComponentModel.DataAnnotations;

namespace RazorPagesContacts.Data
{
    public class Customer
    {
        public int Id { get; set; }

        [Required, StringLength(100)]
        public string Name { get; set; }
    }
}
```

The db context:

```
using Microsoft.EntityFrameworkCore;

namespace RazorPagesContacts.Data
{
    public class AppDbContext : DbContext
    {
        public AppDbContext(DbContextOptions options)
            : base(options)
        {
        }

        public DbSet<Customer> Customers { get; set; }
    }
}
```

The *Pages/Create.cshtml* view file:

```
@page
@model RazorPagesContacts.Pages.CreateModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<html>
<body>
    <p>
        Enter your name.
    </p>
    <div asp-validation-summary="All"></div>
    <form method="POST">
        <div>Name: <input asp-for="Customer.Name" /></div>
        <input type="submit" />
    </form>
</body>
</html>
```

The *Pages/Create.cshtml.cs* page model:

```
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using RazorPagesContacts.Data;

namespace RazorPagesContacts.Pages
{
    public class CreateModel : PageModel
    {
        private readonly AppDbContext _db;

        public CreateModel(AppDbContext db)
        {
            _db = db;
        }

        [BindProperty]
        public Customer Customer { get; set; }

        public async Task<IActionResult> OnPostAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            _db.Customers.Add(Customer);
            await _db.SaveChangesAsync();
            return RedirectToPage("/Index");
        }
    }
}
```

By convention, the `PageModel` class is called `<PageName>Model` and is in the same namespace as the page.

The `PageModel` class allows separation of the logic of a page from its presentation. It defines page handlers for requests sent to the page and the data used to render the page. This separation allows:

- Managing of page dependencies through dependency injection.
- Unit testing the pages.

The page has an `OnPostAsync` *handler method*, which runs on `POST` requests (when a user posts the form). You can add handler methods for any HTTP verb. The most common handlers are:

- `OnGet` to initialize state needed for the page. OnGet sample.
- `OnPost` to handle form submissions.

The `Async` naming suffix is optional but is often used by convention for asynchronous functions. The preceding code is typical for Razor Pages.

If you're familiar with ASP.NET apps using controllers and views:

- The `OnPostAsync` code in the preceding example looks similar to typical controller code.
- Most of the MVC primitives like model binding, validation, Validation, and action results are shared.

The previous `OnPostAsync` method:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _db.Customers.Add(Customer);
    await _db.SaveChangesAsync();
    return RedirectToPage("/Index");
}
```

The basic flow of `OnPostAsync`:

Check for validation errors.

- If there are no errors, save the data and redirect.
- If there are errors, show the page again with validation messages. Client-side validation is identical to traditional ASP.NET Core MVC applications. In many cases, validation errors would be detected on the client, and never submitted to the server.

When the data is entered successfully, the `OnPostAsync` handler method calls the `RedirectToPage` helper method to return an instance of `RedirectToPageResult`. `RedirectToPage` is a new action result, similar to `RedirectToAction` or `RedirectToRoute`, but customized for pages. In the preceding sample, it redirects to the root Index page (`/Index`). `RedirectToPage` is detailed in the URL generation for Pages section.

When the submitted form has validation errors (that are passed to the server), the `OnPostAsync` handler method calls the `Page` helper method. `Page` returns an instance of `PageResult`. Returning `Page` is similar to how actions in controllers return `View`. `PageResult` is the default return type for a handler method. A handler method that returns `void` renders the page.

The `Customer` property uses `[BindProperty]` attribute to opt in to model binding.

```
public class CreateModel : PageModel
{
    private readonly AppDbContext _db;

    public CreateModel(AppDbContext db)
    {
        _db = db;
    }

    [BindProperty]
    public Customer Customer { get; set; }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _db.Customers.Add(Customer);
        await _db.SaveChangesAsync();
        return RedirectToPage("/Index");
    }
}
```

Razor Pages, by default, bind properties only with non-`GET` verbs. Binding to properties can reduce the amount of code you have to write. Binding reduces code by using the same property to render form fields (`<input asp-for="Customer.Name">`) and accept the input.

WARNING

For security reasons, you must opt in to binding `GET` request data to page model properties. Verify user input before mapping it to properties. Opting into `GET` binding is useful when addressing scenarios that rely on query string or route values.

To bind a property on `GET` requests, set the `[BindProperty]` attribute's `SupportsGet` property to `true`:

```
[BindProperty(SupportsGet = true)]
```

For more information, see ASP.NET Core Community Standup: Bind on GET discussion (YouTube).

The home page (*Index.cshtml*):

```
@page
@model RazorPagesContacts.Pages.IndexModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<h1>Contacts</h1>
<form method="post">
    <table class="table">
        <thead>
            <tr>
                <th>ID</th>
                <th>Name</th>
            </tr>
        </thead>
        <tbody>
            @foreach (var contact in Model.Customers)
            {
                <tr>
                    <td>@contact.Id</td>
                    <td>@contact.Name</td>
                    <td>
                        <a asp-page="./Edit" asp-route-id="@contact.Id">edit</a>
                        <button type="submit" asp-page-handler="delete"
                                asp-route-id="@contact.Id">delete</button>
                    </td>
                </tr>
            }
        </tbody>
    </table>

    <a asp-page="./Create">Create</a>
</form>
```

The associated `PageModel` class (*Index.cshtml.cs*):

```
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using RazorPagesContacts.Data;
using System.Collections.Generic;
using Microsoft.EntityFrameworkCore;

namespace RazorPagesContacts.Pages
{
    public class IndexModel : PageModel
    {
        private readonly AppDbContext _db;

        public IndexModel(AppDbContext db)
        {
            _db = db;
        }

        public IList<Customer> Customers { get; private set; }

        public async Task OnGetAsync()
        {
            Customers = await _db.Customers.AsNoTracking().ToListAsync();
        }

        public async Task<IActionResult> OnPostDeleteAsync(int id)
        {
            var contact = await _db.Customers.FindAsync(id);

            if (contact != null)
            {
                _db.Customers.Remove(contact);
                await _db.SaveChangesAsync();
            }

            return RedirectToPage();
        }
    }
}
```

The *Index.cshtml* file contains the following markup to create an edit link for each contact:

```
<a asp-page="./Edit" asp-route-id="@contact.Id">edit</a>
```

The `<a asp-page="./Edit" asp-route-id="@contact.Id">Edit</a>` Anchor Tag Helper used the `asp-route-{value}` attribute to generate a link to the Edit page. The link contains route data with the contact ID. For example, `https://localhost:5001/Edit/1`. Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files. Tag Helpers are enabled by `@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers`

The *Pages/Edit.cshtml* file:

```
@page "{id:int}"
@model RazorPagesContacts.Pages.EditModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

@{
    ViewData["Title"] = "Edit Customer";
}

<h1>Edit Customer - @Model.Customer.Id</h1>
<form method="post">
    <div asp-validation-summary="All"></div>
    <input asp-for="Customer.Id" type="hidden" />
    <div>
        <label asp-for="Customer.Name"></label>
        <div>
            <input asp-for="Customer.Name" />
            <span asp-validation-for="Customer.Name" ></span>
        </div>
    </div>

    <div>
        <button type="submit">Save</button>
    </div>
</form>
```

The first line contains the `@page "{id:int}"` directive. The routing constraint `"{id:int}"` tells the page to accept requests to the page that contain `int` route data. If a request to the page doesn't contain route data that can be converted to an `int`, the runtime returns an HTTP 404 (not found) error. To make the ID optional, append `?` to the route constraint:

```
@page "{id:int?}"
```

The *Pages/Edit.cshtml.cs* file:

```
using System;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using RazorPagesContacts.Data;

namespace RazorPagesContacts.Pages
{
    public class EditModel : PageModel
    {
        private readonly AppDbContext _db;

        public EditModel(AppDbContext db)
        {
            _db = db;
        }

        [BindProperty]
        public Customer Customer { get; set; }

        public async Task<IActionResult> OnGetAsync(int id)
        {
            Customer = await _db.Customers.FindAsync(id);

            if (Customer == null)
            {
                return RedirectToPage("/Index");
            }

            return Page();
        }

        public async Task<IActionResult> OnPostAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            _db.Attach(Customer).State = EntityState.Modified;

            try
            {
                await _db.SaveChangesAsync();
            }
            catch (DbUpdateConcurrencyException)
            {
                throw new Exception($"Customer {Customer.Id} not found!");
            }

            return RedirectToPage("/Index");
        }
    }
}
```

The *Index.cshtml* file also contains markup to create a delete button for each customer contact:

```
<button type="submit" asp-page-handler="delete"
        asp-route-id="@contact.Id">delete</button>
```

When the delete button is rendered in HTML, its `formaction` includes parameters for:

- The customer contact ID specified by the `asp-route-id` attribute.

- The `handler` specified by the `asp-page-handler` attribute.

Here is an example of a rendered delete button with a customer contact ID of `1`:

```
<button type="submit" formaction="/?id=1&amp;handler=delete">delete</button>
```

When the button is selected, a form `POST` request is sent to the server. By convention, the name of the handler method is selected based on the value of the `handler` parameter according to the scheme `OnPost[handler]Async`.

Because the `handler` is `delete` in this example, the `OnPostDeleteAsync` handler method is used to process the `POST` request. If the `asp-page-handler` is set to a different value, such as `remove`, a handler method with the name `OnPostRemoveAsync` is selected. The following code shows the `OnPostDeleteAsync` handler:

```
public async Task<IActionResult> OnPostDeleteAsync(int id)
{
    var contact = await _db.Customers.FindAsync(id);

    if (contact != null)
    {
        _db.Customers.Remove(contact);
        await _db.SaveChangesAsync();
    }

    return RedirectToPage();
}
```

The `OnPostDeleteAsync` method:

- Accepts the `id` from the query string. If the *Index.cshtml* page directive contained routing constraint `"{id:int?}"`, `id` would come from route data. The route data for `id` is specified in the URI such as `https://localhost:5001/Customers/2`.
- Queries the database for the customer contact with `FindAsync`.
- If the customer contact is found, they're removed from the list of customer contacts. The database is updated.
- Calls `RedirectToPage` to redirect to the root Index page (`/Index`).

Mark page properties as required

Properties on a `PageModel` can be marked with the Required attribute:

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using System.ComponentModel.DataAnnotations;

namespace RazorPagesMovie.Pages.Movies
{
    public class CreateModel : PageModel
    {
        public IActionResult OnGet()
        {
            return Page();
        }

        [BindProperty]
        [Required(ErrorMessage = "Color is required")]
        public string Color { get; set; }

        public IActionResult OnPostAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            // Process color.

            return RedirectToPage("./Index");
        }
    }
}
```

For more information, see Model validation.

Handle HEAD requests with an OnGet handler fallback

`HEAD` requests allow you to retrieve the headers for a specific resource. Unlike `GET` requests, `HEAD` requests don't return a response body.

Ordinarily, an `OnHead` handler is created and called for `HEAD` requests:

```
public void OnHead()
{
    HttpContext.Response.Headers.Add("HandledBy", "Handled by OnHead!");
}
```

In ASP.NET Core 2.1 or later, Razor Pages falls back to calling the `OnGet` handler if no `OnHead` handler is defined. This behavior is enabled by the call to SetCompatibilityVersion in `Startup.ConfigureServices`:

```
services.AddMvc()
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
```

The default templates generate the `SetCompatibilityVersion` call in ASP.NET Core 2.1 and 2.2. `SetCompatibilityVersion` effectively sets the Razor Pages option `AllowMappingHeadRequestsToGetHandler` to `true`.

Rather than opting in to all behaviors with `SetCompatibilityVersion`, you can explicitly opt in to *specific* behaviors. The following code opts in to allowing `HEAD` requests to be mapped to the `OnGet` handler:

```
services.AddMvc()
    .AddRazorPagesOptions(options =>
    {
        options.AllowMappingHeadRequestsToGetHandler = true;
    });
```

XSRF/CSRF and Razor Pages

You don't have to write any code for antiforgery validation. Antiforgery token generation and validation are automatically included in Razor Pages.

Using Layouts, partials, templates, and Tag Helpers with Razor Pages

Pages work with all the capabilities of the Razor view engine. Layouts, partials, templates, Tag Helpers, *_ViewStart.cshtml*, *_ViewImports.cshtml* work in the same way they do for conventional Razor views.

Let's declutter this page by taking advantage of some of those capabilities.

Add a layout page to *Pages/Shared/_Layout.cshtml*:

```
<!DOCTYPE html>
<html>
<head>
    <title>Razor Pages Sample</title>
</head>
<body>
   <a asp-page="/Index">Home</a>
    @RenderBody()
    <a asp-page="/Customers/Create">Create</a> <br />
</body>
</html>
```

The Layout:

- Controls the layout of each page (unless the page opts out of layout).
- Imports HTML structures such as JavaScript and stylesheets.

See layout page for more information.

The Layout property is set in *Pages/_ViewStart.cshtml*:

```
@{
    Layout = "_Layout";
}
```

The layout is in the *Pages/Shared* folder. Pages look for other views (layouts, templates, partials) hierarchically, starting in the same folder as the current page. A layout in the *Pages/Shared* folder can be used from any Razor page under the *Pages* folder.

The layout file should go in the *Pages/Shared* folder.

We recommend you **not** put the layout file in the *Views/Shared* folder. *Views/Shared* is an MVC views pattern. Razor Pages are meant to rely on folder hierarchy, not path conventions.

View search from a Razor Page includes the *Pages* folder. The layouts, templates, and partials you're using with MVC controllers and conventional Razor views *just work*.

Add a *Pages/_ViewImports.cshtml* file:

```
@namespace RazorPagesContacts.Pages
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
```

`@namespace` is explained later in the tutorial. The `@addTagHelper` directive brings in the built-in Tag Helpers to all the pages in the *Pages* folder.

When the `@namespace` directive is used explicitly on a page:

```
@page
@namespace RazorPagesIntro.Pages.Customers

@model NameSpaceModel

<h2>Name space</h2>
<p>
    @Model.Message
</p>
```

The directive sets the namespace for the page. The `@model` directive doesn't need to include the namespace.

When the `@namespace` directive is contained in *_ViewImports.cshtml*, the specified namespace supplies the prefix for the generated namespace in the Page that imports the `@namespace` directive. The rest of the generated namespace (the suffix portion) is the dot-separated relative path between the folder containing *_ViewImports.cshtml* and the folder containing the page.

For example, the `PageModel` class *Pages/Customers/Edit.cshtml.cs* explicitly sets the namespace:

```
namespace RazorPagesContacts.Pages
{
    public class EditModel : PageModel
    {
        private readonly AppDbContext _db;

        public EditModel(AppDbContext db)
        {
            _db = db;
        }

        // Code removed for brevity.
```

The *Pages/_ViewImports.cshtml* file sets the following namespace:

```
@namespace RazorPagesContacts.Pages
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
```

The generated namespace for the *Pages/Customers/Edit.cshtml* Razor Page is the same as the `PageModel` class.

`@namespace` *also works with conventional Razor views.*

The original *Pages/Create.cshtml* view file:

```
@page
@model RazorPagesContacts.Pages.CreateModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<html>
<body>
    <p>
        Enter your name.
    </p>
    <div asp-validation-summary="All"></div>
    <form method="POST">
        <div>Name: <input asp-for="Customer.Name" /></div>
        <input type="submit" />
    </form>
</body>
</html>
```

The updated *Pages/Create.cshtml* view file:

```
@page
@model CreateModel

<html>
<body>
    <p>
        Enter your name.
    </p>
    <div asp-validation-summary="All"></div>
    <form method="POST">
        <div>Name: <input asp-for="Customer.Name" /></div>
        <input type="submit" />
    </form>
</body>
</html>
```

The Razor Pages starter project contains the *Pages/_ValidationScriptsPartial.cshtml*, which hooks up client-side validation.

For more information on partial views, see Partial views in ASP.NET Core.

URL generation for Pages

The `Create` page, shown previously, uses `RedirectToPage`:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _db.Customers.Add(Customer);
    await _db.SaveChangesAsync();
    return RedirectToPage("/Index");
}
```

The app has the following file/folder structure:

- */Pages*
    - *Index.cshtml*

- */Customers*
  - *Create.cshtml*
  - *Edit.cshtml*
  - *Index.cshtml*

The *Pages/Customers/Create.cshtml* and *Pages/Customers/Edit.cshtml* pages redirect to *Pages/Index.cshtml* after success. The string `/Index` is part of the URI to access the preceding page. The string `/Index` can be used to generate URIs to the *Pages/Index.cshtml* page. For example:

- `Url.Page("/Index", ...)`
- `<a asp-page="/Index">My Index Page</a>`
- `RedirectToPage("/Index")`

The page name is the path to the page from the root */Pages* folder including a leading `/` (for example, `/Index`). The preceding URL generation samples offer enhanced options and functional capabilities over hardcoding a URL. URL generation uses routing and can generate and encode parameters according to how the route is defined in the destination path.

URL generation for pages supports relative names. The following table shows which Index page is selected with different `RedirectToPage` parameters from *Pages/Customers/Create.cshtml*:

REDIRECTTOPAGE(X)	PAGE
RedirectToPage("/Index")	*Pages/Index*
RedirectToPage("./Index");	*Pages/Customers/Index*
RedirectToPage("../Index")	*Pages/Index*
RedirectToPage("Index")	*Pages/Customers/Index*

`RedirectToPage("Index")`, `RedirectToPage("./Index")`, and `RedirectToPage("../Index")` are *relative names*. The `RedirectToPage` parameter is *combined* with the path of the current page to compute the name of the destination page.

Relative name linking is useful when building sites with a complex structure. If you use relative names to link between pages in a folder, you can rename that folder. All the links still work (because they didn't include the folder name).

To redirect to a page in a different Area, specify the area:

```
RedirectToPage("/Index", new { area = "Services" });
```

For more information, see Areas in ASP.NET Core.

ViewData attribute

Data can be passed to a page with ViewDataAttribute. Properties on controllers or Razor Page models with the `[ViewData]` attribute have their values stored and loaded from the ViewDataDictionary.

In the following example, the `AboutModel` contains a `Title` property marked with `[ViewData]`. The `Title` property is set to the title of the About page:

```
public class AboutModel : PageModel
{
    [ViewData]
    public string Title { get; } = "About";

    public void OnGet()
    {
    }
}
```

In the About page, access the `Title` property as a model property:

```
<h1>@Model.Title</h1>
```

In the layout, the title is read from the ViewData dictionary:

```
<!DOCTYPE html>
<html lang="en">
<head>
    <title>@ViewData["Title"] - WebApplication</title>
    ...
```

TempData

ASP.NET Core exposes the TempData property on a controller. This property stores data until it's read. The `Keep` and `Peek` methods can be used to examine the data without deletion. `TempData` is useful for redirection, when data is needed for more than a single request.

The following code sets the value of `Message` using `TempData`:

```
public class CreateDotModel : PageModel
{
    private readonly AppDbContext _db;

    public CreateDotModel(AppDbContext db)
    {
        _db = db;
    }

    [TempData]
    public string Message { get; set; }

    [BindProperty]
    public Customer Customer { get; set; }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _db.Customers.Add(Customer);
        await _db.SaveChangesAsync();
        Message = $"Customer {Customer.Name} added";
        return RedirectToPage("./Index");
    }
}
```

The following markup in the *Pages/Customers/Index.cshtml* file displays the value of `Message` using `TempData`.

```
<h3>Msg: @Model.Message</h3>
```

The *Pages/Customers/Index.cshtml.cs* page model applies the `[TempData]` attribute to the `Message` property.

```
[TempData]
public string Message { get; set; }
```

For more information, see TempData .

Multiple handlers per page

The following page generates markup for two handlers using the `asp-page-handler` Tag Helper:

```
@page
@model CreateFATHModel

<html>
<body>
    <p>
        Enter your name.
    </p>
    <div asp-validation-summary="All"></div>
    <form method="POST">
        <div>Name: <input asp-for="Customer.Name" /></div>
        <input type="submit" asp-page-handler="JoinList" value="Join" />
        <input type="submit" asp-page-handler="JoinListUC" value="JOIN UC" />
    </form>
</body>
</html>
```

The form in the preceding example has two submit buttons, each using the `FormActionTagHelper` to submit to a different URL. The `asp-page-handler` attribute is a companion to `asp-page`. `asp-page-handler` generates URLs that submit to each of the handler methods defined by a page. `asp-page` isn't specified because the sample is linking to the current page.

The page model:

```
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using RazorPagesContacts.Data;

namespace RazorPagesContacts.Pages.Customers
{
    public class CreateFATHModel : PageModel
    {
        private readonly AppDbContext _db;

        public CreateFATHModel(AppDbContext db)
        {
            _db = db;
        }

        [BindProperty]
        public Customer Customer { get; set; }

        public async Task<IActionResult> OnPostJoinListAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            _db.Customers.Add(Customer);
            await _db.SaveChangesAsync();
            return RedirectToPage("/Index");
        }

        public async Task<IActionResult> OnPostJoinListUCAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }
            Customer.Name = Customer.Name?.ToUpperInvariant();
            return await OnPostJoinListAsync();
        }
    }
}
```

The preceding code uses *named handler methods*. Named handler methods are created by taking the text in the name after `On<HTTP Verb>` and before `Async` (if present). In the preceding example, the page methods are OnPost**JoinList**Async and OnPost**JoinListUC**Async. With *OnPost* and *Async* removed, the handler names are `JoinList` and `JoinListUC`.

```
<input type="submit" asp-page-handler="JoinList" value="Join" />
<input type="submit" asp-page-handler="JoinListUC" value="JOIN UC" />
```

Using the preceding code, the URL path that submits to `OnPostJoinListAsync` is `https://localhost:5001/Customers/CreateFATH?handler=JoinList`. The URL path that submits to `OnPostJoinListUCAsync` is `https://localhost:5001/Customers/CreateFATH?handler=JoinListUC`.

Custom routes

Use the `@page` directive to:

- Specify a custom route to a page. For example, the route to the About page can be set to `/Some/Other/Path` with `@page "/Some/Other/Path"`.

- Append segments to a page's default route. For example, an "item" segment can be added to a page's default route with `@page "item"`.
- Append parameters to a page's default route. For example, an ID parameter, `id`, can be required for a page with `@page "{id}"`.

A root-relative path designated by a tilde (`~`) at the beginning of the path is supported. For example, `@page "~/Some/Other/Path"` is the same as `@page "/Some/Other/Path"`.

If you don't like the query string `?handler=JoinList` in the URL, change the route to put the handler name in the path portion of the URL. The route can be customized by adding a route template enclosed in double quotes after the `@page` directive.

```
@page "{handler?}"
@model CreateRouteModel

<html>
<body>
    <p>
        Enter your name.
    </p>
    <div asp-validation-summary="All"></div>
    <form method="POST">
        <div>Name: <input asp-for="Customer.Name" /></div>
        <input type="submit" asp-page-handler="JoinList" value="Join" />
        <input type="submit" asp-page-handler="JoinListUC" value="JOIN UC" />
    </form>
</body>
</html>
```

Using the preceding code, the URL path that submits to `OnPostJoinListAsync` is `https://localhost:5001/Customers/CreateFATH/JoinList`. The URL path that submits to `OnPostJoinListUCAsync` is `https://localhost:5001/Customers/CreateFATH/JoinListUC`.

The `?` following `handler` means the route parameter is optional.

Configuration and settings

To configure advanced options, use the extension method `AddRazorPagesOptions` on the MVC builder:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
        .AddRazorPagesOptions(options =>
        {
            options.RootDirectory = "/MyPages";
            options.Conventions.AuthorizeFolder("/MyPages/Admin");
        });
}
```

Currently you can use the `RazorPagesOptions` to set the root directory for pages, or add application model conventions for pages. We'll enable more extensibility this way in the future.

To precompile views, see Razor view compilation .

Download or view sample code.

See Get started with Razor Pages, which builds on this introduction.

Specify that Razor Pages are at the content root

By default, Razor Pages are rooted in the */Pages* directory. Add WithRazorPagesAtContentRoot to AddMvc to specify that your Razor Pages are at the content root (ContentRootPath) of the app:

```
services.AddMvc()
    .AddRazorPagesOptions(options =>
    {
        ...
    })
    .WithRazorPagesAtContentRoot();
```

Specify that Razor Pages are at a custom root directory

Add WithRazorPagesRoot to AddMvc to specify that your Razor Pages are at a custom root directory in the app (provide a relative path):

```
services.AddMvc()
    .AddRazorPagesOptions(options =>
    {
        ...
    })
    .WithRazorPagesRoot("/path/to/razor/pages");
```

Tutorial: Create a Razor Pages web app with ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

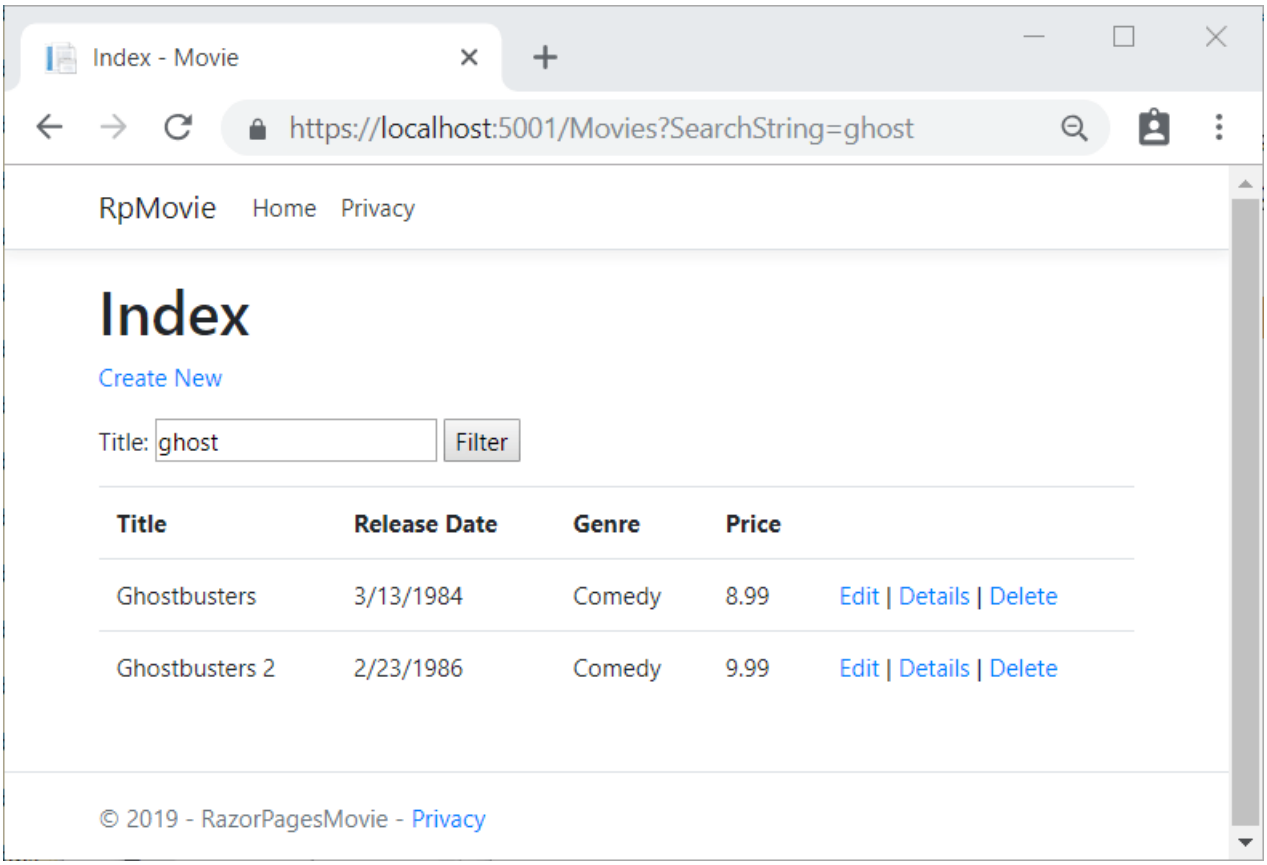
This series of tutorials explains the basics of building a Razor Pages web app.

For a more advanced introduction aimed at developers who are familiar with controllers and views, see Introduction to Razor Pages.

This series includes the following tutorials:

1. Create a Razor Pages web app
2. Add a model to a Razor Pages app
3. Scaffold (generate) Razor pages
4. Work with a database
5. Update Razor pages
6. Add search
7. Add a new field
8. Add validation

At the end, you'll have an app that can display and manage a database of movies.



Tutorial: Get started with Razor Pages in ASP.NET Core

9/22/2020 • 10 minutes to read • Edit Online

By Rick Anderson

This is the first tutorial of a series that teaches the basics of building an ASP.NET Core Razor Pages web app.

For a more advanced introduction aimed at developers who are familiar with controllers and views, see Introduction to Razor Pages.

At the end of the series, you'll have an app that manages a database of movies.

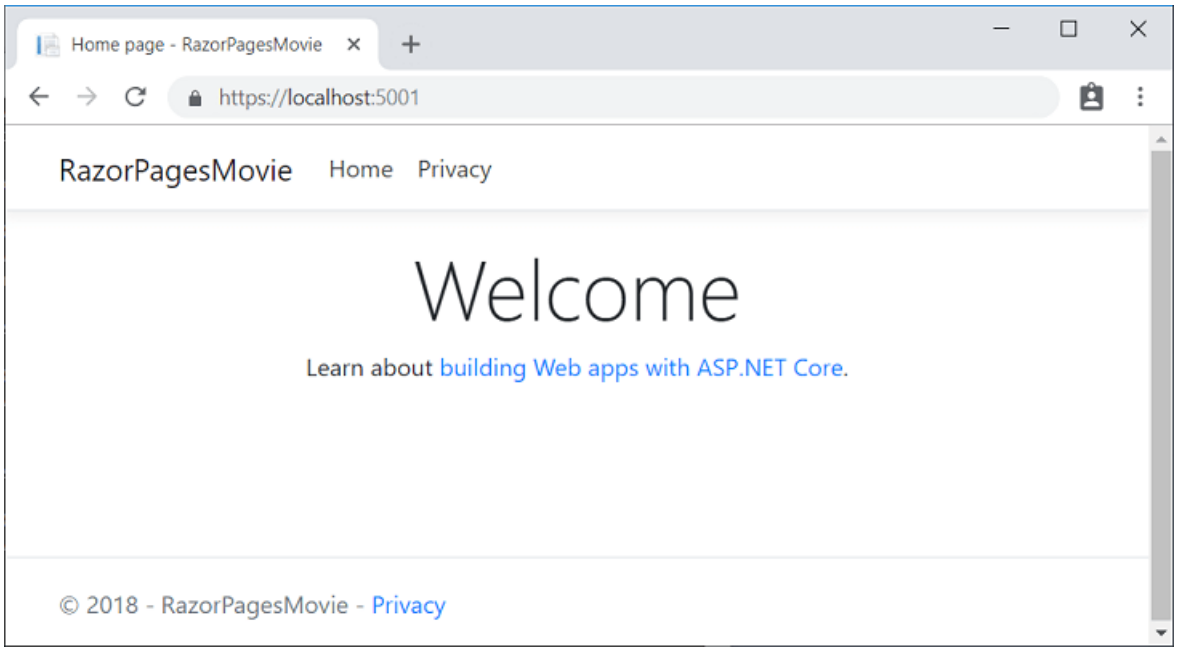
View or download sample code (how to download).

View or download sample code (how to download).

In this tutorial, you:

- Create a Razor Pages web app.
- Run the app.
- Examine the project files.

At the end of this tutorial, you'll have a working Razor Pages web app that you'll build on in later tutorials.



Prerequisites

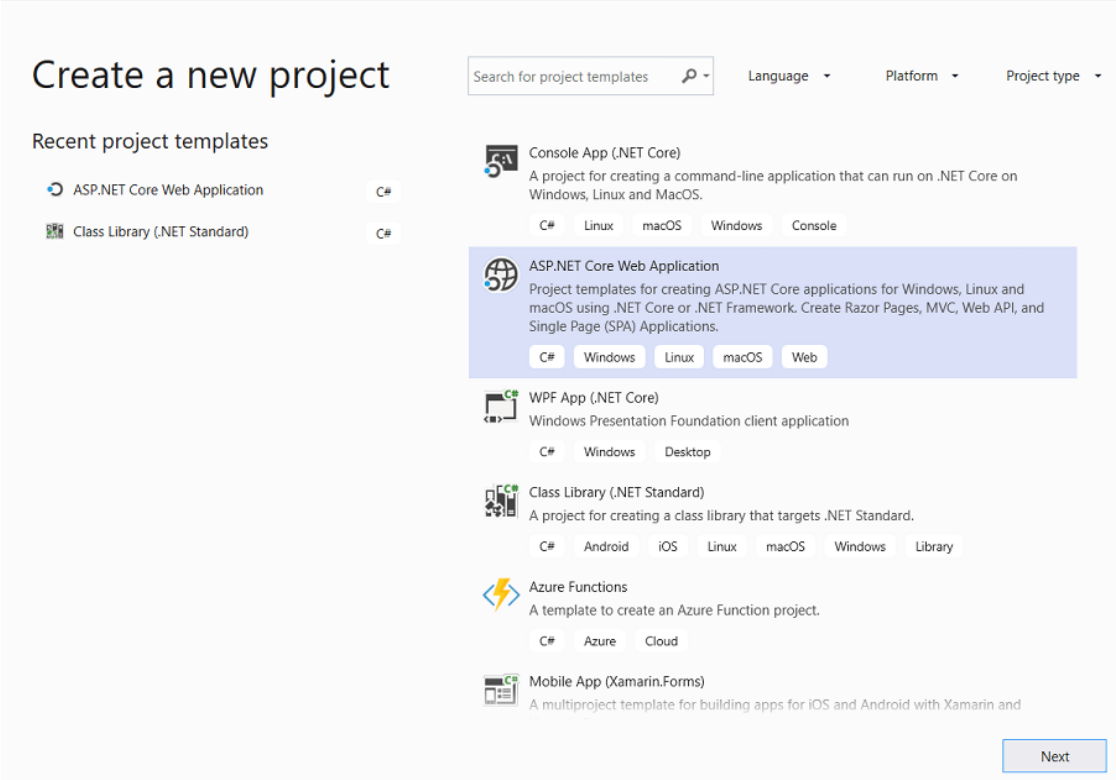
- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 16.4 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

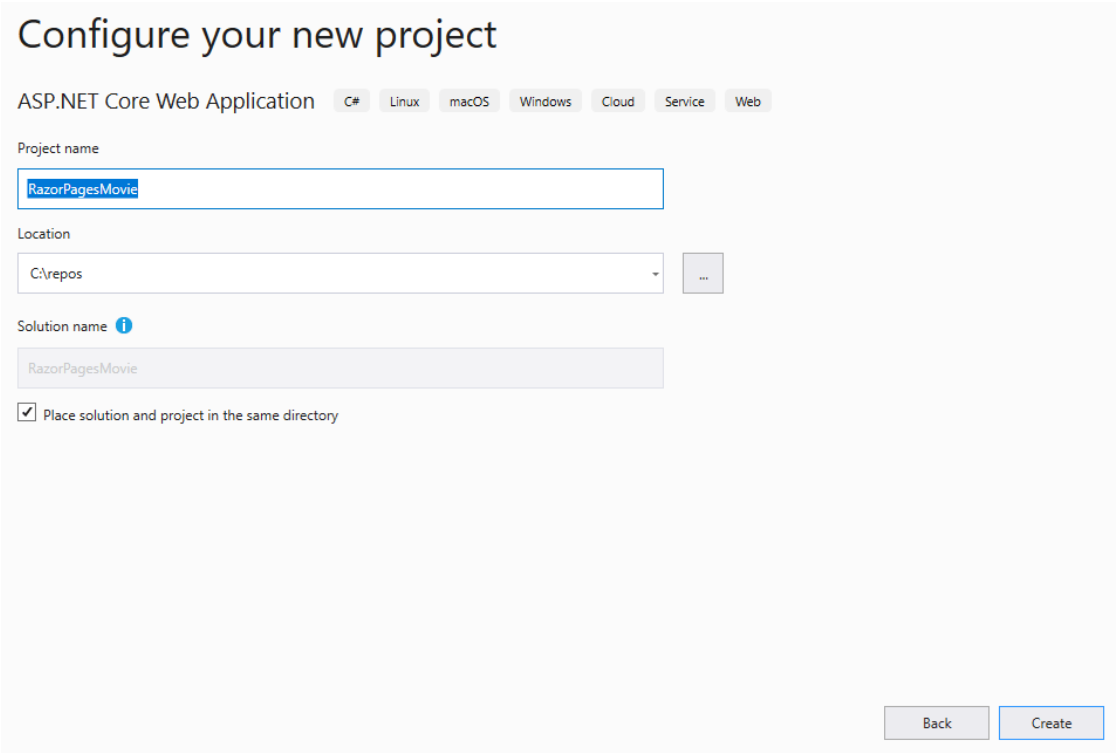
Create a Razor Pages web app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

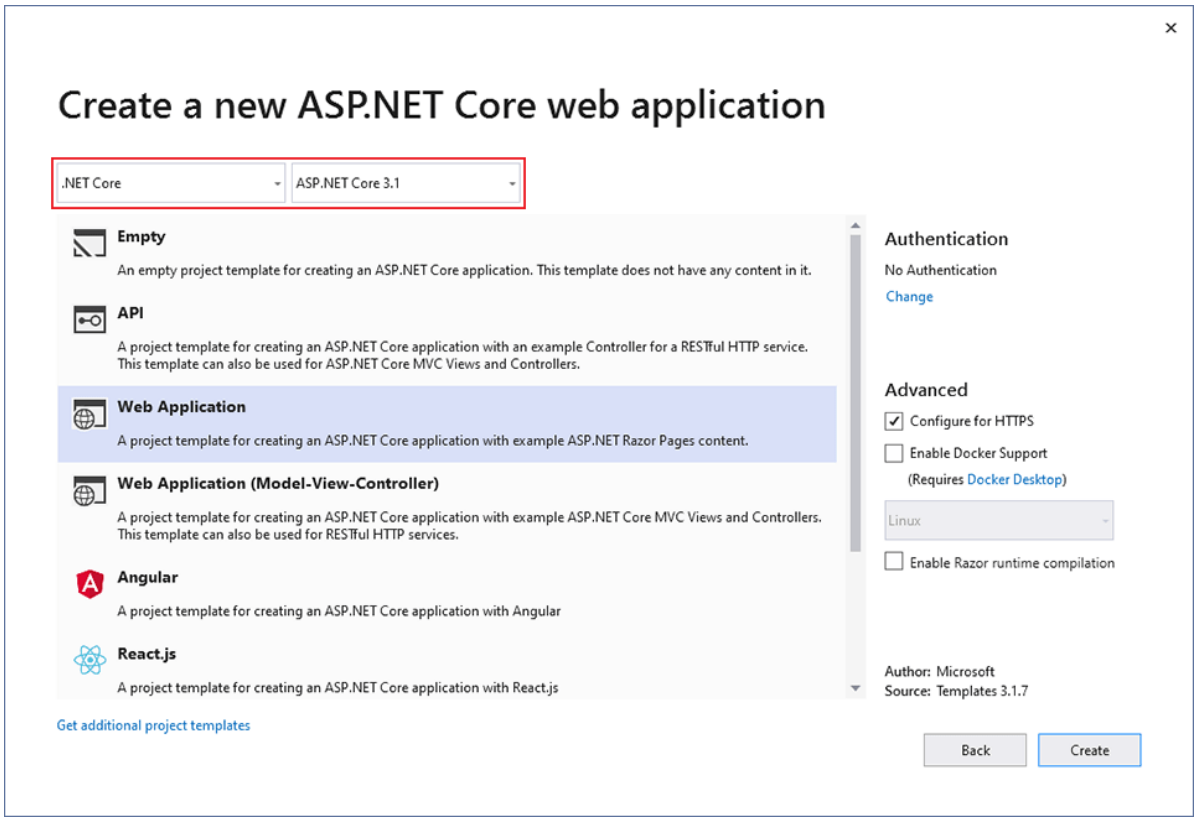
- From the Visual Studio **File** menu, select **New** > **Project**.
- Create a new ASP.NET Core Web Application and select **Next**.



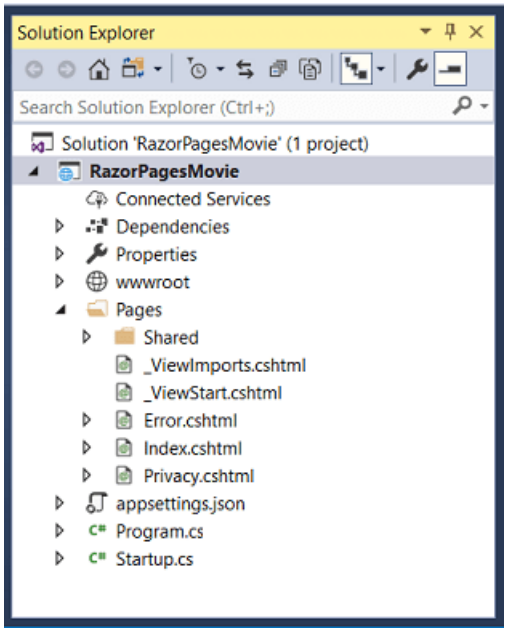
- Name the project **RazorPagesMovie**. It's important to name the project *RazorPagesMovie* so the namespaces will match when you copy and paste code.



- Select **ASP.NET Core 3.1** in the dropdown, **Web Application**, and then select **Create**.



The following starter project is created:

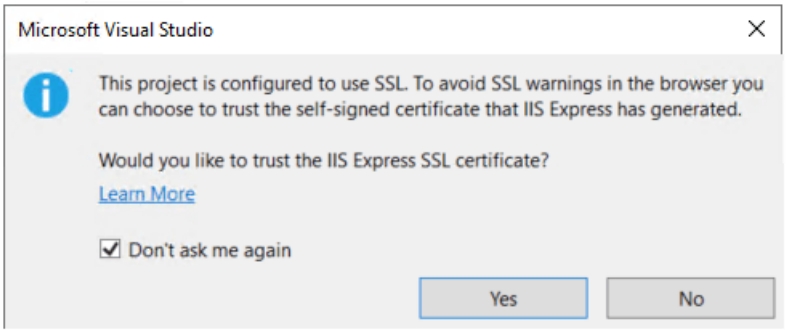


Run the app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

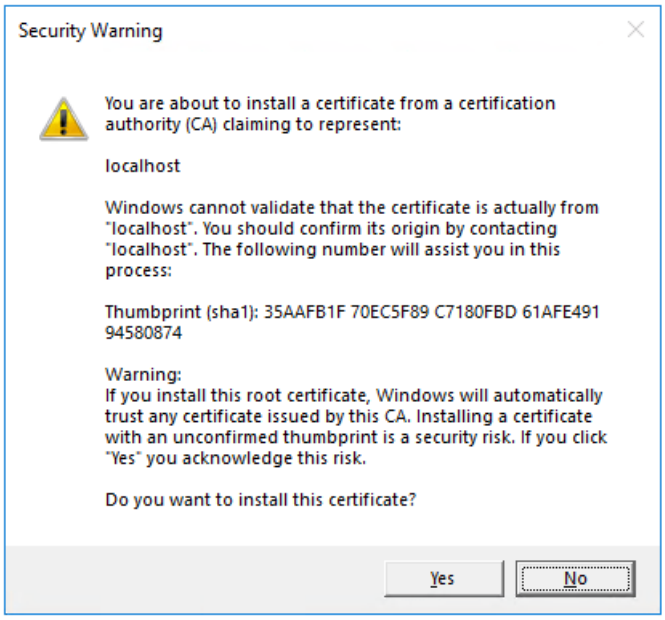
- Press Ctrl+F5 to run without the debugger.

  Visual Studio displays the following dialog:



Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:



Select **Yes** if you agree to trust the development certificate.

Visual Studio starts IIS Express and runs the app. The address bar shows `localhost:port#` and not something like `example.com`. That's because `localhost` is the standard hostname for the local computer. Localhost only serves web requests from the local computer. When Visual Studio creates a web project, a random port is used for the web server.

Examine the project files

Here's an overview of the main project folders and files that you'll work with in later tutorials.

Pages folder

Contains Razor pages and supporting files. Each Razor page is a pair of files:

- A *.cshtml* file that contains HTML markup with C# code using Razor syntax.
- A *.cshtml.cs* file that contains C# code that handles page events.

Supporting files have names that begin with an underscore. For example, the *_Layout.cshtml* file configures UI elements common to all pages. This file sets up the navigation menu at the top of the page and the copyright notice at the bottom of the page. For more information, see Layout in ASP.NET Core.

wwwroot folder

Contains static files, such as HTML files, JavaScript files, and CSS files. For more information, see Static files in ASP.NET Core.

appSettings.json

Contains configuration data, such as connection strings. For more information, see Configuration in ASP.NET Core.

Program.cs

Contains the entry point for the program. For more information, see .NET Generic Host.

Startup.cs

Contains code that configures app behavior. For more information, see App startup in ASP.NET Core.

Next steps

Advance to the next tutorial in the series:

ADD A MODEL

This is the first tutorial of a series. The series teaches the basics of building an ASP.NET Core Razor Pages web app.

For a more advanced introduction aimed at developers who are familiar with controllers and views, see Introduction to Razor Pages.

At the end of the series, you'll have an app that manages a database of movies.

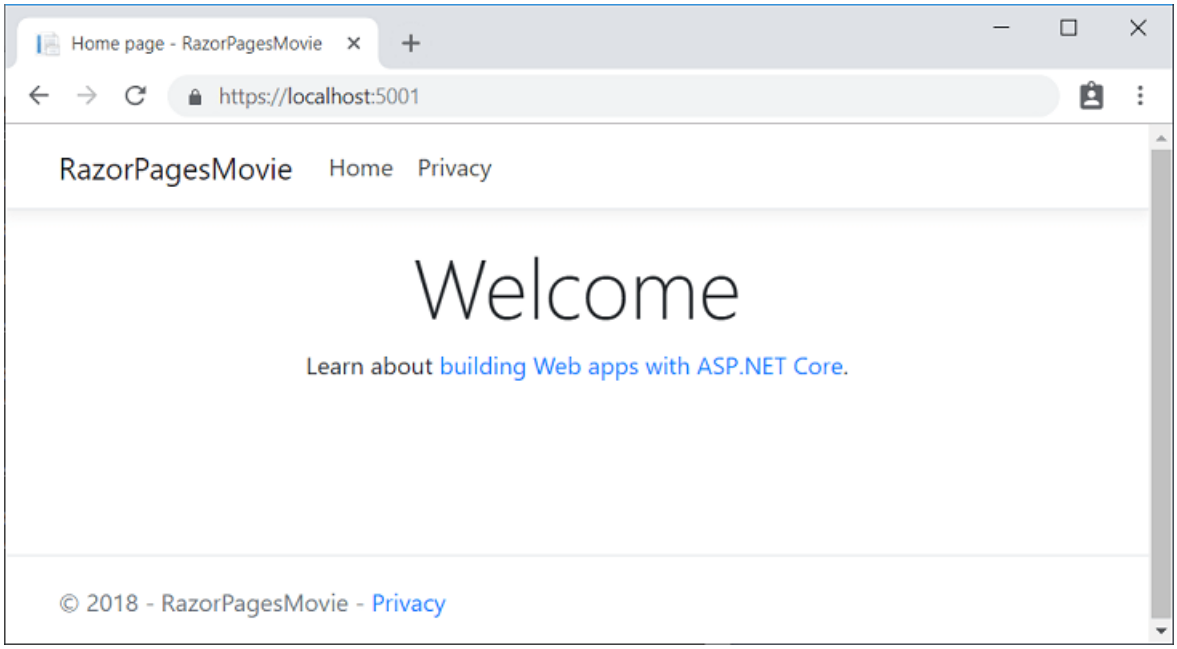
View or download sample code (how to download).

View or download sample code (how to download).

In this tutorial, you:

- Create a Razor Pages web app.
- Run the app.
- Examine the project files.

At the end of this tutorial, you'll have a working Razor Pages web app that you'll build on in later tutorials.



Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

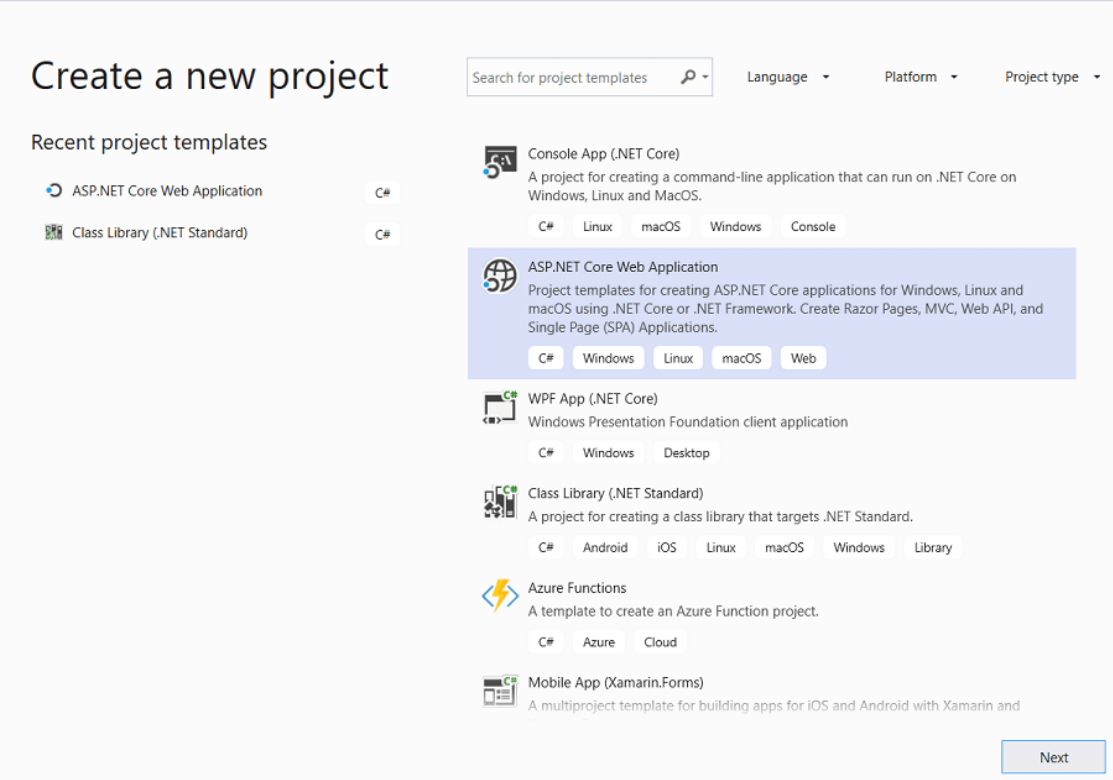
- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core SDK 2.2 or later

> **WARNING**
> If you use Visual Studio 2017, see dotnet/sdk issue #3124 for information about .NET Core SDK versions that don't work with Visual Studio.

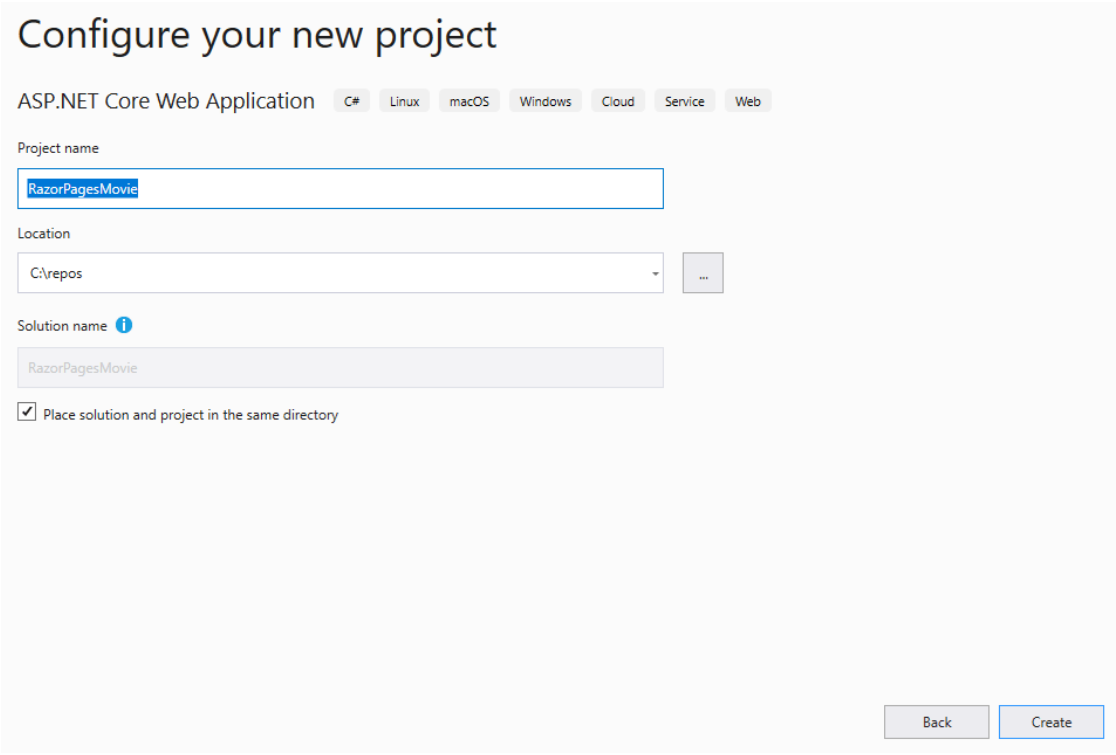
Create a Razor Pages web app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

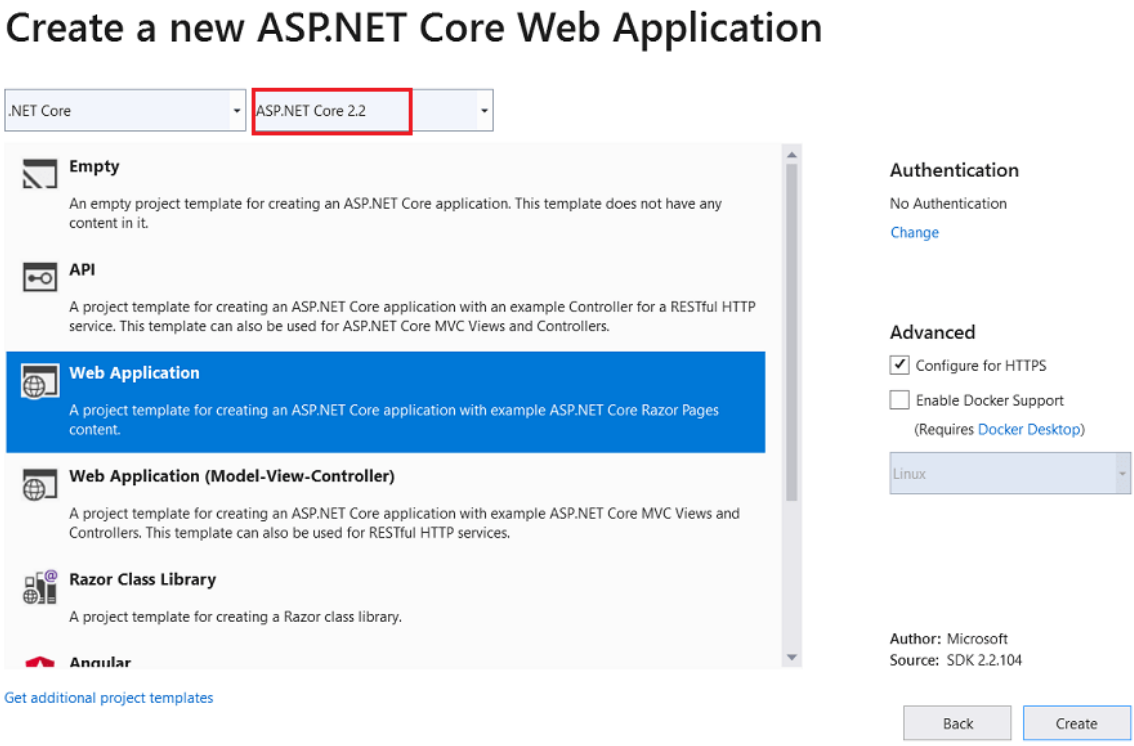
- From the Visual Studio **File** menu, select **New** > **Project**.
- Create a new ASP.NET Core Web Application and select **Next**.



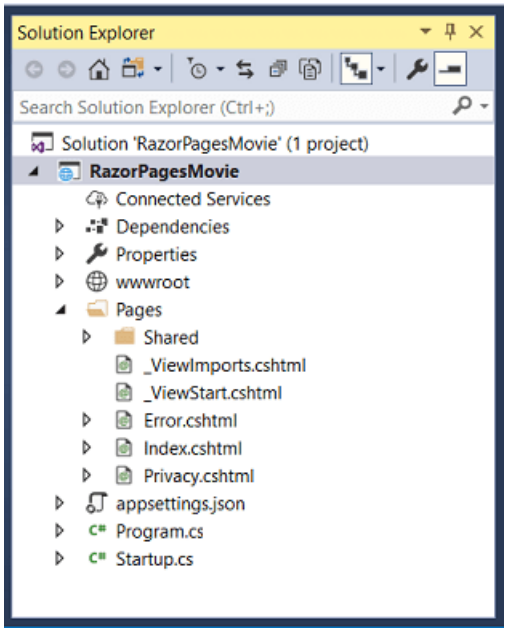
- Name the project **RazorPagesMovie**. It's important to name the project *RazorPagesMovie* so the namespaces will match when you copy and paste code.



- Select **ASP.NET Core 2.2** in the dropdown, **Web Application**, and then select **Create**.



The following starter project is created:



Run the app

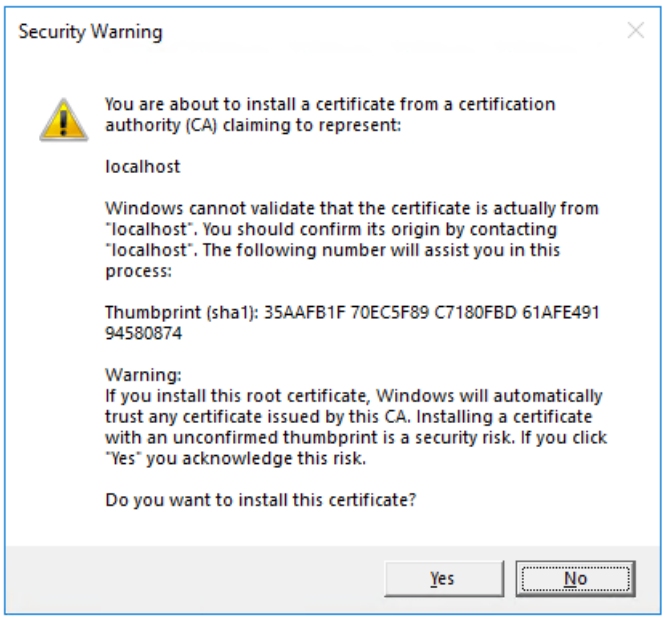
- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Press Ctrl+F5 to run without the debugger.

  Visual Studio displays the following dialog:

  Select **Yes** if you trust the IIS Express SSL certificate.

  The following dialog is displayed:

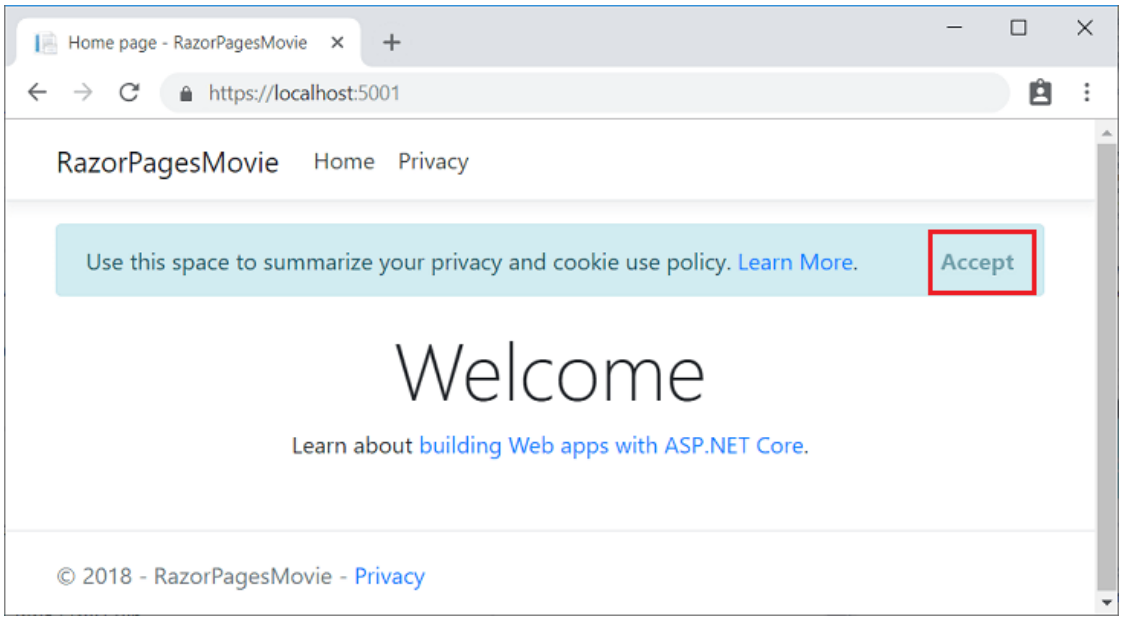


Select **Yes** if you agree to trust the development certificate.

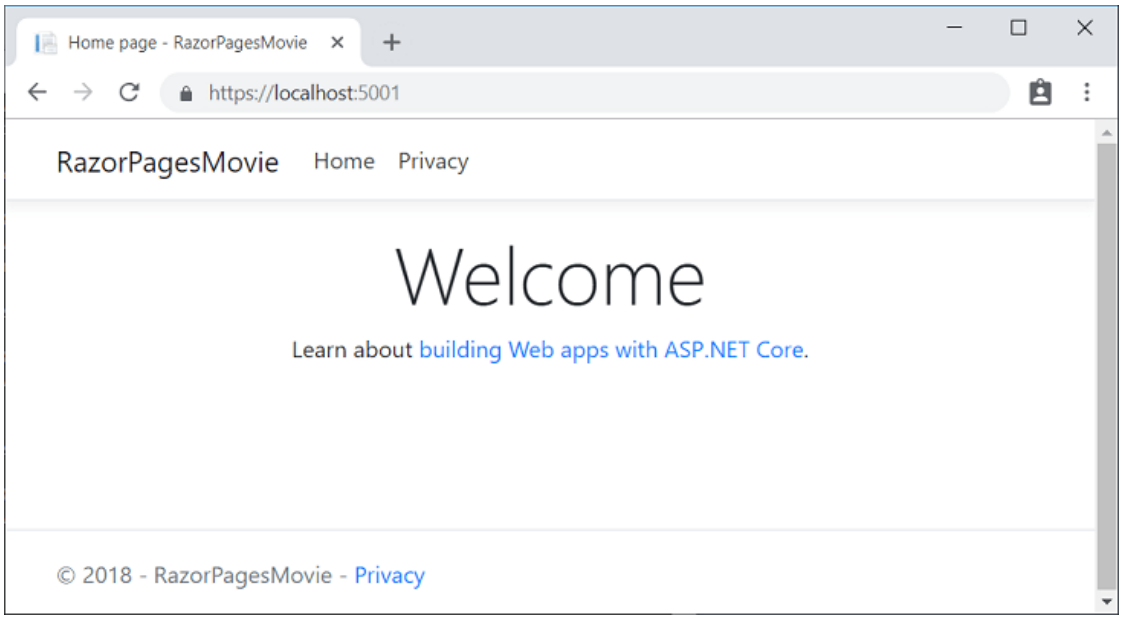
Visual Studio starts IIS Express and runs the app. The address bar shows `localhost:port#` and not something like `example.com`. That's because `localhost` is the standard hostname for the local computer. Localhost only serves web requests from the local computer. When Visual Studio creates a web project, a random port is used for the web server.

- On the app's home page, select **Accept** to consent to tracking.

  This app doesn't track personal information, but the project template includes the consent feature in case you need it to comply with the European Union's General Data Protection Regulation (GDPR).



The following image shows the app after you give consent to tracking:



Examine the project files

Here's an overview of the main project folders and files that you'll work with in later tutorials.

Pages folder

Contains Razor pages and supporting files. Each Razor page is a pair of files:

- A *.cshtml* file that contains HTML markup with C# code using Razor syntax.
- A *.cshtml.cs* file that contains C# code that handles page events.

Supporting files have names that begin with an underscore. For example, the *_Layout.cshtml* file configures UI elements common to all pages. This file sets up the navigation menu at the top of the page and the copyright notice at the bottom of the page. For more information, see Layout in ASP.NET Core.

wwwroot folder

Contains static files, such as HTML files, JavaScript files, and CSS files. For more information, see Static files in ASP.NET Core.

appSettings.json

Contains configuration data, such as connection strings. For more information, see Configuration in ASP.NET Core.

Program.cs

Contains the entry point for the program. For more information, see .NET Generic Host.

Startup.cs

Contains code that configures app behavior, such as whether it requires consent for cookies. For more information, see App startup in ASP.NET Core.

Next steps

Advance to the next tutorial in the series:

ADD A MODEL

Part 2, add a model to a Razor Pages app in ASP.NET Core

9/22/2020 • 22 minutes to read • Edit Online

By Rick Anderson

In this section, classes are added for managing movies. The app's model classes use Entity Framework Core (EF Core) to work with the database. EF Core is an object-relational mapper (O/RM) that simplifies data access.

The model classes are known as POCO classes (from "plain-old CLR objects") because they don't have any dependency on EF Core. They define the properties of the data that are stored in the database.

View or download sample code (how to download).

View or download sample code (how to download).

Add a data model

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Right-click the **RazorPagesMovie** project > **Add** > **New Folder**. Name the folder *Models*.

Right click the *Models* folder. Select **Add** > **Class**. Name the class **Movie**.

Add the following properties to the `Movie` class:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace RazorPagesMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }
        public string Title { get; set; }

        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }
        public decimal Price { get; set; }
    }
}
```

The `Movie` class contains:

- The `ID` field is required by the database for the primary key.
- `[DataType(DataType.Date)]`: The DataType attribute specifies the type of the data (Date). With this attribute:
  - The user is not required to enter time information in the date field.
  - Only the date is displayed, not time information.

DataAnnotations are covered in a later tutorial.

Build the project to verify there are no compilation errors.

Scaffold the movie model

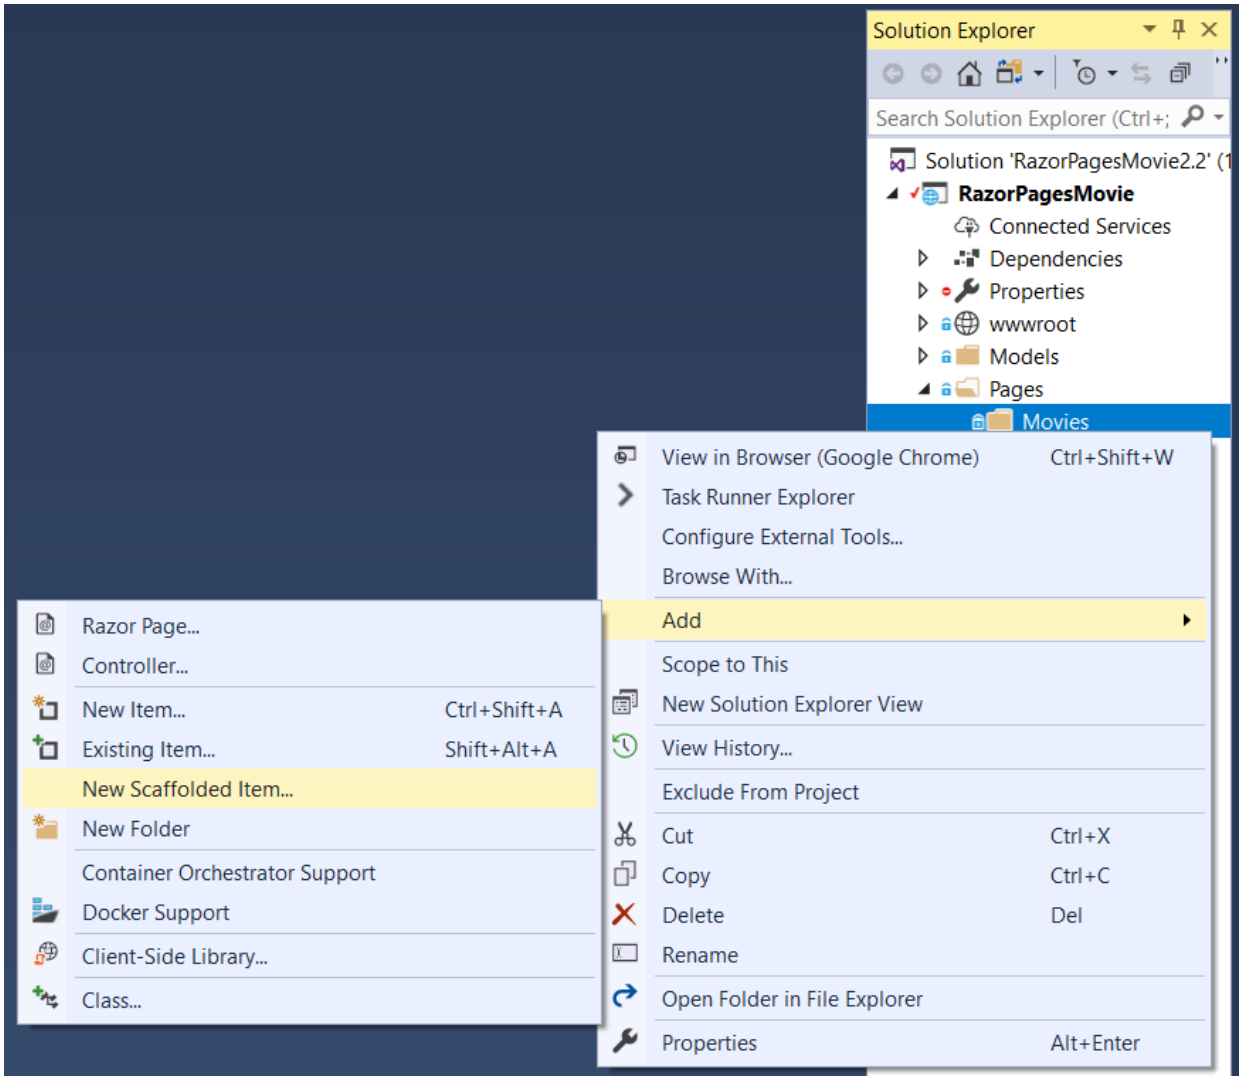
In this section, the movie model is scaffolded. That is, the scaffolding tool produces pages for Create, Read, Update, and Delete (CRUD) operations for the movie model.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

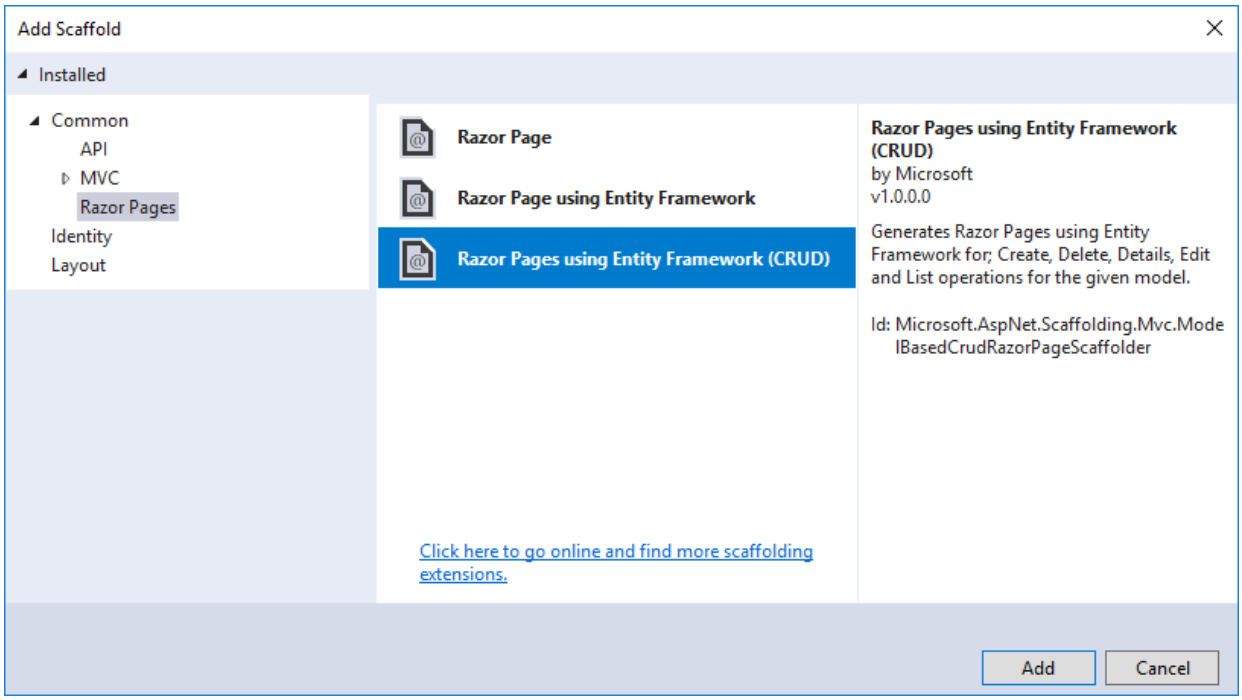
Create a *Pages/Movies* folder:

- Right click on the *Pages* folder > **Add** > **New Folder**.
- Name the folder *Movies*

Right click on the *Pages/Movies* folder > **Add** > **New Scaffolded Item**.

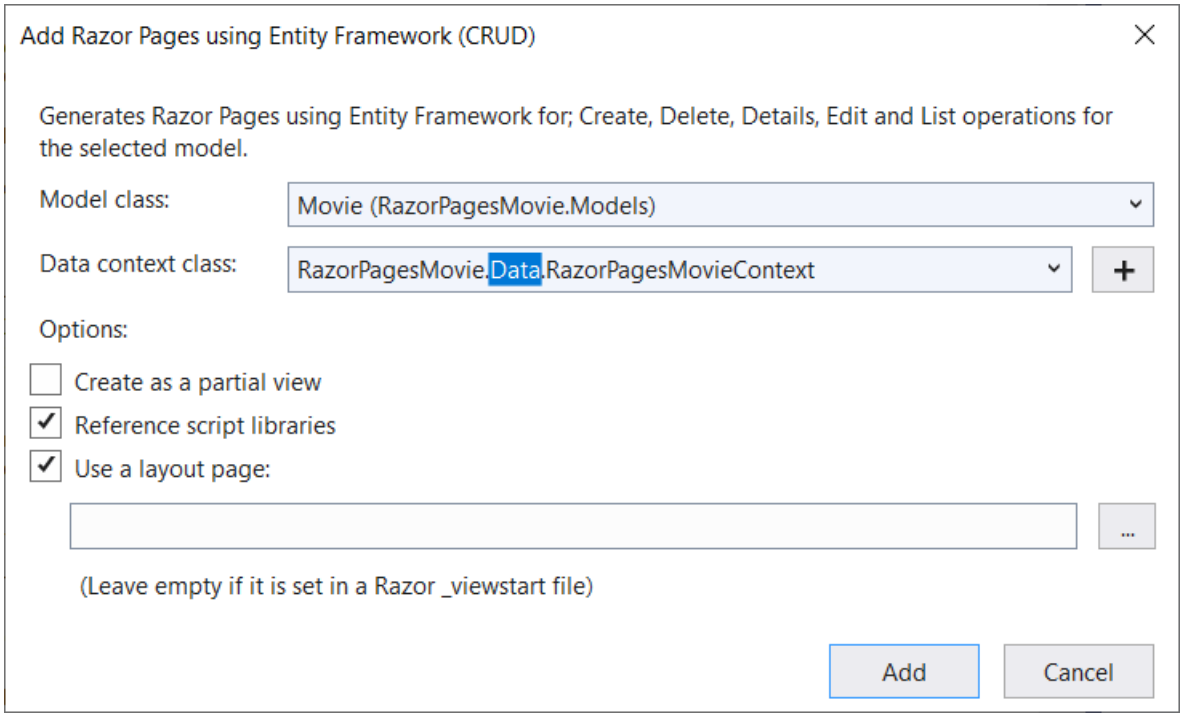


In the **Add Scaffold** dialog, select **Razor Pages using Entity Framework (CRUD)** > **Add**.



Complete the **Add Razor Pages using Entity Framework (CRUD)** dialog:

- In the **Model class** drop down, select **Movie (RazorPagesMovie.Models)**.
- In the **Data context class** row, select the + (plus) sign and change the generated name from RazorPagesMovie.**Models**.RazorPagesMovieContext to RazorPagesMovie.**Data**.RazorPagesMovieContext. This change is not required. It creates the database context class with the correct namespace.
- Select **Add**.



The *appsettings.json* file is updated with the connection string used to connect to a local database.

Files created

- Visual Studio
- Visual Studio for Mac
- Visual Studio Code

The scaffold process creates and updates the following files:

- *Pages/Movies*: Create, Delete, Details, Edit, and Index.
- *Data/RazorPagesMovieContext.cs*

Updated

- *Startup.cs*

The created and updated files are explained in the next section.

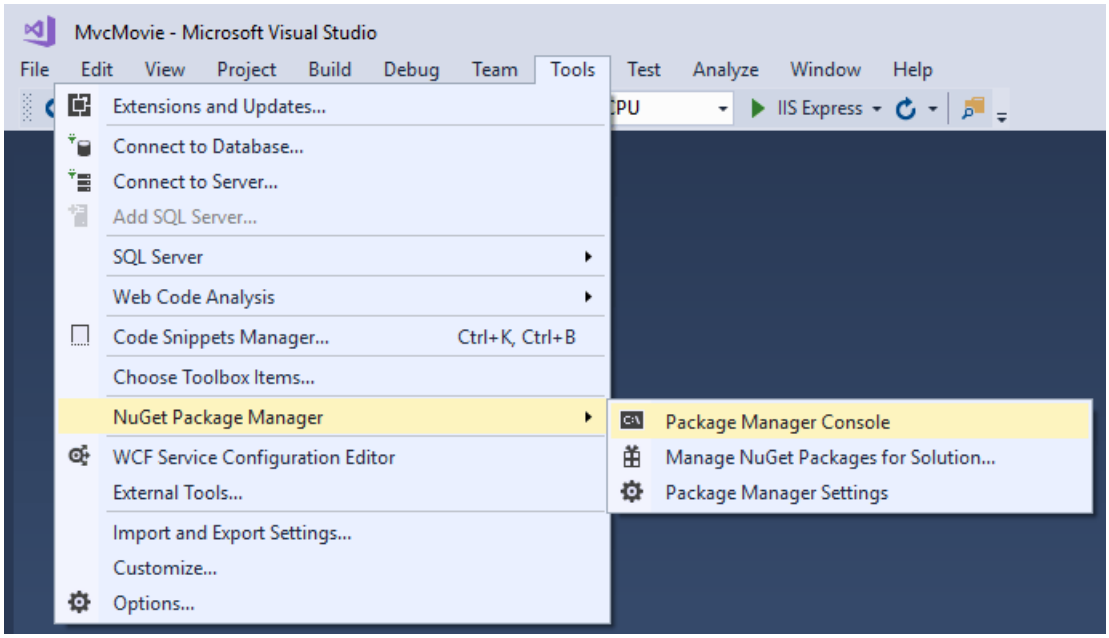
Initial migration

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

In this section, the Package Manager Console (PMC) is used to:

- Add an initial migration.
- Update the database with the initial migration.

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**.



In the PMC, enter the following commands:

```
Add-Migration InitialCreate
Update-Database
```

The preceding commands generate the following warning: "No type was specified for the decimal column 'Price' on entity type 'Movie'. This will cause values to be silently truncated if they do not fit in the default precision and scale. Explicitly specify the SQL server column type that can accommodate all the values using 'HasColumnType()'."

You can ignore that warning, it will be fixed in a later tutorial.

The migrations command generates code to create the initial database schema. The schema is based on the model specified in `DbContext`. The `InitialCreate` argument is used to name the migrations. Any name can be used, but by convention a name is selected that describes the migration.

The `update` command runs the `Up` method in migrations that have not been applied. In this case, `update` runs

the `Up` method in *Migrations/<time-stamp>_InitialCreate.cs* file, which creates the database.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Examine the context registered with dependency injection

ASP.NET Core is built with dependency injection. Services (such as the EF Core DB context) are registered with dependency injection during application startup. Components that require these services (such as Razor Pages) are provided these services via constructor parameters. The constructor code that gets a DB context instance is shown later in the tutorial.

The scaffolding tool automatically created a DB context and registered it with the dependency injection container.

Examine the `Startup.ConfigureServices` method. The highlighted line was added by the scaffolder:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();

    services.AddDbContext<RazorPagesMovieContext>(options =>
      options.UseSqlServer(Configuration.GetConnectionString("RazorPagesMovieContext")));
}
```

The `RazorPagesMovieContext` coordinates EF Core functionality (Create, Read, Update, Delete, etc.) for the `Movie` model. The data context (`RazorPagesMovieContext`) is derived from Microsoft.EntityFrameworkCore.DbContext. The data context specifies which entities are included in the data model.

```
using Microsoft.EntityFrameworkCore;

namespace RazorPagesMovie.Models
{
    public class RazorPagesMovieContext : DbContext
    {
        public RazorPagesMovieContext (DbContextOptions<RazorPagesMovieContext> options)
            : base(options)
        {
        }

        public DbSet<RazorPagesMovie.Models.Movie> Movie { get; set; }
    }
}
```

The preceding code creates a DbSet<Movie> property for the entity set. In Entity Framework terminology, an entity set typically corresponds to a database table. An entity corresponds to a row in the table.

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Test the app

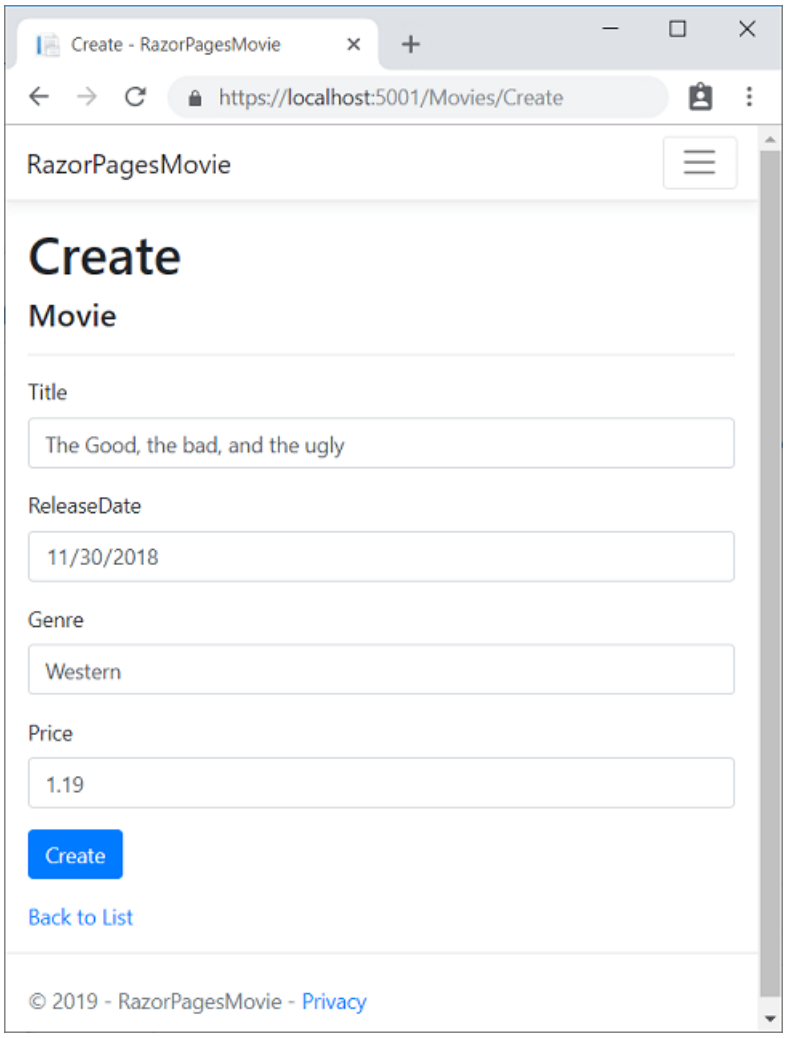
- Run the app and append `/Movies` to the URL in the browser (`http://localhost:port/movies`).

If you get the error:

```
SqlException: Cannot open database "RazorPagesMovieContext-GUID" requested by the login. The login failed.
Login failed for user 'User-name'.
```

You missed the migrations step.

- Test the **Create** link.



> **NOTE**
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point and for non US-English date formats, the app must be globalized. For globalization instructions, see this GitHub issue.

- Test the **Edit**, **Details**, and **Delete** links.

The next tutorial explains the files created by scaffolding.

Additional resources

PREVIOUS: GET STARTED
NEXT: SCAFFOLDED RAZOR PAGES

In this section, classes are added for managing movies in a cross-platform SQLite database. Apps created from an ASP.NET Core template use a SQLite database. The app's model classes are used with Entity Framework Core

(EF Core) (SQLite EF Core Database Provider) to work with the database. EF Core is an object-relational mapping (ORM) framework that simplifies data access.

The model classes are known as POCO classes (from "plain-old CLR objects") because they don't have any dependency on EF Core. They define the properties of the data that are stored in the database.

View or download sample code (how to download).

View or download sample code (how to download).

Add a data model

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Right-click the **RazorPagesMovie** project > **Add** > **New Folder**. Name the folder *Models*.

Right click the *Models* folder. Select **Add** > **Class**. Name the class **Movie**.

Add the following properties to the `Movie` class:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace RazorPagesMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }
        public string Title { get; set; }

        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }
        public decimal Price { get; set; }
    }
}
```

The `Movie` class contains:

- The `ID` field is required by the database for the primary key.
- `[DataType(DataType.Date)]`: The DataType attribute specifies the type of the data (Date). With this attribute:
  - The user is not required to enter time information in the date field.
  - Only the date is displayed, not time information.

DataAnnotations are covered in a later tutorial.

Build the project to verify there are no compilation errors.

Scaffold the movie model

In this section, the movie model is scaffolded. That is, the scaffolding tool produces pages for Create, Read, Update, and Delete (CRUD) operations for the movie model.

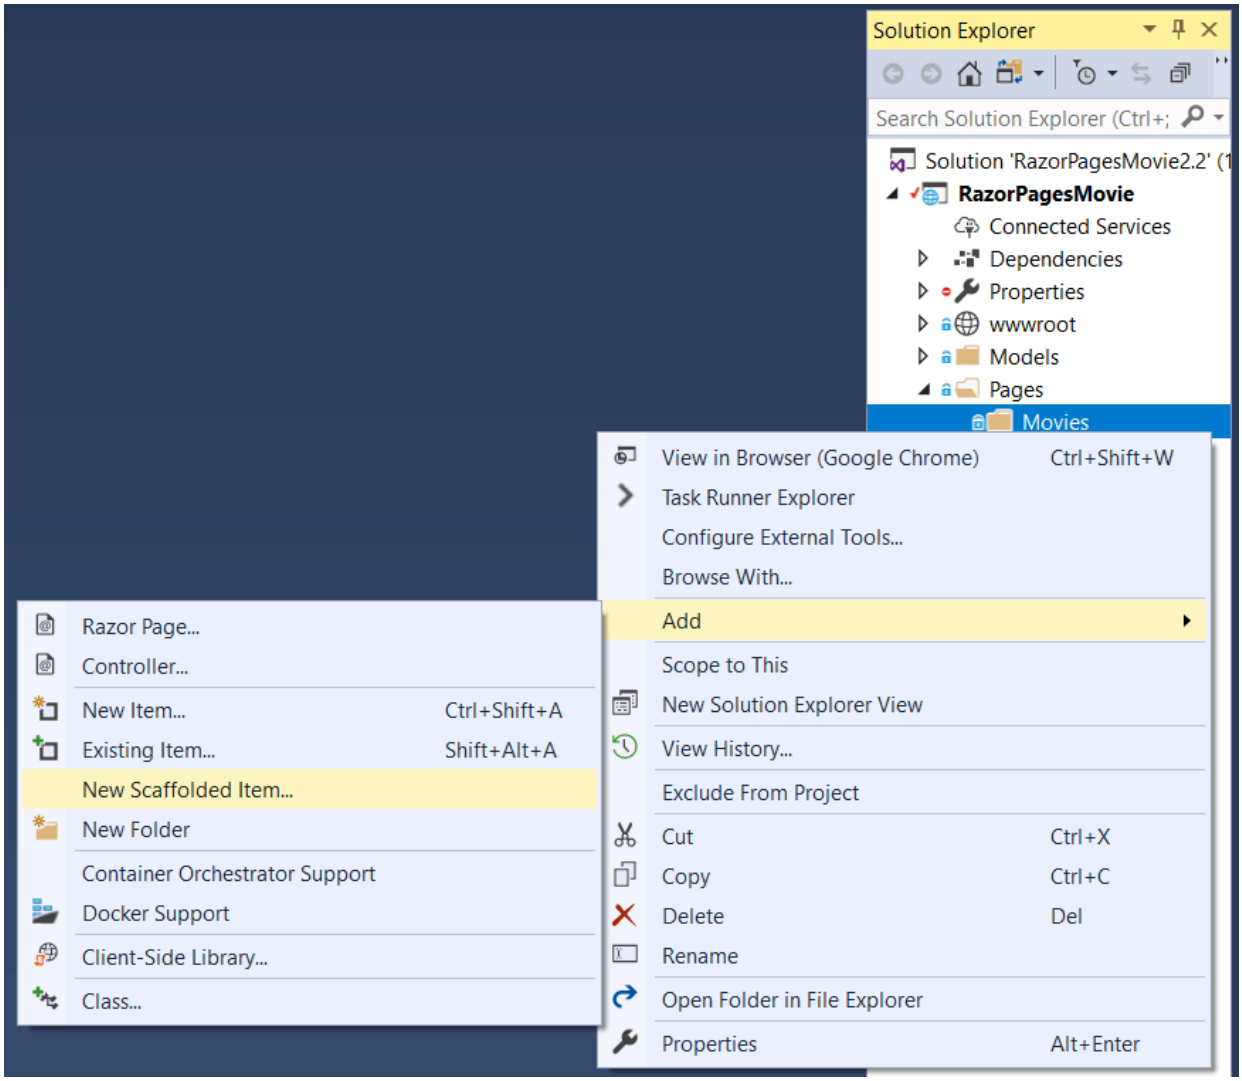
- Visual Studio
- Visual Studio Code

- Visual Studio for Mac

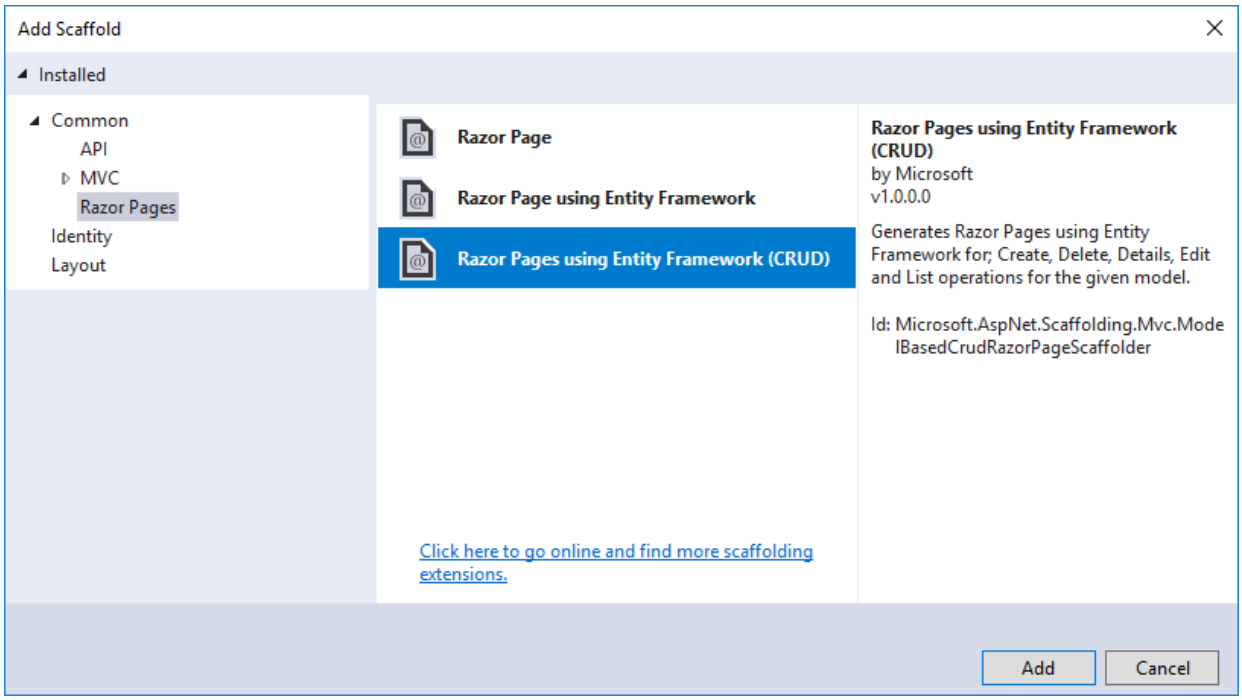
Create a *Pages/Movies* folder:

- Right click on the *Pages* folder > **Add** > **New Folder**.
- Name the folder *Movies*

Right click on the *Pages/Movies* folder > **Add** > **New Scaffolded Item**.

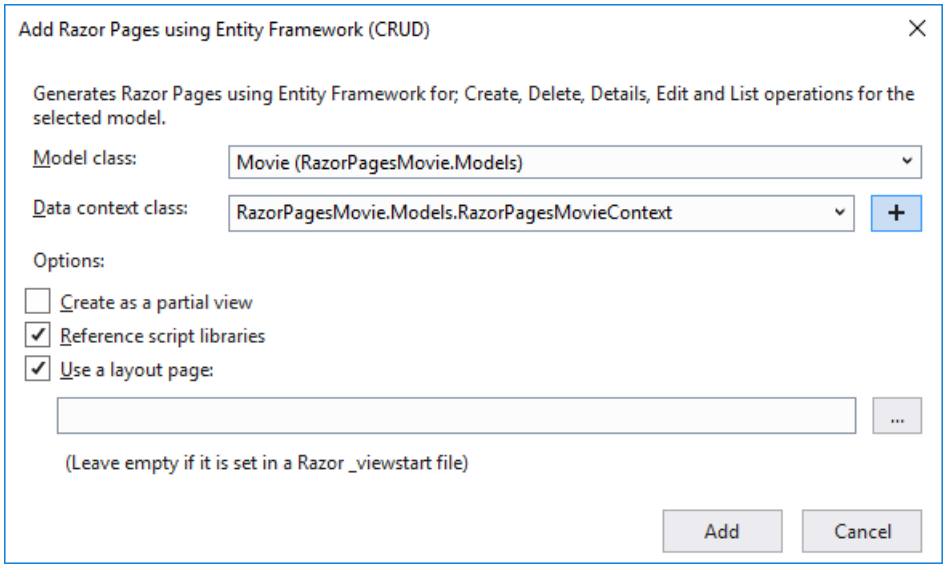


In the **Add Scaffold** dialog, select **Razor Pages using Entity Framework (CRUD)** > **Add**.



Complete the **Add Razor Pages using Entity Framework (CRUD)** dialog:

- In the **Model class** drop down, select **Movie (RazorPagesMovie.Models)**.
- In the **Data context class** row, select the **+** (plus) sign and accept the generated name **RazorPagesMovie.Models.RazorPagesMovieContext**.
- Select **Add**.



The *appsettings.json* file is updated with the connection string used to connect to a local database.

The scaffold process creates and updates the following files:

Files created

- *Pages/Movies*: Create, Delete, Details, Edit, and Index.
- *Data/RazorPagesMovieContext.cs*

File updated

- *Startup.cs*

The created and updated files are explained in the next section.

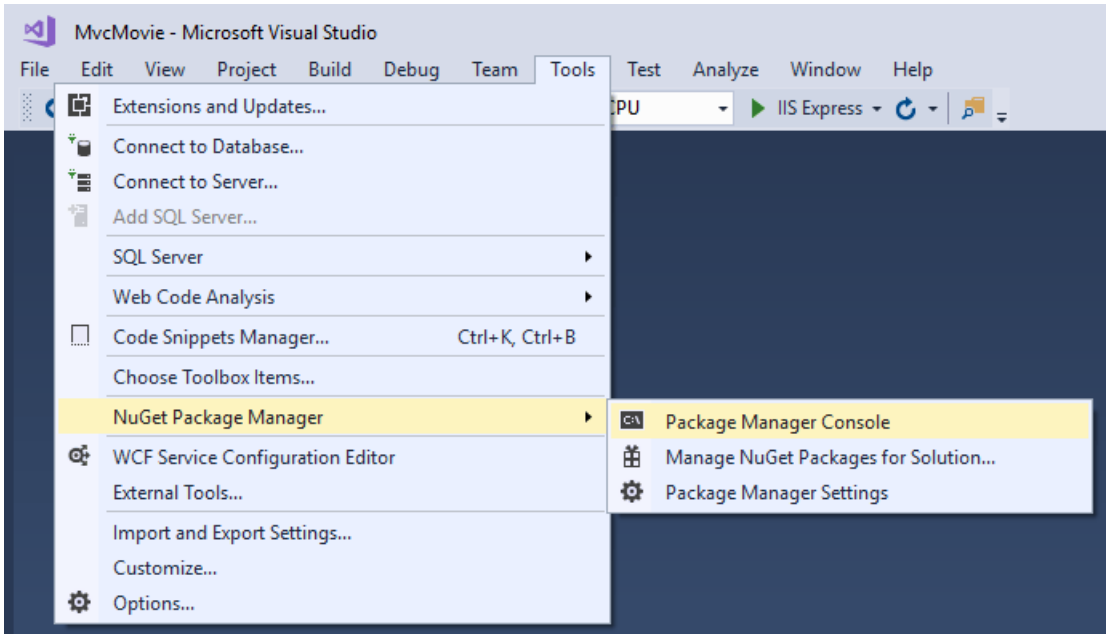
Initial migration

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

In this section, the Package Manager Console (PMC) is used to:

- Add an initial migration.
- Update the database with the initial migration.

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**.



In the PMC, enter the following commands:

```
Add-Migration Initial
Update-Database
```

The `Add-Migration` command generates code to create the initial database schema. The schema is based on the model specified in the `DbContext` (In the *RazorPagesMovieContext.cs* file). The `InitialCreate` argument is used to name the migration. Any name can be used, but by convention a name that describes the migration is used. For more information, see Tutorial: Using the migrations feature - ASP.NET MVC with EF Core.

The `Update-Database` command runs the `Up` method in the *Migrations/<time-stamp>_InitialCreate.cs* file. The `Up` method creates the database.

> **NOTE**
>
> The preceding commands generate the following warning: "*No type was specified for the decimal column 'Price' on entity type 'Movie'. This will cause values to be silently truncated if they do not fit in the default precision and scale. Explicitly specify the SQL server column type that can accommodate all the values using 'HasColumnType()'.*" You can ignore that warning, it will be fixed in a later tutorial.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Examine the context registered with dependency injection

ASP.NET Core is built with dependency injection. Services (such as the EF Core DB context) are registered with dependency injection during application startup. Components that require these services (such as Razor Pages) are provided these services via constructor parameters. The constructor code that gets a DB context instance is shown later in the tutorial.

The scaffolding tool automatically created a DB context and registered it with the dependency injection container.

Examine the `Startup.ConfigureServices` method. The highlighted line was added by the scaffolder:

```
// This method gets called by the runtime.
// Use this method to add services to the container.
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        // This lambda determines whether user consent for non-essential cookies is
        // needed for a given request.
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    services.AddDbContext<RazorPagesMovieContext>(options =>
      options.UseSqlServer(
          Configuration.GetConnectionString("RazorPagesMovieContext")));
}
```

The `RazorPagesMovieContext` coordinates EF Core functionality (Create, Read, Update, Delete, etc.) for the `Movie` model. The data context (`RazorPagesMovieContext`) is derived from Microsoft.EntityFrameworkCore.DbContext. The data context specifies which entities are included in the data model.

```
using Microsoft.EntityFrameworkCore;

namespace RazorPagesMovie.Models
{
    public class RazorPagesMovieContext : DbContext
    {
        public RazorPagesMovieContext (DbContextOptions<RazorPagesMovieContext> options)
            : base(options)
        {
        }

        public DbSet<RazorPagesMovie.Models.Movie> Movie { get; set; }
    }
}
```

The preceding code creates a DbSet<Movie> property for the entity set. In Entity Framework terminology, an entity set typically corresponds to a database table. An entity corresponds to a row in the table.

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Test the app

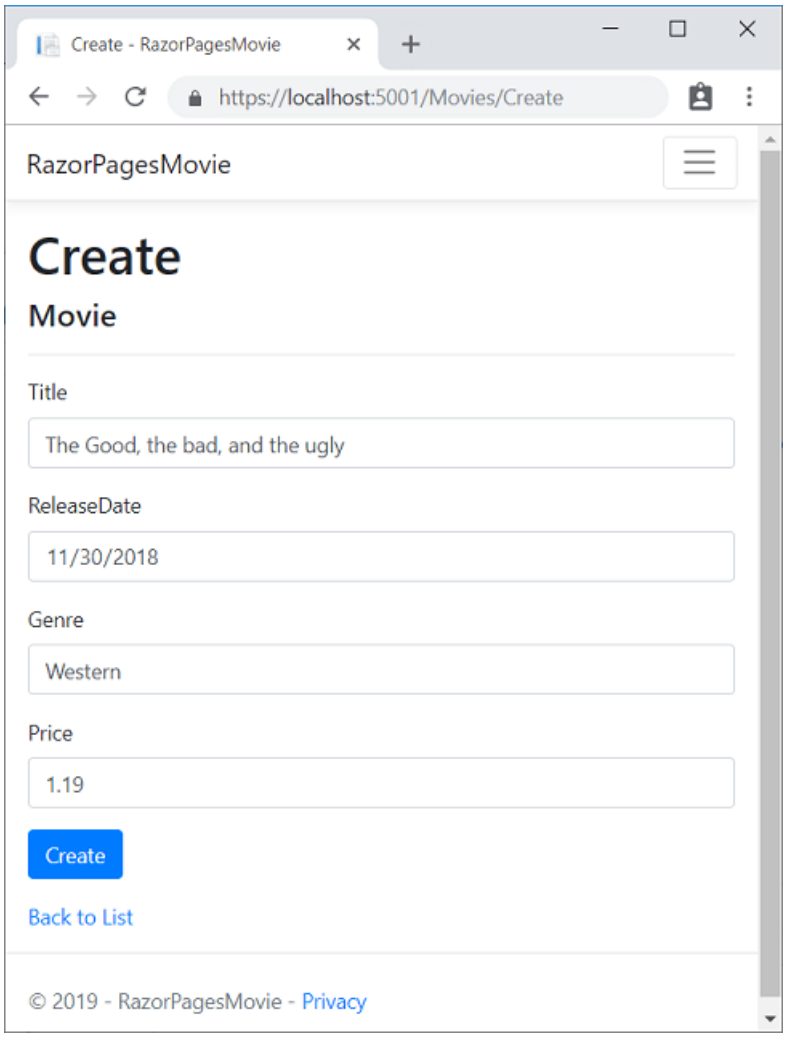
- Run the app and append `/Movies` to the URL in the browser (`http://localhost:port/movies`).

If you get the error:

```
SqlException: Cannot open database "RazorPagesMovieContext-GUID" requested by the login. The login failed.
Login failed for user 'User-name'.
```

You missed the migrations step.

- Test the **Create** link.



> **NOTE**
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point and for non US-English date formats, the app must be globalized. For globalization instructions, see this GitHub issue.

- Test the **Edit**, **Details**, and **Delete** links.

The next tutorial explains the files created by scaffolding.

Part 3, scaffolded Razor Pages in ASP.NET Core

9/22/2020 • 16 minutes to read • Edit Online

By Rick Anderson

This tutorial examines the Razor Pages created by scaffolding in the previous tutorial.

View or download sample code (how to download).

View or download sample code (how to download).

The Create, Delete, Details, and Edit pages

Examine the *Pages/Movies/Index.cshtml.cs* Page Model:

```
// Unused usings removed.
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using RazorPagesMovie.Models;
using System.Collections.Generic;
using System.Threading.Tasks;

namespace RazorPagesMovie.Pages.Movies
{
    public class IndexModel : PageModel
    {
        private readonly RazorPagesMovie.Data.RazorPagesMovieContext _context;

        public IndexModel(RazorPagesMovie.Data.RazorPagesMovieContext context)
        {
            _context = context;
        }

        public IList<Movie> Movie { get;set; }

        public async Task OnGetAsync()
        {
            Movie = await _context.Movie.ToListAsync();
        }
    }
}
```

Razor Pages are derived from `PageModel`. By convention, the `PageModel`-derived class is called `<PageName>Model`. The constructor uses dependency injection to add the `RazorPagesMovieContext` to the page. All the scaffolded pages follow this pattern. See Asynchronous code for more information on asynchronous programming with Entity Framework.

When a request is made for the page, the `OnGetAsync` method returns a list of movies to the Razor Page. `OnGetAsync` or `OnGet` is called to initialize the state of the page. In this case, `OnGetAsync` gets a list of movies and displays them.

When `OnGet` returns `void` or `OnGetAsync` returns `Task`, no return statement is used. When the return type is `IActionResult` or `Task<IActionResult>`, a return statement must be provided. For example, the *Pages/Movies/Create.cshtml.cs* `OnPostAsync` method:

```
    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _context.Movie.Add(Movie);
        await _context.SaveChangesAsync();

        return RedirectToPage("./Index");
    }
}
```

Examine the *Pages/Movies/Index.cshtml* Razor Page:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model.Movie) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Razor can transition from HTML into C# or into Razor-specific markup. When an `@` symbol is followed by a Razor reserved keyword, it transitions into Razor-specific markup, otherwise it transitions into C#.

The @page directive

The `@page` Razor directive makes the file an MVC action, which means that it can handle requests. `@page` must be the first Razor directive on a page. `@page` is an example of transitioning into Razor-specific markup. See Razor syntax for more information.

Examine the lambda expression used in the following HTML Helper:

```
@Html.DisplayNameFor(model => model.Movie[0].Title)
```

The `DisplayNameFor` HTML Helper inspects the `Title` property referenced in the lambda expression to determine the display name. The lambda expression is inspected rather than evaluated. That means there is no access violation when `model`, `model.Movie`, or `model.Movie[0]` is `null` or empty. When the lambda expression is evaluated (for example, with `@Html.DisplayFor(modelItem => item.Title)`), the model's property values are evaluated.

The @model directive

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel
```

The `@model` directive specifies the type of the model passed to the Razor Page. In the preceding example, the `@model` line makes the `PageModel`-derived class available to the Razor Page. The model is used in the `@Html.DisplayNameFor` and `@Html.DisplayFor` HTML Helpers on the page.

The layout page

Select the menu links (**RazorPagesMovie**, **Home**, and **Privacy**). Each page shows the same menu layout. The menu layout is implemented in the *Pages/Shared/_Layout.cshtml* file. Open the *Pages/Shared/_Layout.cshtml* file.

Layout templates allow the HTML container layout to be:

- Specified in one place.
- Applied in multiple pages in the site.

Find the `@RenderBody()` line. `RenderBody` is a placeholder where all the page-specific views show up, *wrapped* in the layout page. For example, select the **Privacy** link and the *Pages/Privacy.cshtml* view is rendered inside the `RenderBody` method.

ViewData and layout

Consider the following markup from the *Pages/Movies/Index.cshtml* file:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}
```

The preceding highlighted markup is an example of Razor transitioning into C#. The `{` and `}` characters enclose a block of C# code.

The `PageModel` base class contains a `ViewData` dictionary property that can be used to pass data to a View. Objects are added to the `ViewData` dictionary using a key/value pattern. In the preceding sample, the `"Title"` property is added to the `ViewData` dictionary.

The `"Title"` property is used in the *Pages/Shared/_Layout.cshtml* file. The following markup shows the first few lines of the *_Layout.cshtml* file.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - RazorPagesMovie</title>

    @*Markup removed for brevity.*@
```

The line `@*Markup removed for brevity.*@` is a Razor comment. Unlike HTML comments (`<!-- -->`), Razor comments are not sent to the client.

Update the layout

Change the `<title>` element in the *Pages/Shared/_Layout.cshtml* file to display **Movie** rather than **RazorPagesMovie**.

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Movie</title>
```

Find the following anchor element in the *Pages/Shared/_Layout.cshtml* file.

```
<a class="navbar-brand" asp-area="" asp-page="/Index">RazorPagesMovie</a>
```

Replace the preceding element with the following markup:

```
<a class="navbar-brand" asp-page="/Movies/Index">RpMovie</a>
```

The preceding anchor element is a Tag Helper. In this case, it's the Anchor Tag Helper. The `asp-page="/Movies/Index"` Tag Helper attribute and value creates a link to the `/Movies/Index` Razor Page. The `asp-area` attribute value is empty, so the area isn't used in the link. See Areas for more information.

Save your changes, and test the app by clicking on the **RpMovie** link. See the _Layout.cshtml file in GitHub if you have any problems.

Test the other links (**Home**, **RpMovie**, **Create**, **Edit**, and **Delete**). Each page sets the title, which you can see in the browser tab. When you bookmark a page, the title is used for the bookmark.

> **NOTE**
>
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. See this GitHub issue 4076 for instructions on adding decimal comma.

The `Layout` property is set in the *Pages/_ViewStart.cshtml* file:

```
@{
    Layout = "_Layout";
}
```

The preceding markup sets the layout file to *Pages/Shared/_Layout.cshtml* for all Razor files under the *Pages*

folder. See Layout for more information.

The Create page model

Examine the *Pages/Movies/Create.cshtml.cs* page model:

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using RazorPagesMovie.Models;
using System;
using System.Threading.Tasks;

namespace RazorPagesMovie.Pages.Movies
{
    public class CreateModel : PageModel
    {
        private readonly RazorPagesMovie.Data.RazorPagesMovieContext _context;

        public CreateModel(RazorPagesMovie.Data.RazorPagesMovieContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            return Page();
        }

        [BindProperty]
        public Movie Movie { get; set; }

        public async Task<IActionResult> OnPostAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            _context.Movie.Add(Movie);
            await _context.SaveChangesAsync();

            return RedirectToPage("./Index");
        }
    }
}
```

The `OnGet` method initializes any state needed for the page. The Create page doesn't have any state to initialize, so `Page` is returned. Later in the tutorial, an example of `OnGet` initializing state is shown. The `Page` method creates a `PageResult` object that renders the *Create.cshtml* page.

The `Movie` property uses the `[BindProperty]` attribute to opt-in to model binding. When the Create form posts the form values, the ASP.NET Core runtime binds the posted values to the `Movie` model.

The `OnPostAsync` method is run when the page posts form data:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Movie.Add(Movie);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

If there are any model errors, the form is redisplayed, along with any form data posted. Most model errors can be caught on the client-side before the form is posted. An example of a model error is posting a value for the date field that cannot be converted to a date. Client-side validation and model validation are discussed later in the tutorial.

If there are no model errors, the data is saved, and the browser is redirected to the Index page.

The Create Razor Page

Examine the *Pages/Movies/Create.cshtml* Razor Page file:

```
@page
@model RazorPagesMovie.Pages.Movies.CreateModel

@{
    ViewData["Title"] = "Create";
}

<h1>Create</h1>

<h4>Movie</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Movie.Title" class="control-label"></label>
                <input asp-for="Movie.Title" class="form-control" />
                <span asp-validation-for="Movie.Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.ReleaseDate" class="control-label"></label>
                <input asp-for="Movie.ReleaseDate" class="form-control" />
                <span asp-validation-for="Movie.ReleaseDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.Genre" class="control-label"></label>
                <input asp-for="Movie.Genre" class="form-control" />
                <span asp-validation-for="Movie.Genre" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.Price" class="control-label"></label>
                <input asp-for="Movie.Price" class="form-control" />
                <span asp-validation-for="Movie.Price" class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

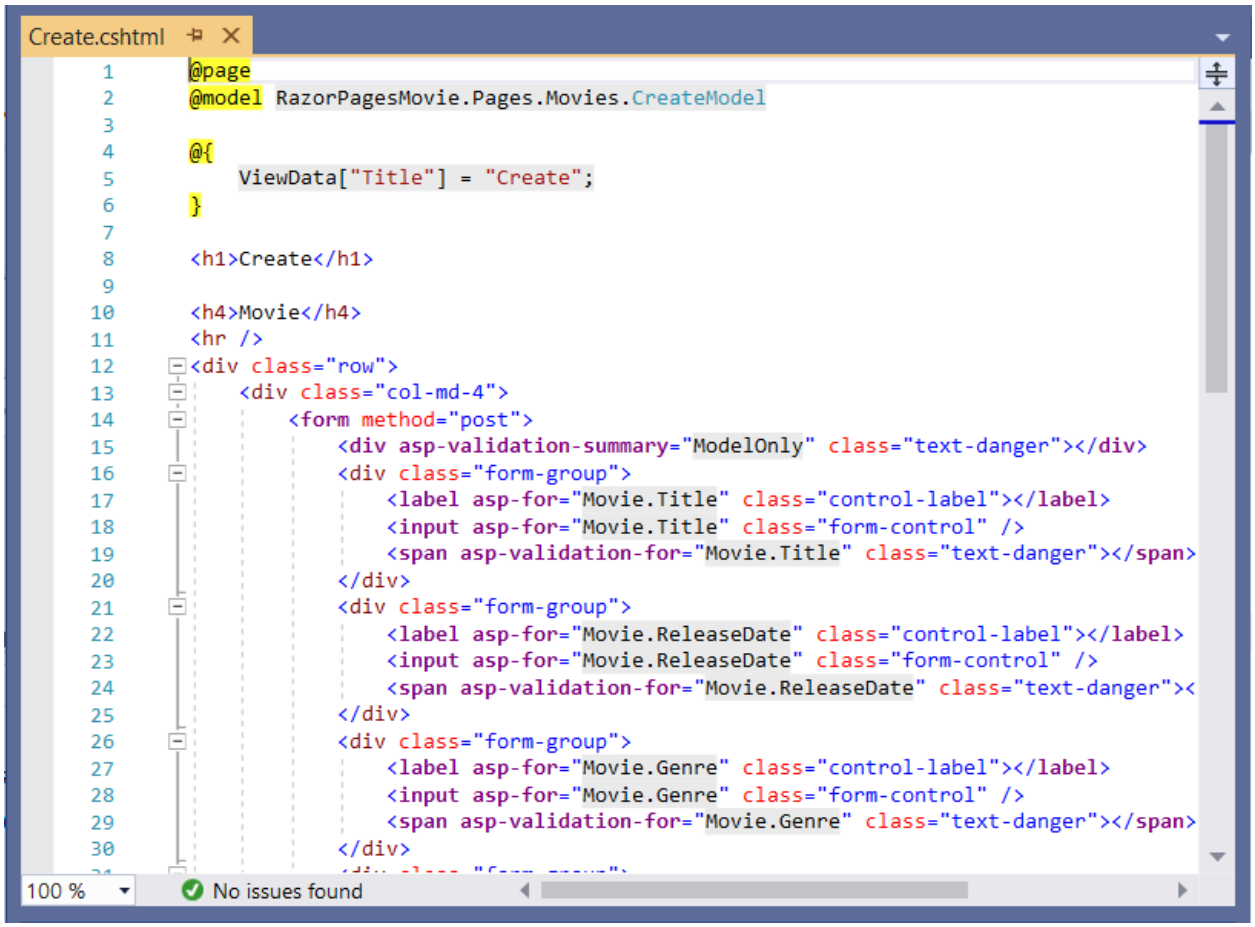
<div>
    <a asp-page="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Visual Studio displays the following tags in a distinctive bold font used for Tag Helpers:

- `<form method="post">`
- `<div asp-validation-summary="ModelOnly" class="text-danger"></div>`
- `<label asp-for="Movie.Title" class="control-label"></label>`
- `<input asp-for="Movie.Title" class="form-control" />`
- `<span asp-validation-for="Movie.Title" class="text-danger"></span>`



The `<form method="post">` element is a Form Tag Helper. The Form Tag Helper automatically includes an antiforgery token.

The scaffolding engine creates Razor markup for each field in the model (except the ID) similar to the following:

```
<div asp-validation-summary="ModelOnly" class="text-danger"></div>
<div class="form-group">
    <label asp-for="Movie.Title" class="control-label"></label>
    <input asp-for="Movie.Title" class="form-control" />
    <span asp-validation-for="Movie.Title" class="text-danger"></span>
</div>
```

The Validation Tag Helpers (`<div asp-validation-summary` and `<span asp-validation-for`) display validation errors. Validation is covered in more detail later in this series.

The Label Tag Helper (`<label asp-for="Movie.Title" class="control-label"></label>`) generates the label caption and `for` attribute for the `Title` property.

The Input Tag Helper (`<input asp-for="Movie.Title" class="form-control">`) uses the DataAnnotations attributes and produces HTML attributes needed for jQuery Validation on the client-side.

For more information on Tag Helpers such as `<form method="post">`, see Tag Helpers in ASP.NET Core.

Additional resources

PREVIOUS: ADDING A MODEL
NEXT: DATABASE

By Rick Anderson

This tutorial examines the Razor Pages created by scaffolding in the previous tutorial.

View or download sample.

The Create, Delete, Details, and Edit pages

Examine the *Pages/Movies/Index.cshtml.cs* Page Model:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using RazorPagesMovie.Models;

namespace RazorPagesMovie.Pages.Movies
{
    public class IndexModel : PageModel
    {
        private readonly RazorPagesMovie.Models.RazorPagesMovieContext _context;

        public IndexModel(RazorPagesMovie.Models.RazorPagesMovieContext context)
        {
            _context = context;
        }

        public IList<Movie> Movie { get;set; }

        public async Task OnGetAsync()
        {
            Movie = await _context.Movie.ToListAsync();
        }
    }
}
```

Razor Pages are derived from `PageModel`. By convention, the `PageModel`-derived class is called `<PageName>Model`. The constructor uses dependency injection to add the `RazorPagesMovieContext` to the page. All the scaffolded pages follow this pattern. See Asynchronous code for more information on asynchronous programming with Entity Framework.

When a request is made for the page, the `OnGetAsync` method returns a list of movies to the Razor Page. `OnGetAsync` or `OnGet` is called on a Razor Page to initialize the state for the page. In this case, `OnGetAsync` gets a list of movies and displays them.

When `OnGet` returns `void` or `OnGetAsync` returns `Task`, no return method is used. When the return type is `IActionResult` or `Task<IActionResult>`, a return statement must be provided. For example, the *Pages/Movies/Create.cshtml.cs* `OnPostAsync` method:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Movie.Add(Movie);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

Examine the *Pages/Movies/Index.cshtml* Razor Page:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model.Movie) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Razor can transition from HTML into C# or into Razor-specific markup. When an `@` symbol is followed by a Razor reserved keyword, it transitions into Razor-specific markup, otherwise it transitions into C#.

The `@page` Razor directive makes the file into an MVC action, which means that it can handle requests. `@page` must be the first Razor directive on a page. `@page` is an example of transitioning into Razor-specific markup. See Razor syntax for more information.

Examine the lambda expression used in the following HTML Helper:

```
@Html.DisplayNameFor(model => model.Movie[0].Title)
```

The `DisplayNameFor` HTML Helper inspects the `Title` property referenced in the lambda expression to determine the display name. The lambda expression is inspected rather than evaluated. That means there is no access violation when `model`, `model.Movie`, or `model.Movie[0]` are `null` or empty. When the lambda expression is evaluated (for example, with `@Html.DisplayFor(modelItem => item.Title)`), the model's property values are evaluated.

The @model directive

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel
```

The `@model` directive specifies the type of the model passed to the Razor Page. In the preceding example, the `@model` line makes the `PageModel`-derived class available to the Razor Page. The model is used in the `@Html.DisplayNameFor` and `@Html.DisplayFor` HTML Helpers on the page.

The layout page

Select the menu links (**RazorPagesMovie**, **Home**, and **Privacy**). Each page shows the same menu layout. The menu layout is implemented in the *Pages/Shared/_Layout.cshtml* file. Open the *Pages/Shared/_Layout.cshtml* file.

Layout templates allow you to specify the HTML container layout of your site in one place and then apply it across multiple pages in your site. Find the `@RenderBody()` line. `RenderBody` is a placeholder where all the page-specific views you create show up, *wrapped* in the layout page. For example, if you select the **Privacy** link, the **Pages/Privacy.cshtml** view is rendered inside the `RenderBody` method.

ViewData and layout

Consider the following code from the *Pages/Movies/Index.cshtml* file:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}
```

The preceding highlighted code is an example of Razor transitioning into C#. The `{` and `}` characters enclose a block of C# code.

The `PageModel` base class has a `ViewData` dictionary property that can be used to add data that you want to pass to a View. You add objects into the `ViewData` dictionary using a key/value pattern. In the preceding sample, the "Title" property is added to the `ViewData` dictionary.

The "Title" property is used in the *Pages/Shared/_Layout.cshtml* file. The following markup shows the first few lines of the *_Layout.cshtml* file.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - RazorPagesMovie</title>

    @*Markup removed for brevity.*@
```

The line `@*Markup removed for brevity.*@` is a Razor comment which doesn't appear in your layout file. Unlike HTML comments (`<!-- -->`), Razor comments are not sent to the client.

Update the layout

Change the `<title>` element in the *Pages/Shared/_Layout.cshtml* file to display **Movie** rather than **RazorPagesMovie**.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Movie</title>
```

Find the following anchor element in the *Pages/Shared/_Layout.cshtml* file.

```
<a class="navbar-brand" asp-area="" asp-page="/Index">RazorPagesMovie</a>
```

Replace the preceding element with the following markup.

```
<a class="navbar-brand" asp-page="/Movies/Index">RpMovie</a>
```

The preceding anchor element is a Tag Helper. In this case, it's the Anchor Tag Helper. The `asp-page="/Movies/Index"` Tag Helper attribute and value creates a link to the `/Movies/Index` Razor Page. The `asp-area` attribute value is empty, so the area isn't used in the link. See Areas for more information.

Save your changes, and test the app by clicking on the **RpMovie** link. See the _Layout.cshtml file in GitHub if you have any problems.

Test the other links (**Home**, **RpMovie**, **Create**, **Edit**, and **Delete**). Each page sets the title, which you can see in the browser tab. When you bookmark a page, the title is used for the bookmark.

> **NOTE**
>
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. This GitHub issue 4076 for instructions on adding decimal comma.

The `Layout` property is set in the *Pages/_ViewStart.cshtml* file:

```
@{
    Layout = "_Layout";
}
```

The preceding markup sets the layout file to *Pages/Shared/_Layout.cshtml* for all Razor files under the *Pages*

folder. See Layout for more information.

The Create page model

Examine the *Pages/Movies/Create.cshtml.cs* page model:

```
// Unused usings removed.
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using RazorPagesMovie.Models;
using System;
using System.Threading.Tasks;

namespace RazorPagesMovie.Pages.Movies
{
    public class CreateModel : PageModel
    {
        private readonly RazorPagesMovie.Models.RazorPagesMovieContext _context;

        public CreateModel(RazorPagesMovie.Models.RazorPagesMovieContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            return Page();
        }

        [BindProperty]
        public Movie Movie { get; set; }

        public async Task<IActionResult> OnPostAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            _context.Movie.Add(Movie);
            await _context.SaveChangesAsync();

            return RedirectToPage("./Index");
        }
    }
}
```

The `OnGet` method initializes any state needed for the page. The Create page doesn't have any state to initialize, so `Page` is returned. Later in the tutorial you see `OnGet` method initialize state. The `Page` method creates a `PageResult` object that renders the *Create.cshtml* page.

The `Movie` property uses the `[BindProperty]` attribute to opt-in to model binding. When the Create form posts the form values, the ASP.NET Core runtime binds the posted values to the `Movie` model.

The `OnPostAsync` method is run when the page posts form data:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Movie.Add(Movie);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

If there are any model errors, the form is redisplayed, along with any form data posted. Most model errors can be caught on the client-side before the form is posted. An example of a model error is posting a value for the date field that cannot be converted to a date. Client-side validation and model validation are discussed later in the tutorial.

If there are no model errors, the data is saved, and the browser is redirected to the Index page.

The Create Razor Page

Examine the *Pages/Movies/Create.cshtml* Razor Page file:

```
@page
@model RazorPagesMovie.Pages.Movies.CreateModel

@{
    ViewData["Title"] = "Create";
}

<h1>Create</h1>

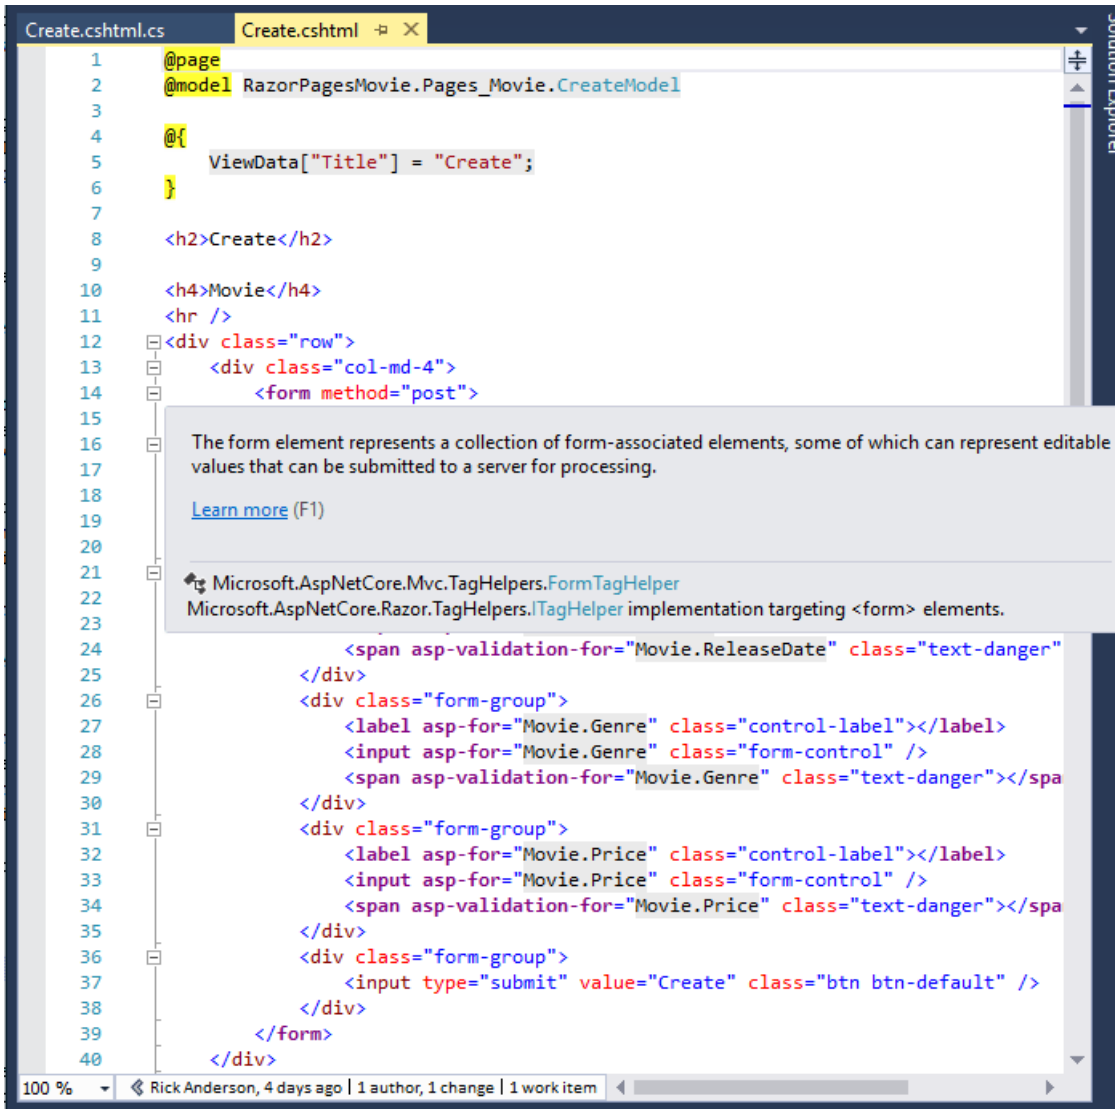
<h4>Movie</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Movie.Title" class="control-label"></label>
                <input asp-for="Movie.Title" class="form-control" />
                <span asp-validation-for="Movie.Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.ReleaseDate" class="control-label"></label>
                <input asp-for="Movie.ReleaseDate" class="form-control" />
                <span asp-validation-for="Movie.ReleaseDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.Genre" class="control-label"></label>
                <input asp-for="Movie.Genre" class="form-control" />
                <span asp-validation-for="Movie.Genre" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.Price" class="control-label"></label>
                <input asp-for="Movie.Price" class="form-control" />
                <span asp-validation-for="Movie.Price" class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Visual Studio displays the `<form method="post">` tag in a distinctive bold font used for Tag Helpers:



The `<form method="post">` element is a Form Tag Helper. The Form Tag Helper automatically includes an antiforgery token.

The scaffolding engine creates Razor markup for each field in the model (except the ID) similar to the following:

```
<div asp-validation-summary="ModelOnly" class="text-danger"></div>
<div class="form-group">
    <label asp-for="Movie.Title" class="control-label"></label>
    <input asp-for="Movie.Title" class="form-control" />
    <span asp-validation-for="Movie.Title" class="text-danger"></span>
</div>
```

The Validation Tag Helpers (`<div asp-validation-summary` and `<span asp-validation-for`) display validation errors. Validation is covered in more detail later in this series.

The Label Tag Helper (`<label asp-for="Movie.Title" class="control-label"></label>`) generates the label caption and `for` attribute for the `Title` property.

The Input Tag Helper (`<input asp-for="Movie.Title" class="form-control">`) uses the DataAnnotations attributes and produces HTML attributes needed for jQuery Validation on the client-side.

PREVIOUS: ADDING A MODEL

NEXT: DATABASE

Part 4, with a database and ASP.NET Core

9/22/2020 • 12 minutes to read • Edit Online

By Rick Anderson and Joe Audette

View or download sample code (how to download).

View or download sample code (how to download).

The `RazorPagesMovieContext` object handles the task of connecting to the database and mapping `Movie` objects to database records. The database context is registered with the Dependency Injection container in the `ConfigureServices` method in *Startup.cs*:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();

    services.AddDbContext<RazorPagesMovieContext>(options =>
      options.UseSqlServer(Configuration.GetConnectionString("RazorPagesMovieContext")));
}
```

The ASP.NET Core Configuration system reads the `ConnectionString`. For local development, it gets the connection string from the *appsettings.json* file.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

The name value for the database (`Database={Database name}`) will be different for your generated code. The name value is arbitrary.

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "RazorPagesMovieContext": "Server=(localdb)\\mssqllocaldb;Database=RazorPagesMovieContext-
bc;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

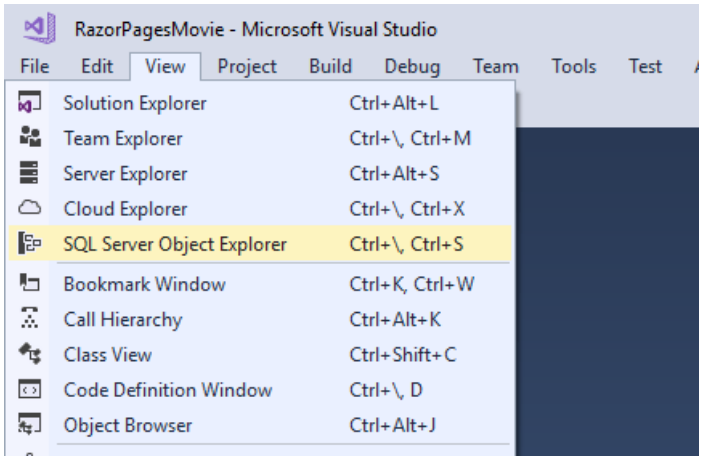
When the app is deployed to a test or production server, an environment variable can be used to set the connection string to a real database server. See Configuration for more information.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

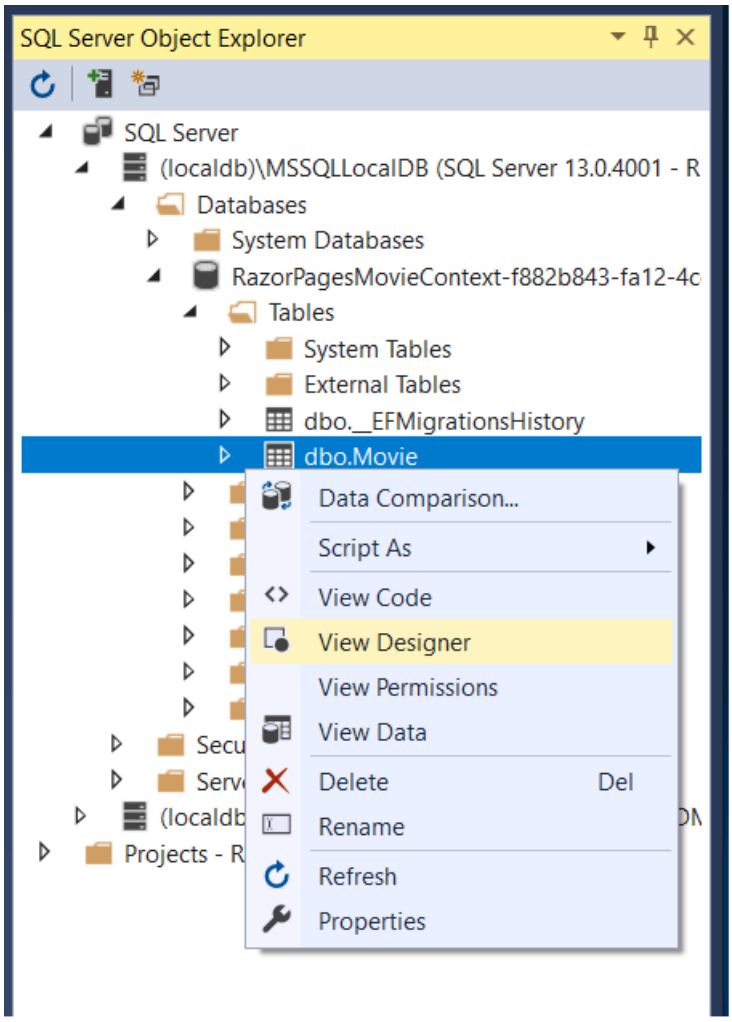
SQL Server Express LocalDB

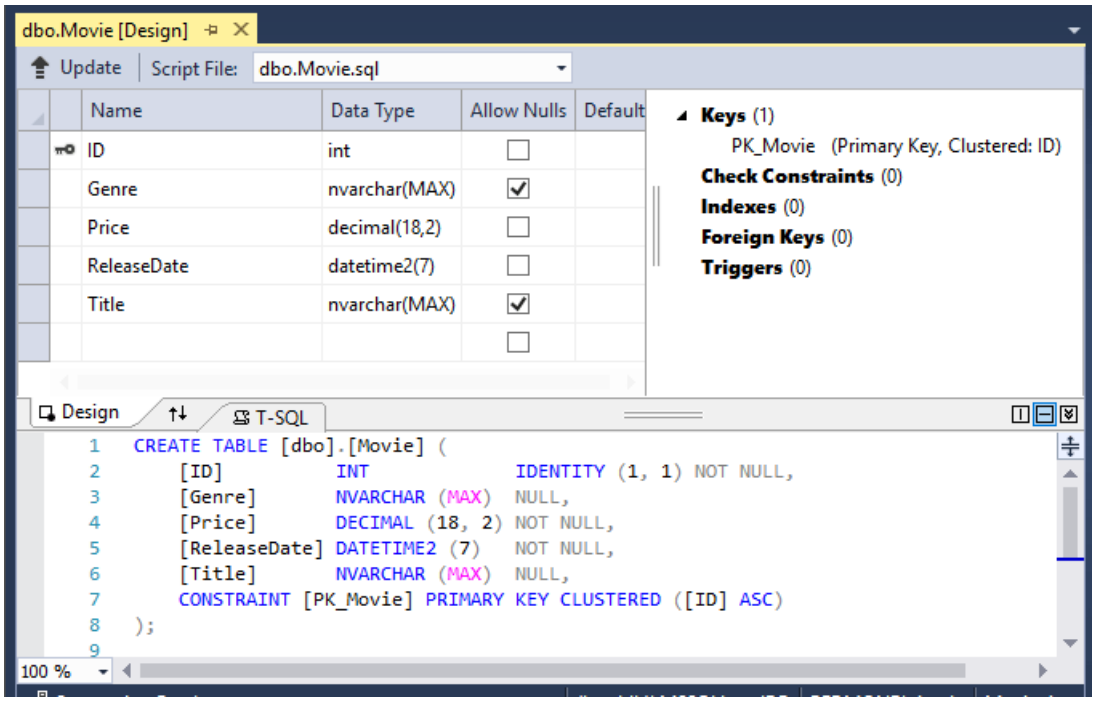
LocalDB is a lightweight version of the SQL Server Express database engine that's targeted for program development. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB database creates `*.mdf` files in the `C:\Users\<user>\` directory.

- From the **View** menu, open **SQL Server Object Explorer** (SSOX).



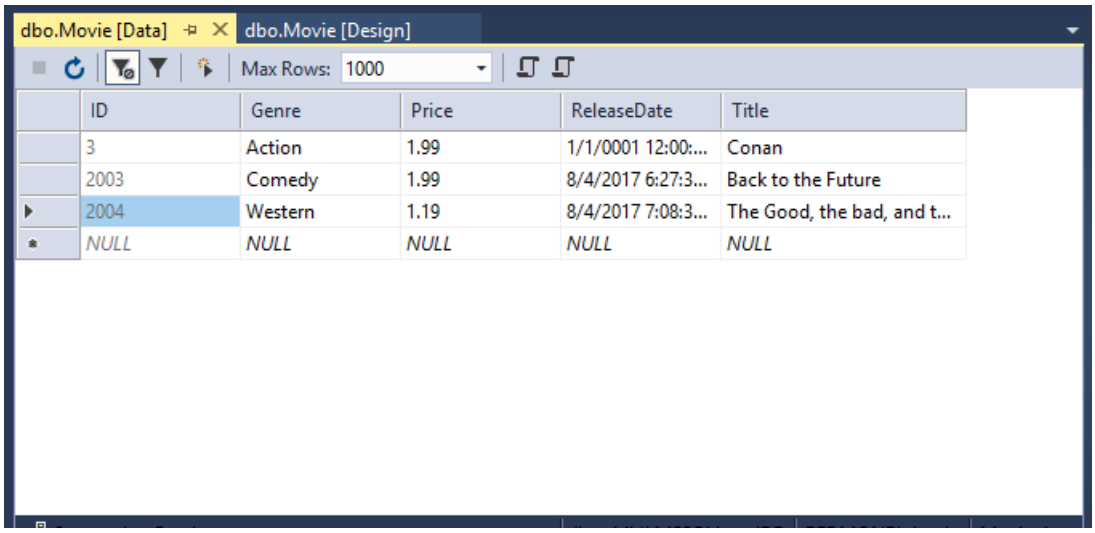
- Right click on the `Movie` table and select **View Designer**:





Note the key icon next to `ID`. By default, EF creates a property named `ID` for the primary key.

- Right click on the `Movie` table and select **View Data**:



Seed the database

Create a new class named `SeedData` in the *Models* folder with the following code:

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using RazorPagesMovie.Data;
using System;
using System.Linq;

namespace RazorPagesMovie.Models
{
    public static class SeedData
    {
        public static void Initialize(IServiceProvider serviceProvider)
        {
            using (var context = new RazorPagesMovieContext(
                serviceProvider.GetRequiredService<
                    DbContextOptions<RazorPagesMovieContext>>()))
            {
                // Look for any movies.
                if (context.Movie.Any())
                {
                    return;   // DB has been seeded
                }

                context.Movie.AddRange(
                    new Movie
                    {
                        Title = "When Harry Met Sally",
                        ReleaseDate = DateTime.Parse("1989-2-12"),
                        Genre = "Romantic Comedy",
                        Price = 7.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters ",
                        ReleaseDate = DateTime.Parse("1984-3-13"),
                        Genre = "Comedy",
                        Price = 8.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters 2",
                        ReleaseDate = DateTime.Parse("1986-2-23"),
                        Genre = "Comedy",
                        Price = 9.99M
                    },

                    new Movie
                    {
                        Title = "Rio Bravo",
                        ReleaseDate = DateTime.Parse("1959-4-15"),
                        Genre = "Western",
                        Price = 3.99M
                    }
                );
                context.SaveChanges();
            }
        }
    }
}
```

If there are any movies in the DB, the seed initializer returns and no movies are added.

```
if (context.Movie.Any())
{
    return;   // DB has been seeded.
}
```

Add the seed initializer

In *Program.cs*, modify the `Main` method to do the following:

- Get a DB context instance from the dependency injection container.
- Call the seed method, passing to it the context.
- Dispose the context when the seed method completes.

The following code shows the updated *Program.cs* file.

```
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
using RazorPagesMovie.Models;
using System;

namespace RazorPagesMovie
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateHostBuilder(args).Build();

            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    SeedData.Initialize(services);
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred seeding the DB.");
                }
            }

            host.Run();

        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureWebHostDefaults(webBuilder =>
                {
                    webBuilder.UseStartup<Startup>();
                });
    }
}
```

The following exception occurs when `Update-Database` has not been run:

```
SqlException: Cannot open database "RazorPagesMovieContext-" requested by the login. The login failed.
Login failed for user 'user name'.
```

Test the app

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Delete all the records in the DB. You can do this with the delete links in the browser or from SSOX
- Force the app to initialize (call the methods in the `Startup` class) so the seed method runs. To force initialization, IIS Express must be stopped and restarted. You can do this with any of the following approaches:
  - Right click the IIS Express system tray icon in the notification area and tap **Exit** or **Stop Site**:

  - If you were running VS in non-debug mode, press F5 to run in debug mode.
  - If you were running VS in debug mode, stop the debugger and press F5.

The next tutorial will improve the presentation of the data.

The `RazorPagesMovieContext` object handles the task of connecting to the database and mapping `Movie` objects to database records. The database context is registered with the Dependency Injection container in the `ConfigureServices` method in *Startup.cs*:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
// This method gets called by the runtime.
// Use this method to add services to the container.
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        // This lambda determines whether user consent for non-essential cookies is
        // needed for a given request.
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    services.AddDbContext<RazorPagesMovieContext>(options =>
      options.UseSqlServer(
          Configuration.GetConnectionString("RazorPagesMovieContext")));
}
```

For more information on the methods used in `ConfigureServices`, see:

- EU General Data Protection Regulation (GDPR) support in ASP.NET Core for `CookiePolicyOptions`.
- SetCompatibilityVersion

The ASP.NET Core Configuration system reads the `ConnectionString`. For local development, it gets the connection string from the *appsettings.json* file.

- Visual Studio

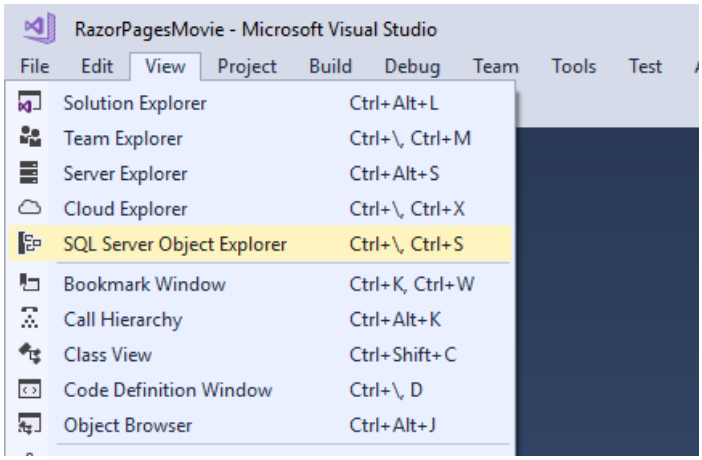
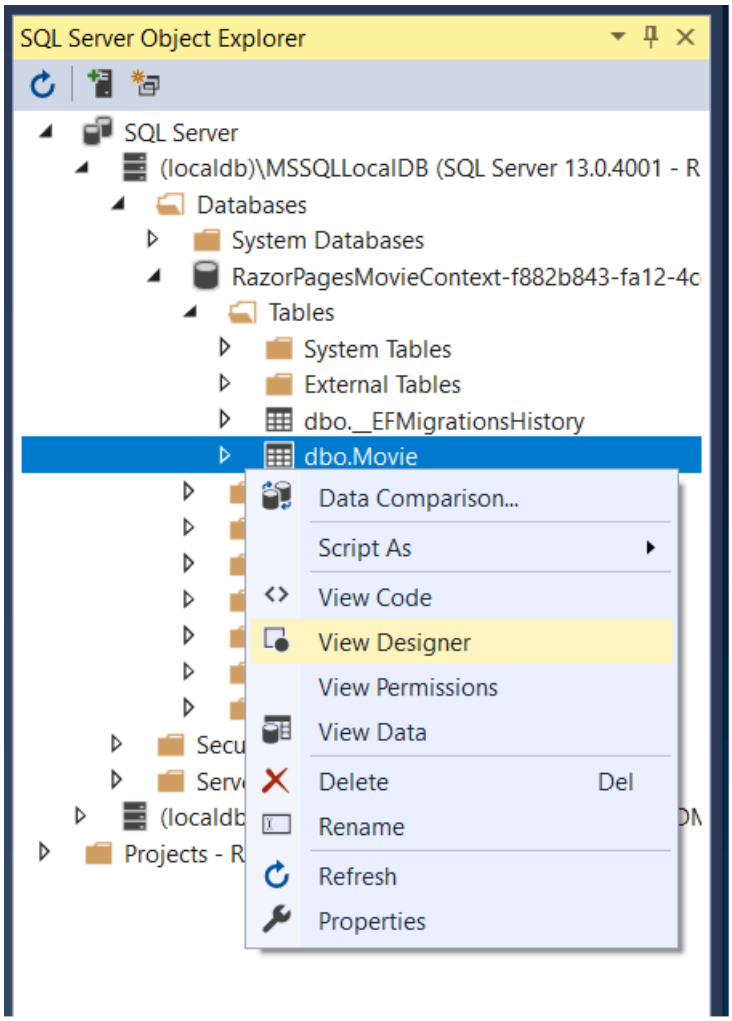
SQL Server Express LocalDB

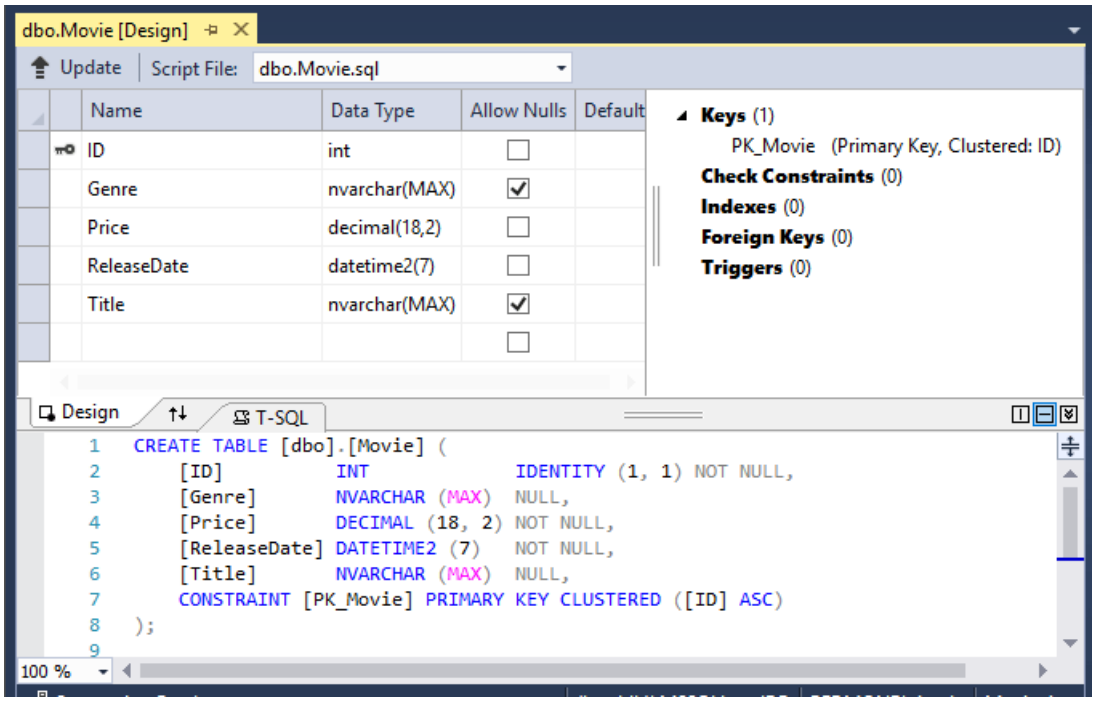
LocalDB is a lightweight version of the SQL Server Express database engine that's targeted for program development. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB database creates `*.mdf` files in the `C:/Users/<user/>` directory.

- From the **View** menu, open **SQL Server Object Explorer** (SSOX).



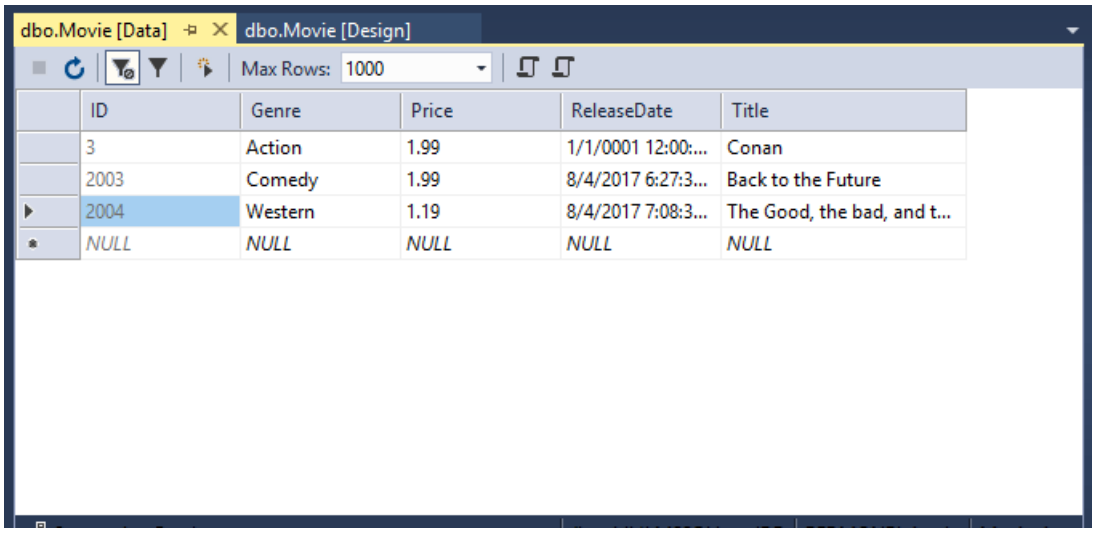
- Right click on the `Movie` table and select **View Designer**:





Note the key icon next to `ID`. By default, EF creates a property named `ID` for the primary key.

- Right click on the `Movie` table and select **View Data**:



Seed the database

Create a new class named `SeedData` in the *Models* folder with the following code:

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using System;
using System.Linq;

namespace RazorPagesMovie.Models
{
    public static class SeedData
    {
        public static void Initialize(IServiceProvider serviceProvider)
        {
            using (var context = new RazorPagesMovieContext(
                serviceProvider.GetRequiredService<
                    DbContextOptions<RazorPagesMovieContext>>()))
            {
                // Look for any movies.
                if (context.Movie.Any())
                {
                    return;   // DB has been seeded
                }

                context.Movie.AddRange(
                    new Movie
                    {
                        Title = "When Harry Met Sally",
                        ReleaseDate = DateTime.Parse("1989-2-12"),
                        Genre = "Romantic Comedy",
                        Price = 7.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters ",
                        ReleaseDate = DateTime.Parse("1984-3-13"),
                        Genre = "Comedy",
                        Price = 8.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters 2",
                        ReleaseDate = DateTime.Parse("1986-2-23"),
                        Genre = "Comedy",
                        Price = 9.99M
                    },

                    new Movie
                    {
                        Title = "Rio Bravo",
                        ReleaseDate = DateTime.Parse("1959-4-15"),
                        Genre = "Western",
                        Price = 3.99M
                    }
                );
                context.SaveChanges();
            }
        }
    }
}
```

If there are any movies in the DB, the seed initializer returns and no movies are added.

```
if (context.Movie.Any())
{
    return;   // DB has been seeded.
}
```

Add the seed initializer

In *Program.cs*, modify the `Main` method to do the following:

- Get a DB context instance from the dependency injection container.
- Call the seed method, passing to it the context.
- Dispose the context when the seed method completes.

The following code shows the updated *Program.cs* file.

```
using Microsoft.AspNetCore;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Logging;
using RazorPagesMovie.Models;
using System;
using Microsoft.EntityFrameworkCore;

namespace RazorPagesMovie
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateWebHostBuilder(args).Build();

            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    var context=services.
                        GetRequiredService<RazorPagesMovieContext>();
                    context.Database.Migrate();
                    SeedData.Initialize(services);
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred seeding the DB.");
                }
            }

            host.Run();
        }

        public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>();
    }
}
```

A production app would not call `Database.Migrate`. It's added to the preceding code to prevent the following exception when `Update-Database` has not been run:

SqlException: Cannot open database "RazorPagesMovieContext-21" requested by the login. The login failed.
Login failed for user 'user name'.

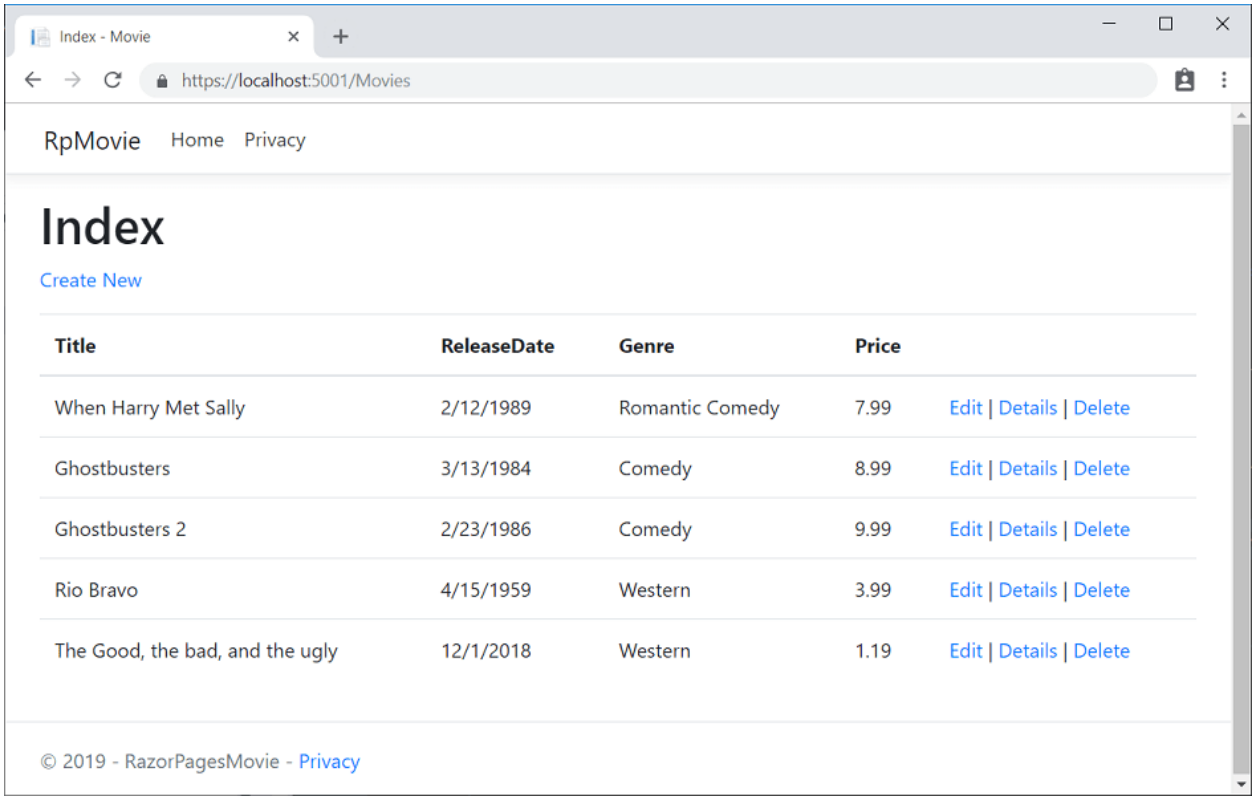
Test the app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Delete all the records in the DB. You can do this with the delete links in the browser or from SSOX
- Force the app to initialize (call the methods in the `Startup` class) so the seed method runs. To force initialization, IIS Express must be stopped and restarted. You can do this with any of the following approaches:
  - Right-click the IIS Express system tray icon in the notification area and tap **Exit** or **Stop Site**:

  - If you were running VS in non-debug mode, press F5 to run in debug mode.
  - If you were running VS in debug mode, stop the debugger and press F5.

The app shows the seeded data:



The next tutorial will clean up the presentation of the data.

PREVIOUS: SCAFFOLDED RAZOR PAGES

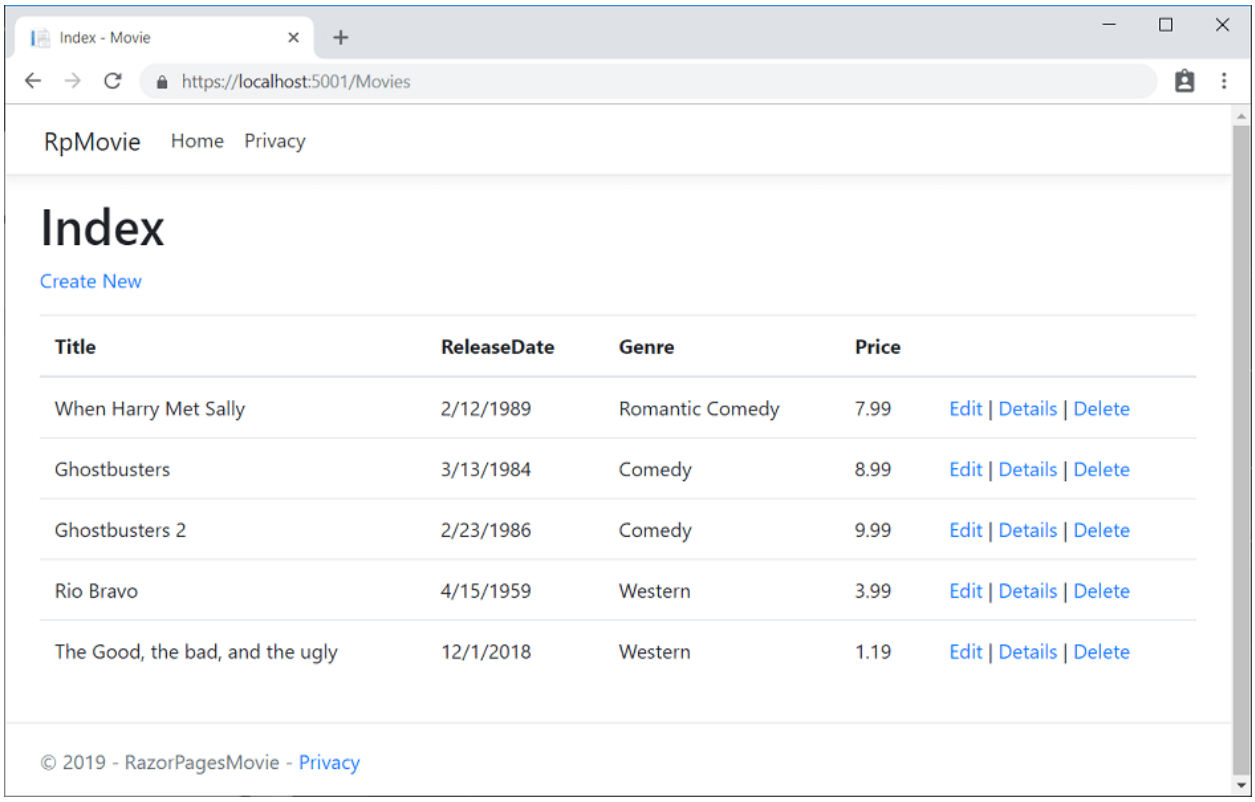
NEXT: UPDATING THE PAGES

Part 5, update the generated pages in an ASP.NET Core app

9/22/2020 • 9 minutes to read • Edit Online

By Rick Anderson

The scaffolded movie app has a good start, but the presentation isn't ideal. **ReleaseDate** should be **Release Date** (two words).



Update the generated code

Open the *Models/Movie.cs* file and add the highlighted lines shown in the following code:

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace RazorPagesMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }
        public string Title { get; set; }

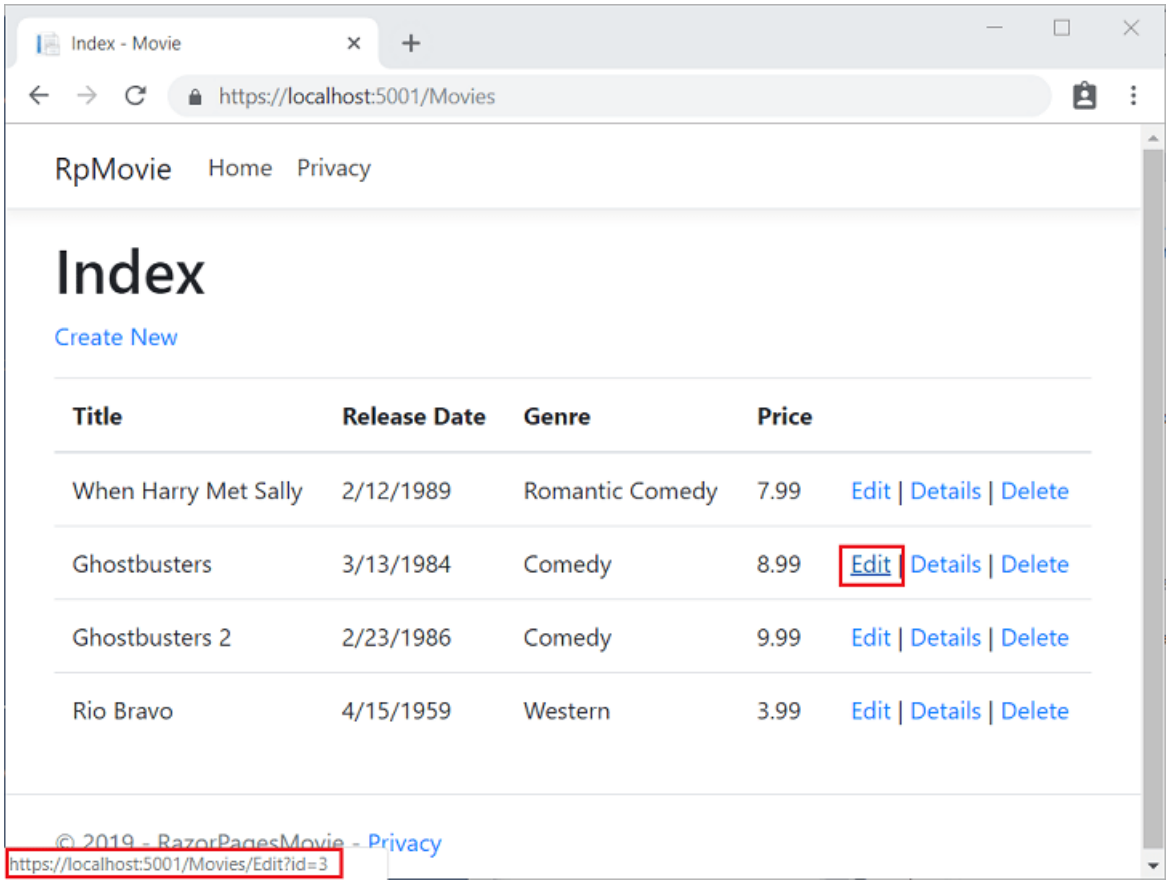
        [Display(Name = "Release Date")]
        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }

        [Column(TypeName = "decimal(18, 2)")]
        public decimal Price { get; set; }
    }
}
```

The `[Column(TypeName = "decimal(18, 2)")]` data annotation enables Entity Framework Core to correctly map `Price` to currency in the database. For more information, see Data Types.

DataAnnotations is covered in the next tutorial. The Display attribute specifies what to display for the name of a field (in this case "Release Date" instead of "ReleaseDate"). The DataType attribute specifies the type of the data (Date), so the time information stored in the field isn't displayed.

Browse to Pages/Movies and hover over an **Edit** link to see the target URL.



The **Edit**, **Details**, and **Delete** links are generated by the Anchor Tag Helper in the *Pages/Movies/Index.cshtml* file.

```
@foreach (var item in Model.Movie) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files. In the preceding code, the `AnchorTagHelper` dynamically generates the HTML `href` attribute value from the Razor Page (the route is relative), the `asp-page`, and the route id (`asp-route-id`). See URL generation for Pages for more information.

Use **View Source** from your favorite browser to examine the generated markup. A portion of the generated HTML is shown below:

```
<td>
  <a href="/Movies/Edit?id=1">Edit</a> |
  <a href="/Movies/Details?id=1">Details</a> |
  <a href="/Movies/Delete?id=1">Delete</a>
</td>
```

The dynamically-generated links pass the movie ID with a query string (for example, the `?id=1` in `https://localhost:5001/Movies/Details?id=1`).

Add route template

Update the Edit, Details, and Delete Razor Pages to use the "{id:int}" route template. Change the page directive for each of these pages from `@page` to `@page "{id:int}"`. Run the app and then view source. The generated HTML adds the ID to the path portion of the URL:

```
<td>
  <a href="/Movies/Edit/1">Edit</a> |
  <a href="/Movies/Details/1">Details</a> |
  <a href="/Movies/Delete/1">Delete</a>
</td>
```

A request to the page with the "{id:int}" route template that does **not** include the integer will return an HTTP 404 (not found) error. For example, `http://localhost:5000/Movies/Details` will return a 404 error. To make the ID optional, append `?` to the route constraint:

```
@page "{id:int?}"
```

To test the behavior of `@page "{id:int?}"`:

- Set the page directive in *Pages/Movies/Details.cshtml* to `@page "{id:int?}"`.
- Set a break point in `public async Task<IActionResult> OnGetAsync(int? id)` (in *Pages/Movies/Details.cshtml.cs*).
- Navigate to `https://localhost:5001/Movies/Details/`.

With the `@page "{id:int}"` directive, the break point is never hit. The routing engine returns HTTP 404. Using `@page "{id:int?}"`, the `OnGetAsync` method returns `NotFound` (HTTP 404).

Review concurrency exception handling

Review the `OnPostAsync` method in the *Pages/Movies/Edit.cshtml.cs* file:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Attach(Movie).State = EntityState.Modified;

    try
    {
        await _context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!MovieExists(Movie.ID))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }

    return RedirectToPage("./Index");
}

private bool MovieExists(int id)
{
    return _context.Movie.Any(e => e.ID == id);
}
```

The previous code detects concurrency exceptions when the one client deletes the movie and the other client posts changes to the movie.

To test the `catch` block:

- Set a breakpoint on `catch (DbUpdateConcurrencyException)`
- Select **Edit** for a movie, make changes, but don't enter **Save**.
- In another browser window, select the **Delete** link for the same movie, and then delete the movie.
- In the previous browser window, post changes to the movie.

Production code may want to detect concurrency conflicts. See Handle concurrency conflicts for more information.

Posting and binding review

Examine the *Pages/Movies/Edit.cshtml.cs* file:

```
public class EditModel : PageModel
{
    private readonly RazorPagesMovie.Data.RazorPagesMovieContext _context;

    public EditModel(RazorPagesMovie.Data.RazorPagesMovieContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Movie Movie { get; set; }

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Movie = await _context.Movie.FirstOrDefaultAsync(m => m.ID == id);

        if (Movie == null)
        {
            return NotFound();
        }
        return Page();
    }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _context.Attach(Movie).State = EntityState.Modified;

        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(Movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }

        return RedirectToPage("./Index");
    }

    private bool MovieExists(int id)
    {
        return _context.Movie.Any(e => e.ID == id);
    }
```

When an HTTP GET request is made to the Movies/Edit page (for example, `http://localhost:5000/Movies/Edit/2`):

- The `OnGetAsync` method fetches the movie from the database and returns the `Page` method.
- The `Page` method renders the *Pages/Movies/Edit.cshtml* Razor Page. The *Pages/Movies/Edit.cshtml* file

contains the model directive (`@model RazorPagesMovie.Pages.Movies.EditModel`), which makes the movie model available on the page.

- The Edit form is displayed with the values from the movie.

When the Movies/Edit page is posted:

- The form values on the page are bound to the `Movie` property. The `[BindProperty]` attribute enables Model binding.

```
[BindProperty]
public Movie Movie { get; set; }
```

- If there are errors in the model state (for example, `ReleaseDate` cannot be converted to a date), the form is redisplayed with the submitted values.
- If there are no model errors, the movie is saved.

The HTTP GET methods in the Index, Create, and Delete Razor pages follow a similar pattern. The HTTP POST `OnPostAsync` method in the Create Razor Page follows a similar pattern to the `OnPostAsync` method in the Edit Razor Page.

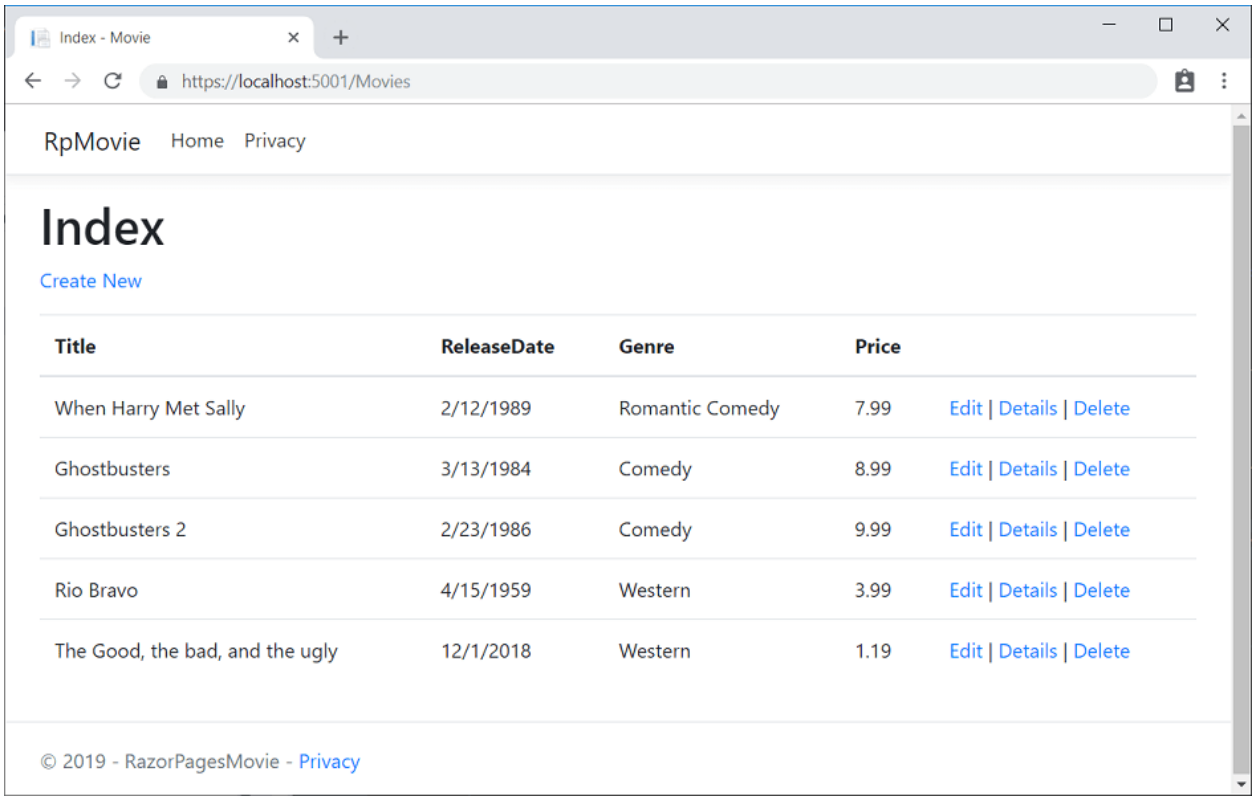
PREVIOUS: WORKING WITH A DATABASE

NEXT: ADD SEARCH

The scaffolded movie app has a good start, but the presentation isn't ideal. **ReleaseDate** should be **Release Date** (two words).



Update the generated code

Open the *Models/Movie.cs* file and add the highlighted lines shown in the following code:

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace RazorPagesMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }
        public string Title { get; set; }

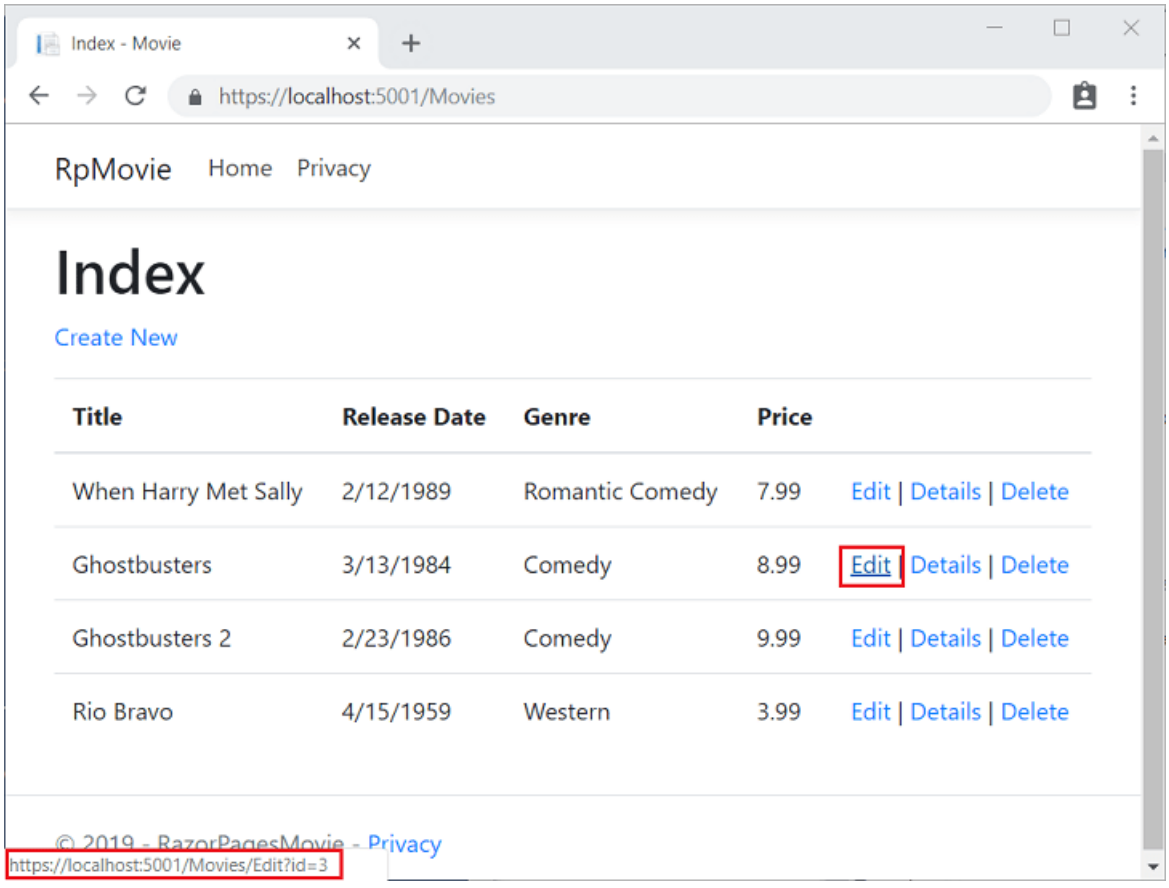
        [Display(Name = "Release Date")]
        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }

        [Column(TypeName = "decimal(18, 2)")]
        public decimal Price { get; set; }
    }
}
```

The `[Column(TypeName = "decimal(18, 2)")]` data annotation enables Entity Framework Core to correctly map `Price` to currency in the database. For more information, see Data Types.

DataAnnotations is covered in the next tutorial. The Display attribute specifies what to display for the name of a field (in this case "Release Date" instead of "ReleaseDate"). The DataType attribute specifies the type of the data (Date), so the time information stored in the field isn't displayed.

Browse to Pages/Movies and hover over an **Edit** link to see the target URL.



The **Edit**, **Details**, and **Delete** links are generated by the Anchor Tag Helper in the *Pages/Movies/Index.cshtml* file.

```
@foreach (var item in Model.Movie) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files. In the preceding code, the `AnchorTagHelper` dynamically generates the HTML `href` attribute value from the Razor Page (the route is relative), the `asp-page`, and the route id (`asp-route-id`). See URL generation for Pages for more information.

Use **View Source** from your favorite browser to examine the generated markup. A portion of the generated HTML is shown below:

```
<td>
  <a href="/Movies/Edit?id=1">Edit</a> |
  <a href="/Movies/Details?id=1">Details</a> |
  <a href="/Movies/Delete?id=1">Delete</a>
</td>
```

The dynamically-generated links pass the movie ID with a query string (for example, the `?id=1` in `https://localhost:5001/Movies/Details?id=1`).

Update the Edit, Details, and Delete Razor Pages to use the "{id:int}" route template. Change the page directive for each of these pages from `@page` to `@page "{id:int}"` . Run the app and then view source. The generated HTML adds the ID to the path portion of the URL:

```
<td>
  <a href="/Movies/Edit/1">Edit</a> |
  <a href="/Movies/Details/1">Details</a> |
  <a href="/Movies/Delete/1">Delete</a>
</td>
```

A request to the page with the "{id:int}" route template that does **not** include the integer will return an HTTP 404 (not found) error. For example, `http://localhost:5000/Movies/Details` will return a 404 error. To make the ID optional, append `?` to the route constraint:

```
@page "{id:int?}"
```

To test the behavior of `@page "{id:int?}"` :

- Set the page directive in *Pages/Movies/Details.cshtml* to `@page "{id:int?}"`.
- Set a break point in `public async Task<IActionResult> OnGetAsync(int? id)` (in *Pages/Movies/Details.cshtml.cs*).
- Navigate to `https://localhost:5001/Movies/Details/`.

With the `@page "{id:int}"` directive, the break point is never hit. The routing engine returns HTTP 404. Using `@page "{id:int?}"`, the `OnGetAsync` method returns `NotFound` (HTTP 404).

Review concurrency exception handling

Review the `OnPostAsync` method in the *Pages/Movies/Edit.cshtml.cs* file:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Attach(Movie).State = EntityState.Modified;

    try
    {
        await _context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!MovieExists(Movie.ID))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }

    return RedirectToPage("./Index");
}

private bool MovieExists(int id)
{
    return _context.Movie.Any(e => e.ID == id);
}
```

The previous code detects concurrency exceptions when the one client deletes the movie and the other client posts changes to the movie.

To test the `catch` block:

- Set a breakpoint on `catch (DbUpdateConcurrencyException)`
- Select **Edit** for a movie, make changes, but don't enter **Save**.
- In another browser window, select the **Delete** link for the same movie, and then delete the movie.
- In the previous browser window, post changes to the movie.

Production code may want to detect concurrency conflicts. See Handle concurrency conflicts for more information.

Posting and binding review

Examine the *Pages/Movies/Edit.cshtml.cs* file:

```
public class EditModel : PageModel
{
    private readonly RazorPagesMovieContext _context;

    public EditModel(RazorPagesMovieContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Movie Movie { get; set; }

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Movie = await _context.Movie.SingleOrDefaultAsync(m => m.ID == id);

        if (Movie == null)
        {
            return NotFound();
        }
        return Page();
    }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _context.Attach(Movie).State = EntityState.Modified;

        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!_context.Movie.Any(e => e.ID == Movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }

        return RedirectToPage("./Index");
    }
}
```

When an HTTP GET request is made to the Movies/Edit page (for example, `http://localhost:5000/Movies/Edit/2`):

- The `OnGetAsync` method fetches the movie from the database and returns the `Page` method.
- The `Page` method renders the *Pages/Movies/Edit.cshtml* Razor Page. The *Pages/Movies/Edit.cshtml* file contains the model directive (`@model RazorPagesMovie.Pages.Movies.EditModel`), which makes the movie model available on the page.
- The Edit form is displayed with the values from the movie.

When the Movies/Edit page is posted:

- The form values on the page are bound to the `Movie` property. The `[BindProperty]` attribute enables Model binding.

```
[BindProperty]
public Movie Movie { get; set; }
```

- If there are errors in the model state (for example, `ReleaseDate` cannot be converted to a date), the form is displayed with the submitted values.
- If there are no model errors, the movie is saved.

The HTTP GET methods in the Index, Create, and Delete Razor pages follow a similar pattern. The HTTP POST `OnPostAsync` method in the Create Razor Page follows a similar pattern to the `OnPostAsync` method in the Edit Razor Page.

Search is added in the next tutorial.

Additional resources

- YouTube version of this tutorial

PREVIOUS: WORKING WITH A DATABASE

NEXT: ADD SEARCH

Part 6, add search to ASP.NET Core Razor Pages

9/22/2020 • 9 minutes to read • Edit Online

By Rick Anderson

View or download sample code (how to download).

View or download sample code (how to download).

In the following sections, searching movies by *genre* or *name* is added.

Add the following highlighted properties to *Pages/Movies/Index.cshtml.cs*:

```
public class IndexModel : PageModel
{
    private readonly RazorPagesMovie.Data.RazorPagesMovieContext _context;

    public IndexModel(RazorPagesMovie.Data.RazorPagesMovieContext context)
    {
        _context = context;
    }

    public IList<Movie> Movie { get; set; }
    [BindProperty(SupportsGet = true)]
    public string SearchString { get; set; }
    // Requires using Microsoft.AspNetCore.Mvc.Rendering;
    public SelectList Genres { get; set; }
    [BindProperty(SupportsGet = true)]
    public string MovieGenre { get; set; }
```

- `SearchString`: contains the text users enter in the search text box. `SearchString` has the `[BindProperty]` attribute. `[BindProperty]` binds form values and query strings with the same name as the property. `(SupportsGet = true)` is required for binding on GET requests.
- `Genres`: contains the list of genres. `Genres` allows the user to select a genre from the list. `SelectList` requires `using Microsoft.AspNetCore.Mvc.Rendering;`
- `MovieGenre`: contains the specific genre the user selects (for example, "Western").
- `Genres` and `MovieGenre` are used later in this tutorial.

WARNING

For security reasons, you must opt in to binding `GET` request data to page model properties. Verify user input before mapping it to properties. Opting into `GET` binding is useful when addressing scenarios that rely on query string or route values.

To bind a property on `GET` requests, set the `[BindProperty]` attribute's `SupportsGet` property to `true`:

```
[BindProperty(SupportsGet = true)]
```

For more information, see ASP.NET Core Community Standup: Bind on GET discussion (YouTube).

Update the Index page's `OnGetAsync` method with the following code:

```
public async Task OnGetAsync()
{
    var movies = from m in _context.Movie
                 select m;
    if (!string.IsNullOrEmpty(SearchString))
    {
        movies = movies.Where(s => s.Title.Contains(SearchString));
    }

    Movie = await movies.ToListAsync();
}
```

The first line of the `OnGetAsync` method creates a LINQ query to select the movies:

```
// using System.Linq;
var movies = from m in _context.Movie
             select m;
```

The query is *only* defined at this point, it has **not** been run against the database.

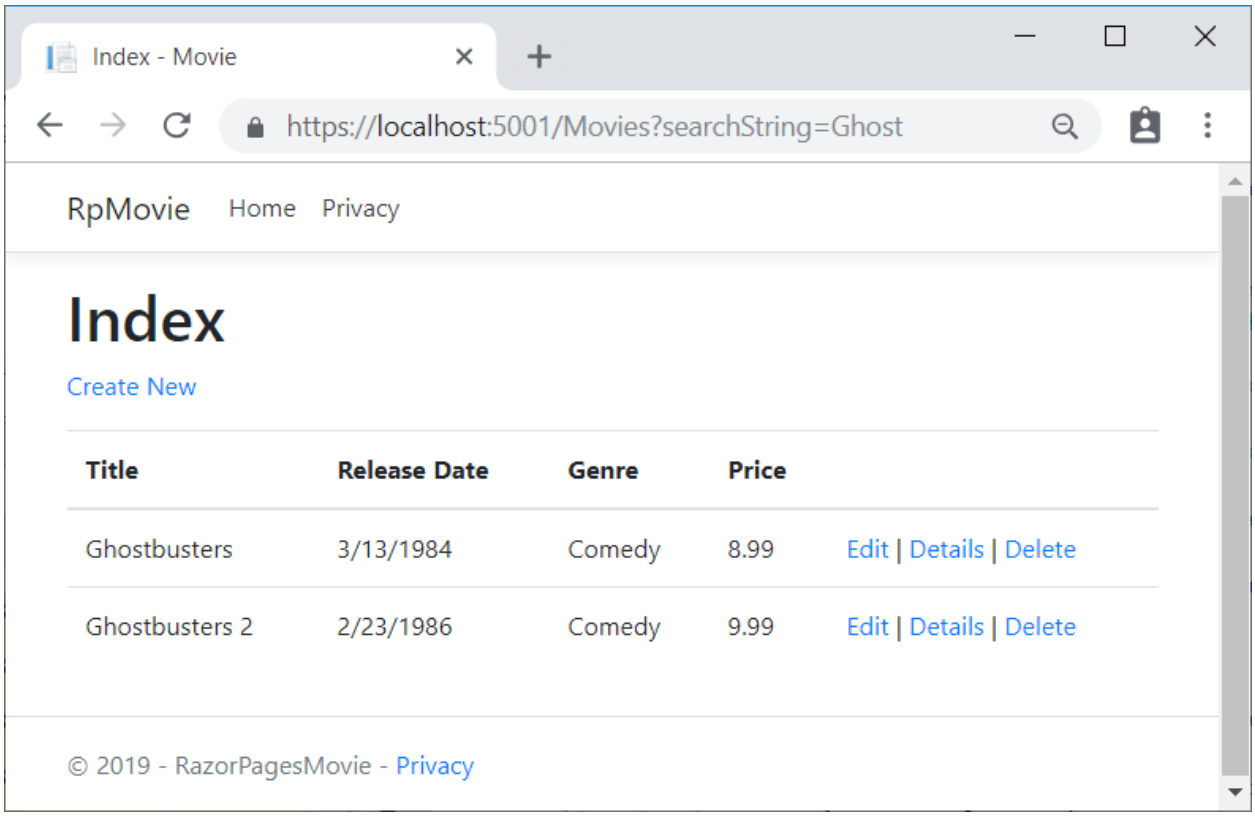
If the `SearchString` property is not null or empty, the movies query is modified to filter on the search string:

```
if (!string.IsNullOrEmpty(SearchString))
{
    movies = movies.Where(s => s.Title.Contains(SearchString));
}
```

The `s => s.Title.Contains()` code is a Lambda Expression. Lambdas are used in method-based LINQ queries as arguments to standard query operator methods such as the Where method or `Contains` (used in the preceding code). LINQ queries are not executed when they're defined or when they're modified by calling a method (such as `Where`, `Contains` or `OrderBy`). Rather, query execution is deferred. That means the evaluation of an expression is delayed until its realized value is iterated over or the `ToListAsync` method is called. See Query Execution for more information.

> **NOTE**
>
> The Contains method is run on the database, not in the C# code. The case sensitivity on the query depends on the database and the collation. On SQL Server, `Contains` maps to SQL LIKE, which is case insensitive. In SQLite, with the default collation, it's case sensitive.

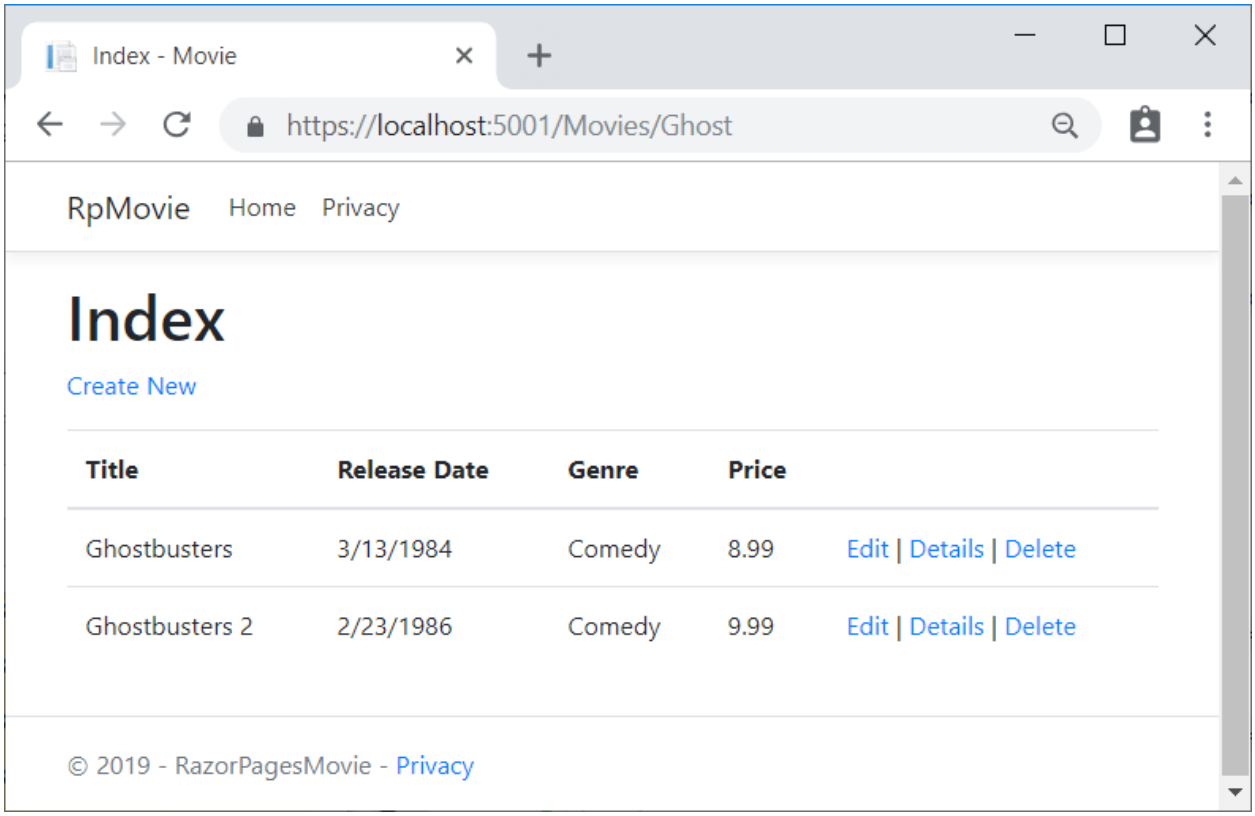
Navigate to the Movies page and append a query string such as `?searchString=Ghost` to the URL (for example, `https://localhost:5001/Movies?searchString=Ghost`). The filtered movies are displayed.



If the following route template is added to the Index page, the search string can be passed as a URL segment (for example, `https://localhost:5001/Movies/Ghost`).

```
@page "{searchString?}"
```

The preceding route constraint allows searching the title as route data (a URL segment) instead of as a query string value. The `?` in `"{searchString?}"` means this is an optional route parameter.



The ASP.NET Core runtime uses model binding to set the value of the `SearchString` property from the query string (`?searchString=Ghost`) or route data (`https://localhost:5001/Movies/Ghost`). Model binding is not case

sensitive.

However, you can't expect users to modify the URL to search for a movie. In this step, UI is added to filter movies. If you added the route constraint `"{searchString?}"`, remove it.

Open the *Pages/Movies/Index.cshtml* file, and add the `<form>` markup highlighted in the following code:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>

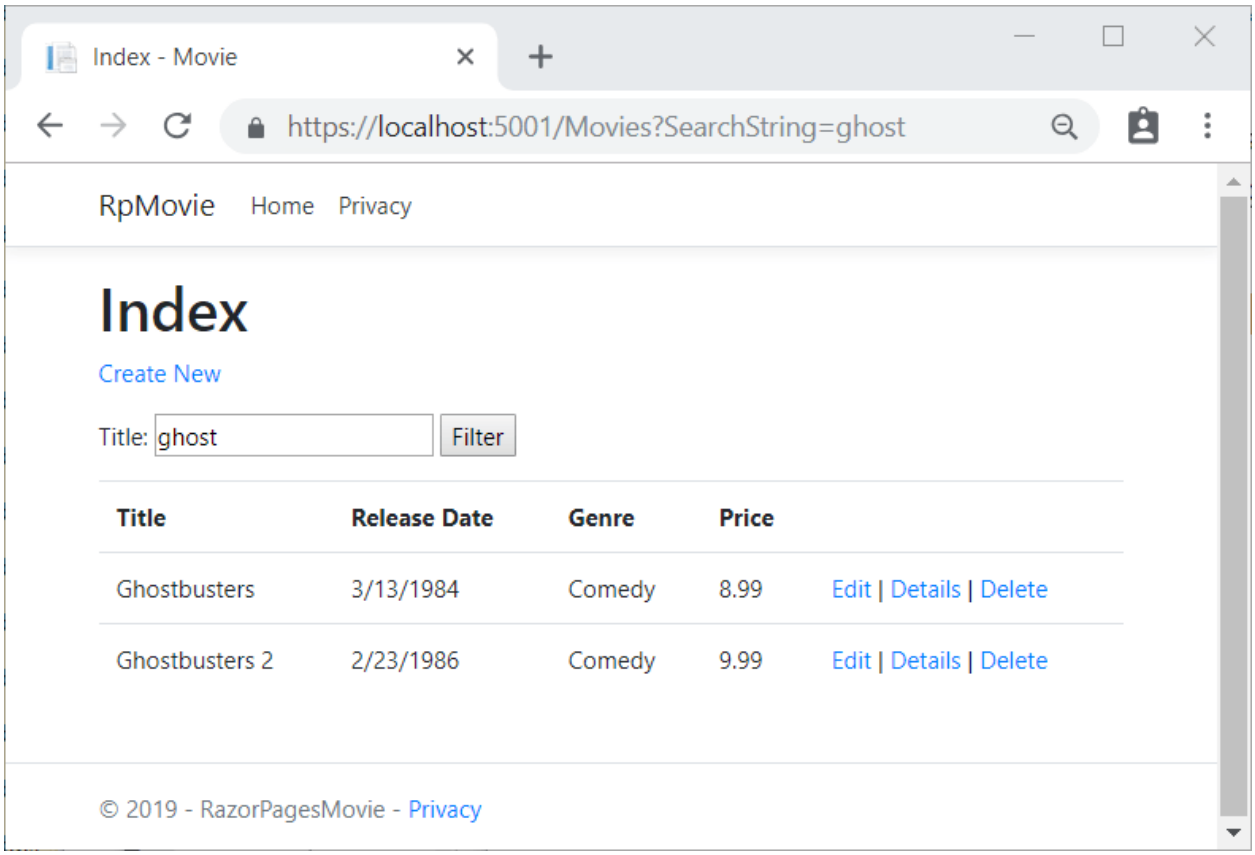
<form>
    <p>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">
    @*Markup removed for brevity.*@
```

The HTML `<form>` tag uses the following Tag Helpers:

- Form Tag Helper. When the form is submitted, the filter string is sent to the *Pages/Movies/Index* page via query string.
- Input Tag Helper

Save the changes and test the filter.



Search by genre

Update the `OnGetAsync` method with the following code:

```
public async Task OnGetAsync()
{
    // Use LINQ to get list of genres.
    IQueryable<string> genreQuery = from m in _context.Movie
                                    orderby m.Genre
                                    select m.Genre;

    var movies = from m in _context.Movie
                 select m;

    if (!string.IsNullOrEmpty(SearchString))
    {
        movies = movies.Where(s => s.Title.Contains(SearchString));
    }

    if (!string.IsNullOrEmpty(MovieGenre))
    {
        movies = movies.Where(x => x.Genre == MovieGenre);
    }
    Genres = new SelectList(await genreQuery.Distinct().ToListAsync());
    Movie = await movies.ToListAsync();
}
```

The following code is a LINQ query that retrieves all the genres from the database.

```
// Use LINQ to get list of genres.
IQueryable<string> genreQuery = from m in _context.Movie
                                orderby m.Genre
                                select m.Genre;
```

The `SelectList` of genres is created by projecting the distinct genres.

```
Genres = new SelectList(await genreQuery.Distinct().ToListAsync());
```

Add search by genre to the Razor Page

Update *Index.cshtml* as follows:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form>
    <p>
        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">
    @*Markup removed for brevity.*@
```

Test the app by searching by genre, by movie title, and by both.

Additional resources

- YouTube version of this tutorial

PREVIOUS: UPDATING THE PAGES

NEXT: ADDING A NEW FIELD

View or download sample code (how to download).

View or download sample code (how to download).

In the following sections, searching movies by *genre* or *name* is added.

Add the following highlighted properties to *Pages/Movies/Index.cshtml.cs*:

```
public class IndexModel : PageModel
{
    private readonly RazorPagesMovie.Models.RazorPagesMovieContext _context;

    public IndexModel(RazorPagesMovie.Models.RazorPagesMovieContext context)
    {
        _context = context;
    }

    public IList<Movie> Movie { get; set; }
    [BindProperty(SupportsGet = true)]
    public string SearchString { get; set; }
    // Requires using Microsoft.AspNetCore.Mvc.Rendering;
    public SelectList Genres { get; set; }
    [BindProperty(SupportsGet = true)]
    public string MovieGenre { get; set; }
```

- `SearchString`: contains the text users enter in the search text box. `SearchString` has the `[BindProperty]` attribute. `[BindProperty]` binds form values and query strings with the same name as the property. `(SupportsGet = true)` is required for binding on GET requests.
- `Genres`: contains the list of genres. `Genres` allows the user to select a genre from the list. `SelectList` requires `using Microsoft.AspNetCore.Mvc.Rendering;`
- `MovieGenre`: contains the specific genre the user selects (for example, "Western").
- `Genres` and `MovieGenre` are used later in this tutorial.

WARNING

For security reasons, you must opt in to binding `GET` request data to page model properties. Verify user input before mapping it to properties. Opting into `GET` binding is useful when addressing scenarios that rely on query string or route values.

To bind a property on `GET` requests, set the `[BindProperty]` attribute's `SupportsGet` property to `true`:

```
[BindProperty(SupportsGet = true)]
```

For more information, see ASP.NET Core Community Standup: Bind on GET discussion (YouTube).

Update the Index page's `OnGetAsync` method with the following code:

```
public async Task OnGetAsync()
{
    var movies = from m in _context.Movie
                 select m;
    if (!string.IsNullOrEmpty(SearchString))
    {
        movies = movies.Where(s => s.Title.Contains(SearchString));
    }

    Movie = await movies.ToListAsync();
}
```

The first line of the `OnGetAsync` method creates a LINQ query to select the movies:

```
// using System.Linq;
var movies = from m in _context.Movie
             select m;
```

The query is *only* defined at this point, it has **not** been run against the database.

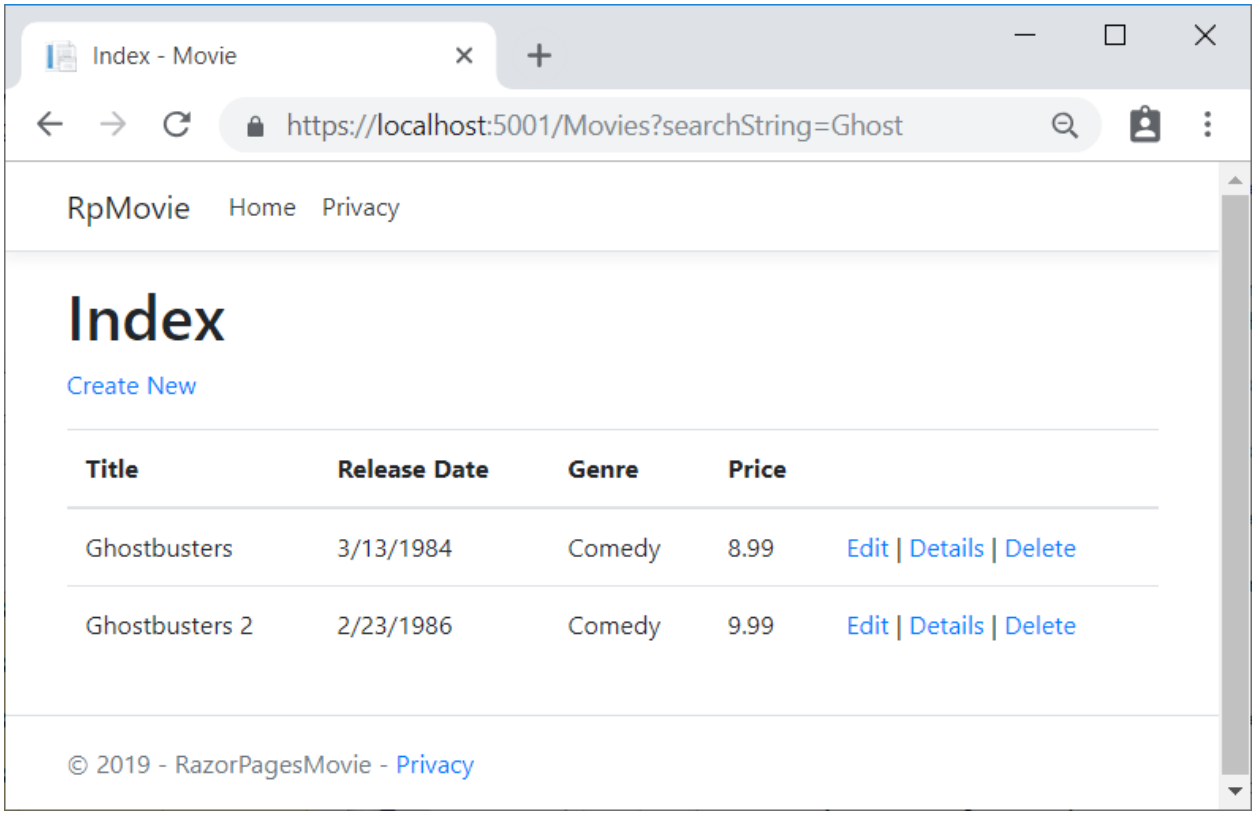
If the `SearchString` property is not null or empty, the movies query is modified to filter on the search string:

```
if (!string.IsNullOrEmpty(SearchString))
{
    movies = movies.Where(s => s.Title.Contains(SearchString));
}
```

The `s => s.Title.Contains()` code is a Lambda Expression. Lambdas are used in method-based LINQ queries as arguments to standard query operator methods such as the Where method or `Contains` (used in the preceding code). LINQ queries are not executed when they're defined or when they're modified by calling a method (such as `Where`, `Contains` or `OrderBy`). Rather, query execution is deferred. That means the evaluation of an expression is delayed until its realized value is iterated over or the `ToListAsync` method is called. See Query Execution for more information.

Note: The Contains method is run on the database, not in the C# code. The case sensitivity on the query depends on the database and the collation. On SQL Server, `Contains` maps to SQL LIKE, which is case insensitive. In SQLite, with the default collation, it's case sensitive.

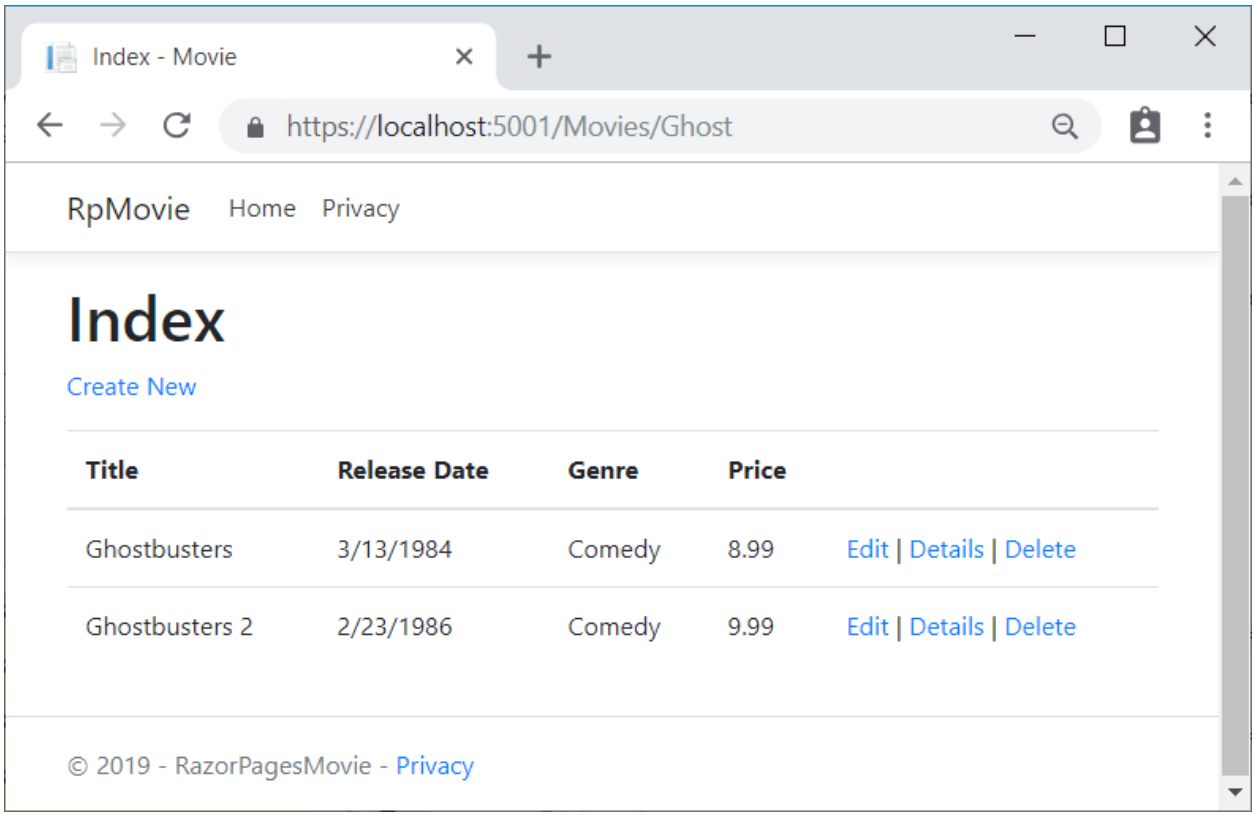
Navigate to the Movies page and append a query string such as `?searchString=Ghost` to the URL (for example, `https://localhost:5001/Movies?searchString=Ghost`). The filtered movies are displayed.



If the following route template is added to the Index page, the search string can be passed as a URL segment (for example, `https://localhost:5001/Movies/Ghost`).

```
@page "{searchString?}"
```

The preceding route constraint allows searching the title as route data (a URL segment) instead of as a query string value. The `?` in `"{searchString?}"` means this is an optional route parameter.



The ASP.NET Core runtime uses model binding to set the value of the `SearchString` property from the query string (`?searchString=Ghost`) or route data (`https://localhost:5001/Movies/Ghost`). Model binding is not case sensitive.

However, you can't expect users to modify the URL to search for a movie. In this step, UI is added to filter movies. If you added the route constraint `"{searchString?}"`, remove it.

Open the *Pages/Movies/Index.cshtml* file, and add the `<form>` markup highlighted in the following code:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>

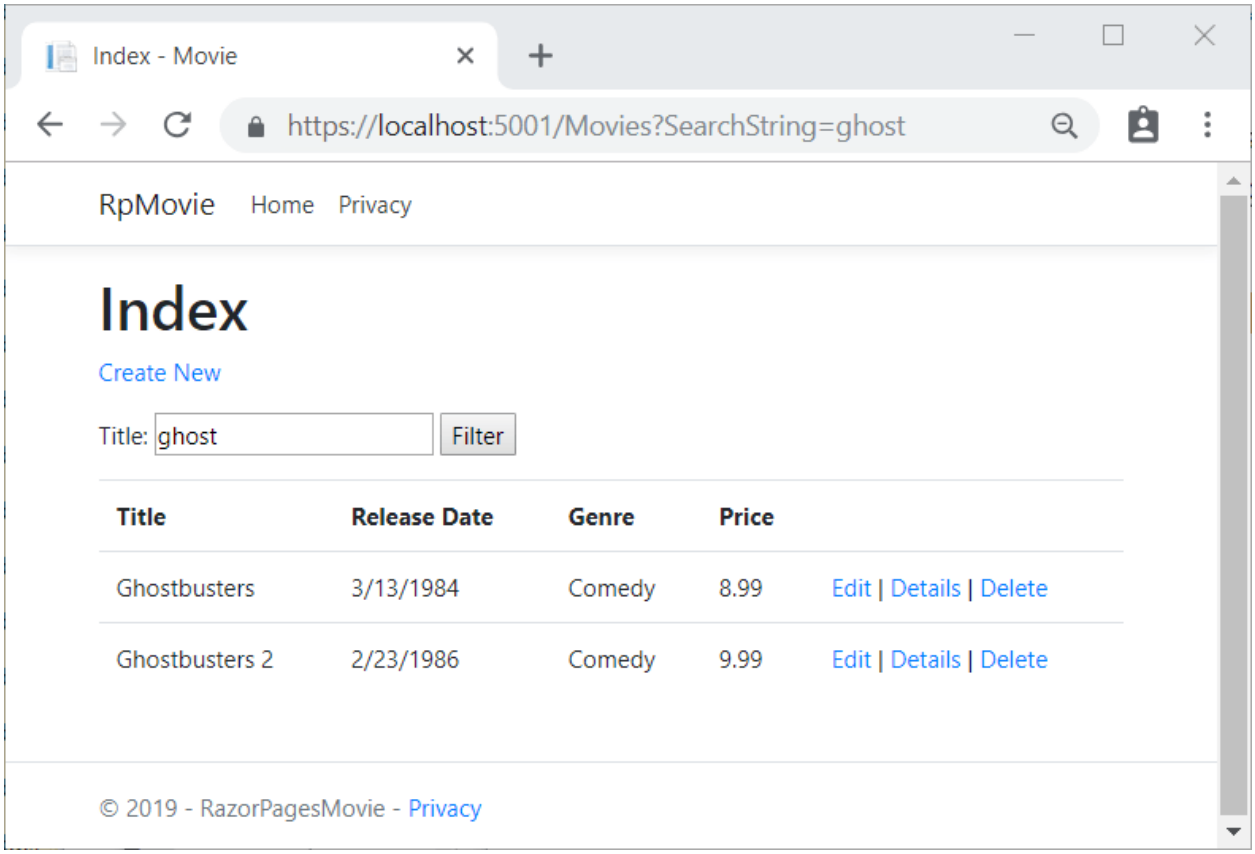
<form>
    <p>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">
    @*Markup removed for brevity.*@
```

The HTML `<form>` tag uses the following Tag Helpers:

- Form Tag Helper. When the form is submitted, the filter string is sent to the *Pages/Movies/Index* page via query string.
- Input Tag Helper

Save the changes and test the filter.



Search by genre

Update the `OnGetAsync` method with the following code:

```
public async Task OnGetAsync()
{
    // Use LINQ to get list of genres.
    IQueryable<string> genreQuery = from m in _context.Movie
                                    orderby m.Genre
                                    select m.Genre;

    var movies = from m in _context.Movie
                 select m;

    if (!string.IsNullOrEmpty(SearchString))
    {
        movies = movies.Where(s => s.Title.Contains(SearchString));
    }

    if (!string.IsNullOrEmpty(MovieGenre))
    {
        movies = movies.Where(x => x.Genre == MovieGenre);
    }
    Genres = new SelectList(await genreQuery.Distinct().ToListAsync());
    Movie = await movies.ToListAsync();
}
```

The following code is a LINQ query that retrieves all the genres from the database.

```
// Use LINQ to get list of genres.
IQueryable<string> genreQuery = from m in _context.Movie
                                orderby m.Genre
                                select m.Genre;
```

The `SelectList` of genres is created by projecting the distinct genres.

```
Genres = new SelectList(await genreQuery.Distinct().ToListAsync());
```

Add search by genre to the Razor Page

Update *Index.cshtml* as follows:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form>
    <p>
        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">
    @*Markup removed for brevity.*@
```

Test the app by searching by genre, by movie title, and by both. The preceding code uses the Select Tag Helper and Option Tag Helper.

PREVIOUS: UPDATING THE PAGES

NEXT: ADDING A NEW FIELD

Part 7, add a new field to a Razor Page in ASP.NET Core

9/22/2020 • 10 minutes to read • Edit Online

By Rick Anderson

View or download sample code (how to download).

View or download sample code (how to download).

In this section Entity Framework Code First Migrations is used to:

- Add a new field to the model.
- Migrate the new field schema change to the database.

When using EF Code First to automatically create a database, Code First:

- Adds an `__EFMigrationsHistory` table to the database to track whether the schema of the database is in sync with the model classes it was generated from.
- If the model classes aren't in sync with the DB, EF throws an exception.

Automatic verification of schema/model in sync makes it easier to find inconsistent database/code issues.

Adding a Rating Property to the Movie Model

Open the *Models/Movie.cs* file and add a `Rating` property:

```
public class Movie
{
    public int ID { get; set; }
    public string Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; }

    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
    public string Rating { get; set; }
}
```

Build the app.

Edit *Pages/Movies/Index.cshtml*, and add a `Rating` field:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
```

```
    <a asp-page="Create">Create New</a>
</p>

<form>
    <p>
        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">

    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Price)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Rating)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Movie)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.ReleaseDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Genre)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Price)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Rating)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

Update the following pages:

- Add the `Rating` field to the Delete and Details pages.

- Update Create.cshtml with a `Rating` field.
- Add the `Rating` field to the Edit Page.

The app won't work until the DB is updated to include the new field. Running the app without updating the database throws a `SqlException`:

```
SqlException: Invalid column name 'Rating'.
```

The `SqlException` exception is caused by the updated Movie model class being different than the schema of the Movie table of the database. (There's no `Rating` column in the database table.)

There are a few approaches to resolving the error:

1. Have the Entity Framework automatically drop and re-create the database using the new model class schema. This approach is convenient early in the development cycle; it allows you to quickly evolve the model and database schema together. The downside is that you lose existing data in the database. Don't use this approach on a production database! Dropping the DB on schema changes and using an initializer to automatically seed the database with test data is often a productive way to develop an app.
2. Explicitly modify the schema of the existing database so that it matches the model classes. The advantage of this approach is that you keep your data. You can make this change either manually or by creating a database change script.
3. Use Code First Migrations to update the database schema.

For this tutorial, use Code First Migrations.

Update the `SeedData` class so that it provides a value for the new column. A sample change is shown below, but you'll want to make this change for each `new Movie` block.

```
context.Movie.AddRange(
    new Movie
    {
        Title = "When Harry Met Sally",
        ReleaseDate = DateTime.Parse("1989-2-12"),
        Genre = "Romantic Comedy",
        Price = 7.99M,
        Rating = "R"
    },
```

See the completed SeedData.cs file.

Build the solution.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

Add a migration for the rating field

From the **Tools** menu, select **NuGet Package Manager > Package Manager Console**. In the PMC, enter the following commands:

```
Add-Migration Rating
Update-Database
```

The `Add-Migration` command tells the framework to:

- Compare the `Movie` model with the `Movie` DB schema.
- Create code to migrate the DB schema to the new model.

The name "Rating" is arbitrary and is used to name the migration file. It's helpful to use a meaningful name for the migration file.

The `Update-Database` command tells the framework to apply the schema changes to the database and to preserve existing data.

If you delete all the records in the DB, the initializer will seed the DB and include the `Rating` field. You can do this with the delete links in the browser or from Sql Server Object Explorer (SSOX).

Another option is to delete the database and use migrations to re-create the database. To delete the database in SSOX:

- Select the database in SSOX.
- Right click on the database, and select *Delete*.
- Check **Close existing connections**.
- Select **OK**.
- In the PMC, update the database:

```
Update-Database
```

Run the app and verify you can create/edit/display movies with a `Rating` field. If the database isn't seeded, set a break point in the `SeedData.Initialize` method.

PREVIOUS: ADDING SEARCH

NEXT: ADDING VALIDATION

View or download sample code (how to download).

View or download sample code (how to download).

In this section Entity Framework Code First Migrations is used to:

- Add a new field to the model.
- Migrate the new field schema change to the database.

When using EF Code First to automatically create a database, Code First:

- Adds a table to the database to track whether the schema of the database is in sync with the model classes it was generated from.
- If the model classes aren't in sync with the DB, EF throws an exception.

Automatic verification of schema/model in sync makes it easier to find inconsistent database/code issues.

Adding a Rating Property to the Movie Model

Open the *Models/Movie.cs* file and add a `Rating` property:

```
public class Movie
{
    public int ID { get; set; }
    public string Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; }

    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
    public string Rating { get; set; }
}
```

Build the app.

Edit *Pages/Movies/Index.cshtml*, and add a `Rating` field:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form>
    <p>
        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">

    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Price)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Rating)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Movie)
```

```
        {
        <tr><td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Rating)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
        }
    </tbody>
</table>
```

Update the following pages:

- Add the `Rating` field to the Delete and Details pages.
- Update Create.cshtml with a `Rating` field.
- Add the `Rating` field to the Edit Page.

The app won't work until the DB is updated to include the new field. If run now, the app throws a `SqlException`:

```
SqlException: Invalid column name 'Rating'.
```

This error is caused by the updated Movie model class being different than the schema of the Movie table of the database. (There's no `Rating` column in the database table.)

There are a few approaches to resolving the error:

1. Have the Entity Framework automatically drop and re-create the database using the new model class schema. This approach is convenient early in the development cycle; it allows you to quickly evolve the model and database schema together. The downside is that you lose existing data in the database. Don't use this approach on a production database! Dropping the DB on schema changes and using an initializer to automatically seed the database with test data is often a productive way to develop an app.
2. Explicitly modify the schema of the existing database so that it matches the model classes. The advantage of this approach is that you keep your data. You can make this change either manually or by creating a database change script.
3. Use Code First Migrations to update the database schema.

For this tutorial, use Code First Migrations.

Update the `SeedData` class so that it provides a value for the new column. A sample change is shown below, but you'll want to make this change for each `new Movie` block.

```
context.Movie.AddRange(
    new Movie
    {
        Title = "When Harry Met Sally",
        ReleaseDate = DateTime.Parse("1989-2-12"),
        Genre = "Romantic Comedy",
        Price = 7.99M,
        Rating = "R"
    },
```

See the completed SeedData.cs file.

Build the solution.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

Add a migration for the rating field

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**. In the PMC, enter the following commands:

```
Add-Migration Rating
Update-Database
```

The `Add-Migration` command tells the framework to:

- Compare the `Movie` model with the `Movie` DB schema.
- Create code to migrate the DB schema to the new model.

The name "Rating" is arbitrary and is used to name the migration file. It's helpful to use a meaningful name for the migration file.

The `Update-Database` command tells the framework to apply the schema changes to the database.

If you delete all the records in the DB, the initializer will seed the DB and include the `Rating` field. You can do this with the delete links in the browser or from Sql Server Object Explorer (SSOX).

Another option is to delete the database and use migrations to re-create the database. To delete the database in SSOX:

- Select the database in SSOX.
- Right click on the database, and select *Delete*.
- Check **Close existing connections**.
- Select **OK**.
- In the PMC, update the database:

  ```
  Update-Database
  ```

Run the app and verify you can create/edit/display movies with a `Rating` field. If the database isn't seeded, set a break point in the `SeedData.Initialize` method.

PREVIOUS: ADDING SEARCH

NEXT: ADDING VALIDATION

Part 8, add validation to an ASP.NET Core Razor Page

9/22/2020 • 9 minutes to read • Edit Online

By Rick Anderson

In this section, validation logic is added to the `Movie` model. The validation rules are enforced any time a user creates or edits a movie.

Validation

A key tenet of software development is called DRY ("**D**on't **R**epeat **Y**ourself"). Razor Pages encourages development where functionality is specified once, and it's reflected throughout the app. DRY can help:

- Reduce the amount of code in an app.
- Make the code less error prone, and easier to test and maintain.

The validation support provided by Razor Pages and Entity Framework is a good example of the DRY principle. Validation rules are declaratively specified in one place (in the model class), and the rules are enforced everywhere in the app.

Add validation rules to the movie model

The DataAnnotations namespace provides a set of built-in validation attributes that are applied declaratively to a class or property. DataAnnotations also contains formatting attributes like `DataType` that help with formatting and don't provide any validation.

Update the `Movie` class to take advantage of the built-in `Required`, `StringLength`, `RegularExpression`, and `Range` validation attributes.

```
public class Movie
{
    public int ID { get; set; }

    [StringLength(60, MinimumLength = 3)]
    [Required]
    public string Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [Range(1, 100)]
    [DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
    [Required]
    [StringLength(30)]
    public string Genre { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$")]
    [StringLength(5)]
    [Required]
    public string Rating { get; set; }
}
```

The validation attributes specify behavior that you want to enforce on the model properties they're applied to:

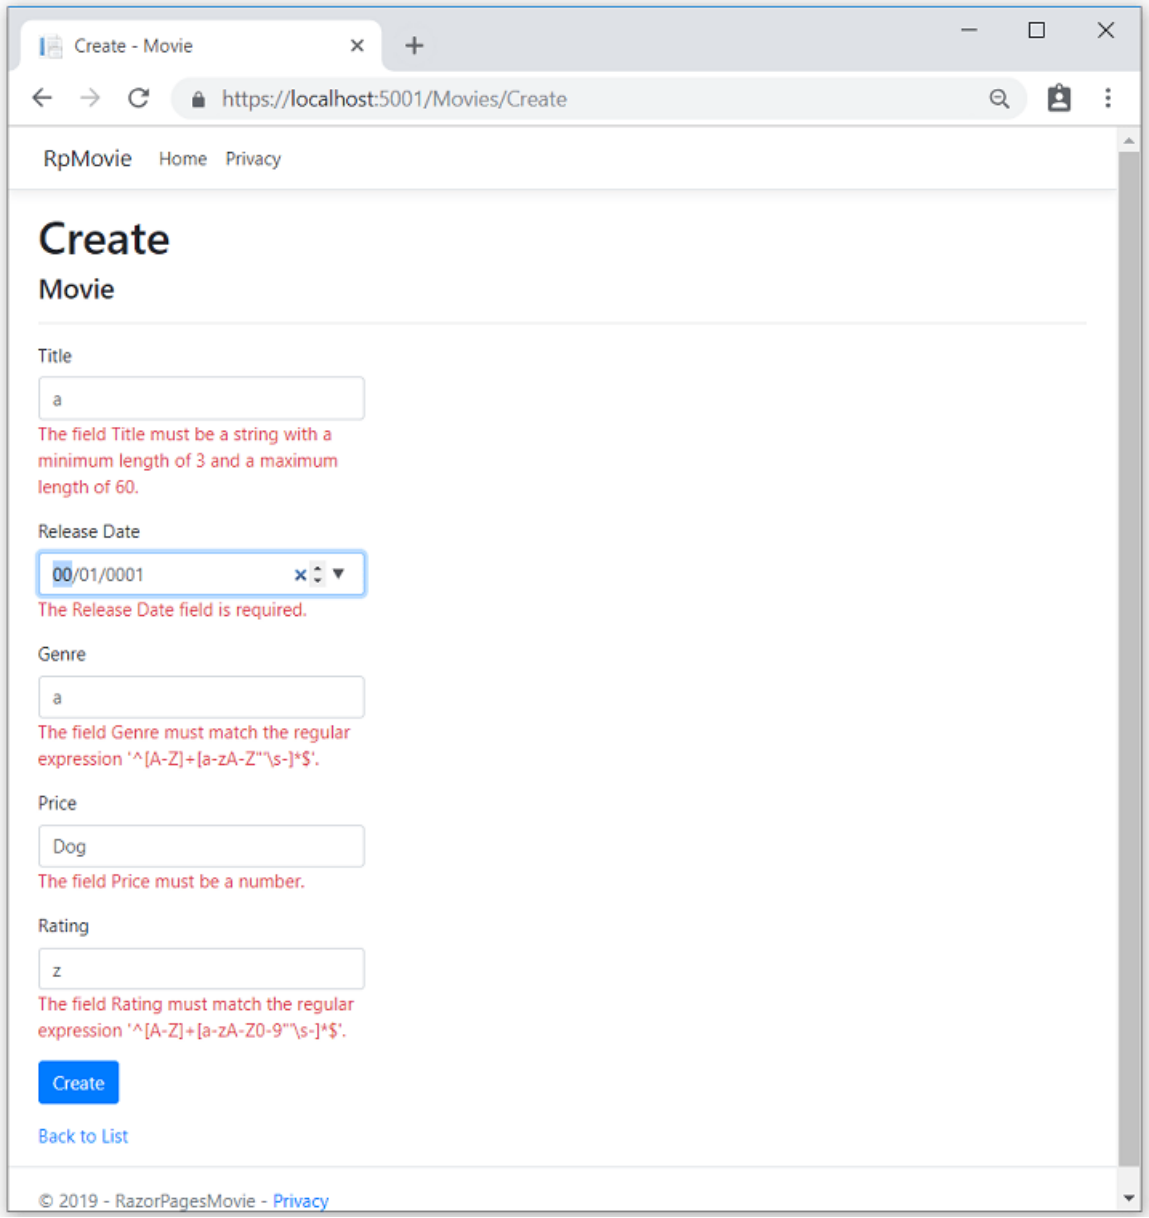
- The `Required` and `MinimumLength` attributes indicate that a property must have a value; but nothing prevents a user from entering white space to satisfy this validation.
- The `RegularExpression` attribute is used to limit what characters can be input. In the preceding code, "Genre":
  - Must only use letters.
  - The first letter is required to be uppercase. White space, numbers, and special characters are not allowed.
- The `RegularExpression` "Rating":
  - Requires that the first character be an uppercase letter.
  - Allows special characters and numbers in subsequent spaces. "PG-13" is valid for a rating, but fails for a "Genre".
- The `Range` attribute constrains a value to within a specified range.
- The `StringLength` attribute lets you set the maximum length of a string property, and optionally its minimum length.
- Value types (such as `decimal`, `int`, `float`, `DateTime`) are inherently required and don't need the `[Required]` attribute.

Having validation rules automatically enforced by ASP.NET Core helps make your app more robust. It also ensures that you can't forget to validate something and inadvertently let bad data into the database.

Validation Error UI in Razor Pages

Run the app and navigate to Pages/Movies.

Select the **Create New** link. Complete the form with some invalid values. When jQuery client-side validation detects the error, it displays an error message.



NOTE

You may not be able to enter decimal commas in decimal fields. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. See this GitHub issue 4076 for instructions on adding decimal comma.

Notice how the form has automatically rendered a validation error message in each field containing an invalid value. The errors are enforced both client-side (using JavaScript and jQuery) and server-side (when a user has JavaScript disabled).

A significant benefit is that **no** code changes were necessary in the Create or Edit pages. Once DataAnnotations were applied to the model, the validation UI was enabled. The Razor Pages created in this tutorial automatically picked up the validation rules (using validation attributes on the properties of the `Movie` model class). Test validation using the Edit page, the same validation is applied.

The form data isn't posted to the server until there are no client-side validation errors. Verify form data isn't posted by one or more of the following approaches:

- Put a break point in the `OnPostAsync` method. Submit the form (select **Create** or **Save**). The break point is never hit.
- Use the Fiddler tool.

- Use the browser developer tools to monitor network traffic.

Server-side validation

When JavaScript is disabled in the browser, submitting the form with errors will post to the server.

Optional, test server-side validation:

- Disable JavaScript in the browser. You can disable JavaScript using browser's developer tools. If you can't disable JavaScript in the browser, try another browser.
- Set a break point in the `OnPostAsync` method of the Create or Edit page.
- Submit a form with invalid data.
- Verify the model state is invalid:

```
if (!ModelState.IsValid)
{
    return Page();
}
```

Alternatively, you can Disable client-side validation on the server.

The following code shows a portion of the *Create.cshtml* page scaffolded earlier in the tutorial. It's used by the Create and Edit pages to display the initial form and to redisplay the form in the event of an error.

```
<form method="post">
    <div asp-validation-summary="ModelOnly" class="text-danger"></div>
    <div class="form-group">
        <label asp-for="Movie.Title" class="control-label"></label>
        <input asp-for="Movie.Title" class="form-control" />
        <span asp-validation-for="Movie.Title" class="text-danger"></span>
    </div>
```

The Input Tag Helper uses the DataAnnotations attributes and produces HTML attributes needed for jQuery Validation on the client-side. The Validation Tag Helper displays validation errors. See Validation for more information.

The Create and Edit pages have no validation rules in them. The validation rules and the error strings are specified only in the `Movie` class. These validation rules are automatically applied to Razor Pages that edit the `Movie` model.

When validation logic needs to change, it's done only in the model. Validation is applied consistently throughout the application (validation logic is defined in one place). Validation in one place helps keep the code clean, and makes it easier to maintain and update.

Using DataType Attributes

Examine the `Movie` class. The `System.ComponentModel.DataAnnotations` namespace provides formatting attributes in addition to the built-in set of validation attributes. The `DataType` attribute is applied to the `ReleaseDate` and `Price` properties.

```
[Display(Name = "Release Date")]
[DataType(DataType.Date)]
public DateTime ReleaseDate { get; set; }

[Range(1, 100)]
[DataType(DataType.Currency)]
public decimal Price { get; set; }
```

The `DataType` attributes only provide hints for the view engine to format the data (and supplies attributes such as `<a>` for URL's and `<a href="mailto:EmailAddress.com">` for email). Use the `RegularExpression` attribute to validate the format of the data. The `DataType` attribute is used to specify a data type that's more specific than the database intrinsic type. `DataType` attributes are not validation attributes. In the sample application, only the date is displayed, without time.

The `DataType` Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress, and more. The `DataType` attribute can also enable the application to automatically provide type-specific features. For example, a `mailto:` link can be created for `DataType.EmailAddress`. A date selector can be provided for `DataType.Date` in browsers that support HTML5. The `DataType` attributes emit HTML 5 `data-` (pronounced data dash) attributes that HTML 5 browsers consume. The `DataType` attributes do **not** provide any validation.

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the data field is displayed according to the default formats based on the server's `CultureInfo`.

The `[Column(TypeName = "decimal(18, 2)")]` data annotation is required so Entity Framework Core can correctly map `Price` to currency in the database. For more information, see Data Types.

The `DisplayFormat` attribute is used to explicitly specify the date format:

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
public DateTime ReleaseDate { get; set; }
```

The `ApplyFormatInEditMode` setting specifies that the formatting should be applied when the value is displayed for editing. You might not want that behavior for some fields. For example, in currency values, you probably don't want the currency symbol in the edit UI.

The `DisplayFormat` attribute can be used by itself, but it's generally a good idea to use the `DataType` attribute. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen, and provides the following benefits that you don't get with DisplayFormat:

- The browser can enable HTML5 features (for example to show a calendar control, the locale-appropriate currency symbol, email links, etc.)
- By default, the browser will render data using the correct format based on your locale.
- The `DataType` attribute can enable the ASP.NET Core framework to choose the right field template to render the data. The `DisplayFormat`, if used by itself, uses the string template.

Note: jQuery validation doesn't work with the `Range` attribute and `DateTime`. For example, the following code will always display a client-side validation error, even when the date is in the specified range:

```
[Range(typeof(DateTime), "1/1/1966", "1/1/2020")]
```

It's generally not a good practice to compile hard dates in your models, so using the `Range` attribute and `DateTime` is discouraged.

The following code shows combining attributes on one line:

```
public class Movie
{
    public int ID { get; set; }

    [StringLength(60, MinimumLength = 3)]
    public string Title { get; set; }

    [Display(Name = "Release Date"), DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z]*$"), Required, StringLength(30)]
    public string Genre { get; set; }

    [Range(1, 100), DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$"), StringLength(5)]
    public string Rating { get; set; }
}
```

Get started with Razor Pages and EF Core shows advanced EF Core operations with Razor Pages.

Apply migrations

The DataAnnotations applied to the class changes the schema. For example, the DataAnnotations applied to the `Title` field:

```
[StringLength(60, MinimumLength = 3)]
[Required]
public string Title { get; set; }
```

- Limits the characters to 60.
- Doesn't allow a `null` value.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

The `Movie` table currently has the following schema:

```
CREATE TABLE [dbo].[Movie] (
    [ID]          INT             IDENTITY (1, 1) NOT NULL,
    [Title]       NVARCHAR (MAX)  NULL,
    [ReleaseDate] DATETIME2 (7)   NOT NULL,
    [Genre]       NVARCHAR (MAX)  NULL,
    [Price]       DECIMAL (18, 2) NOT NULL,
    [Rating]      NVARCHAR (MAX)  NULL,
    CONSTRAINT [PK_Movie] PRIMARY KEY CLUSTERED ([ID] ASC)
);
```

The preceding schema changes don't cause EF to throw an exception. However, create a migration so the schema is consistent with the model.

From the **Tools** menu, select **NuGet Package Manager > Package Manager Console**. In the PMC, enter the following commands:

```
Add-Migration New_DataAnnotations
Update-Database
```

`Update-Database` runs the `Up` methods of the `New_DataAnnotations` class. Examine the `Up` method:

```
public partial class New_DataAnnotations : Migration
{
    protected override void Up(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.AlterColumn<string>(
            name: "Title",
            table: "Movie",
            maxLength: 60,
            nullable: false,
            oldClrType: typeof(string),
            oldNullable: true);

        migrationBuilder.AlterColumn<string>(
            name: "Rating",
            table: "Movie",
            maxLength: 5,
            nullable: false,
            oldClrType: typeof(string),
            oldNullable: true);

        migrationBuilder.AlterColumn<string>(
            name: "Genre",
            table: "Movie",
            maxLength: 30,
            nullable: false,
            oldClrType: typeof(string),
            oldNullable: true);
    }
```

The updated `Movie` table has the following schema:

```
CREATE TABLE [dbo].[Movie] (
    [ID]          INT             IDENTITY (1, 1) NOT NULL,
    [Title]       NVARCHAR (60)   NOT NULL,
    [ReleaseDate] DATETIME2 (7)   NOT NULL,
    [Genre]       NVARCHAR (30)   NOT NULL,
    [Price]       DECIMAL (18, 2) NOT NULL,
    [Rating]      NVARCHAR (5)    NOT NULL,
    CONSTRAINT [PK_Movie] PRIMARY KEY CLUSTERED ([ID] ASC)
);
```

Publish to Azure

For information on deploying to Azure, see Tutorial: Build an ASP.NET Core app in Azure with SQL Database.

Thanks for completing this introduction to Razor Pages. Get started with Razor Pages and EF Core is an excellent follow up to this tutorial.

Filter methods for Razor Pages in ASP.NET Core

9/22/2020 • 8 minutes to read • Edit Online

By Rick Anderson

Razor Page filters IPageFilter and IAsyncPageFilter allow Razor Pages to run code before and after a Razor Page handler is run. Razor Page filters are similar to ASP.NET Core MVC action filters, except they can't be applied to individual page handler methods.

Razor Page filters:

- Run code after a handler method has been selected, but before model binding occurs.
- Run code before the handler method executes, after model binding is complete.
- Run code after the handler method executes.
- Can be implemented on a page or globally.
- Cannot be applied to specific page handler methods.
- Can have constructor dependencies populated by Dependency Injection (DI). For more information, see ServiceFilterAttribute and TypeFilterAttribute.

While page constructors and middleware enable executing custom code before a handler method executes, only Razor Page filters enable access to HttpContext and the page. Middleware has access to the `HttpContext`, but not to the "page context". Filters have a FilterContext derived parameter, which provides access to `HttpContext`. Here's a sample for a page filter: Implement a filter attribute that adds a header to the response, something that can't be done with constructors or middleware. Access to the page context, which includes access to the instances of the page and it's model, are only available when executing filters, handlers, or the body of a Razor Page.

View or download sample code (how to download)

Razor Page filters provide the following methods, which can be applied globally or at the page level:

- Synchronous methods:
  - OnPageHandlerSelected : Called after a handler method has been selected, but before model binding occurs.
  - OnPageHandlerExecuting : Called before the handler method executes, after model binding is complete.
  - OnPageHandlerExecuted : Called after the handler method executes, before the action result.
- Asynchronous methods:
  - OnPageHandlerSelectionAsync : Called asynchronously after the handler method has been selected, but before model binding occurs.
  - OnPageHandlerExecutionAsync : Called asynchronously before the handler method is invoked, after model binding is complete.

Implement **either** the synchronous or the async version of a filter interface, **not** both. The framework checks first to see if the filter implements the async interface, and if so, it calls that. If not, it calls the synchronous interface's method(s). If both interfaces are implemented, only the async methods are called. The same rule applies to overrides in pages, implement the synchronous or the async version of the override, not both.

Implement Razor Page filters globally

The following code implements `IAsyncPageFilter`:

```
public class SampleAsyncPageFilter : IAsyncPageFilter
{
    private readonly IConfiguration _config;

    public SampleAsyncPageFilter(IConfiguration config)
    {
        _config = config;
    }

    public Task OnPageHandlerSelectionAsync(PageHandlerSelectedContext context)
    {
        var key = _config["UserAgentID"];
        context.HttpContext.Request.Headers.TryGetValue("user-agent",
                                                        out StringValues value);
        ProcessUserAgent.Write(context.ActionDescriptor.DisplayName,
                               "SampleAsyncPageFilter.OnPageHandlerSelectionAsync",
                               value, key.ToString());

        return Task.CompletedTask;
    }

    public async Task OnPageHandlerExecutionAsync(PageHandlerExecutingContext context,
                                                  PageHandlerExecutionDelegate next)
    {
        // Do post work.
        await next.Invoke();
    }
}
```

In the preceding code, `ProcessUserAgent.Write` is user supplied code that works with the user agent string.

The following code enables the `SampleAsyncPageFilter` in the `Startup` class:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages()
        .AddMvcOptions(options =>
        {
            options.Filters.Add(new SampleAsyncPageFilter(Configuration));
        });
}
```

The following code calls AddFolderApplicationModelConvention to apply the `SampleAsyncPageFilter` to only pages in */Movies*:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages(options =>
    {
        options.Conventions.AddFolderApplicationModelConvention(
            "/Movies",
            model => model.Filters.Add(new SampleAsyncPageFilter(Configuration)));
    });
}
```

The following code implements the synchronous `IPageFilter`:

```
public class SamplePageFilter : IPageFilter
{
    private readonly IConfiguration _config;

    public SamplePageFilter(IConfiguration config)
    {
        _config = config;
    }

    public void OnPageHandlerSelected(PageHandlerSelectedContext context)
    {
        var key = _config["UserAgentID"];
        context.HttpContext.Request.Headers.TryGetValue("user-agent", out StringValues value);
        ProcessUserAgent.Write(context.ActionDescriptor.DisplayName,
                               "SamplePageFilter.OnPageHandlerSelected",
                               value, key.ToString());
    }

    public void OnPageHandlerExecuting(PageHandlerExecutingContext context)
    {
        Debug.WriteLine("Global sync OnPageHandlerExecuting called.");
    }

    public void OnPageHandlerExecuted(PageHandlerExecutedContext context)
    {
        Debug.WriteLine("Global sync OnPageHandlerExecuted called.");
    }
}
```

The following code enables the `SamplePageFilter`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages()
        .AddMvcOptions(options =>
        {
            options.Filters.Add(new SamplePageFilter(Configuration));
        });
}
```

Implement Razor Page filters by overriding filter methods

The following code overrides the asynchronous Razor Page filters:

```
public class IndexModel : PageModel
{
    private readonly IConfiguration _config;

    public IndexModel(IConfiguration config)
    {
        _config = config;
    }

    public override Task OnPageHandlerSelectionAsync(PageHandlerSelectedContext context)
    {
        Debug.WriteLine("/IndexModel OnPageHandlerSelectionAsync");
        return Task.CompletedTask;
    }

    public async override Task OnPageHandlerExecutionAsync(PageHandlerExecutingContext context,
                                                           PageHandlerExecutionDelegate next)
    {
        var key = _config["UserAgentID"];
        context.HttpContext.Request.Headers.TryGetValue("user-agent", out StringValues value);
        ProcessUserAgent.Write(context.ActionDescriptor.DisplayName,
                               "/IndexModel-OnPageHandlerExecutionAsync",
                                value, key.ToString());

        await next.Invoke();
    }
}
```

Implement a filter attribute

The built-in attribute-based filter OnResultExecutionAsync filter can be subclassed. The following filter adds a header to the response:

```
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc.Filters;

namespace PageFilter.Filters
{
    public class AddHeaderAttribute  : ResultFilterAttribute
    {
        private readonly string _name;
        private readonly string _value;

        public AddHeaderAttribute (string name, string value)
        {
            _name = name;
            _value = value;
        }

        public override void OnResultExecuting(ResultExecutingContext context)
        {
            context.HttpContext.Response.Headers.Add(_name, new string[] { _value });
        }
    }
}
```

The following code applies the `AddHeader` attribute:

```
using Microsoft.AspNetCore.Mvc.RazorPages;
using PageFilter.Filters;

namespace PageFilter.Movies
{
    [AddHeader("Author", "Rick")]
    public class TestModel : PageModel
    {
        public void OnGet()
        {

        }
    }
}
```

Use a tool such as the browser developer tools to examine the headers. Under **Response Headers**, `author: Rick` is displayed.

See Overriding the default order for instructions on overriding the order.

See Cancellation and short circuiting for instructions to short-circuit the filter pipeline from a filter.

Authorize filter attribute

The Authorize attribute can be applied to a `PageModel`:

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace PageFilter.Pages
{
    [Authorize]
    public class ModelWithAuthFilterModel : PageModel
    {
        public IActionResult OnGet() => Page();
    }
}
```

By Rick Anderson

Razor Page filters IPageFilter and IAsyncPageFilter allow Razor Pages to run code before and after a Razor Page handler is run. Razor Page filters are similar to ASP.NET Core MVC action filters, except they can't be applied to individual page handler methods.

Razor Page filters:

- Run code after a handler method has been selected, but before model binding occurs.
- Run code before the handler method executes, after model binding is complete.
- Run code after the handler method executes.
- Can be implemented on a page or globally.
- Cannot be applied to specific page handler methods.

Code can be run before a handler method executes using the page constructor or middleware, but only Razor Page filters have access to HttpContext. Filters have a FilterContext derived parameter, which provides access to `HttpContext`. For example, the Implement a filter attribute sample adds a header to the response, something that can't be done with constructors or middleware.

View or download sample code (how to download)

Razor Page filters provide the following methods, which can be applied globally or at the page level:

- Synchronous methods:
  - OnPageHandlerSelected : Called after a handler method has been selected, but before model binding occurs.
  - OnPageHandlerExecuting : Called before the handler method executes, after model binding is complete.
  - OnPageHandlerExecuted : Called after the handler method executes, before the action result.
- Asynchronous methods:
  - OnPageHandlerSelectionAsync : Called asynchronously after the handler method has been selected, but before model binding occurs.
  - OnPageHandlerExecutionAsync : Called asynchronously before the handler method is invoked, after model binding is complete.

> **NOTE**
>
> Implement **either** the synchronous or the async version of a filter interface, not both. The framework checks first to see if the filter implements the async interface, and if so, it calls that. If not, it calls the synchronous interface's method(s). If both interfaces are implemented, only the async methods are called. The same rule applies to overrides in pages, implement the synchronous or the async version of the override, not both.

Implement Razor Page filters globally

The following code implements `IAsyncPageFilter`:

```
using Microsoft.AspNetCore.Mvc.Filters;
using Microsoft.Extensions.Logging;
using System.Threading.Tasks;

namespace PageFilter.Filters
{
    public class SampleAsyncPageFilter : IAsyncPageFilter
    {
        private readonly ILogger _logger;

        public SampleAsyncPageFilter(ILogger logger)
        {
            _logger = logger;
        }

        public async Task OnPageHandlerSelectionAsync(
                                        PageHandlerSelectedContext context)
        {
            _logger.LogDebug("Global OnPageHandlerSelectionAsync called.");
            await Task.CompletedTask;
        }

        public async Task OnPageHandlerExecutionAsync(
                                        PageHandlerExecutingContext context,
                                        PageHandlerExecutionDelegate next)
        {
            _logger.LogDebug("Global OnPageHandlerExecutionAsync called.");
            await next.Invoke();
        }
    }
}
```

In the preceding code, ILogger is not required. It's used in the sample to provide trace information for the

application.

The following code enables the `SampleAsyncPageFilter` in the `Startup` class:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc(options =>
    {
        options.Filters.Add(new SampleAsyncPageFilter(_logger));
    });
}
```

The following code shows the complete `Startup` class:

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Logging;
using PageFilter.Filters;

namespace PageFilter
{
    public class Startup
    {
        ILogger _logger;
        public Startup(ILoggerFactory loggerFactory, IConfiguration configuration)
        {
            _logger = loggerFactory.CreateLogger<GlobalFiltersLogger>();
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        public void ConfigureServices(IServiceCollection services)
        {
            services.AddMvc(options =>
            {
                options.Filters.Add(new SampleAsyncPageFilter(_logger));
            });
        }

        public void Configure(IApplicationBuilder app, IHostingEnvironment env)
        {
            if (env.IsDevelopment())
            {
                app.UseDeveloperExceptionPage();
            }
            else
            {
                app.UseExceptionHandler("/Error");
                app.UseHsts();
            }

            app.UseHttpsRedirection();
            app.UseStaticFiles();
            app.UseCookiePolicy();

            app.UseMvc();
        }
    }
}
```

The following code calls `AddFolderApplicationModelConvention` to apply the `SampleAsyncPageFilter` to only pages in

/subFolder:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
       .AddRazorPagesOptions(options =>
       {
           options.Conventions.AddFolderApplicationModelConvention(
               "/subFolder",
               model => model.Filters.Add(new SampleAsyncPageFilter(_logger)));
       });
}
```

The following code implements the synchronous `IPageFilter`:

```
using Microsoft.AspNetCore.Mvc.Filters;
using Microsoft.Extensions.Logging;

namespace PageFilter.Filters
{
    public class SamplePageFilter : IPageFilter
    {
        private readonly ILogger _logger;

        public SamplePageFilter(ILogger logger)
        {
            _logger = logger;
        }

        public void OnPageHandlerSelected(PageHandlerSelectedContext context)
        {
            _logger.LogDebug("Global sync OnPageHandlerSelected called.");
        }

        public void OnPageHandlerExecuting(PageHandlerExecutingContext context)
        {
            _logger.LogDebug("Global sync PageHandlerExecutingContext called.");
        }

        public void OnPageHandlerExecuted(PageHandlerExecutedContext context)
        {
            _logger.LogDebug("Global sync OnPageHandlerExecuted called.");
        }
    }
}
```

The following code enables the `SamplePageFilter`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc(options =>
    {
        options.Filters.Add(new SamplePageFilter(_logger));
    });
}
```

Implement Razor Page filters by overriding filter methods

The following code overrides the synchronous Razor Page filters:

```
using Microsoft.AspNetCore.Mvc.Filters;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.Extensions.Logging;

namespace PageFilter.Pages
{
    public class IndexModel : PageModel
    {
        private readonly ILogger _logger;

        public IndexModel(ILogger<IndexModel> logger)
        {
            _logger = logger;
        }
        public string Message { get; set; }

        public void OnGet()
        {
            _logger.LogDebug("IndexModel/OnGet");
        }

        public override void OnPageHandlerSelected(
                                    PageHandlerSelectedContext context)
        {
            _logger.LogDebug("IndexModel/OnPageHandlerSelected");
        }

        public override void OnPageHandlerExecuting(
                                    PageHandlerExecutingContext context)
        {
            Message = "Message set in handler executing";
            _logger.LogDebug("IndexModel/OnPageHandlerExecuting");
        }

        public override void OnPageHandlerExecuted(
                                    PageHandlerExecutedContext context)
        {
            _logger.LogDebug("IndexModel/OnPageHandlerExecuted");
        }
    }
}
```

Implement a filter attribute

The built-in attribute-based filter OnResultExecutionAsync filter can be subclassed. The following filter adds a header to the response:

```
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc.Filters;

namespace PageFilter.Filters
{
    public class AddHeaderAttribute  : ResultFilterAttribute
    {
        private readonly string _name;
        private readonly string _value;

        public AddHeaderAttribute (string name, string value)
        {
            _name = name;
            _value = value;
        }

        public override void OnResultExecuting(ResultExecutingContext context)
        {
            context.HttpContext.Response.Headers.Add(_name, new string[] { _value });
        }
    }
}
```

The following code applies the `AddHeader` attribute:

```
[AddHeader("Author", "Rick")]
public class ContactModel : PageModel
{
    private readonly ILogger _logger;

    public ContactModel(ILogger<ContactModel> logger)
    {
        _logger = logger;
    }
    public string Message { get; set; }

    public async Task OnGetAsync()
    {
        Message = "Your contact page.";
        _logger.LogDebug("Contact/OnGet");
        await Task.CompletedTask;
    }
}
```

See Overriding the default order for instructions on overriding the order.

See Cancellation and short circuiting for instructions to short-circuit the filter pipeline from a filter.

Authorize filter attribute

The Authorize attribute can be applied to a `PageModel`:

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace PageFilter.Pages
{
    [Authorize]
    public class ModelWithAuthFilterModel : PageModel
    {
        public IActionResult OnGet() => Page();
    }
}
```

Razor Pages route and app conventions in ASP.NET Core

9/22/2020 • 35 minutes to read • Edit Online

Learn how to use page route and app model provider conventions to control page routing, discovery, and processing in Razor Pages apps.

When you need to configure custom page routes for individual pages, configure routing to pages with the AddPageRoute convention described later in this topic.

To specify a page route, add route segments, or add parameters to a route, use the page's `@page` directive. For more information, see Custom routes.

There are reserved words that can't be used as route segments or parameter names. For more information, see Routing: Reserved routing names.

View or download sample code (how to download)

SCENARIO	THE SAMPLE DEMONSTRATES ...
Model conventions Conventions.Add • IPageRouteModelConvention • IPageApplicationModelConvention • IPageHandlerModelConvention	Add a route template and header to an app's pages.
Page route action conventions • AddFolderRouteModelConvention • AddPageRouteModelConvention • AddPageRoute	Add a route template to pages in a folder and to a single page.
Page model action conventions • AddFolderApplicationModelConvention • AddPageApplicationModelConvention • ConfigureFilter (filter class, lambda expression, or filter factory)	Add a header to pages in a folder, add a header to a single page, and configure a filter factory to add a header to an app's pages.

Razor Pages conventions are configured using an AddRazorPages overload that configures RazorPagesOptions in `Startup.ConfigureServices`. The following convention examples are explained later in this topic:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages(options =>
    {
        options.Conventions.Add( ... );
        options.Conventions.AddFolderRouteModelConvention(
            "/OtherPages", model => { ... });
        options.Conventions.AddPageRouteModelConvention(
            "/About", model => { ... });
        options.Conventions.AddPageRoute(
            "/Contact", "TheContactPage/{text?}");
        options.Conventions.AddFolderApplicationModelConvention(
            "/OtherPages", model => { ... });
        options.Conventions.AddPageApplicationModelConvention(
            "/About", model => { ... });
        options.Conventions.ConfigureFilter(model => { ... });
        options.Conventions.ConfigureFilter( ... );
    });
}
```

Route order

Routes specify an Order for processing (route matching).

ORDER	BEHAVIOR
-1	The route is processed before other routes are processed.
0	Order isn't specified (default value). Not assigning `Order` (`Order = null`) defaults the route `Order` to 0 (zero) for processing.
1, 2, ... n	Specifies the route processing order.

Route processing is established by convention:

- Routes are processed in sequential order (-1, 0, 1, 2, ... n).
- When routes have the same `Order`, the most specific route is matched first followed by less specific routes.
- When routes with the same `Order` and the same number of parameters match a request URL, routes are processed in the order that they're added to the PageConventionCollection.

If possible, avoid depending on an established route processing order. Generally, routing selects the correct route with URL matching. If you must set route `Order` properties to route requests correctly, the app's routing scheme is probably confusing to clients and fragile to maintain. Seek to simplify the app's routing scheme. The sample app requires an explicit route processing order to demonstrate several routing scenarios using a single app. However, you should attempt to avoid the practice of setting route `Order` in production apps.

Razor Pages routing and MVC controller routing share an implementation. Information on route order in the MVC topics is available at Routing to controller actions: Ordering attribute routes.

Model conventions

Add a delegate for IPageConvention to add model conventions that apply to Razor Pages.

Add a route model convention to all pages

Use Conventions to create and add an IPageRouteModelConvention to the collection of IPageConvention instances that are applied during page route model construction.

The sample app adds a `{globalTemplate?}` route template to all of the pages in the app:

```
public class GlobalTemplatePageRouteModelConvention
    : IPageRouteModelConvention
{
    public void Apply(PageRouteModel model)
    {
        var selectorCount = model.Selectors.Count;
        for (var i = 0; i < selectorCount; i++)
        {
            var selector = model.Selectors[i];
            model.Selectors.Add(new SelectorModel
            {
                AttributeRouteModel = new AttributeRouteModel
                {
                    Order = 1,
                    Template = AttributeRouteModel.CombineTemplates(
                        selector.AttributeRouteModel.Template,
                        "{globalTemplate?}"),
                }
            });
        }
    }
}
```

The Order property for the AttributeRouteModel is set to `1`. This ensures the following route matching behavior in the sample app:

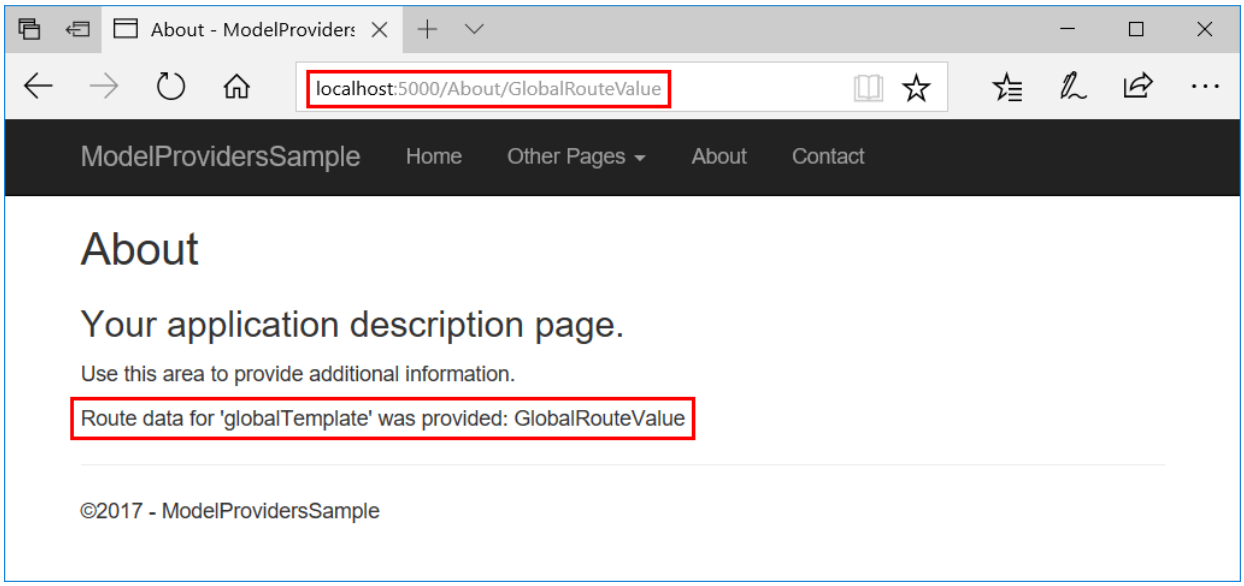
- A route template for `TheContactPage/{text?}` is added later in the topic. The Contact Page route has a default order of `null` (`Order = 0`), so it matches before the `{globalTemplate?}` route template.
- An `{aboutTemplate?}` route template is added later in the topic. The `{aboutTemplate?}` template is given an `Order` of `2`. When the About page is requested at `/About/RouteDataValue`, "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["aboutTemplate"]` (`Order = 2`) due to setting the `Order` property.
- An `{otherPagesTemplate?}` route template is added later in the topic. The `{otherPagesTemplate?}` template is given an `Order` of `2`. When any page in the *Pages/OtherPages* folder is requested with a route parameter (for example, `/OtherPages/Page1/RouteDataValue`), "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["otherPagesTemplate"]` (`Order = 2`) due to setting the `Order` property.

Wherever possible, don't set the `Order`, which results in `Order = 0`. Rely on routing to select the correct route.

Razor Pages options, such as adding Conventions, are added when Razor Pages is added to the service collection in `Startup.ConfigureServices`. For an example, see the sample app.

```
options.Conventions.Add(new GlobalTemplatePageRouteModelConvention());
```

Request the sample's About page at `localhost:5000/About/GlobalRouteValue` and inspect the result:



Add an app model convention to all pages

Use Conventions to create and add an IPageApplicationModelConvention to the collection of IPageConvention instances that are applied during page app model construction.

To demonstrate this and other conventions later in the topic, the sample app includes an `AddHeaderAttribute` class. The class constructor accepts a `name` string and a `values` string array. These values are used in its `OnResultExecuting` method to set a response header. The full class is shown in the Page model action conventions section later in the topic.

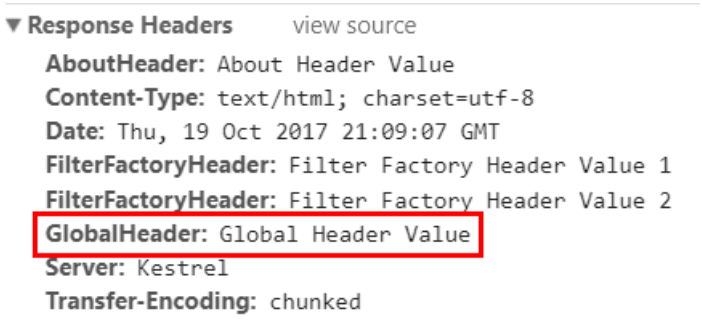
The sample app uses the `AddHeaderAttribute` class to add a header, `GlobalHeader`, to all of the pages in the app:

```
public class GlobalHeaderPageApplicationModelConvention
    : IPageApplicationModelConvention
{
    public void Apply(PageApplicationModel model)
    {
        model.Filters.Add(new AddHeaderAttribute(
            "GlobalHeader", new string[] { "Global Header Value" }));
    }
}
```

Startup.cs:

```
options.Conventions.Add(new GlobalHeaderPageApplicationModelConvention());
```

Request the sample's About page at `localhost:5000/About` and inspect the headers to view the result:



Add a handler model convention to all pages

Use Conventions to create and add an IPageHandlerModelConvention to the collection of IPageConvention instances that are applied during page handler model construction.

```
public class GlobalPageHandlerModelConvention
    : IPageHandlerModelConvention
{
    public void Apply(PageHandlerModel model)
    {
        // Access the PageHandlerModel
    }
}
```

Startup.cs:

```
options.Conventions.Add(new GlobalPageHandlerModelConvention());
```

Page route action conventions

The default route model provider that derives from IPageRouteModelProvider invokes conventions which are designed to provide extensibility points for configuring page routes.

Folder route model convention

Use AddFolderRouteModelConvention to create and add an IPageRouteModelConvention that invokes an action on the PageRouteModel for all of the pages under the specified folder.

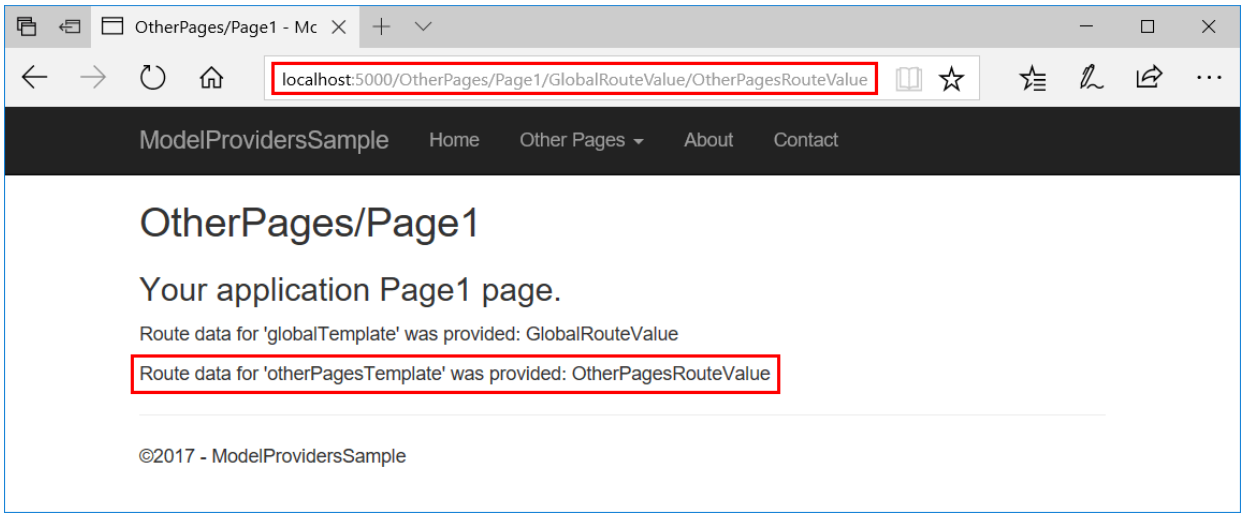
The sample app uses AddFolderRouteModelConvention to add an `{otherPagesTemplate?}` route template to the pages in the *OtherPages* folder:

```
options.Conventions.AddFolderRouteModelConvention("/OtherPages", model =>
{
    var selectorCount = model.Selectors.Count;
    for (var i = 0; i < selectorCount; i++)
    {
        var selector = model.Selectors[i];
        model.Selectors.Add(new SelectorModel
        {
            AttributeRouteModel = new AttributeRouteModel
            {
                Order = 2,
                Template = AttributeRouteModel.CombineTemplates(
                    selector.AttributeRouteModel.Template,
                    "{otherPagesTemplate?}"),
            }
        });
    }
});
```

The Order property for the AttributeRouteModel is set to `2`. This ensures that the template for `{globalTemplate?}` (set earlier in the topic to `1`) is given priority for the first route data value position when a single route value is provided. If a page in the *Pages/OtherPages* folder is requested with a route parameter value (for example, `/OtherPages/Page1/RouteDataValue`), "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["otherPagesTemplate"]` (`Order = 2`) due to setting the `Order` property.

Wherever possible, don't set the `Order`, which results in `Order = 0`. Rely on routing to select the correct route.

Request the sample's Page1 page at `localhost:5000/OtherPages/Page1/GlobalRouteValue/OtherPagesRouteValue` and inspect the result:



Page route model convention

Use AddPageRouteModelConvention to create and add an IPageRouteModelConvention that invokes an action on the PageRouteModel for the page with the specified name.

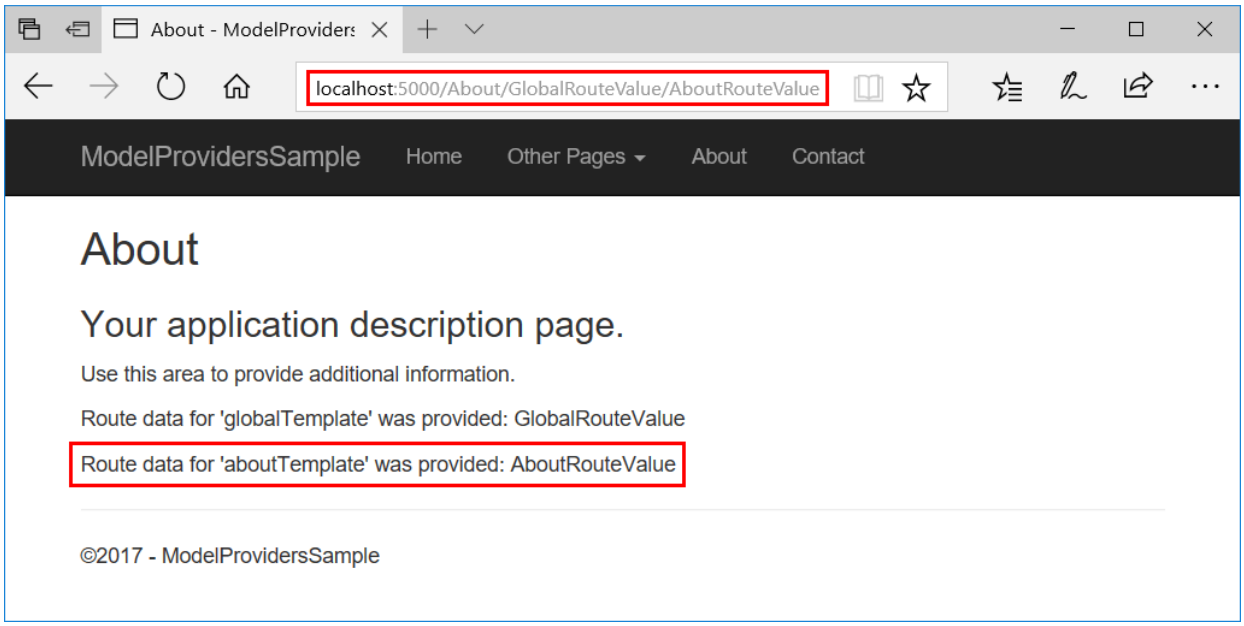
The sample app uses `AddPageRouteModelConvention` to add an `{aboutTemplate?}` route template to the About page:

```
options.Conventions.AddPageRouteModelConvention("/About", model =>
{
    var selectorCount = model.Selectors.Count;
    for (var i = 0; i < selectorCount; i++)
    {
        var selector = model.Selectors[i];
        model.Selectors.Add(new SelectorModel
        {
            AttributeRouteModel = new AttributeRouteModel
            {
                Order = 2,
                Template = AttributeRouteModel.CombineTemplates(
                    selector.AttributeRouteModel.Template,
                    "{aboutTemplate?}"),
            }
        });
    }
});
```

The Order property for the AttributeRouteModel is set to `2`. This ensures that the template for `{globalTemplate?}` (set earlier in the topic to `1`) is given priority for the first route data value position when a single route value is provided. If the About page is requested with a route parameter value at `/About/RouteDataValue`, "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["aboutTemplate"]` (`Order = 2`) due to setting the `Order` property.

Wherever possible, don't set the `Order`, which results in `Order = 0`. Rely on routing to select the correct route.

Request the sample's About page at `localhost:5000/About/GlobalRouteValue/AboutRouteValue` and inspect the result:



Use a parameter transformer to customize page routes

Page routes generated by ASP.NET Core can be customized using a parameter transformer. A parameter transformer implements `IOutboundParameterTransformer` and transforms the value of parameters. For example, a custom `SlugifyParameterTransformer` parameter transformer changes the `SubscriptionManagement` route value to `subscription-management`.

The `PageRouteTransformerConvention` page route model convention applies a parameter transformer to the folder and file name segments of automatically generated page routes in an app. For example, the Razor Pages file at */Pages/SubscriptionManagement/ViewAll.cshtml* would have its route rewritten from `/SubscriptionManagement/ViewAll` to `/subscription-management/view-all`.

`PageRouteTransformerConvention` only transforms the automatically generated segments of a page route that come from the Razor Pages folder and file name. It doesn't transform route segments added with the `@page` directive. The convention also doesn't transform routes added by AddPageRoute.

The `PageRouteTransformerConvention` is registered as an option in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages(options =>
    {
        options.Conventions.Add(
            new PageRouteTransformerConvention(
                new SlugifyParameterTransformer()));
    });
}
```

```
public class SlugifyParameterTransformer : IOutboundParameterTransformer
{
    public string TransformOutbound(object value)
    {
        if (value == null) { return null; }

        return Regex.Replace(value.ToString(),
                             "([a-z])([A-Z])",
                             "$1-$2",
                             RegexOptions.CultureInvariant,
                             TimeSpan.FromMilliseconds(100)).ToLowerInvariant();
    }
}
```

WARNING

When using System.Text.RegularExpressions to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions` causing a Denial-of-Service attack. ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

Configure a page route

Use AddPageRoute to configure a route to a page at the specified page path. Generated links to the page use your specified route. `AddPageRoute` uses `AddPageRouteModelConvention` to establish the route.

The sample app creates a route to `/TheContactPage` for *Contact.cshtml*:

```
options.Conventions.AddPageRoute("/Contact", "TheContactPage/{text?}");
```

The Contact page can also be reached at `/Contact` via its default route.

The sample app's custom route to the Contact page allows for an optional `text` route segment (`{text?}`). The page also includes this optional segment in its `@page` directive in case the visitor accesses the page at its `/Contact` route:

```
@page "{text?}"
@model ContactModel
@{
    ViewData["Title"] = "Contact";
}

<h1>@ViewData["Title"]</h1>
<h2>@Model.Message</h2>

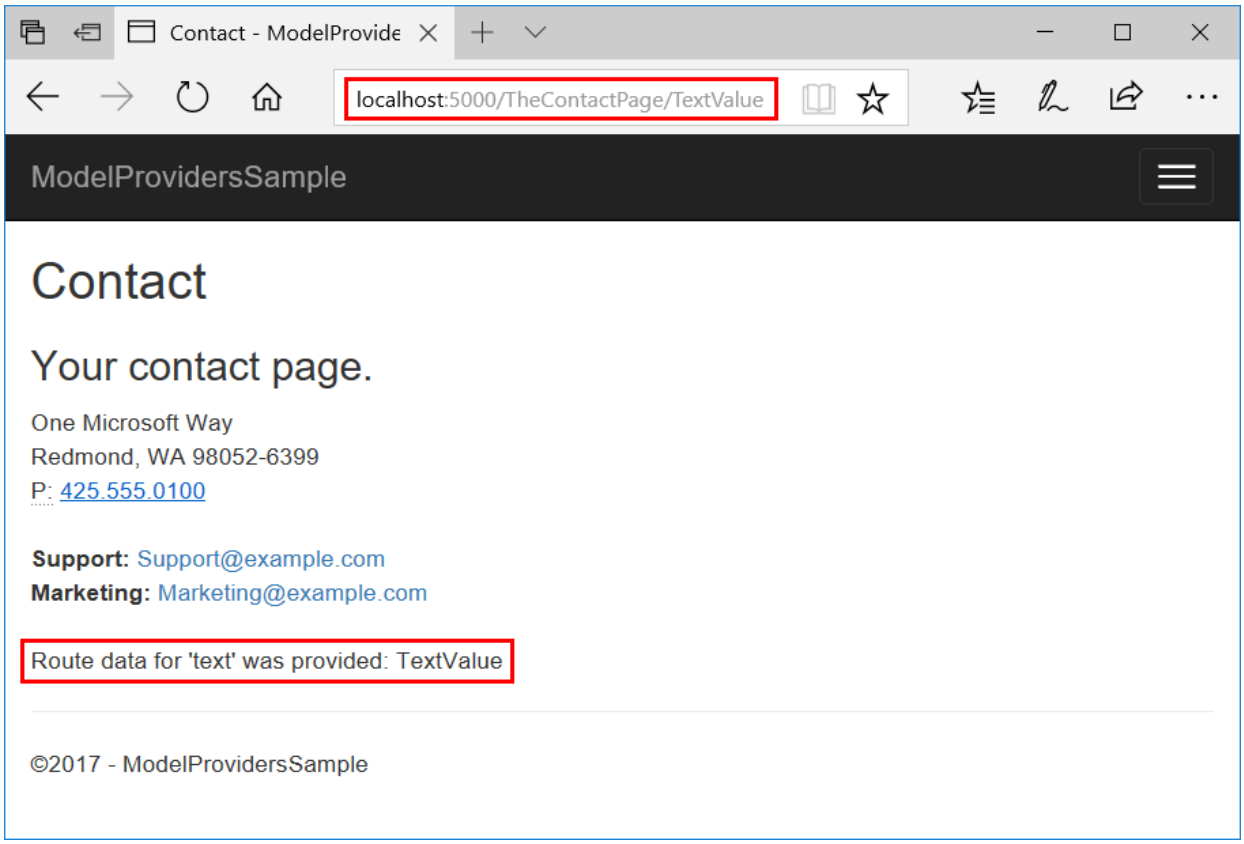
<address>
    One Microsoft Way<br>
    Redmond, WA 98052-6399<br>
    <abbr title="Phone">P:</abbr>
    425.555.0100
</address>

<address>
    <strong>Support:</strong> <a href="mailto:Support@example.com">Support@example.com</a><br>
    <strong>Marketing:</strong> <a href="mailto:Marketing@example.com">Marketing@example.com</a>
</address>

<p>@Model.RouteDataTextTemplateValue</p>
```

Note that the URL generated for the **Contact** link in the rendered page reflects the updated route:

Visit the Contact page at either its ordinary route, `/Contact`, or the custom route, `/TheContactPage`. If you supply an additional `text` route segment, the page shows the HTML-encoded segment that you provide:



Page model action conventions

The default page model provider that implements IPageApplicationModelProvider invokes conventions which are designed to provide extensibility points for configuring page models. These conventions are useful when building and modifying page discovery and processing scenarios.

For the examples in this section, the sample app uses an `AddHeaderAttribute` class, which is a ResultFilterAttribute, that applies a response header:

```
public class AddHeaderAttribute : ResultFilterAttribute
{
    private readonly string _name;
    private readonly string[] _values;

    public AddHeaderAttribute(string name, string[] values)
    {
        _name = name;
        _values = values;
    }

    public override void OnResultExecuting(ResultExecutingContext context)
    {
        context.HttpContext.Response.Headers.Add(_name, _values);
        base.OnResultExecuting(context);
    }
}
```

Using conventions, the sample demonstrates how to apply the attribute to all of the pages in a folder and to a single page.

Folder app model convention

Use AddFolderApplicationModelConvention to create and add an IPageApplicationModelConvention that invokes an action on PageApplicationModel instances for all pages under the specified folder.

The sample demonstrates the use of `AddFolderApplicationModelConvention` by adding a header, `OtherPagesHeader`, to the pages inside the *OtherPages* folder of the app:

```
options.Conventions.AddFolderApplicationModelConvention("/OtherPages", model =>
{
    model.Filters.Add(new AddHeaderAttribute(
        "OtherPagesHeader", new string[] { "OtherPages Header Value" }));
});
```

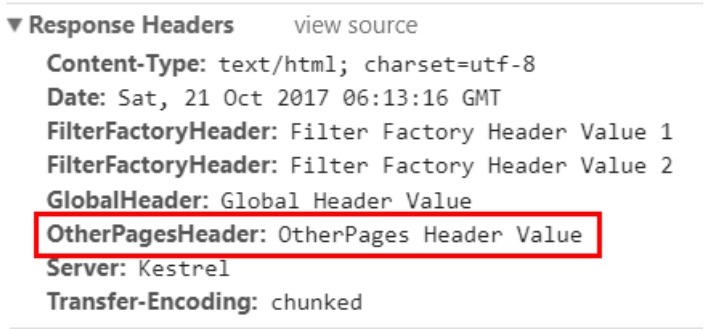
Request the sample's Page1 page at `localhost:5000/OtherPages/Page1` and inspect the headers to view the result:



Page app model convention

Use AddPageApplicationModelConvention to create and add an IPageApplicationModelConvention that invokes an action on the PageApplicationModel for the page with the specified name.

The sample demonstrates the use of `AddPageApplicationModelConvention` by adding a header, `AboutHeader`, to the About page:

```
options.Conventions.AddPageApplicationModelConvention("/About", model =>
{
    model.Filters.Add(new AddHeaderAttribute(
        "AboutHeader", new string[] { "About Header Value" }));
});
```

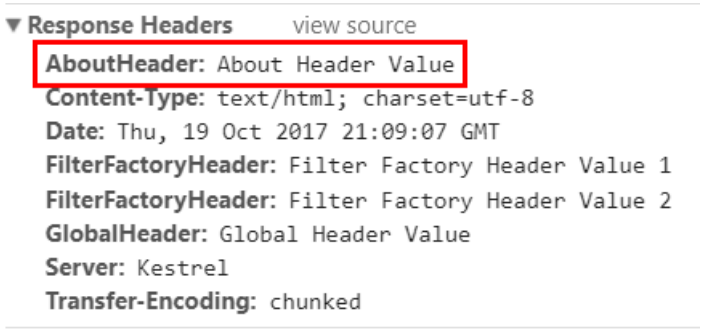
Request the sample's About page at `localhost:5000/About` and inspect the headers to view the result:



Configure a filter

ConfigureFilter configures the specified filter to apply. You can implement a filter class, but the sample app shows how to implement a filter in a lambda expression, which is implemented behind-the-scenes as a factory that returns a filter:

```
options.Conventions.ConfigureFilter(model =>
{
    if (model.RelativePath.Contains("OtherPages/Page2"))
    {
        return new AddHeaderAttribute(
            "OtherPagesPage2Header",
            new string[] { "OtherPages/Page2 Header Value" });
    }
    return new EmptyFilter();
});
```

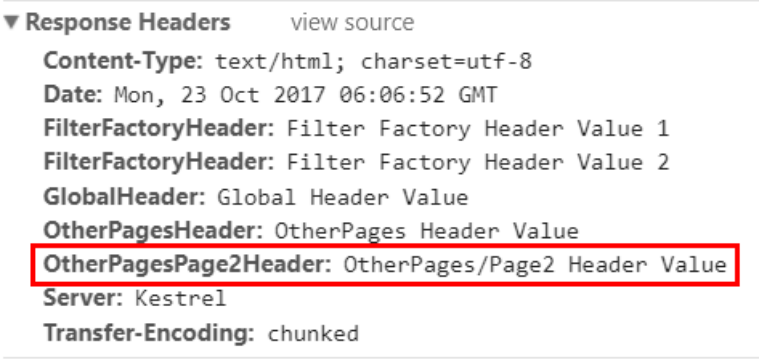
The page app model is used to check the relative path for segments that lead to the Page2 page in the *OtherPages* folder. If the condition passes, a header is added. If not, the `EmptyFilter` is applied.

`EmptyFilter` is an Action filter. Since Action filters are ignored by Razor Pages, the `EmptyFilter` has no effect as intended if the path doesn't contain `OtherPages/Page2`.

Request the sample's Page2 page at `localhost:5000/OtherPages/Page2` and inspect the headers to view the result:



Configure a filter factory

ConfigureFilter configures the specified factory to apply filters to all Razor Pages.

The sample app provides an example of using a filter factory by adding a header, `FilterFactoryHeader`, with two

values to the app's pages:

```
options.Conventions.ConfigureFilter(new AddHeaderWithFactory());
```

AddHeaderWithFactory.cs:

```
public class AddHeaderWithFactory : IFilterFactory
{
    // Implement IFilterFactory
    public IFilterMetadata CreateInstance(IServiceProvider serviceProvider)
    {
        return new AddHeaderFilter();
    }

    private class AddHeaderFilter : IResultFilter
    {
        public void OnResultExecuting(ResultExecutingContext context)
        {
            context.HttpContext.Response.Headers.Add(
                "FilterFactoryHeader",
                new string[]
                {
                    "Filter Factory Header Value 1",
                    "Filter Factory Header Value 2"
                });
        }

        public void OnResultExecuted(ResultExecutedContext context)
        {
        }
    }

    public bool IsReusable
    {
        get
        {
            return false;
        }
    }
}
```

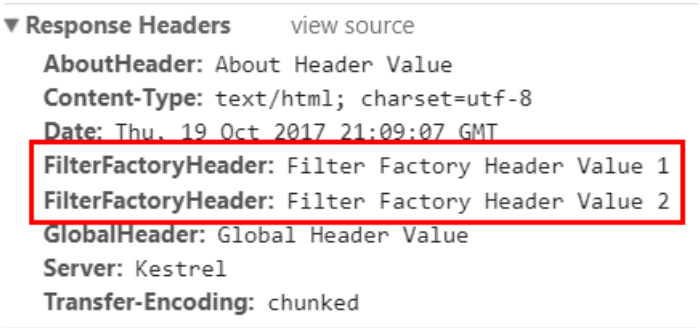
Request the sample's About page at `localhost:5000/About` and inspect the headers to view the result:



MVC Filters and the Page filter (IPageFilter)

MVC Action filters are ignored by Razor Pages, since Razor Pages use handler methods. Other types of MVC filters are available for you to use: Authorization, Exception, Resource, and Result. For more information, see the Filters topic.

The Page filter (IPageFilter) is a filter that applies to Razor Pages. For more information, see Filter methods for Razor Pages.

- Areas in ASP.NET Core

Learn how to use page route and app model provider conventions to control page routing, discovery, and processing in Razor Pages apps.

When you need to configure custom page routes for individual pages, configure routing to pages with the AddPageRoute convention described later in this topic.

To specify a page route, add route segments, or add parameters to a route, use the page's `@page` directive. For more information, see Custom routes.

There are reserved words that can't be used as route segments or parameter names. For more information, see Routing: Reserved routing names.

View or download sample code (how to download)

SCENARIO	THE SAMPLE DEMONSTRATES ...
Model conventions Conventions.Add • IPageRouteModelConvention • IPageApplicationModelConvention • IPageHandlerModelConvention	Add a route template and header to an app's pages.
Page route action conventions • AddFolderRouteModelConvention • AddPageRouteModelConvention • AddPageRoute	Add a route template to pages in a folder and to a single page.
Page model action conventions • AddFolderApplicationModelConvention • AddPageApplicationModelConvention • ConfigureFilter (filter class, lambda expression, or filter factory)	Add a header to pages in a folder, add a header to a single page, and configure a filter factory to add a header to an app's pages.

Razor Pages conventions are added and configured using the AddRazorPagesOptions extension method to AddMvc on the service collection in the `Startup` class. The following convention examples are explained later in this topic:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
        .AddRazorPagesOptions(options =>
        {
            options.Conventions.Add( ... );
            options.Conventions.AddFolderRouteModelConvention(
                "/OtherPages", model => { ... });
            options.Conventions.AddPageRouteModelConvention(
                "/About", model => { ... });
            options.Conventions.AddPageRoute(
                "/Contact", "TheContactPage/{text?}");
            options.Conventions.AddFolderApplicationModelConvention(
                "/OtherPages", model => { ... });
            options.Conventions.AddPageApplicationModelConvention(
                "/About", model => { ... });
            options.Conventions.ConfigureFilter(model => { ... });
            options.Conventions.ConfigureFilter( ... );
        });
}
```

Route order

Routes specify an Order for processing (route matching).

ORDER	BEHAVIOR
-1	The route is processed before other routes are processed.
0	Order isn't specified (default value). Not assigning `Order` (`Order = null`) defaults the route `Order` to 0 (zero) for processing.
1, 2, ... n	Specifies the route processing order.

Route processing is established by convention:

- Routes are processed in sequential order (-1, 0, 1, 2, ... n).
- When routes have the same `Order`, the most specific route is matched first followed by less specific routes.
- When routes with the same `Order` and the same number of parameters match a request URL, routes are processed in the order that they're added to the PageConventionCollection.

If possible, avoid depending on an established route processing order. Generally, routing selects the correct route with URL matching. If you must set route `Order` properties to route requests correctly, the app's routing scheme is probably confusing to clients and fragile to maintain. Seek to simplify the app's routing scheme. The sample app requires an explicit route processing order to demonstrate several routing scenarios using a single app. However, you should attempt to avoid the practice of setting route `Order` in production apps.

Razor Pages routing and MVC controller routing share an implementation. Information on route order in the MVC topics is available at Routing to controller actions: Ordering attribute routes.

Model conventions

Add a delegate for IPageConvention to add model conventions that apply to Razor Pages.

Add a route model convention to all pages

Use Conventions to create and add an IPageRouteModelConvention to the collection of IPageConvention

instances that are applied during page route model construction.

The sample app adds a `{globalTemplate?}` route template to all of the pages in the app:

```
public class GlobalTemplatePageRouteModelConvention
    : IPageRouteModelConvention
{
    public void Apply(PageRouteModel model)
    {
        var selectorCount = model.Selectors.Count;
        for (var i = 0; i < selectorCount; i++)
        {
            var selector = model.Selectors[i];
            model.Selectors.Add(new SelectorModel
            {
                AttributeRouteModel = new AttributeRouteModel
                {
                    Order = 1,
                    Template = AttributeRouteModel.CombineTemplates(
                        selector.AttributeRouteModel.Template,
                        "{globalTemplate?}"),
                }
            });
        }
    }
}
```

The Order property for the AttributeRouteModel is set to `1`. This ensures the following route matching behavior in the sample app:

- A route template for `TheContactPage/{text?}` is added later in the topic. The Contact Page route has a default order of `null` (`Order = 0`), so it matches before the `{globalTemplate?}` route template.
- An `{aboutTemplate?}` route template is added later in the topic. The `{aboutTemplate?}` template is given an `Order` of `2`. When the About page is requested at `/About/RouteDataValue`, "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["aboutTemplate"]` (`Order = 2`) due to setting the `Order` property.
- An `{otherPagesTemplate?}` route template is added later in the topic. The `{otherPagesTemplate?}` template is given an `Order` of `2`. When any page in the *Pages/OtherPages* folder is requested with a route parameter (for example, `/OtherPages/Page1/RouteDataValue`), "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["otherPagesTemplate"]` (`Order = 2`) due to setting the `Order` property.

Wherever possible, don't set the `Order`, which results in `Order = 0`. Rely on routing to select the correct route.

Razor Pages options, such as adding Conventions, are added when MVC is added to the service collection in `Startup.ConfigureServices`. For an example, see the sample app.

```
options.Conventions.Add(new GlobalTemplatePageRouteModelConvention());
```

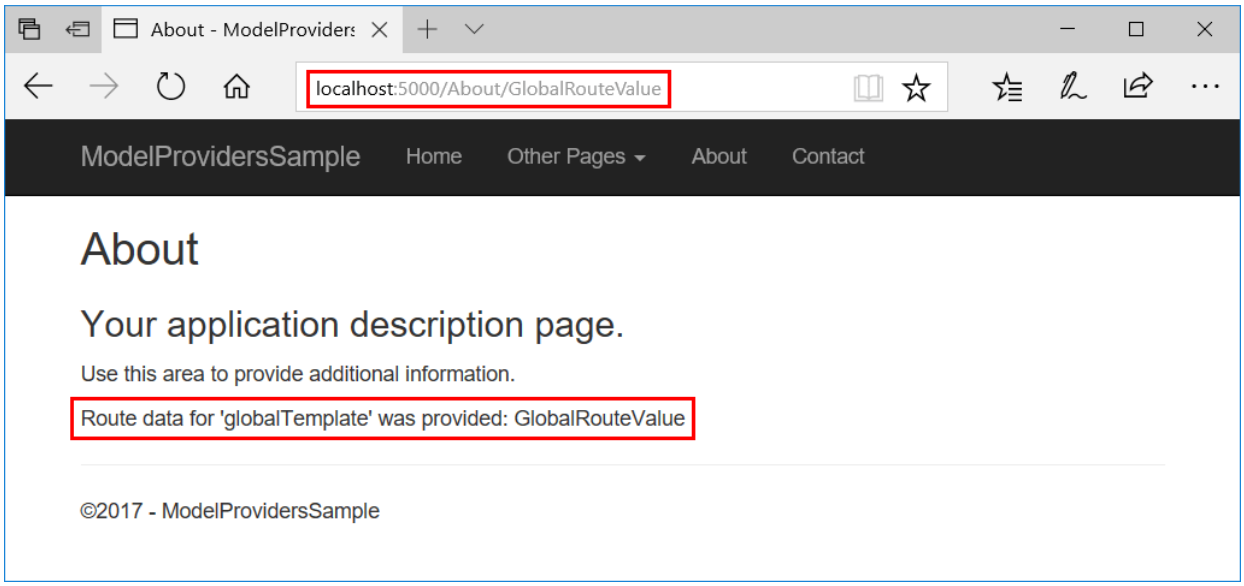
Request the sample's About page at `localhost:5000/About/GlobalRouteValue` and inspect the result:



Add an app model convention to all pages

Use Conventions to create and add an IPageApplicationModelConvention to the collection of IPageConvention instances that are applied during page app model construction.

To demonstrate this and other conventions later in the topic, the sample app includes an `AddHeaderAttribute` class. The class constructor accepts a `name` string and a `values` string array. These values are used in its `OnResultExecuting` method to set a response header. The full class is shown in the Page model action conventions section later in the topic.

The sample app uses the `AddHeaderAttribute` class to add a header, `GlobalHeader`, to all of the pages in the app:

```
public class GlobalHeaderPageApplicationModelConvention
    : IPageApplicationModelConvention
{
    public void Apply(PageApplicationModel model)
    {
        model.Filters.Add(new AddHeaderAttribute(
            "GlobalHeader", new string[] { "Global Header Value" }));
    }
}
```

Startup.cs:

```
options.Conventions.Add(new GlobalHeaderPageApplicationModelConvention());
```

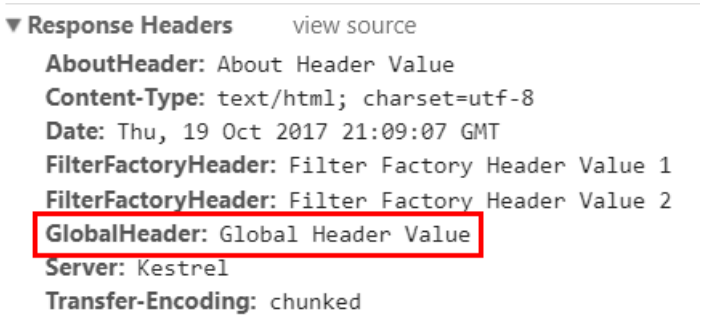
Request the sample's About page at `localhost:5000/About` and inspect the headers to view the result:



Add a handler model convention to all pages

Use Conventions to create and add an IPageHandlerModelConvention to the collection of IPageConvention instances that are applied during page handler model construction.

```
public class GlobalPageHandlerModelConvention
    : IPageHandlerModelConvention
{
    public void Apply(PageHandlerModel model)
    {
        // Access the PageHandlerModel
    }
}
```

Startup.cs:

```
options.Conventions.Add(new GlobalPageHandlerModelConvention());
```

Page route action conventions

The default route model provider that derives from IPageRouteModelProvider invokes conventions which are designed to provide extensibility points for configuring page routes.

Folder route model convention

Use AddFolderRouteModelConvention to create and add an IPageRouteModelConvention that invokes an action on the PageRouteModel for all of the pages under the specified folder.

The sample app uses AddFolderRouteModelConvention to add an `{otherPagesTemplate?}` route template to the pages in the *OtherPages* folder:

```
options.Conventions.AddFolderRouteModelConvention("/OtherPages", model =>
{
    var selectorCount = model.Selectors.Count;
    for (var i = 0; i < selectorCount; i++)
    {
        var selector = model.Selectors[i];
        model.Selectors.Add(new SelectorModel
        {
            AttributeRouteModel = new AttributeRouteModel
            {
                Order = 2,
                Template = AttributeRouteModel.CombineTemplates(
                    selector.AttributeRouteModel.Template,
                    "{otherPagesTemplate?}"),
            }
        });
    }
});
```

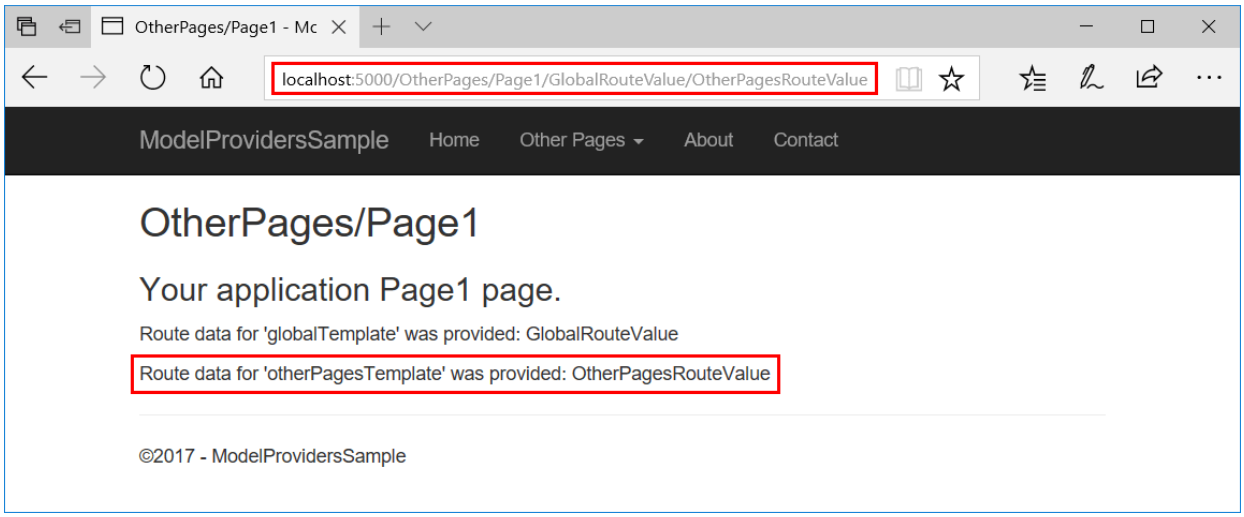
The Order property for the AttributeRouteModel is set to `2`. This ensures that the template for `{globalTemplate?}` (set earlier in the topic to `1`) is given priority for the first route data value position when a single route value is provided. If a page in the *Pages/OtherPages* folder is requested with a route parameter value (for example, `/OtherPages/Page1/RouteDataValue`), "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["otherPagesTemplate"]` (`Order = 2`) due to setting the `Order` property.

Wherever possible, don't set the `Order`, which results in `Order = 0`. Rely on routing to select the correct route.

Request the sample's Page1 page at `localhost:5000/OtherPages/Page1/GlobalRouteValue/OtherPagesRouteValue` and inspect the result:



Page route model convention

Use AddPageRouteModelConvention to create and add an IPageRouteModelConvention that invokes an action on the PageRouteModel for the page with the specified name.

The sample app uses `AddPageRouteModelConvention` to add an `{aboutTemplate?}` route template to the About page:

```
options.Conventions.AddPageRouteModelConvention("/About", model =>
{
    var selectorCount = model.Selectors.Count;
    for (var i = 0; i < selectorCount; i++)
    {
        var selector = model.Selectors[i];
        model.Selectors.Add(new SelectorModel
        {
            AttributeRouteModel = new AttributeRouteModel
            {
                Order = 2,
                Template = AttributeRouteModel.CombineTemplates(
                    selector.AttributeRouteModel.Template,
                    "{aboutTemplate?}"),
            }
        });
    }
});
```

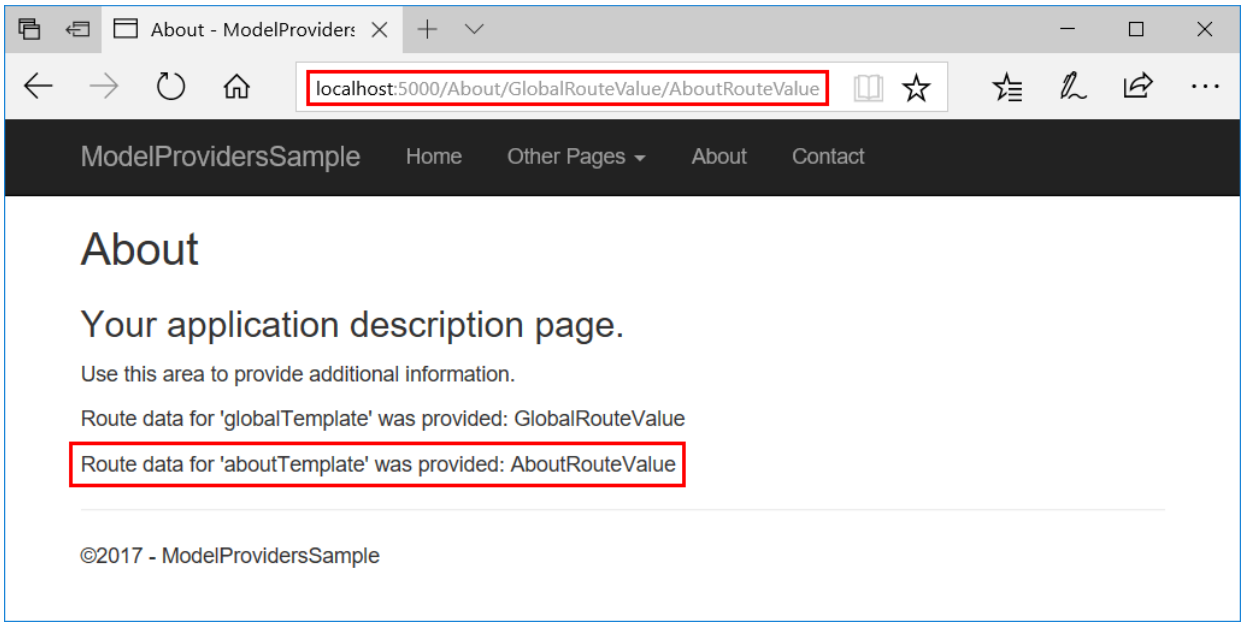
The Order property for the AttributeRouteModel is set to `2`. This ensures that the template for `{globalTemplate?}` (set earlier in the topic to `1`) is given priority for the first route data value position when a single route value is provided. If the About page is requested with a route parameter value at `/About/RouteDataValue`, "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["aboutTemplate"]` (`Order = 2`) due to setting the `Order` property.

Wherever possible, don't set the `Order`, which results in `Order = 0`. Rely on routing to select the correct route.

Request the sample's About page at `localhost:5000/About/GlobalRouteValue/AboutRouteValue` and inspect the result:



Use a parameter transformer to customize page routes

Page routes generated by ASP.NET Core can be customized using a parameter transformer. A parameter transformer implements `IOutboundParameterTransformer` and transforms the value of parameters. For example, a custom `SlugifyParameterTransformer` parameter transformer changes the `SubscriptionManagement` route value to `subscription-management`.

The `PageRouteTransformerConvention` page route model convention applies a parameter transformer to the folder and file name segments of automatically generated page routes in an app. For example, the Razor Pages file at */Pages/SubscriptionManagement/ViewAll.cshtml* would have its route rewritten from `/SubscriptionManagement/ViewAll` to `/subscription-management/view-all`.

`PageRouteTransformerConvention` only transforms the automatically generated segments of a page route that come from the Razor Pages folder and file name. It doesn't transform route segments added with the `@page` directive. The convention also doesn't transform routes added by AddPageRoute.

The `PageRouteTransformerConvention` is registered as an option in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
        .AddRazorPagesOptions(options =>
        {
            options.Conventions.Add(
                new PageRouteTransformerConvention(
                    new SlugifyParameterTransformer()));
        });
}

public class SlugifyParameterTransformer : IOutboundParameterTransformer
{
    public string TransformOutbound(object value)
    {
        if (value == null) { return null; }

        // Slugify value
        return Regex.Replace(value.ToString(), "([a-z])([A-Z])", "$1-$2").ToLower();
    }
}
```

Configure a page route

Use AddPageRoute to configure a route to a page at the specified page path. Generated links to the page use your specified route. `AddPageRoute` uses `AddPageRouteModelConvention` to establish the route.

The sample app creates a route to `/TheContactPage` for *Contact.cshtml*:

```
options.Conventions.AddPageRoute("/Contact", "TheContactPage/{text?}");
```

The Contact page can also be reached at `/Contact` via its default route.

The sample app's custom route to the Contact page allows for an optional `text` route segment (`{text?}`). The page also includes this optional segment in its `@page` directive in case the visitor accesses the page at its `/Contact` route:

```
@page "{text?}"
@model ContactModel
@{
    ViewData["Title"] = "Contact";
}

<h1>@ViewData["Title"]</h1>
<h2>@Model.Message</h2>

<address>
    One Microsoft Way<br>
    Redmond, WA 98052-6399<br>
    <abbr title="Phone">P:</abbr>
    425.555.0100
</address>

<address>
    <strong>Support:</strong> <a href="mailto:Support@example.com">Support@example.com</a><br>
    <strong>Marketing:</strong> <a href="mailto:Marketing@example.com">Marketing@example.com</a>
</address>

<p>@Model.RouteDataTextTemplateValue</p>
```

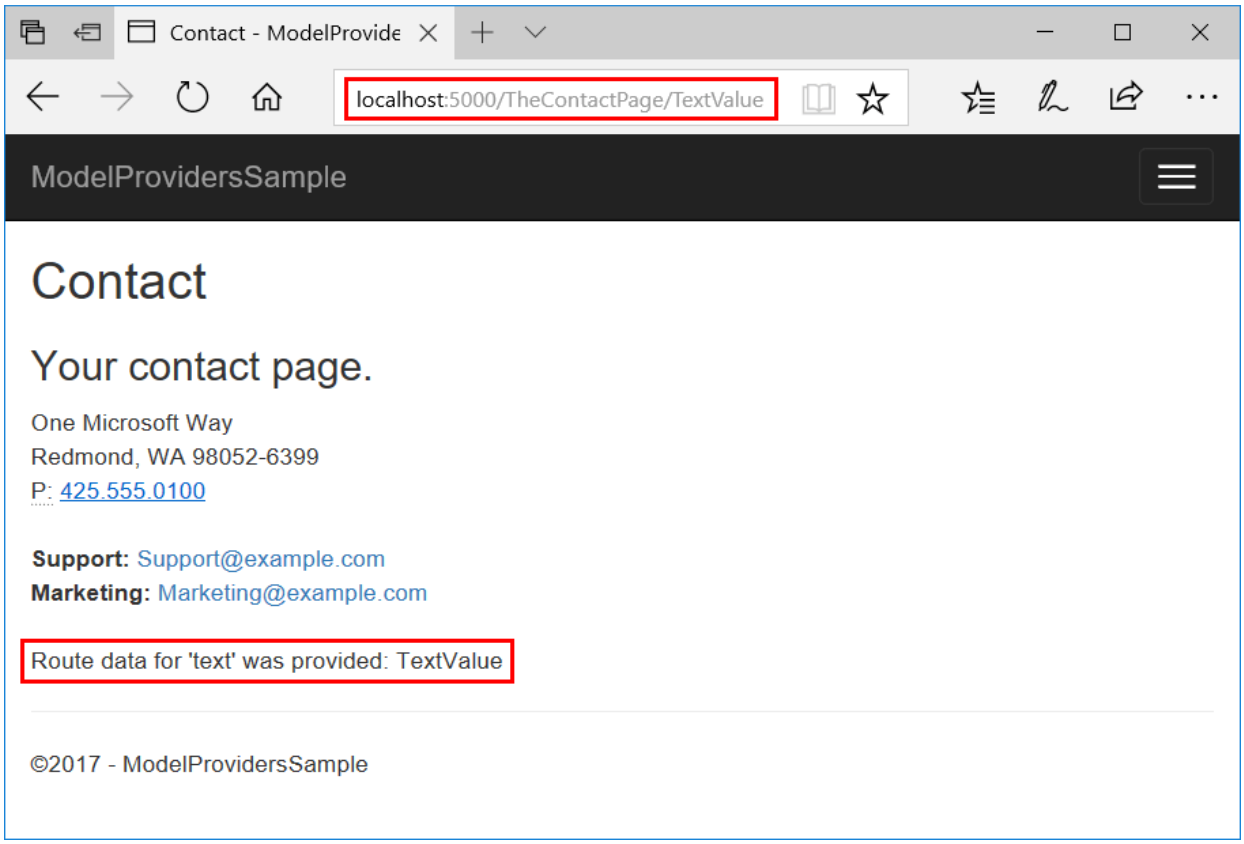
Note that the URL generated for the **Contact** link in the rendered page reflects the updated route:

Visit the Contact page at either its ordinary route, `/Contact` , or the custom route, `/TheContactPage` . If you supply an additional `text` route segment, the page shows the HTML-encoded segment that you provide:



Page model action conventions

The default page model provider that implements IPageApplicationModelProvider invokes conventions which are designed to provide extensibility points for configuring page models. These conventions are useful when building and modifying page discovery and processing scenarios.

For the examples in this section, the sample app uses an `AddHeaderAttribute` class, which is a ResultFilterAttribute, that applies a response header:

```
public class AddHeaderAttribute : ResultFilterAttribute
{
    private readonly string _name;
    private readonly string[] _values;

    public AddHeaderAttribute(string name, string[] values)
    {
        _name = name;
        _values = values;
    }

    public override void OnResultExecuting(ResultExecutingContext context)
    {
        context.HttpContext.Response.Headers.Add(_name, _values);
        base.OnResultExecuting(context);
    }
}
```

Using conventions, the sample demonstrates how to apply the attribute to all of the pages in a folder and to a single page.

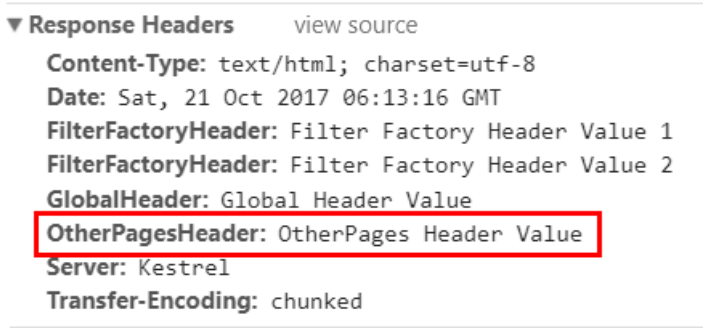
Folder app model convention

Use AddFolderApplicationModelConvention to create and add an IPageApplicationModelConvention that invokes an action on PageApplicationModel instances for all pages under the specified folder.

The sample demonstrates the use of `AddFolderApplicationModelConvention` by adding a header, `OtherPagesHeader`, to the pages inside the *OtherPages* folder of the app:

```
options.Conventions.AddFolderApplicationModelConvention("/OtherPages", model =>
{
    model.Filters.Add(new AddHeaderAttribute(
        "OtherPagesHeader", new string[] { "OtherPages Header Value" }));
});
```

Request the sample's Page1 page at `localhost:5000/OtherPages/Page1` and inspect the headers to view the result:



Page app model convention

Use AddPageApplicationModelConvention to create and add an IPageApplicationModelConvention that invokes an action on the PageApplicationModel for the page with the specified name.

The sample demonstrates the use of `AddPageApplicationModelConvention` by adding a header, `AboutHeader`, to the About page:

```
options.Conventions.AddPageApplicationModelConvention("/About", model =>
{
    model.Filters.Add(new AddHeaderAttribute(
        "AboutHeader", new string[] { "About Header Value" }));
});
```

Request the sample's About page at `localhost:5000/About` and inspect the headers to view the result:

Configure a filter

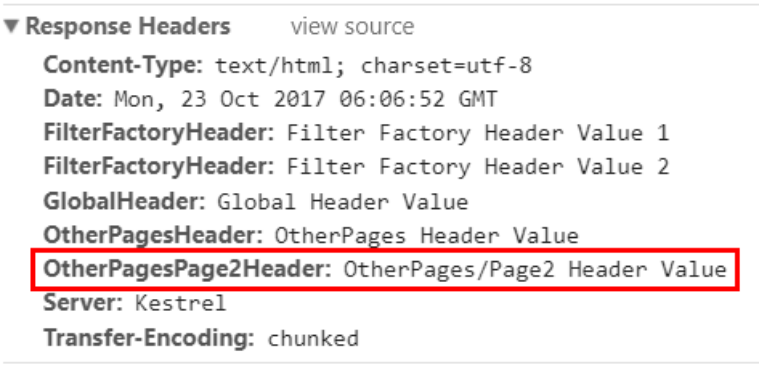
ConfigureFilter configures the specified filter to apply. You can implement a filter class, but the sample app shows how to implement a filter in a lambda expression, which is implemented behind-the-scenes as a factory that returns a filter:

```
options.Conventions.ConfigureFilter(model =>
{
    if (model.RelativePath.Contains("OtherPages/Page2"))
    {
        return new AddHeaderAttribute(
            "OtherPagesPage2Header",
            new string[] { "OtherPages/Page2 Header Value" });
    }
    return new EmptyFilter();
});
```

The page app model is used to check the relative path for segments that lead to the Page2 page in the *OtherPages* folder. If the condition passes, a header is added. If not, the `EmptyFilter` is applied.

`EmptyFilter` is an Action filter. Since Action filters are ignored by Razor Pages, the `EmptyFilter` has no effect as intended if the path doesn't contain `OtherPages/Page2`.

Request the sample's Page2 page at `localhost:5000/OtherPages/Page2` and inspect the headers to view the result:



Configure a filter factory

ConfigureFilter configures the specified factory to apply filters to all Razor Pages.

The sample app provides an example of using a filter factory by adding a header, `FilterFactoryHeader`, with two values to the app's pages:

```
options.Conventions.ConfigureFilter(new AddHeaderWithFactory());
```

AddHeaderWithFactory.cs:

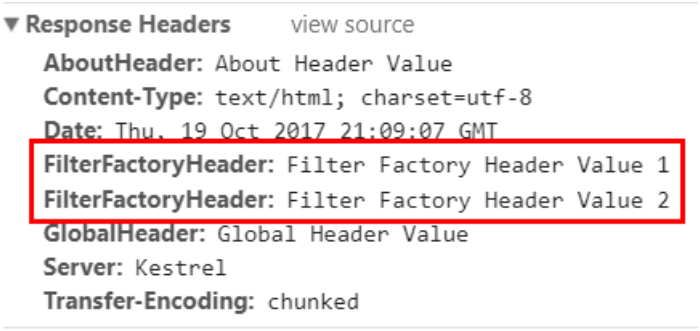
```
public class AddHeaderWithFactory : IFilterFactory
{
    // Implement IFilterFactory
    public IFilterMetadata CreateInstance(IServiceProvider serviceProvider)
    {
        return new AddHeaderFilter();
    }

    private class AddHeaderFilter : IResultFilter
    {
        public void OnResultExecuting(ResultExecutingContext context)
        {
            context.HttpContext.Response.Headers.Add(
                "FilterFactoryHeader",
                new string[]
                {
                    "Filter Factory Header Value 1",
                    "Filter Factory Header Value 2"
                });
        }

        public void OnResultExecuted(ResultExecutedContext context)
        {
        }
    }

    public bool IsReusable
    {
        get
        {
            return false;
        }
    }
}
```

Request the sample's About page at `localhost:5000/About` and inspect the headers to view the result:



MVC Filters and the Page filter (IPageFilter)

MVC Action filters are ignored by Razor Pages, since Razor Pages use handler methods. Other types of MVC filters are available for you to use: Authorization, Exception, Resource, and Result. For more information, see the Filters topic.

The Page filter (IPageFilter) is a filter that applies to Razor Pages. For more information, see Filter methods for Razor Pages.

SCENARIO	THE SAMPLE DEMONSTRATES ...
Model conventions Conventions.Add • IPageRouteModelConvention • IPageApplicationModelConvention • IPageHandlerModelConvention	Add a route template and header to an app's pages.
Page route action conventions • AddFolderRouteModelConvention • AddPageRouteModelConvention • AddPageRoute	Add a route template to pages in a folder and to a single page.
Page model action conventions • AddFolderApplicationModelConvention • AddPageApplicationModelConvention • ConfigureFilter (filter class, lambda expression, or filter factory)	Add a header to pages in a folder, add a header to a single page, and configure a filter factory to add a header to an app's pages.

Razor Pages conventions are added and configured using the AddRazorPagesOptions extension method to AddMvc on the service collection in the `Startup` class. The following convention examples are explained later in this topic:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
        .AddRazorPagesOptions(options =>
        {
            options.Conventions.Add( ... );
            options.Conventions.AddFolderRouteModelConvention(
                "/OtherPages", model => { ... });
            options.Conventions.AddPageRouteModelConvention(
                "/About", model => { ... });
            options.Conventions.AddPageRoute(
                "/Contact", "TheContactPage/{text?}");
            options.Conventions.AddFolderApplicationModelConvention(
                "/OtherPages", model => { ... });
            options.Conventions.AddPageApplicationModelConvention(
                "/About", model => { ... });
            options.Conventions.ConfigureFilter(model => { ... });
            options.Conventions.ConfigureFilter( ... );
        });
}
```

Route order

Routes specify an Order for processing (route matching).

ORDER	BEHAVIOR
-1	The route is processed before other routes are processed.
0	Order isn't specified (default value). Not assigning `Order` (`Order = null`) defaults the route `Order` to 0 (zero) for processing.
1, 2, ... n	Specifies the route processing order.

Route processing is established by convention:

- Routes are processed in sequential order (-1, 0, 1, 2, ... n).
- When routes have the same `Order`, the most specific route is matched first followed by less specific routes.
- When routes with the same `Order` and the same number of parameters match a request URL, routes are processed in the order that they're added to the PageConventionCollection.

If possible, avoid depending on an established route processing order. Generally, routing selects the correct route with URL matching. If you must set route `Order` properties to route requests correctly, the app's routing scheme is probably confusing to clients and fragile to maintain. Seek to simplify the app's routing scheme. The sample app requires an explicit route processing order to demonstrate several routing scenarios using a single app. However, you should attempt to avoid the practice of setting route `Order` in production apps.

Razor Pages routing and MVC controller routing share an implementation. Information on route order in the MVC topics is available at Routing to controller actions: Ordering attribute routes.

Model conventions

Add a delegate for IPageConvention to add model conventions that apply to Razor Pages.

Add a route model convention to all pages

Use Conventions to create and add an IPageRouteModelConvention to the collection of IPageConvention

instances that are applied during page route model construction.

The sample app adds a `{globalTemplate?}` route template to all of the pages in the app:

```
public class GlobalTemplatePageRouteModelConvention
    : IPageRouteModelConvention
{
    public void Apply(PageRouteModel model)
    {
        var selectorCount = model.Selectors.Count;
        for (var i = 0; i < selectorCount; i++)
        {
            var selector = model.Selectors[i];
            model.Selectors.Add(new SelectorModel
            {
                AttributeRouteModel = new AttributeRouteModel
                {
                    Order = 1,
                    Template = AttributeRouteModel.CombineTemplates(
                        selector.AttributeRouteModel.Template,
                        "{globalTemplate?}"),
                }
            });
        }
    }
}
```

The Order property for the AttributeRouteModel is set to `1`. This ensures the following route matching behavior in the sample app:

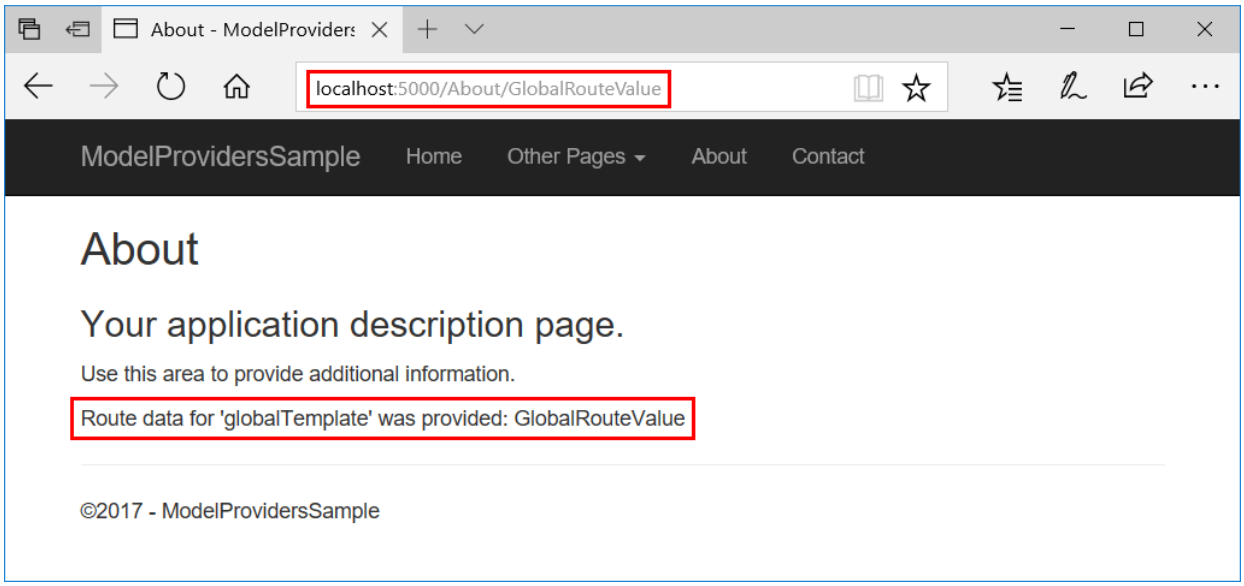
- A route template for `TheContactPage/{text?}` is added later in the topic. The Contact Page route has a default order of `null` (`Order = 0`), so it matches before the `{globalTemplate?}` route template.
- An `{aboutTemplate?}` route template is added later in the topic. The `{aboutTemplate?}` template is given an `Order` of `2`. When the About page is requested at `/About/RouteDataValue`, "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["aboutTemplate"]` (`Order = 2`) due to setting the `Order` property.
- An `{otherPagesTemplate?}` route template is added later in the topic. The `{otherPagesTemplate?}` template is given an `Order` of `2`. When any page in the *Pages/OtherPages* folder is requested with a route parameter (for example, `/OtherPages/Page1/RouteDataValue`), "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["otherPagesTemplate"]` (`Order = 2`) due to setting the `Order` property.

Wherever possible, don't set the `Order`, which results in `Order = 0`. Rely on routing to select the correct route.

Razor Pages options, such as adding Conventions, are added when MVC is added to the service collection in `Startup.ConfigureServices`. For an example, see the sample app.

```
options.Conventions.Add(new GlobalTemplatePageRouteModelConvention());
```

Request the sample's About page at `localhost:5000/About/GlobalRouteValue` and inspect the result:



Add an app model convention to all pages

Use Conventions to create and add an IPageApplicationModelConvention to the collection of IPageConvention instances that are applied during page app model construction.

To demonstrate this and other conventions later in the topic, the sample app includes an `AddHeaderAttribute` class. The class constructor accepts a `name` string and a `values` string array. These values are used in its `OnResultExecuting` method to set a response header. The full class is shown in the Page model action conventions section later in the topic.

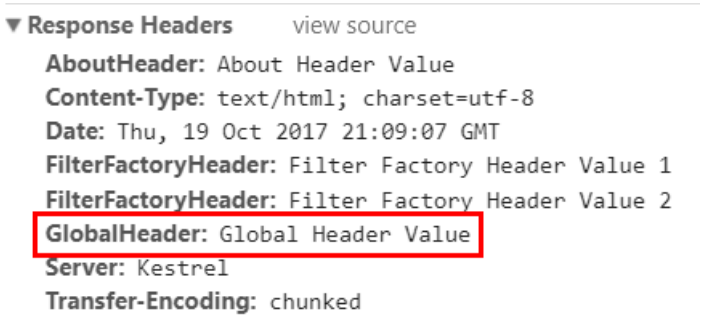
The sample app uses the `AddHeaderAttribute` class to add a header, `GlobalHeader`, to all of the pages in the app:

```
public class GlobalHeaderPageApplicationModelConvention
    : IPageApplicationModelConvention
{
    public void Apply(PageApplicationModel model)
    {
        model.Filters.Add(new AddHeaderAttribute(
            "GlobalHeader", new string[] { "Global Header Value" }));
    }
}
```

Startup.cs:

```
options.Conventions.Add(new GlobalHeaderPageApplicationModelConvention());
```

Request the sample's About page at `localhost:5000/About` and inspect the headers to view the result:



Add a handler model convention to all pages

Use Conventions to create and add an IPageHandlerModelConvention to the collection of IPageConvention instances that are applied during page handler model construction.

```
public class GlobalPageHandlerModelConvention
    : IPageHandlerModelConvention
{
    public void Apply(PageHandlerModel model)
    {
        // Access the PageHandlerModel
    }
}
```

Startup.cs:

```
options.Conventions.Add(new GlobalPageHandlerModelConvention());
```

Page route action conventions

The default route model provider that derives from IPageRouteModelProvider invokes conventions which are designed to provide extensibility points for configuring page routes.

Folder route model convention

Use AddFolderRouteModelConvention to create and add an IPageRouteModelConvention that invokes an action on the PageRouteModel for all of the pages under the specified folder.

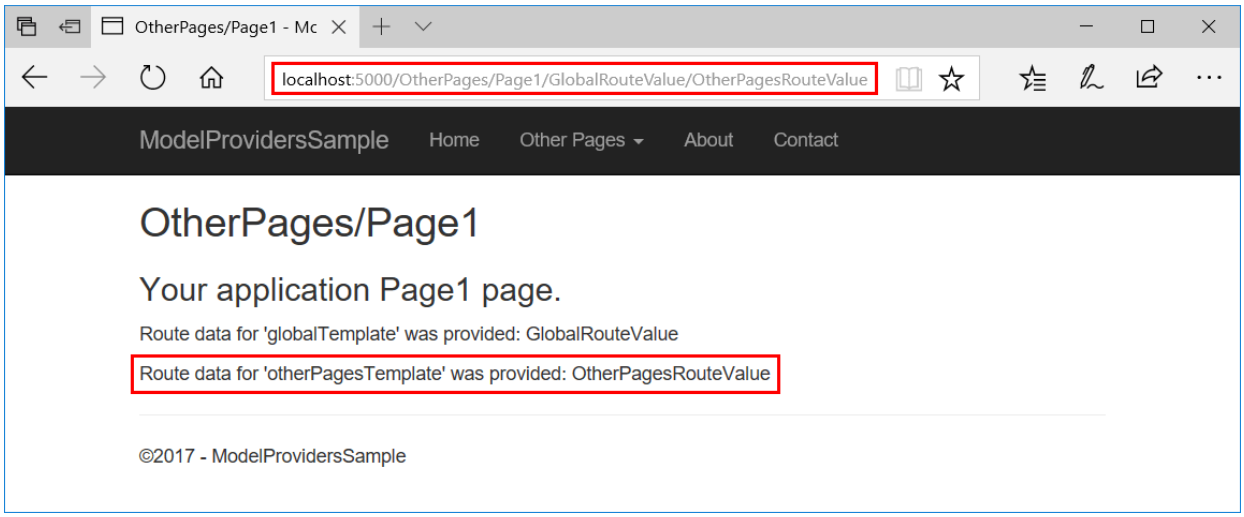
The sample app uses AddFolderRouteModelConvention to add an `{otherPagesTemplate?}` route template to the pages in the *OtherPages* folder:

```
options.Conventions.AddFolderRouteModelConvention("/OtherPages", model =>
{
    var selectorCount = model.Selectors.Count;
    for (var i = 0; i < selectorCount; i++)
    {
        var selector = model.Selectors[i];
        model.Selectors.Add(new SelectorModel
        {
            AttributeRouteModel = new AttributeRouteModel
            {
                Order = 2,
                Template = AttributeRouteModel.CombineTemplates(
                    selector.AttributeRouteModel.Template,
                    "{otherPagesTemplate?}"),
            }
        });
    }
});
```

The Order property for the AttributeRouteModel is set to `2`. This ensures that the template for `{globalTemplate?}` (set earlier in the topic to `1`) is given priority for the first route data value position when a single route value is provided. If a page in the *Pages/OtherPages* folder is requested with a route parameter value (for example, `/OtherPages/Page1/RouteDataValue`), "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["otherPagesTemplate"]` (`Order = 2`) due to setting the `Order` property.

Wherever possible, don't set the `Order`, which results in `Order = 0`. Rely on routing to select the correct route.

Request the sample's Page1 page at `localhost:5000/OtherPages/Page1/GlobalRouteValue/OtherPagesRouteValue` and inspect the result:



Page route model convention

Use AddPageRouteModelConvention to create and add an IPageRouteModelConvention that invokes an action on the PageRouteModel for the page with the specified name.

The sample app uses `AddPageRouteModelConvention` to add an `{aboutTemplate?}` route template to the About page:

```
options.Conventions.AddPageRouteModelConvention("/About", model =>
{
    var selectorCount = model.Selectors.Count;
    for (var i = 0; i < selectorCount; i++)
    {
        var selector = model.Selectors[i];
        model.Selectors.Add(new SelectorModel
        {
            AttributeRouteModel = new AttributeRouteModel
            {
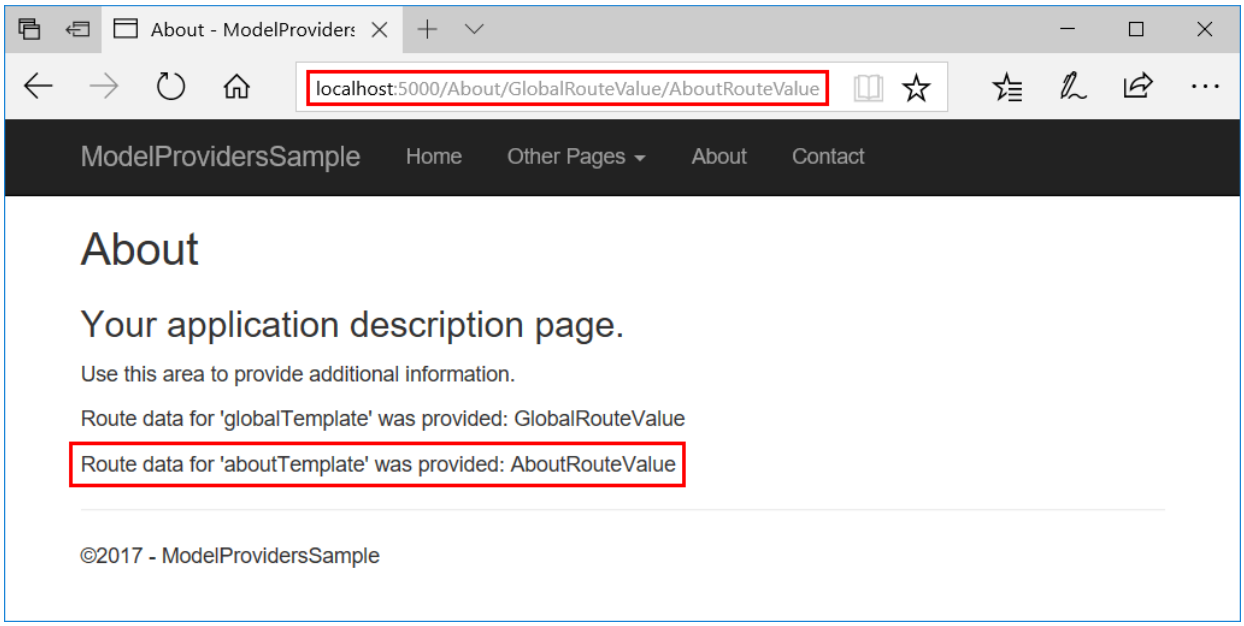
                Order = 2,
                Template = AttributeRouteModel.CombineTemplates(
                    selector.AttributeRouteModel.Template,
                    "{aboutTemplate?}"),
            }
        });
    }
});
```

The Order property for the AttributeRouteModel is set to `2`. This ensures that the template for `{globalTemplate?}` (set earlier in the topic to `1`) is given priority for the first route data value position when a single route value is provided. If the About page is requested with a route parameter value at `/About/RouteDataValue`, "RouteDataValue" is loaded into `RouteData.Values["globalTemplate"]` (`Order = 1`) and not `RouteData.Values["aboutTemplate"]` (`Order = 2`) due to setting the `Order` property.

Wherever possible, don't set the `Order`, which results in `Order = 0`. Rely on routing to select the correct route.

Request the sample's About page at `localhost:5000/About/GlobalRouteValue/AboutRouteValue` and inspect the result:



Configure a page route

Use AddPageRoute to configure a route to a page at the specified page path. Generated links to the page use your specified route. `AddPageRoute` uses `AddPageRouteModelConvention` to establish the route.

The sample app creates a route to `/TheContactPage` for *Contact.cshtml*:

```
options.Conventions.AddPageRoute("/Contact", "TheContactPage/{text?}");
```

The Contact page can also be reached at `/Contact` via its default route.

The sample app's custom route to the Contact page allows for an optional `text` route segment (`{text?}`). The page also includes this optional segment in its `@page` directive in case the visitor accesses the page at its `/Contact` route:

```
@page "{text?}"
@model ContactModel
@{
    ViewData["Title"] = "Contact";
}

<h1>@ViewData["Title"]</h1>
<h2>@Model.Message</h2>

<address>
    One Microsoft Way<br>
    Redmond, WA 98052-6399<br>
    <abbr title="Phone">P:</abbr>
    425.555.0100
</address>

<address>
    <strong>Support:</strong> <a href="mailto:Support@example.com">Support@example.com</a><br>
    <strong>Marketing:</strong> <a href="mailto:Marketing@example.com">Marketing@example.com</a>
</address>

<p>@Model.RouteDataTextTemplateValue</p>
```

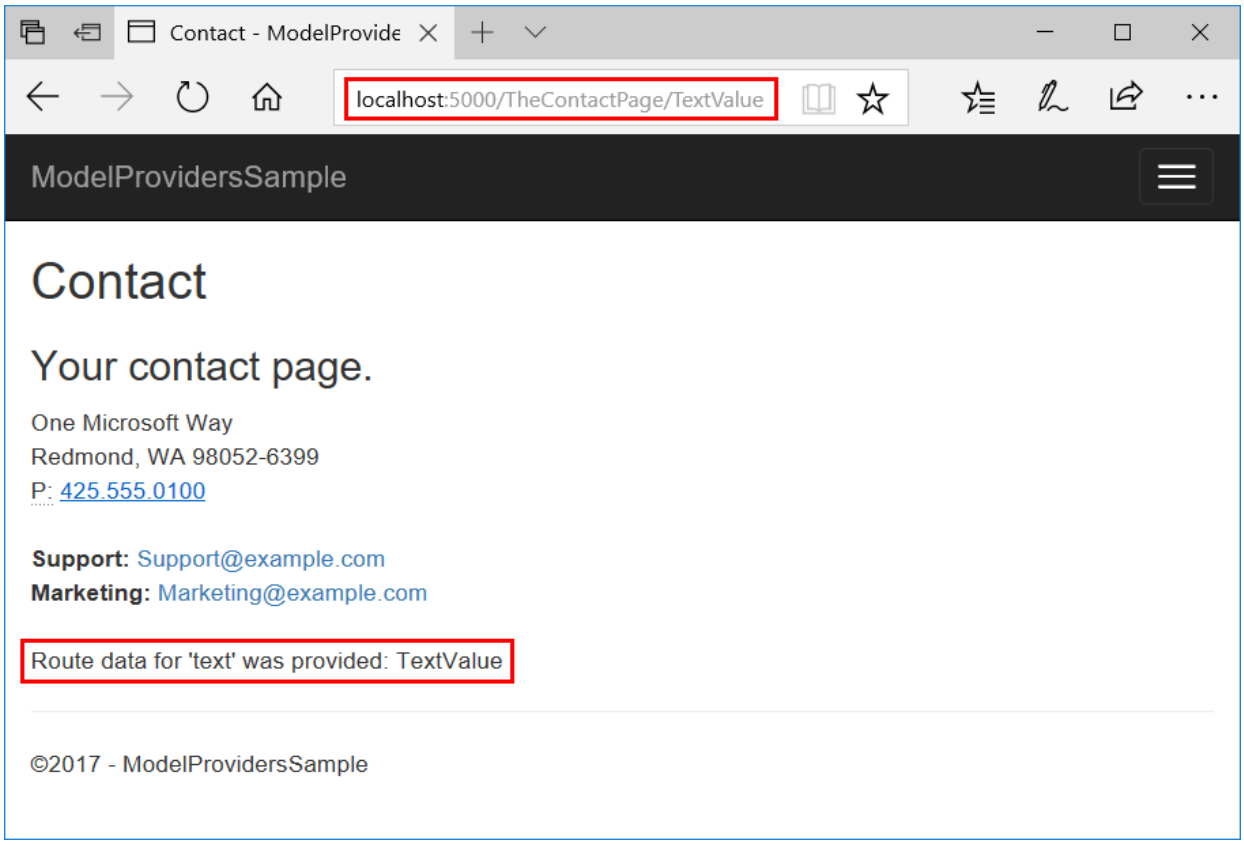
Note that the URL generated for the **Contact** link in the rendered page reflects the updated route:

Visit the Contact page at either its ordinary route, `/Contact`, or the custom route, `/TheContactPage`. If you supply an additional `text` route segment, the page shows the HTML-encoded segment that you provide:



Page model action conventions

The default page model provider that implements IPageApplicationModelProvider invokes conventions which are designed to provide extensibility points for configuring page models. These conventions are useful when building and modifying page discovery and processing scenarios.

For the examples in this section, the sample app uses an `AddHeaderAttribute` class, which is a ResultFilterAttribute, that applies a response header:

```
public class AddHeaderAttribute : ResultFilterAttribute
{
    private readonly string _name;
    private readonly string[] _values;

    public AddHeaderAttribute(string name, string[] values)
    {
        _name = name;
        _values = values;
    }

    public override void OnResultExecuting(ResultExecutingContext context)
    {
        context.HttpContext.Response.Headers.Add(_name, _values);
        base.OnResultExecuting(context);
    }
}
```

Using conventions, the sample demonstrates how to apply the attribute to all of the pages in a folder and to a single page.

Folder app model convention

Use AddFolderApplicationModelConvention to create and add an IPageApplicationModelConvention that invokes an action on PageApplicationModel instances for all pages under the specified folder.

The sample demonstrates the use of `AddFolderApplicationModelConvention` by adding a header, `OtherPagesHeader`, to the pages inside the *OtherPages* folder of the app:

```
options.Conventions.AddFolderApplicationModelConvention("/OtherPages", model =>
{
    model.Filters.Add(new AddHeaderAttribute(
        "OtherPagesHeader", new string[] { "OtherPages Header Value" }));
});
```

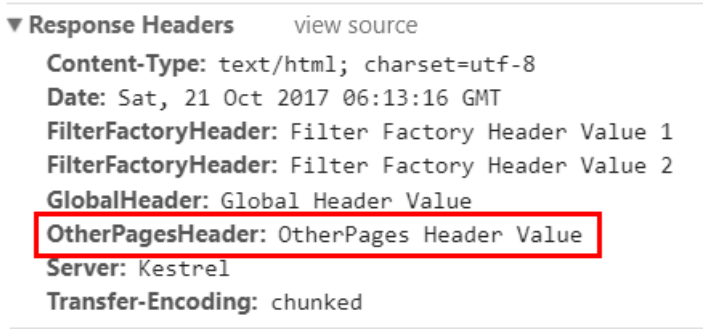
Request the sample's Page1 page at `localhost:5000/OtherPages/Page1` and inspect the headers to view the result:



Page app model convention

Use AddPageApplicationModelConvention to create and add an IPageApplicationModelConvention that invokes an action on the PageApplicationModel for the page with the specified name.

The sample demonstrates the use of `AddPageApplicationModelConvention` by adding a header, `AboutHeader`, to the About page:

```
options.Conventions.AddPageApplicationModelConvention("/About", model =>
{
    model.Filters.Add(new AddHeaderAttribute(
        "AboutHeader", new string[] { "About Header Value" }));
});
```

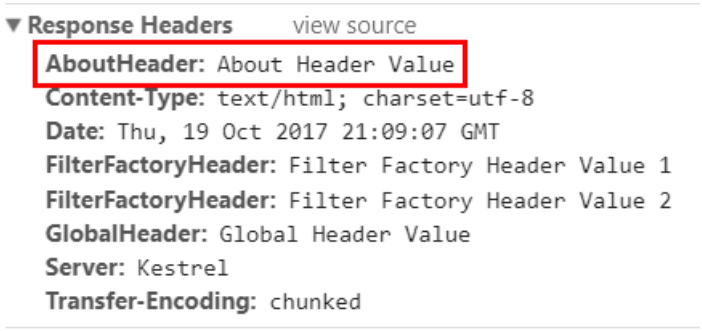
Request the sample's About page at `localhost:5000/About` and inspect the headers to view the result:



Configure a filter

ConfigureFilter configures the specified filter to apply. You can implement a filter class, but the sample app shows how to implement a filter in a lambda expression, which is implemented behind-the-scenes as a factory that returns a filter:

```
options.Conventions.ConfigureFilter(model =>
{
    if (model.RelativePath.Contains("OtherPages/Page2"))
    {
        return new AddHeaderAttribute(
            "OtherPagesPage2Header",
            new string[] { "OtherPages/Page2 Header Value" });
    }
    return new EmptyFilter();
});
```

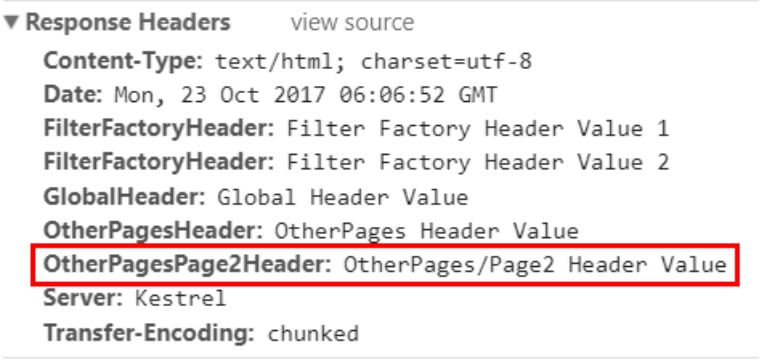
The page app model is used to check the relative path for segments that lead to the Page2 page in the *OtherPages* folder. If the condition passes, a header is added. If not, the `EmptyFilter` is applied.

`EmptyFilter` is an Action filter. Since Action filters are ignored by Razor Pages, the `EmptyFilter` has no effect as intended if the path doesn't contain `OtherPages/Page2`.

Request the sample's Page2 page at `localhost:5000/OtherPages/Page2` and inspect the headers to view the result:



Configure a filter factory

ConfigureFilter configures the specified factory to apply filters to all Razor Pages.

The sample app provides an example of using a filter factory by adding a header, `FilterFactoryHeader`, with two

values to the app's pages:

```
options.Conventions.ConfigureFilter(new AddHeaderWithFactory());
```

AddHeaderWithFactory.cs:

```
public class AddHeaderWithFactory : IFilterFactory
{
    // Implement IFilterFactory
    public IFilterMetadata CreateInstance(IServiceProvider serviceProvider)
    {
        return new AddHeaderFilter();
    }

    private class AddHeaderFilter : IResultFilter
    {
        public void OnResultExecuting(ResultExecutingContext context)
        {
            context.HttpContext.Response.Headers.Add(
                "FilterFactoryHeader",
                new string[]
                {
                    "Filter Factory Header Value 1",
                    "Filter Factory Header Value 2"
                });
        }

        public void OnResultExecuted(ResultExecutedContext context)
        {
        }
    }

    public bool IsReusable
    {
        get
        {
            return false;
        }
    }
}
```

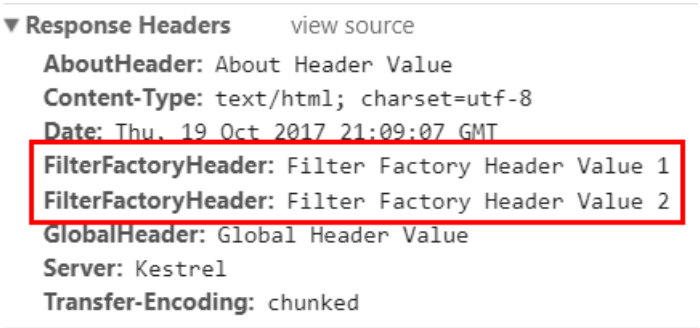
Request the sample's About page at `localhost:5000/About` and inspect the headers to view the result:



MVC Filters and the Page filter (IPageFilter)

MVC Action filters are ignored by Razor Pages, since Razor Pages use handler methods. Other types of MVC filters are available for you to use: Authorization, Exception, Resource, and Result. For more information, see the Filters topic.

The Page filter (IPageFilter) is a filter that applies to Razor Pages. For more information, see Filter methods for Razor Pages.

Overview of ASP.NET Core MVC

9/22/2020 • 9 minutes to read • Edit Online

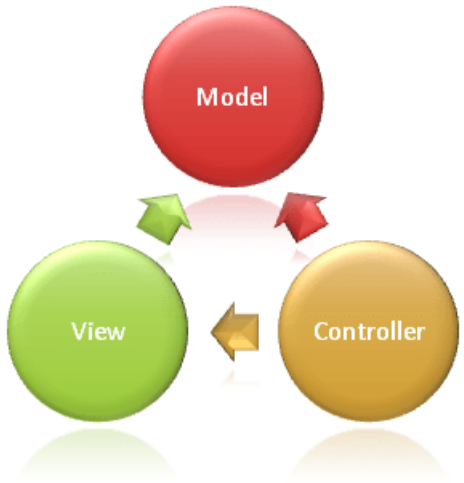
By Steve Smith

ASP.NET Core MVC is a rich framework for building web apps and APIs using the Model-View-Controller design pattern.

What is the MVC pattern?

The Model-View-Controller (MVC) architectural pattern separates an application into three main groups of components: Models, Views, and Controllers. This pattern helps to achieve separation of concerns. Using this pattern, user requests are routed to a Controller which is responsible for working with the Model to perform user actions and/or retrieve results of queries. The Controller chooses the View to display to the user, and provides it with any Model data it requires.

The following diagram shows the three main components and which ones reference the others:



This delineation of responsibilities helps you scale the application in terms of complexity because it's easier to code, debug, and test something (model, view, or controller) that has a single job. It's more difficult to update, test, and debug code that has dependencies spread across two or more of these three areas. For example, user interface logic tends to change more frequently than business logic. If presentation code and business logic are combined in a single object, an object containing business logic must be modified every time the user interface is changed. This often introduces errors and requires the retesting of business logic after every minimal user interface change.

> **NOTE**
> Both the view and the controller depend on the model. However, the model depends on neither the view nor the controller. This is one of the key benefits of the separation. This separation allows the model to be built and tested independent of the visual presentation.

Model Responsibilities

The Model in an MVC application represents the state of the application and any business logic or operations that should be performed by it. Business logic should be encapsulated in the model, along with any implementation logic for persisting the state of the application. Strongly-typed views typically use ViewModel

types designed to contain the data to display on that view. The controller creates and populates these ViewModel instances from the model.

View Responsibilities

Views are responsible for presenting content through the user interface. They use the Razor view engine to embed .NET code in HTML markup. There should be minimal logic within views, and any logic in them should relate to presenting content. If you find the need to perform a great deal of logic in view files in order to display data from a complex model, consider using a View Component, ViewModel, or view template to simplify the view.

Controller Responsibilities

Controllers are the components that handle user interaction, work with the model, and ultimately select a view to render. In an MVC application, the view only displays information; the controller handles and responds to user input and interaction. In the MVC pattern, the controller is the initial entry point, and is responsible for selecting which model types to work with and which view to render (hence its name - it controls how the app responds to a given request).

> **NOTE**
> Controllers shouldn't be overly complicated by too many responsibilities. To keep controller logic from becoming overly complex, push business logic out of the controller and into the domain model.

> **TIP**
> If you find that your controller actions frequently perform the same kinds of actions, move these common actions into filters.

What is ASP.NET Core MVC

The ASP.NET Core MVC framework is a lightweight, open source, highly testable presentation framework optimized for use with ASP.NET Core.

ASP.NET Core MVC provides a patterns-based way to build dynamic websites that enables a clean separation of concerns. It gives you full control over markup, supports TDD-friendly development and uses the latest web standards.

Features

ASP.NET Core MVC includes the following:

- Routing
- Model binding
- Model validation
- Dependency injection
- Filters
- Areas
- Web APIs
- Testability
- Razor view engine
- Strongly typed views
- Tag Helpers

- View Components

Routing

ASP.NET Core MVC is built on top of ASP.NET Core's routing, a powerful URL-mapping component that lets you build applications that have comprehensible and searchable URLs. This enables you to define your application's URL naming patterns that work well for search engine optimization (SEO) and for link generation, without regard for how the files on your web server are organized. You can define your routes using a convenient route template syntax that supports route value constraints, defaults and optional values.

Convention-based routing enables you to globally define the URL formats that your application accepts and how each of those formats maps to a specific action method on given controller. When an incoming request is received, the routing engine parses the URL and matches it to one of the defined URL formats, and then calls the associated controller's action method.

```
routes.MapRoute(name: "Default", template: "{controller=Home}/{action=Index}/{id?}");
```

Attribute routing enables you to specify routing information by decorating your controllers and actions with attributes that define your application's routes. This means that your route definitions are placed next to the controller and action with which they're associated.

```
[Route("api/[controller]")]
public class ProductsController : Controller
{
    [HttpGet("{id}")]
    public IActionResult GetProduct(int id)
    {
      ...
    }
}
```

Model binding

ASP.NET Core MVC model binding converts client request data (form values, route data, query string parameters, HTTP headers) into objects that the controller can handle. As a result, your controller logic doesn't have to do the work of figuring out the incoming request data; it simply has the data as parameters to its action methods.

```
public async Task<IActionResult> Login(LoginViewModel model, string returnUrl = null) { ... }
```

Model validation

ASP.NET Core MVC supports validation by decorating your model object with data annotation validation attributes. The validation attributes are checked on the client side before values are posted to the server, as well as on the server before the controller action is called.

```
using System.ComponentModel.DataAnnotations;
public class LoginViewModel
{
    [Required]
    [EmailAddress]
    public string Email { get; set; }

    [Required]
    [DataType(DataType.Password)]
    public string Password { get; set; }

    [Display(Name = "Remember me?")]
    public bool RememberMe { get; set; }
}
```

A controller action:

```
public async Task<IActionResult> Login(LoginViewModel model, string returnUrl = null)
{
    if (ModelState.IsValid)
    {
      // work with the model
    }
    // At this point, something failed, redisplay form
    return View(model);
}
```

The framework handles validating request data both on the client and on the server. Validation logic specified on model types is added to the rendered views as unobtrusive annotations and is enforced in the browser with jQuery Validation.

Dependency injection

ASP.NET Core has built-in support for dependency injection (DI). In ASP.NET Core MVC, controllers can request needed services through their constructors, allowing them to follow the Explicit Dependencies Principle.

Your app can also use dependency injection in view files, using the `@inject` directive:

```
@inject SomeService ServiceName

<!DOCTYPE html>
<html lang="en">
<head>
    <title>@ServiceName.GetTitle</title>
</head>
<body>
    <h1>@ServiceName.GetTitle</h1>
</body>
</html>
```

Filters

Filters help developers encapsulate cross-cutting concerns, like exception handling or authorization. Filters enable running custom pre- and post-processing logic for action methods, and can be configured to run at certain points within the execution pipeline for a given request. Filters can be applied to controllers or actions as attributes (or can be run globally). Several filters (such as `Authorize`) are included in the framework. `[Authorize]` is the attribute that is used to create MVC authorization filters.

```
[Authorize]
public class AccountController : Controller
```

Areas

Areas provide a way to partition a large ASP.NET Core MVC Web app into smaller functional groupings. An area is an MVC structure inside an application. In an MVC project, logical components like Model, Controller, and View are kept in different folders, and MVC uses naming conventions to create the relationship between these components. For a large app, it may be advantageous to partition the app into separate high level areas of functionality. For instance, an e-commerce app with multiple business units, such as checkout, billing, and search etc. Each of these units have their own logical component views, controllers, and models.

Web APIs

In addition to being a great platform for building web sites, ASP.NET Core MVC has great support for building Web APIs. You can build services that reach a broad range of clients including browsers and mobile devices.

The framework includes support for HTTP content-negotiation with built-in support to format data as JSON or XML. Write custom formatters to add support for your own formats.

Use link generation to enable support for hypermedia. Easily enable support for cross-origin resource sharing (CORS) so that your Web APIs can be shared across multiple Web applications.

Testability

The framework's use of interfaces and dependency injection make it well-suited to unit testing, and the framework includes features (like a TestHost and InMemory provider for Entity Framework) that make integration tests quick and easy as well. Learn more about how to test controller logic.

Razor view engine

ASP.NET Core MVC views use the Razor view engine to render views. Razor is a compact, expressive and fluid template markup language for defining views using embedded C# code. Razor is used to dynamically generate web content on the server. You can cleanly mix server code with client side content and code.

```
<ul>
    @for (int i = 0; i < 5; i++) {
        <li>List item @i</li>
    }
</ul>
```

Using the Razor view engine you can define layouts, partial views and replaceable sections.

Strongly typed views

Razor views in MVC can be strongly typed based on your model. Controllers can pass a strongly typed model to views enabling your views to have type checking and IntelliSense support.

For example, the following view renders a model of type `IEnumerable<Product>`:

```
@model IEnumerable<Product>
<ul>
    @foreach (Product p in Model)
    {
        <li>@p.Name</li>
    }
</ul>
```

Tag Helpers

Tag Helpers enable server side code to participate in creating and rendering HTML elements in Razor files. You

can use tag helpers to define custom tags (for example, `<environment>`) or to modify the behavior of existing tags (for example, `<label>`). Tag Helpers bind to specific elements based on the element name and its attributes. They provide the benefits of server-side rendering while still preserving an HTML editing experience.

There are many built-in Tag Helpers for common tasks - such as creating forms, links, loading assets and more - and even more available in public GitHub repositories and as NuGet packages. Tag Helpers are authored in C#, and they target HTML elements based on element name, attribute name, or parent tag. For example, the built-in LinkTagHelper can be used to create a link to the `Login` action of the `AccountsController`:

```
<p>
    Thank you for confirming your email.
    Please <a asp-controller="Account" asp-action="Login">Click here to Log in</a>.
</p>
```

The `EnvironmentTagHelper` can be used to include different scripts in your views (for example, raw or minified) based on the runtime environment, such as Development, Staging, or Production:

```
<environment names="Development">
    <script src="~/lib/jquery/dist/jquery.js"></script>
</environment>
<environment names="Staging,Production">
    <script src="https://ajax.aspnetcdn.com/ajax/jquery/jquery-2.1.4.min.js"
            asp-fallback-src="~/lib/jquery/dist/jquery.min.js"
            asp-fallback-test="window.jQuery">
    </script>
</environment>
```

Tag Helpers provide an HTML-friendly development experience and a rich IntelliSense environment for creating HTML and Razor markup. Most of the built-in Tag Helpers target existing HTML elements and provide server-side attributes for the element.

View Components

View Components allow you to package rendering logic and reuse it throughout the application. They're similar to partial views, but with associated logic.

Compatibility version

The SetCompatibilityVersion method allows an app to opt-in or opt-out of potentially breaking behavior changes introduced in ASP.NET Core MVC 2.1 or later.

For more information, see Compatibility version for ASP.NET Core MVC.

Create a web app with ASP.NET Core MVC

9/22/2020 • 2 minutes to read • Edit Online

This tutorial teaches ASP.NET Core MVC web development with controllers and views. If you're new to ASP.NET Core web development, consider the Razor Pages version of this tutorial, which provides an easier starting point.

The tutorial series includes the following:

1. Get started
2. Add a controller
3. Add a view
4. Add a model
5. Work with SQL Server LocalDB
6. Controller methods and views
7. Add search
8. Add a new field
9. Add validation
10. Examine the Details and Delete methods

Get started with ASP.NET Core MVC

9/22/2020 • 10 minutes to read • Edit Online

By Rick Anderson

This tutorial teaches ASP.NET Core MVC web development with controllers and views. If you're new to ASP.NET Core web development, consider the Razor Pages version of this tutorial, which provides an easier starting point.

This tutorial teaches the basics of building an ASP.NET Core MVC web app.

The app manages a database of movie titles. You learn how to:

- Create a web app.
- Add and scaffold a model.
- Work with a database.
- Add search and validation.

At the end, you have an app that can manage and display movie data.

View or download sample code (how to download).

Prerequisites

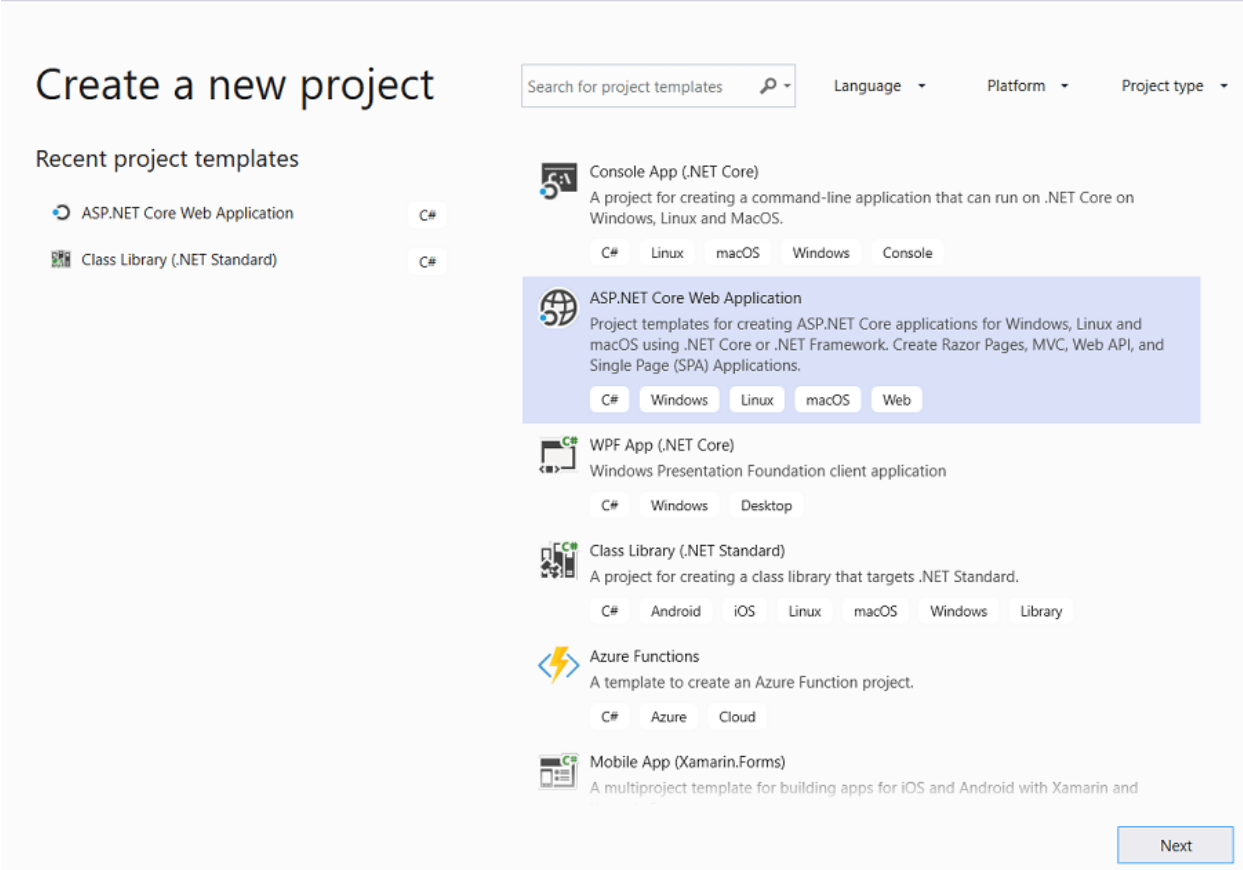
- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 16.4 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

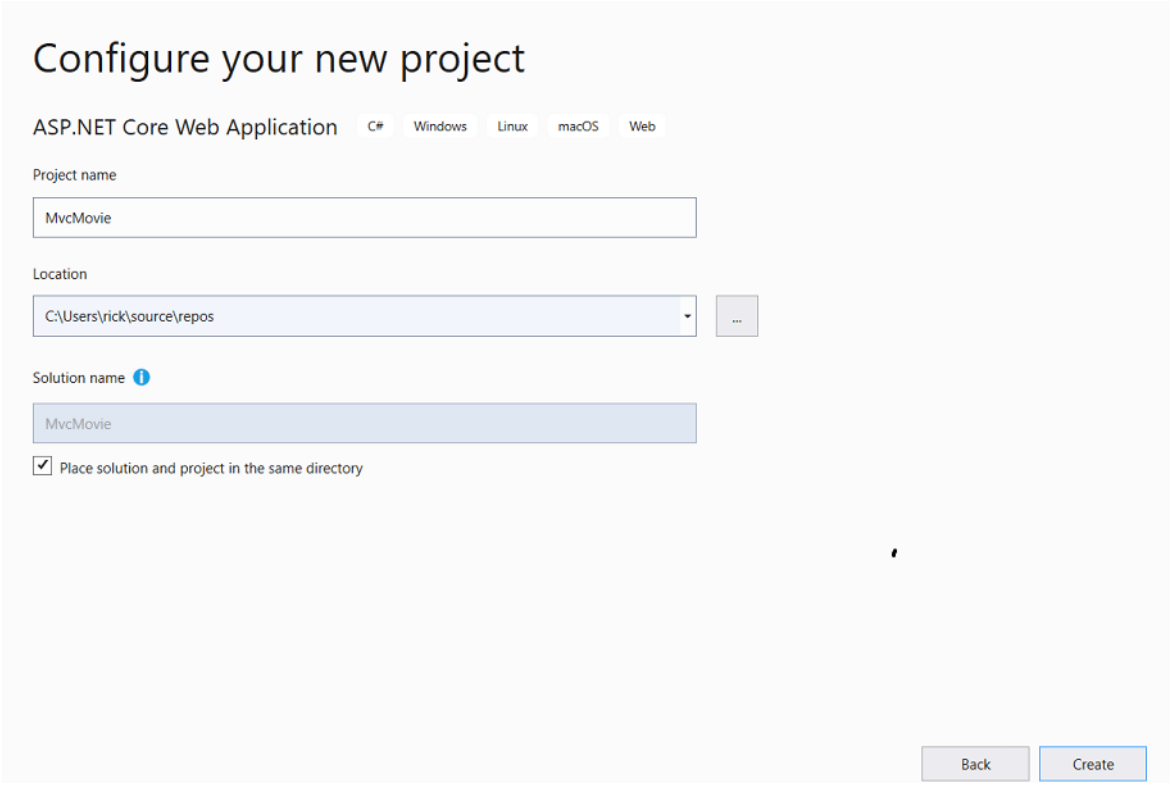
Create a web app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

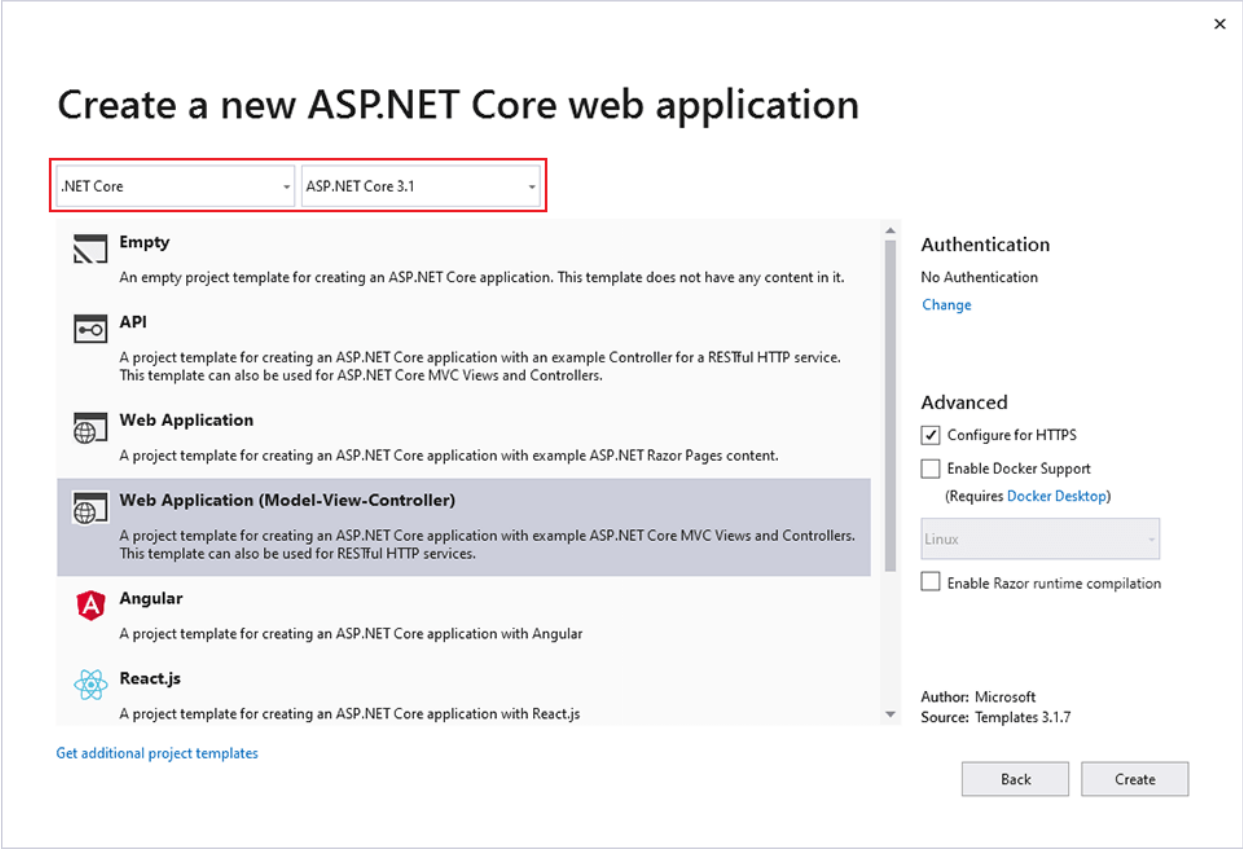
- From the Visual Studio select **Create a new project**.
- Select **ASP.NET Core Web Application** and then select **Next**.



- Name the project **MvcMovie** and select **Create**. It's important to name the project **MvcMovie** so when you copy code, the namespace will match.



- Select **Web Application(Model-View-Controller)**, and then select **Create**.



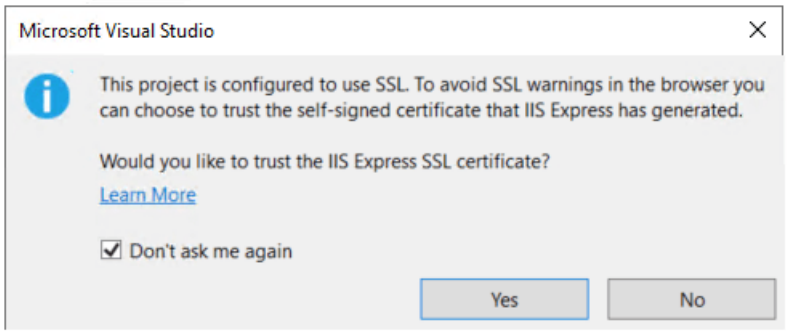
Visual Studio used the default template for the MVC project you just created. You have a working app right now by entering a project name and selecting a few options. This is a basic starter project.

Run the app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

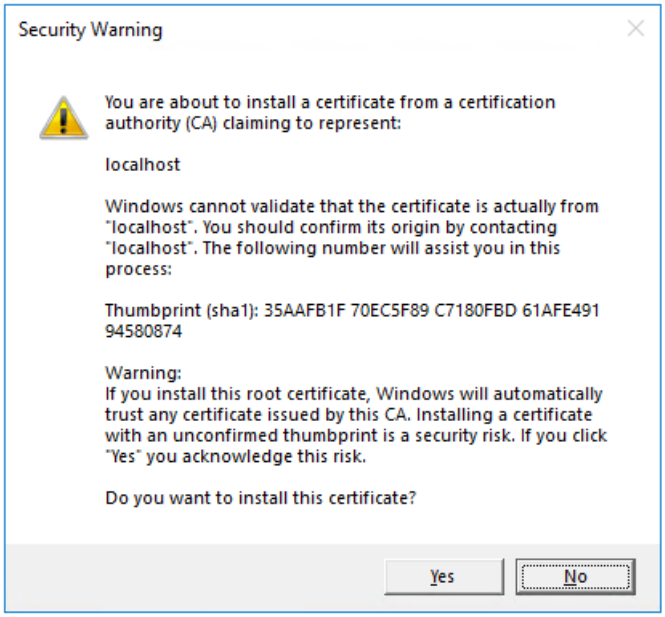
Select **Ctrl-F5** to run the app in non-debug mode.

Visual Studio displays the following dialog:



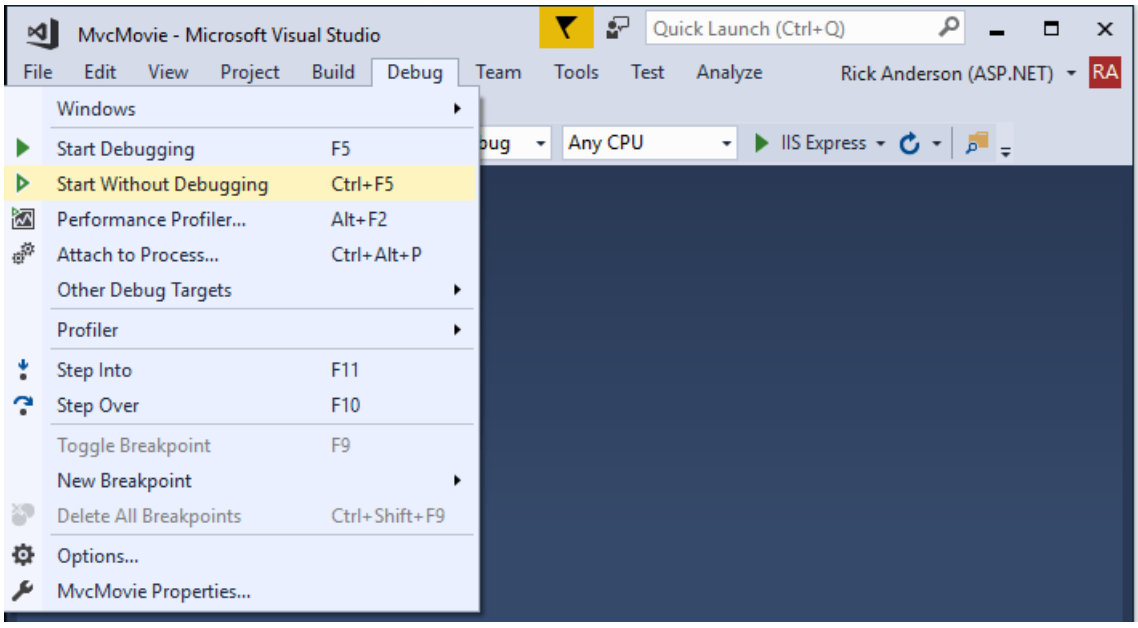
Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:

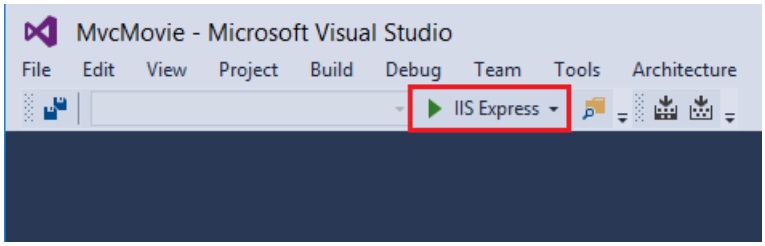


Select **Yes** if you agree to trust the development certificate.

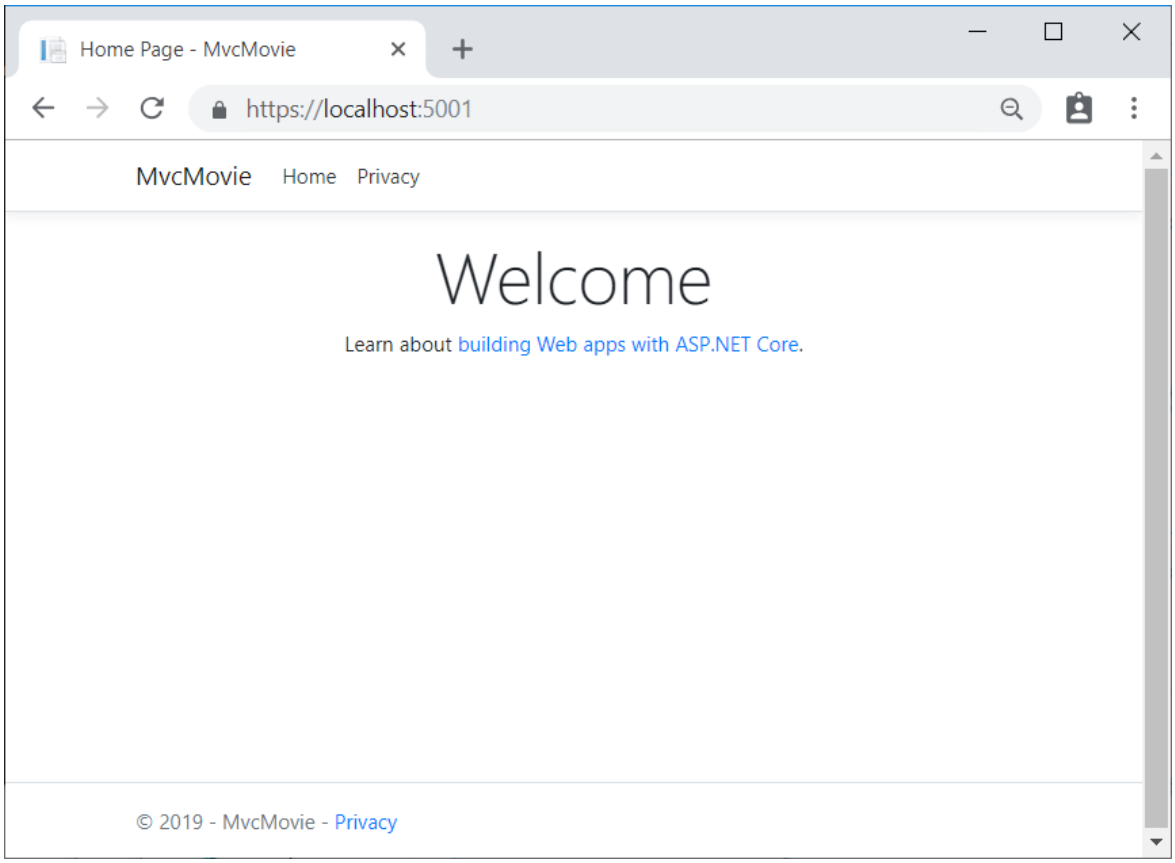
- Visual Studio starts IIS Express and runs the app. Notice that the address bar shows `localhost:port#` and not something like `example.com`. That's because `localhost` is the standard hostname for your local computer. When Visual Studio creates a web project, a random port is used for the web server.
- Launching the app with Ctrl+F5 (non-debug mode) allows you to make code changes, save the file, refresh the browser, and see the code changes. Many developers prefer to use non-debug mode to quickly launch the app and view changes.
- You can launch the app in debug or non-debug mode from the **Debug** menu item:



- You can debug the app by selecting the **IIS Express** button



The following image shows the app:



- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Visual Studio help

- Learn to debug C# code using Visual Studio
- Introduction to the Visual Studio IDE

In the next part of this tutorial, you learn about MVC and start writing some code.

NEXT

This tutorial teaches ASP.NET Core MVC web development with controllers and views. If you're new to ASP.NET Core web development, consider the Razor Pages version of this tutorial, which provides an easier starting point.

This tutorial teaches the basics of building an ASP.NET Core MVC web app.

The app manages a database of movie titles. You learn how to:

- Create a web app.
- Add and scaffold a model.
- Work with a database.
- Add search and validation.

At the end, you have an app that can manage and display movie data.

View or download sample code (how to download).

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

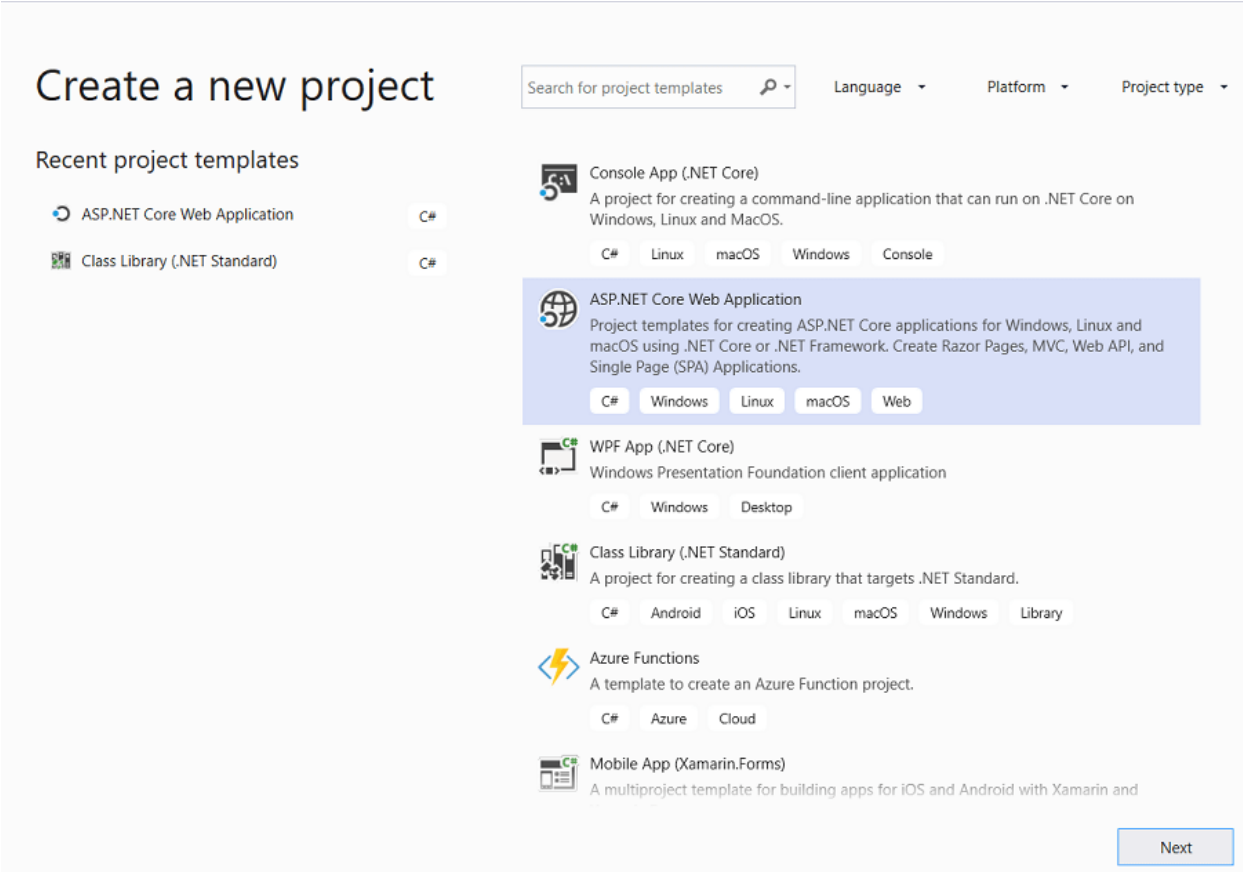
- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core SDK 2.2 or later

> **WARNING**
> If you use Visual Studio 2017, see dotnet/sdk issue #3124 for information about .NET Core SDK versions that don't work with Visual Studio.

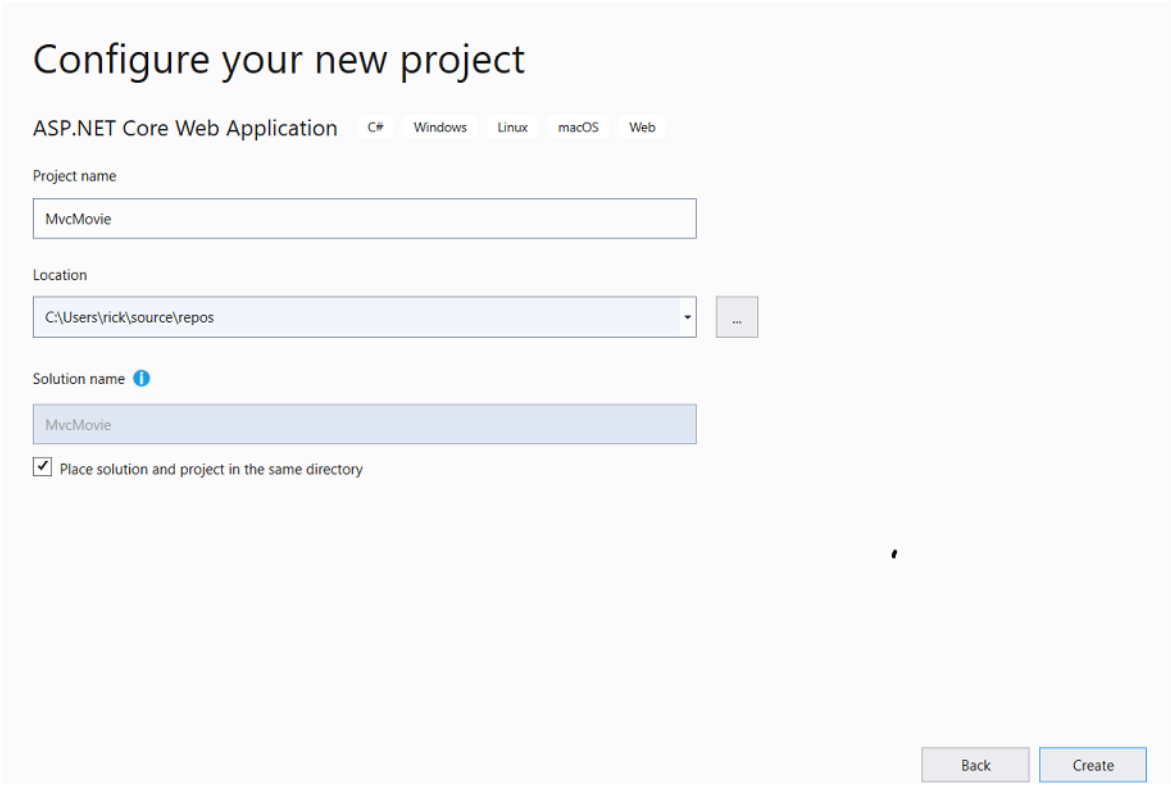
Create a web app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

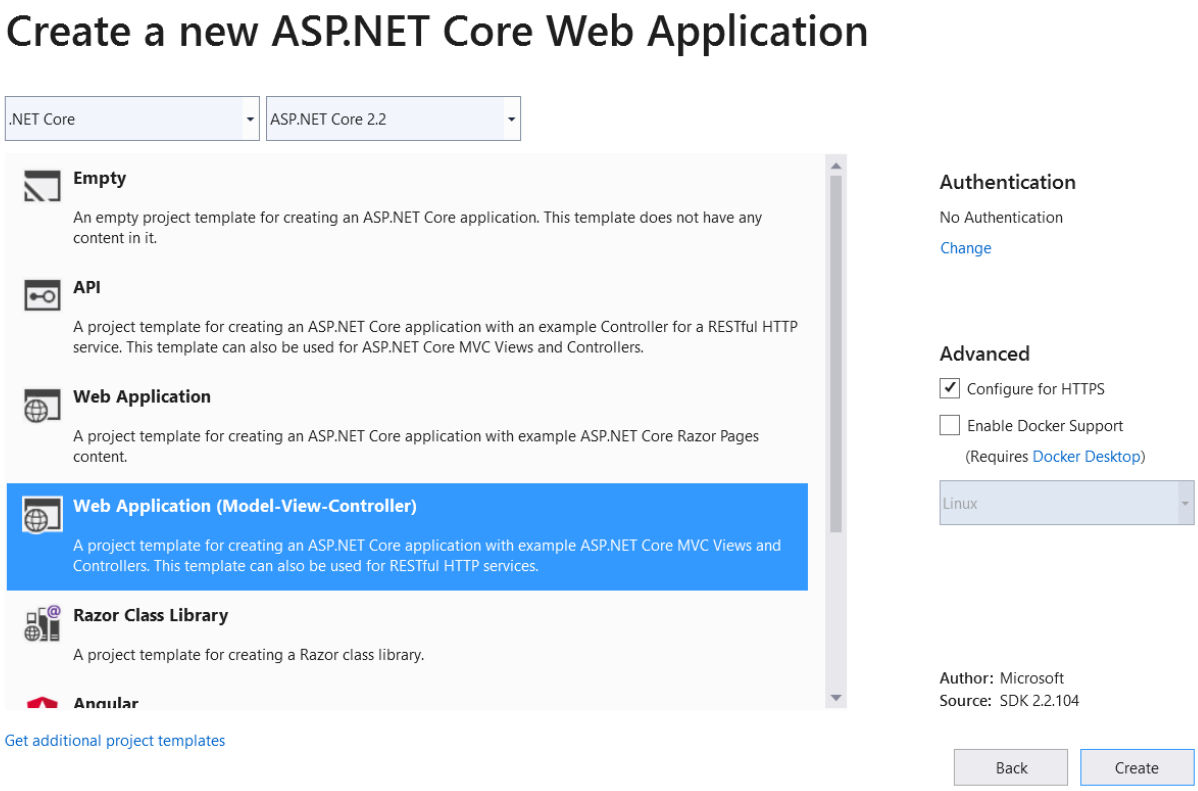
- From the Visual Studio select **Create a new project**.
- Select **ASP.NET Core Web Application** and then select **Next**.



- Name the project **MvcMovie** and select **Create**. It's important to name the project **MvcMovie** so when you copy code, the namespace will match.



- Select **Web Application(Model-View-Controller)**, and then select **Create**.



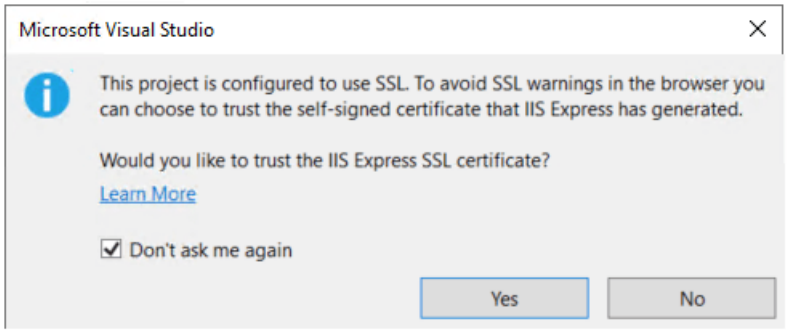
Visual Studio used the default template for the MVC project you just created. You have a working app right now by entering a project name and selecting a few options. This is a basic starter project, and it's a good place to start.

Run the app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

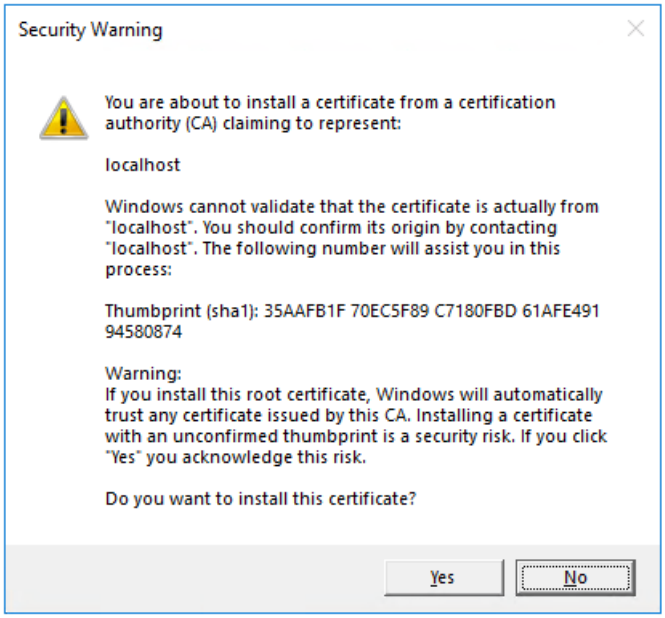
Select **Ctrl-F5** to run the app in non-debug mode.

Visual Studio displays the following dialog:



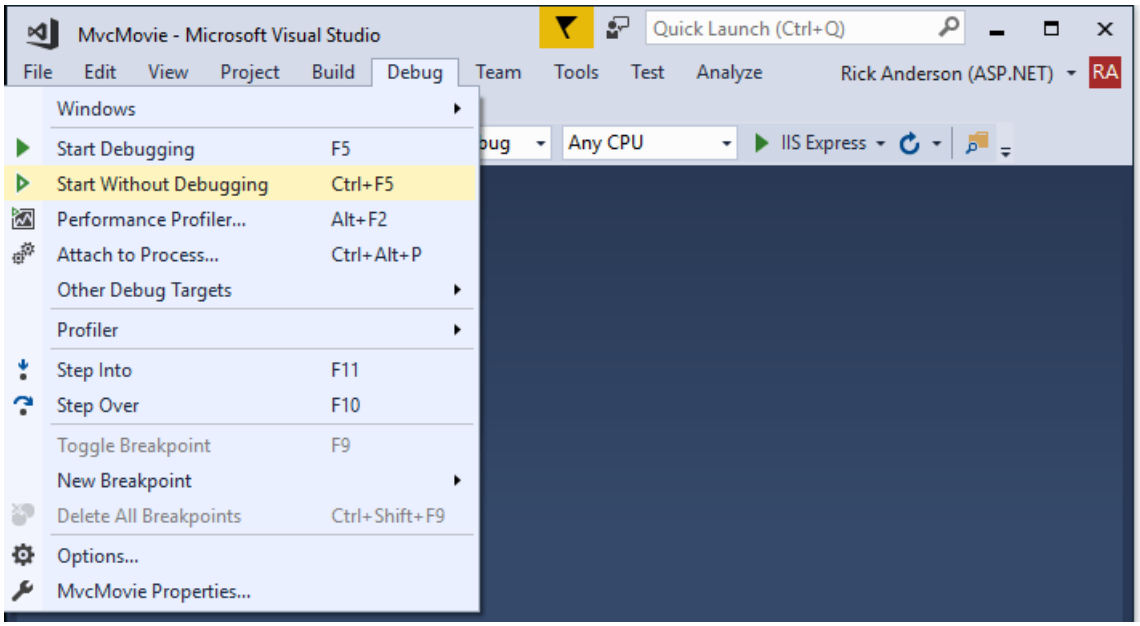
Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:

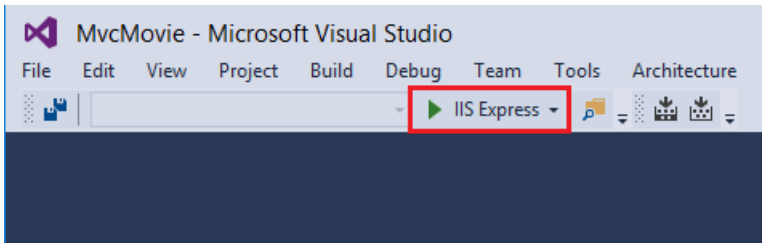


Select **Yes** if you agree to trust the development certificate.

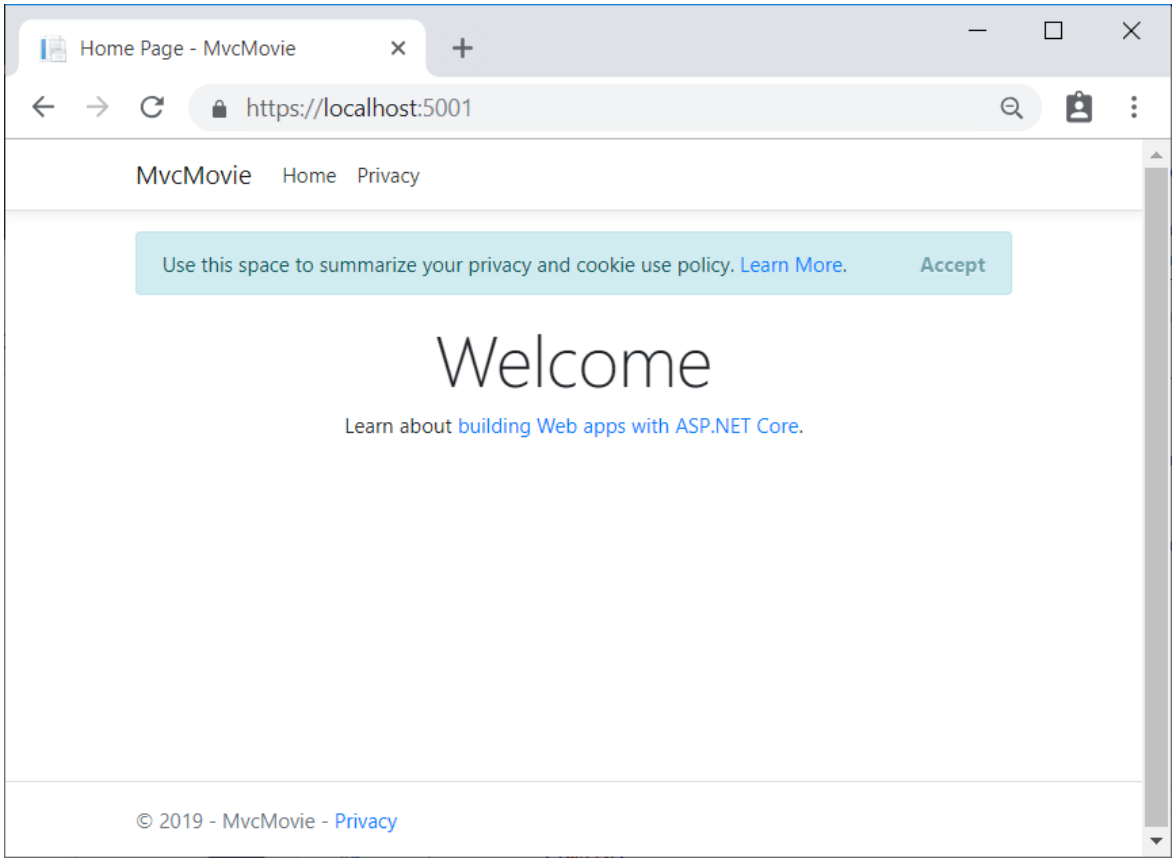
- Visual Studio starts IIS Express and runs the app. Notice that the address bar shows `localhost:port#` and not something like `example.com`. That's because `localhost` is the standard hostname for your local computer. When Visual Studio creates a web project, a random port is used for the web server.
- Launching the app with Ctrl+F5 (non-debug mode) allows you to make code changes, save the file, refresh the browser, and see the code changes. Many developers prefer to use non-debug mode to quickly launch the app and view changes.
- You can launch the app in debug or non-debug mode from the **Debug** menu item:



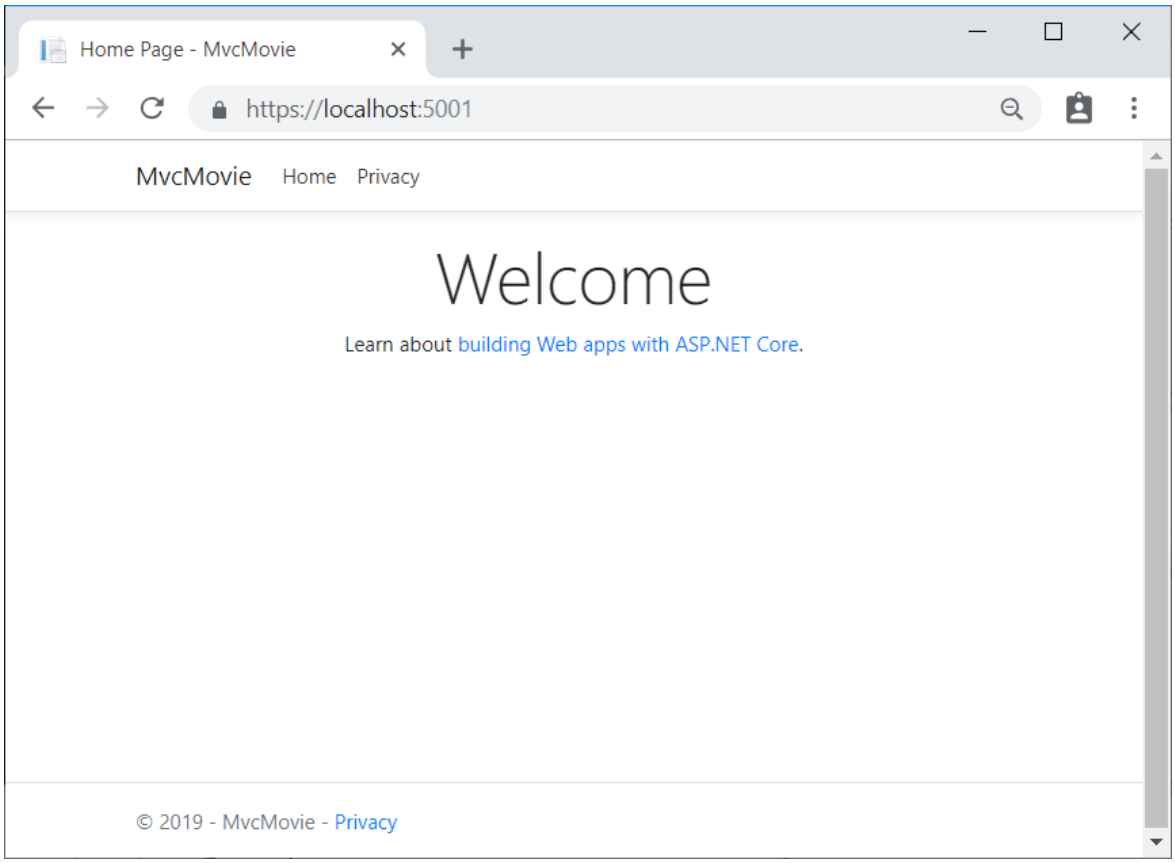
- You can debug the app by selecting the **IIS Express** button



- Select **Accept** to consent to tracking. This app doesn't track personal information. The template generated code includes assets to help meet General Data Protection Regulation (GDPR).



The following image shows the app after accepting tracking:



- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Part 2, add a controller to an ASP.NET Core MVC app

9/22/2020 • 12 minutes to read • Edit Online

By Rick Anderson

The Model-View-Controller (MVC) architectural pattern separates an app into three main components: **M**odel, **V**iew, and **C**ontroller. The MVC pattern helps you create apps that are more testable and easier to update than traditional monolithic apps. MVC-based apps contain:

- **M**odels: Classes that represent the data of the app. The model classes use validation logic to enforce business rules for that data. Typically, model objects retrieve and store model state in a database. In this tutorial, a `Movie` model retrieves movie data from a database, provides it to the view or updates it. Updated data is written to a database.
- **V**iews: Views are the components that display the app's user interface (UI). Generally, this UI displays the model data.
- **C**ontrollers: Classes that handle browser requests. They retrieve model data and call view templates that return a response. In an MVC app, the view only displays information; the controller handles and responds to user input and interaction. For example, the controller handles route data and query-string values, and passes these values to the model. The model might use these values to query the database. For example, `https://localhost:5001/Home/Privacy` has route data of `Home` (the controller) and `Privacy` (the action method to call on the home controller). `https://localhost:5001/Movies/Edit/5` is a request to edit the movie with ID=5 using the movie controller. Route data is explained later in the tutorial.

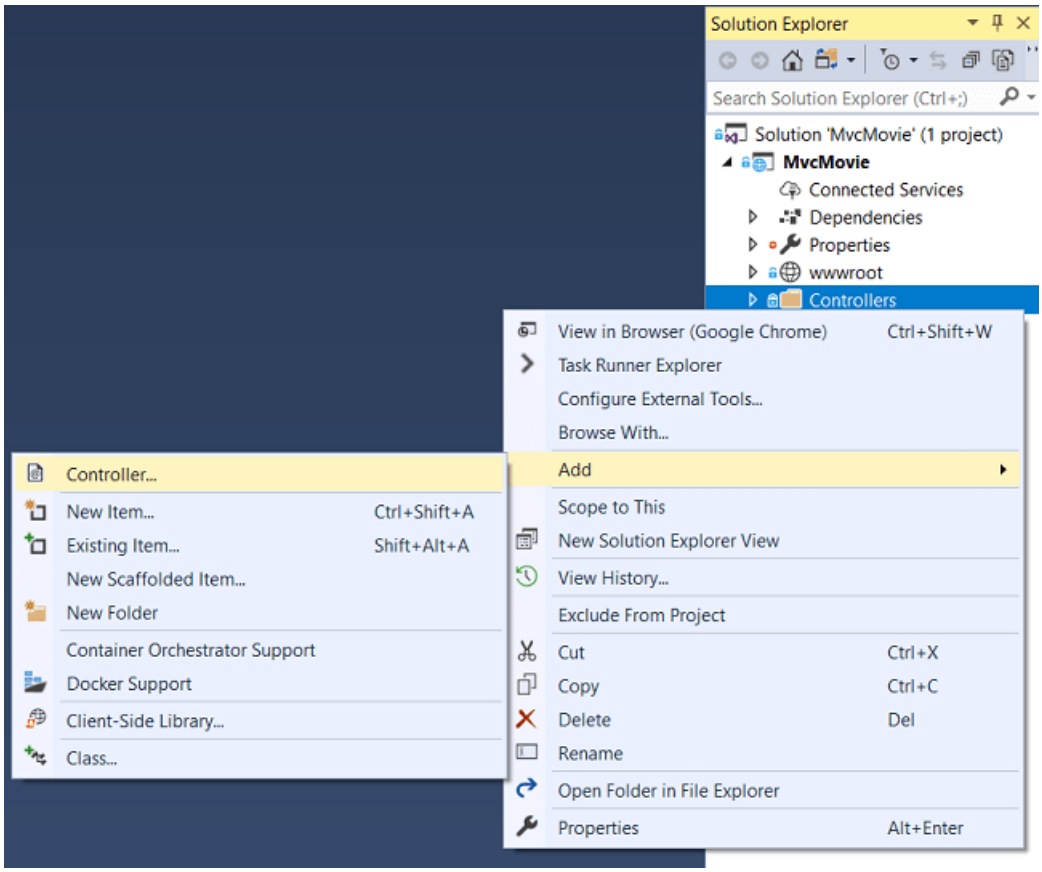
The MVC pattern helps you create apps that separate the different aspects of the app (input logic, business logic, and UI logic), while providing a loose coupling between these elements. The pattern specifies where each kind of logic should be located in the app. The UI logic belongs in the view. Input logic belongs in the controller. Business logic belongs in the model. This separation helps you manage complexity when you build an app, because it enables you to work on one aspect of the implementation at a time without impacting the code of another. For example, you can work on the view code without depending on the business logic code.

We cover these concepts in this tutorial series and show you how to use them to build a movie app. The MVC project contains folders for the *Controllers* and *Views*.

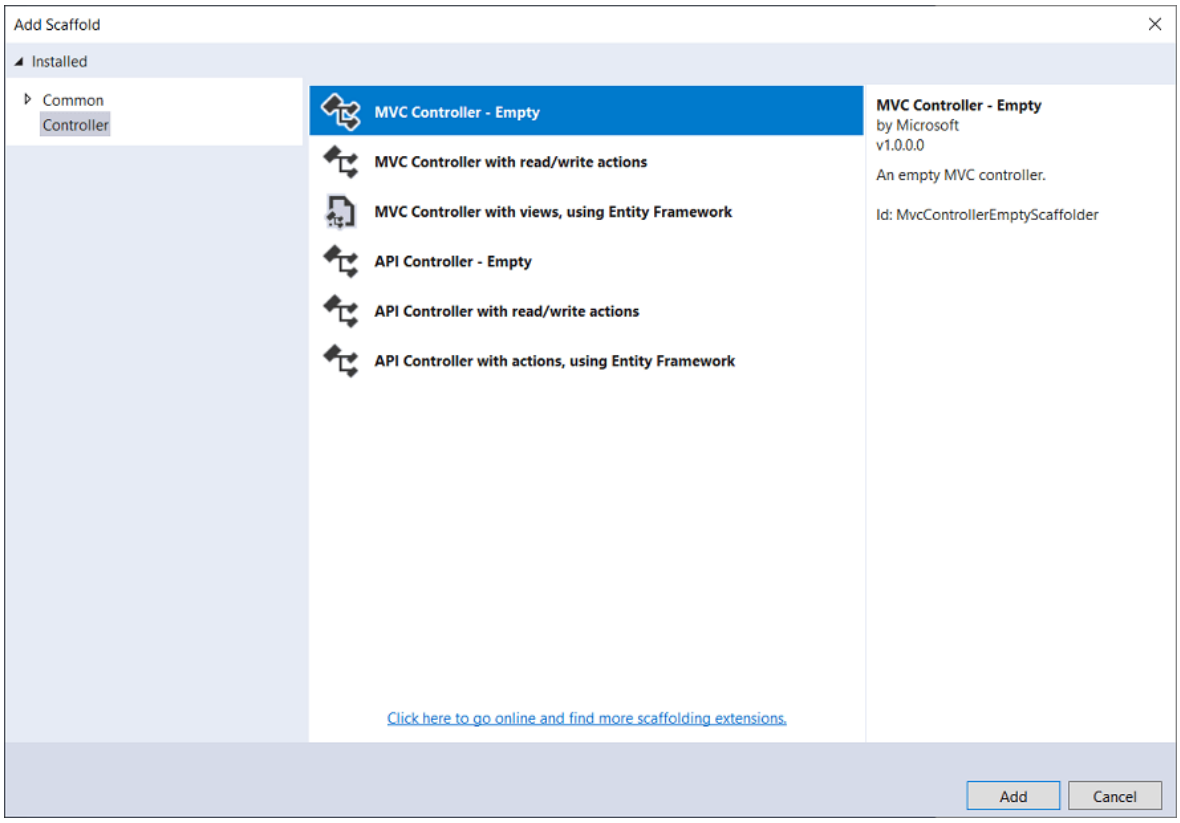
Add a controller

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- In **Solution Explorer**, right-click **Controllers** > **Add** > **Controller**



- In the **Add Scaffold** dialog box, select **Controller Class - Empty**



- In the **Add Empty MVC Controller dialog**, enter **HelloWorldController** and select **ADD**.

Replace the contents of *Controllers/HelloWorldController.cs* with the following:

```
using Microsoft.AspNetCore.Mvc;
using System.Text.Encodings.Web;

namespace MvcMovie.Controllers
{
    public class HelloWorldController : Controller
    {
        //
        // GET: /HelloWorld/

        public string Index()
        {
            return "This is my default action...";
        }

        //
        // GET: /HelloWorld/Welcome/

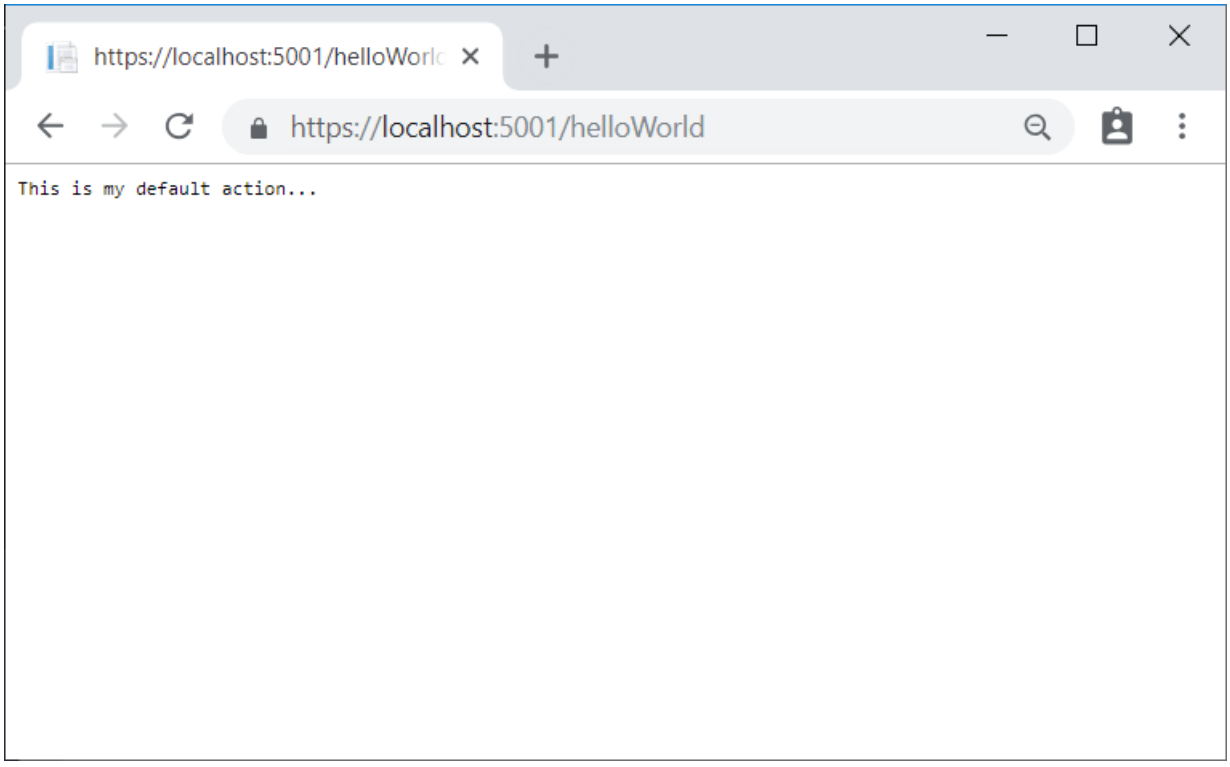
        public string Welcome()
        {
            return "This is the Welcome action method...";
        }
    }
}
```

Every `public` method in a controller is callable as an HTTP endpoint. In the sample above, both methods return a string. Note the comments preceding each method.

An HTTP endpoint is a targetable URL in the web application, such as `https://localhost:5001/HelloWorld`, and combines the protocol used: `HTTPS`, the network location of the web server (including the TCP port): `localhost:5001` and the target URI `HelloWorld`.

The first comment states this is an HTTP GET method that's invoked by appending `/HelloWorld/` to the base URL. The second comment specifies an HTTP GET method that's invoked by appending `/HelloWorld/Welcome/` to the URL. Later on in the tutorial the scaffolding engine is used to generate `HTTP POST` methods which update data.

Run the app in non-debug mode and append "HelloWorld" to the path in the address bar. The `Index` method returns a string.



MVC invokes controller classes (and the action methods within them) depending on the incoming URL. The default URL routing logic used by MVC uses a format like this to determine what code to invoke:

`/[Controller]/[ActionName]/[Parameters]`

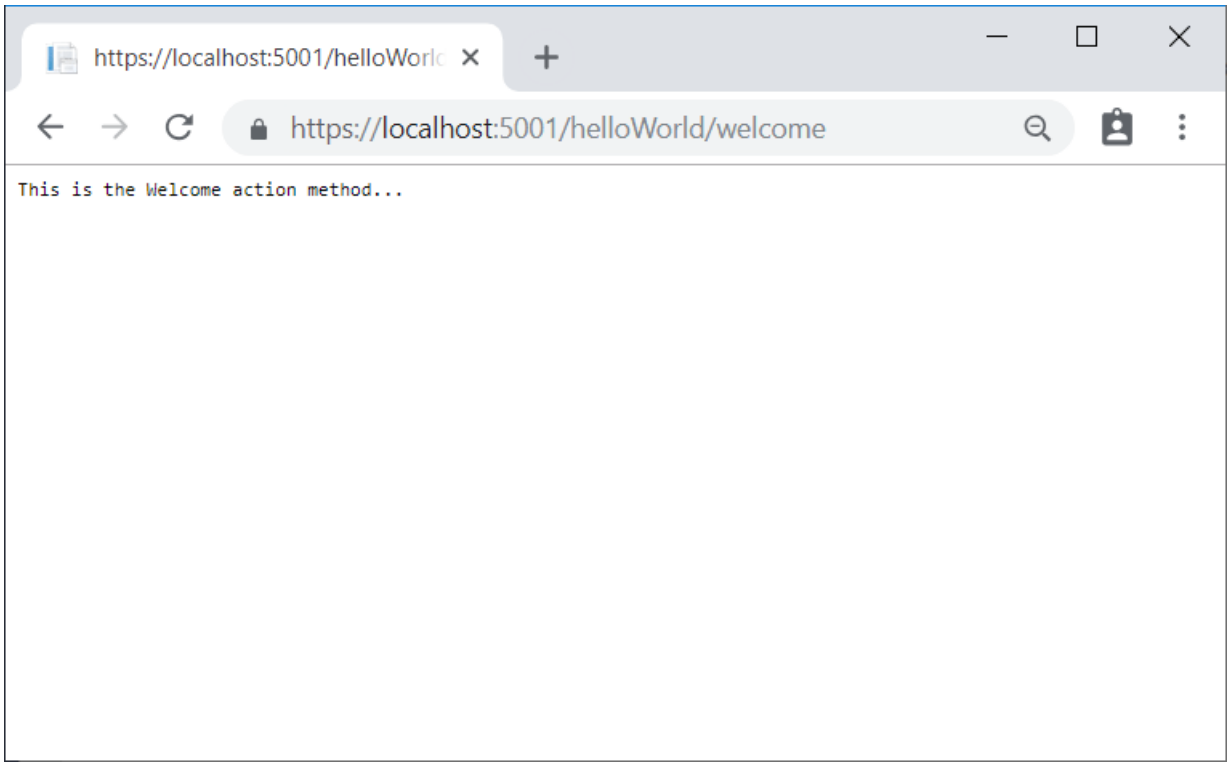
The routing format is set in the `Configure` method in *Startup.cs* file.

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(
        name: "default",
        pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

When you browse to the app and don't supply any URL segments, it defaults to the "Home" controller and the "Index" method specified in the template line highlighted above.

The first URL segment determines the controller class to run. So `localhost:{PORT}/HelloWorld` maps to the **HelloWorld**Controller class. The second part of the URL segment determines the action method on the class. So `localhost:{PORT}/HelloWorld/Index` would cause the `Index` method of the `HelloWorldController` class to run. Notice that you only had to browse to `localhost:{PORT}/HelloWorld` and the `Index` method was called by default. That's because `Index` is the default method that will be called on a controller if a method name isn't explicitly specified. The third part of the URL segment (`id`) is for route data. Route data is explained later in the tutorial.

Browse to `https://localhost:{PORT}/HelloWorld/Welcome`. The `Welcome` method runs and returns the string `This is the Welcome action method...`. For this URL, the controller is `HelloWorld` and `Welcome` is the action method. You haven't used the `[Parameters]` part of the URL yet.



Modify the code to pass some parameter information from the URL to the controller. For example, `/HelloWorld/Welcome?name=Rick&numtimes=4`. Change the `Welcome` method to include two parameters as shown in the following code.

```
// GET: /HelloWorld/Welcome/
// Requires using System.Text.Encodings.Web;
public string Welcome(string name, int numTimes = 1)
{
    return HtmlEncoder.Default.Encode($"Hello {name}, NumTimes is: {numTimes}");
}
```

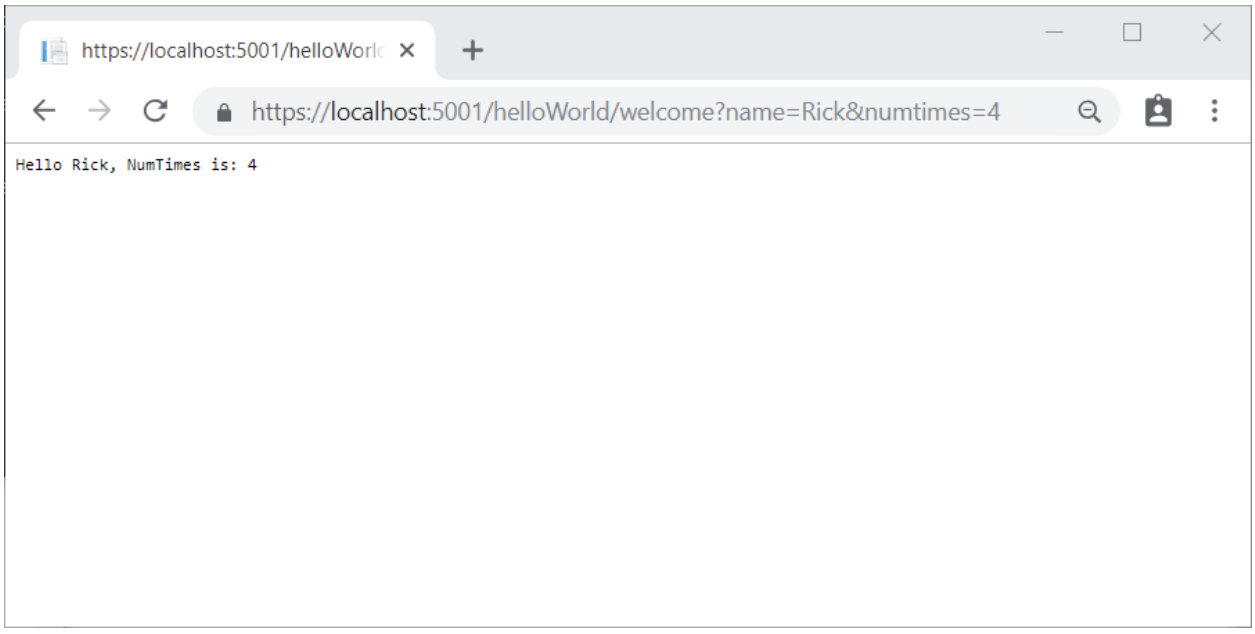
The preceding code:

- Uses the C# optional-parameter feature to indicate that the `numTimes` parameter defaults to 1 if no value is passed for that parameter.
- Uses `HtmlEncoder.Default.Encode` to protect the app from malicious input (namely JavaScript).
- Uses Interpolated Strings in `$"Hello {name}, NumTimes is: {numTimes}"`.

Run the app and browse to:

`https://localhost:{PORT}/HelloWorld/Welcome?name=Rick&numtimes=4`

(Replace `{PORT}` with your port number.) You can try different values for `name` and `numtimes` in the URL. The MVC model binding system automatically maps the named parameters from the query string in the address bar to parameters in your method. See Model Binding for more information.



In the image above, the URL segment (`Parameters`) isn't used, the `name` and `numTimes` parameters are passed in the query string. The `?` (question mark) in the above URL is a separator, and the query string follows. The `&` character separates field-value pairs.

Replace the `Welcome` method with the following code:

```
public string Welcome(string name, int ID = 1)
{
    return HtmlEncoder.Default.Encode($"Hello {name}, ID: {ID}");
}
```

Run the app and enter the following URL: `https://localhost:{PORT}/HelloWorld/Welcome/3?name=Rick`

This time the third URL segment matched the route parameter `id`. The `Welcome` method contains a parameter `id` that matched the URL template in the `MapControllerRoute` method. The trailing `?` (in `id?`) indicates the `id` parameter is optional.

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(
        name: "default",
        pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

In these examples the controller has been doing the "VC" portion of MVC - that is, the **V**iew and the **C**ontroller work. The controller is returning HTML directly. Generally you don't want controllers returning HTML directly, since that becomes very cumbersome to code and maintain. Instead you typically use a separate Razor view template file to generate the HTML response. You do that in the next tutorial.

PREVIOUS NEXT

The Model-View-Controller (MVC) architectural pattern separates an app into three main components: **M**odel, **V**iew, and **C**ontroller. The MVC pattern helps you create apps that are more testable and easier to update than traditional monolithic apps. MVC-based apps contain:

- **M**odels: Classes that represent the data of the app. The model classes use validation logic to enforce business rules for that data. Typically, model objects retrieve and store model state in a database. In this tutorial, a `Movie` model retrieves movie data from a database, provides it to the view or updates it. Updated data is written to a database.
- **V**iews: Views are the components that display the app's user interface (UI). Generally, this UI displays the model data.
- **C**ontrollers: Classes that handle browser requests. They retrieve model data and call view templates that return a response. In an MVC app, the view only displays information; the controller handles and responds to user input and interaction. For example, the controller handles route data and query-string values, and passes these values to the model. The model might use these values to query the database. For example, `https://localhost:5001/Home/About` has route data of `Home` (the controller) and `About` (the action method to call on the home controller). `https://localhost:5001/Movies/Edit/5` is a request to edit the movie with ID=5 using the movie controller. Route data is explained later in the tutorial.

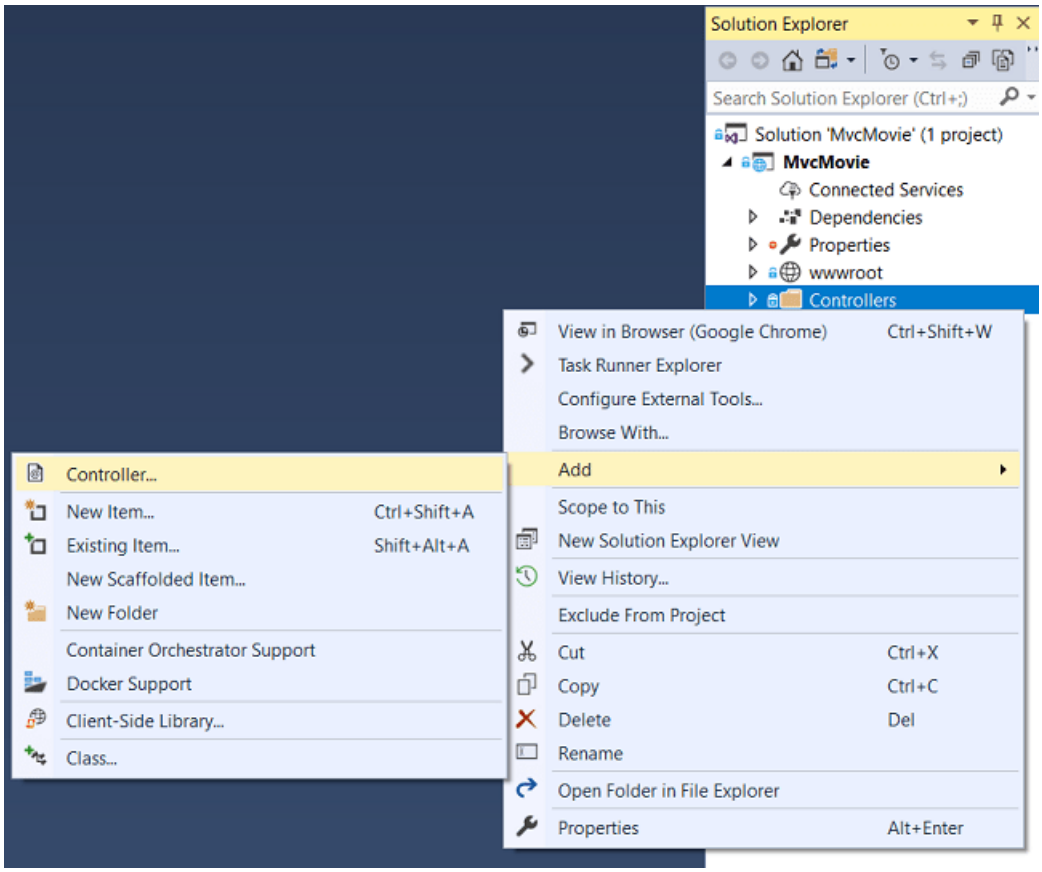
The MVC pattern helps you create apps that separate the different aspects of the app (input logic, business logic, and UI logic), while providing a loose coupling between these elements. The pattern specifies where each kind of logic should be located in the app. The UI logic belongs in the view. Input logic belongs in the controller. Business logic belongs in the model. This separation helps you manage complexity when you build an app, because it enables you to work on one aspect of the implementation at a time without impacting the code of another. For example, you can work on the view code without depending on the business logic code.

We cover these concepts in this tutorial series and show you how to use them to build a movie app. The MVC project contains folders for the *Controllers* and *Views*.

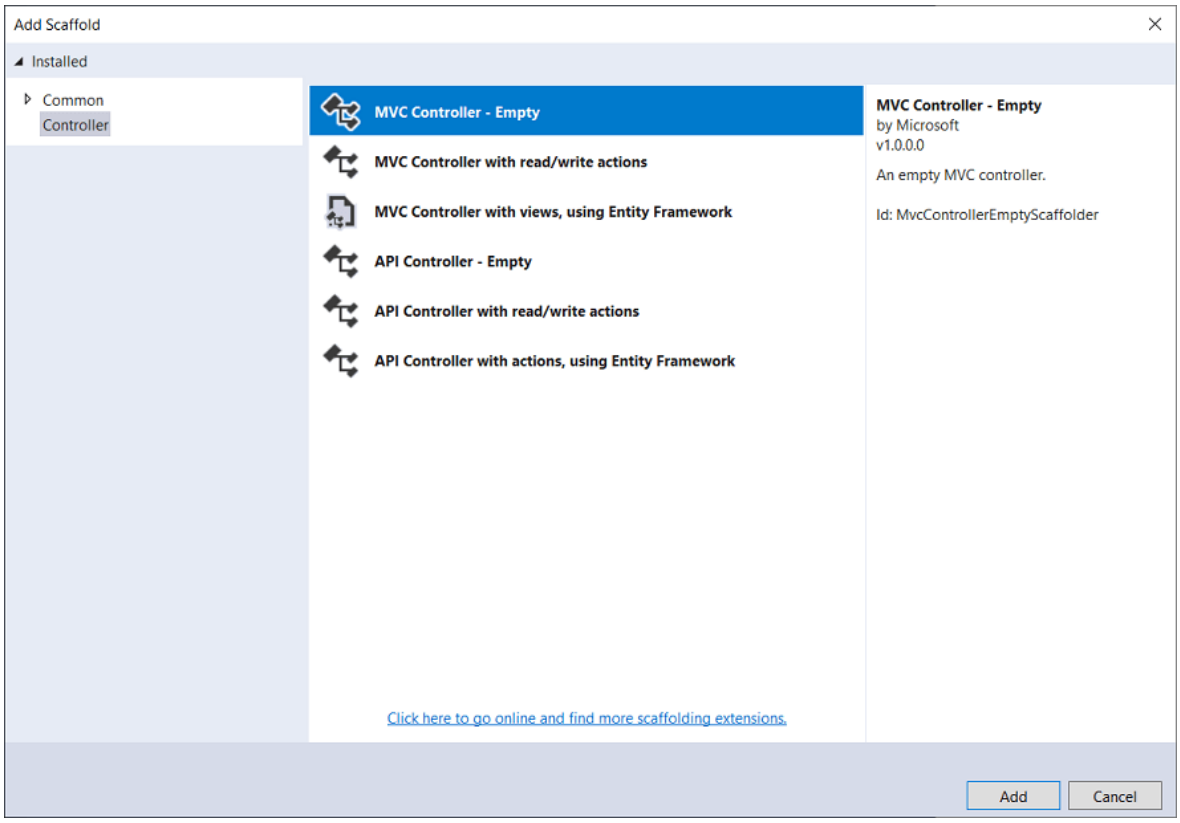
Add a controller

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- In **Solution Explorer**, right-click **Controllers** > **Add** > **Controller**



- In the **Add Scaffold** dialog box, select **MVC Controller - Empty**



- In the **Add Empty MVC Controller dialog**, enter **HelloWorldController** and select **ADD**.

Replace the contents of *Controllers/HelloWorldController.cs* with the following:

```
using Microsoft.AspNetCore.Mvc;
using System.Text.Encodings.Web;

namespace MvcMovie.Controllers
{
    public class HelloWorldController : Controller
    {
        //
        // GET: /HelloWorld/

        public string Index()
        {
            return "This is my default action...";
        }

        //
        // GET: /HelloWorld/Welcome/

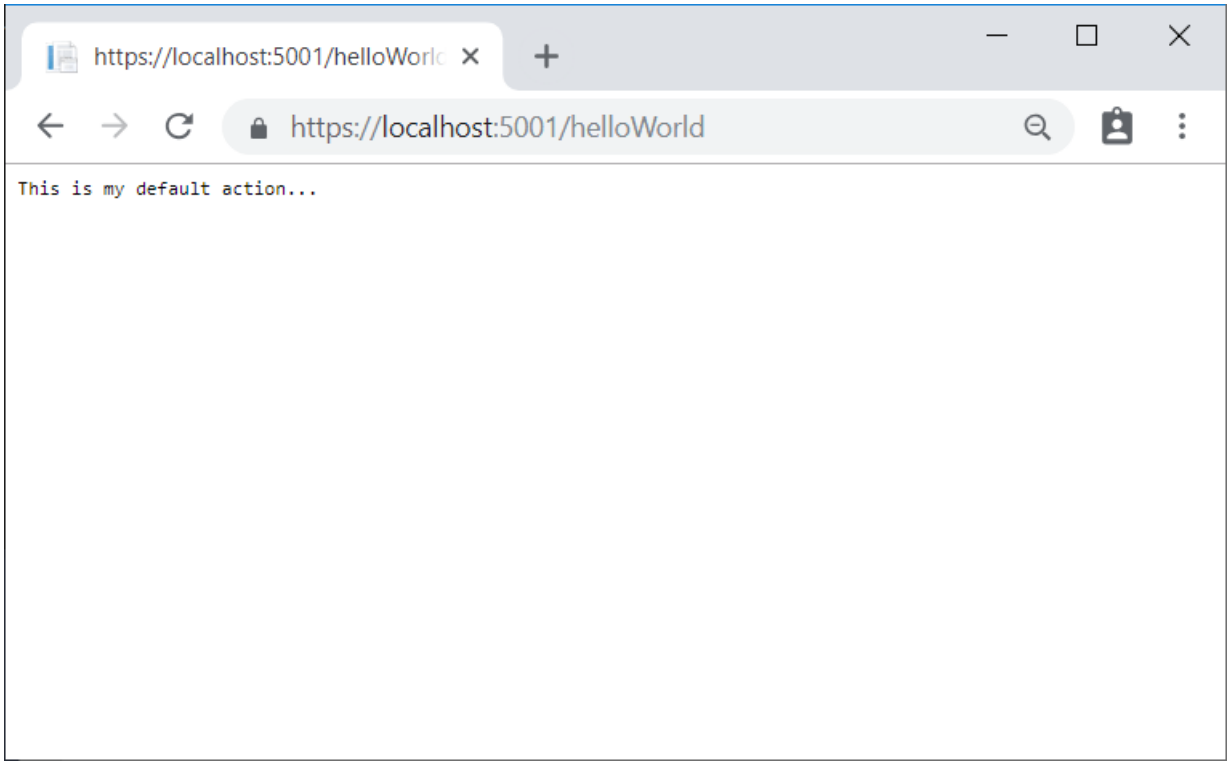
        public string Welcome()
        {
            return "This is the Welcome action method...";
        }
    }
}
```

Every `public` method in a controller is callable as an HTTP endpoint. In the sample above, both methods return a string. Note the comments preceding each method.

An HTTP endpoint is a targetable URL in the web application, such as `https://localhost:5001/HelloWorld`, and combines the protocol used: `HTTPS`, the network location of the web server (including the TCP port): `localhost:5001` and the target URI `HelloWorld`.

The first comment states this is an HTTP GET method that's invoked by appending `/HelloWorld/` to the base URL. The second comment specifies an HTTP GET method that's invoked by appending `/HelloWorld/Welcome/` to the URL. Later on in the tutorial the scaffolding engine is used to generate `HTTP POST` methods which update data.

Run the app in non-debug mode and append "HelloWorld" to the path in the address bar. The `Index` method returns a string.



MVC invokes controller classes (and the action methods within them) depending on the incoming URL. The default URL routing logic used by MVC uses a format like this to determine what code to invoke:

`/[Controller]/[ActionName]/[Parameters]`

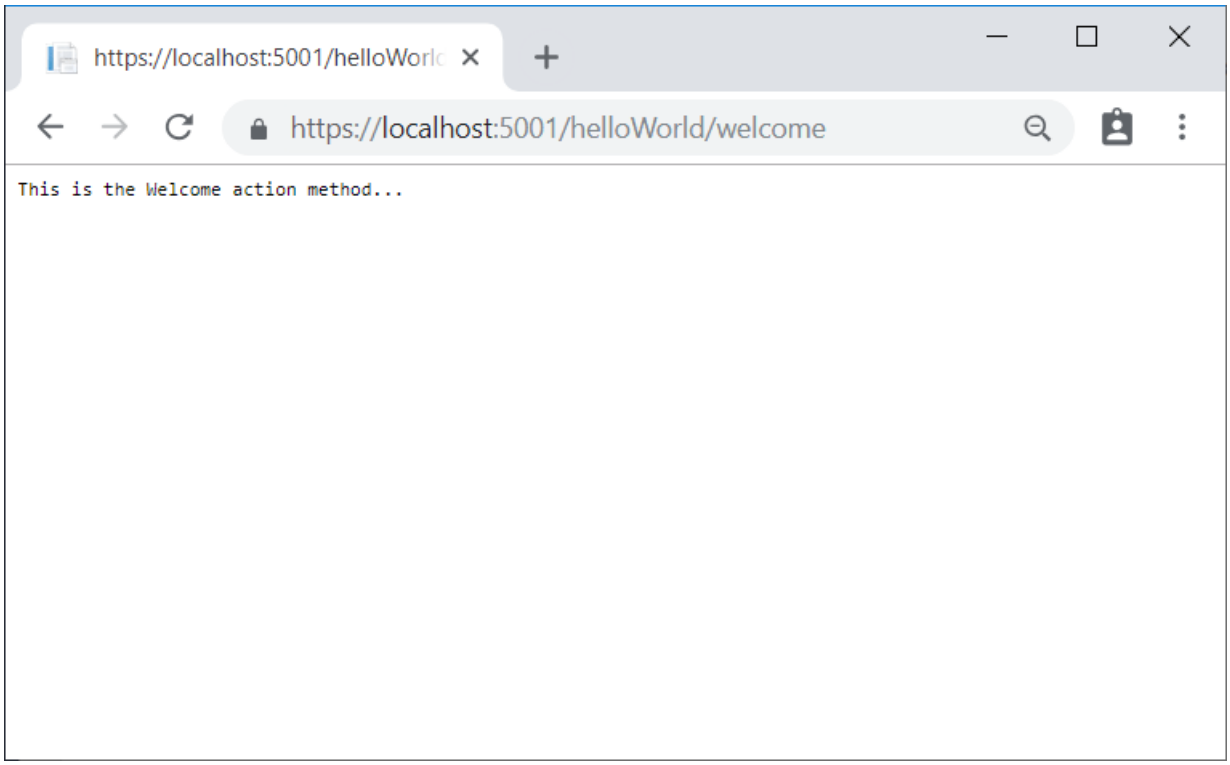
The routing format is set in the `Configure` method in *Startup.cs* file.

```
app.UseMvc(routes =>
{
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");
});
```

When you browse to the app and don't supply any URL segments, it defaults to the "Home" controller and the "Index" method specified in the template line highlighted above.

The first URL segment determines the controller class to run. So `localhost:{PORT}/HelloWorld` maps to the `HelloWorldController` class. The second part of the URL segment determines the action method on the class. So `localhost:{PORT}/HelloWorld/Index` would cause the `Index` method of the `HelloWorldController` class to run. Notice that you only had to browse to `localhost:{PORT}/HelloWorld` and the `Index` method was called by default. This is because `Index` is the default method that will be called on a controller if a method name isn't explicitly specified. The third part of the URL segment (`id`) is for route data. Route data is explained later in the tutorial.

Browse to `https://localhost:{PORT}/HelloWorld/Welcome`. The `Welcome` method runs and returns the string `This is the Welcome action method...`. For this URL, the controller is `HelloWorld` and `Welcome` is the action method. You haven't used the `[Parameters]` part of the URL yet.



Modify the code to pass some parameter information from the URL to the controller. For example, `/HelloWorld/Welcome?name=Rick&numtimes=4`. Change the `Welcome` method to include two parameters as shown in the following code.

```
// GET: /HelloWorld/Welcome/
// Requires using System.Text.Encodings.Web;
public string Welcome(string name, int numTimes = 1)
{
    return HtmlEncoder.Default.Encode($"Hello {name}, NumTimes is: {numTimes}");
}
```

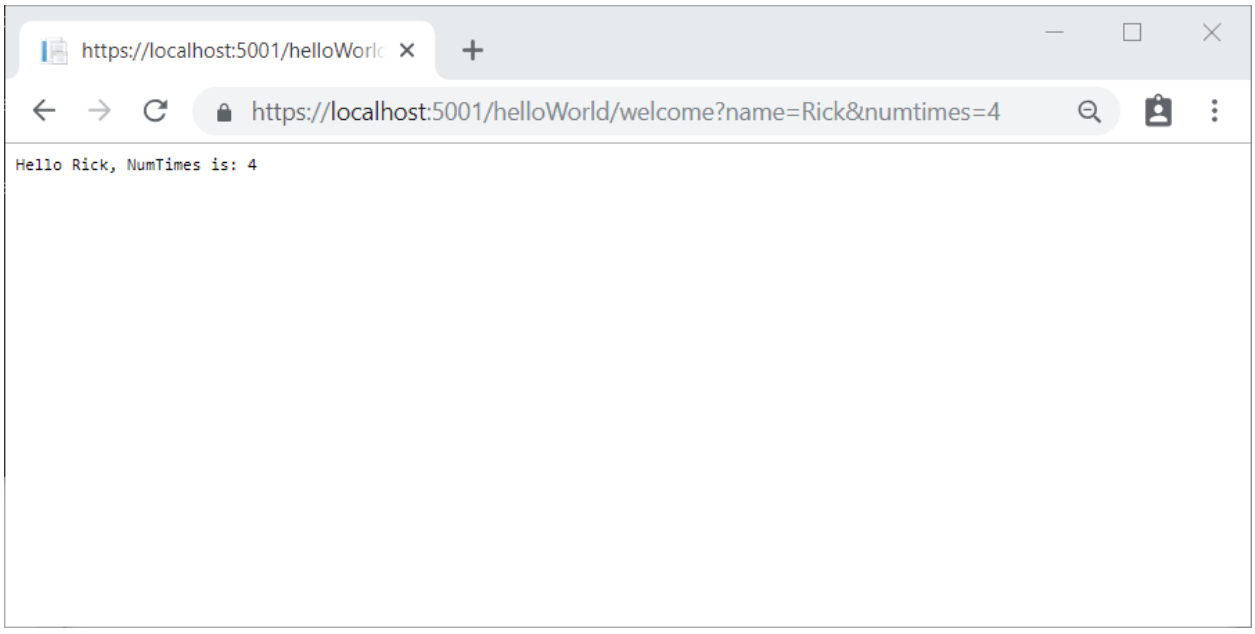
The preceding code:

- Uses the C# optional-parameter feature to indicate that the `numTimes` parameter defaults to 1 if no value is passed for that parameter.
- Uses `HtmlEncoder.Default.Encode` to protect the app from malicious input (namely JavaScript).
- Uses Interpolated Strings in `$"Hello {name}, NumTimes is: {numTimes}"`.

Run the app and browse to:

`https://localhost:{PORT}/HelloWorld/Welcome?name=Rick&numtimes=4`

(Replace `{PORT}` with your port number.) You can try different values for `name` and `numtimes` in the URL. The MVC model binding system automatically maps the named parameters from the query string in the address bar to parameters in your method. See Model Binding for more information.



In the image above, the URL segment (`Parameters`) isn't used, the `name` and `numTimes` parameters are passed in the query string. The `?` (question mark) in the above URL is a separator, and the query string follows. The `&` character separates field-value pairs.

Replace the `Welcome` method with the following code:

```
public string Welcome(string name, int ID = 1)
{
    return HtmlEncoder.Default.Encode($"Hello {name}, ID: {ID}");
}
```

Run the app and enter the following URL: `https://localhost:{PORT}/HelloWorld/Welcome/3?name=Rick`

This time the third URL segment matched the route parameter `id`. The `Welcome` method contains a parameter `id` that matched the URL template in the `MapRoute` method. The trailing `?` (in `id?`) indicates the `id` parameter is optional.

```
app.UseMvc(routes =>
{
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");
});
```

In these examples the controller has been doing the "VC" portion of MVC - that is, the view and controller work. The controller is returning HTML directly. Generally you don't want controllers returning HTML directly, since that becomes very cumbersome to code and maintain. Instead you typically use a separate Razor view template file to help generate the HTML response. You do that in the next tutorial.

Part 3, add a view to an ASP.NET Core MVC app

9/22/2020 • 16 minutes to read • Edit Online

By Rick Anderson

In this section you modify the `HelloWorldController` class to use Razor view files to cleanly encapsulate the process of generating HTML responses to a client.

You create a view template file using Razor. Razor-based view templates have a *.cshtml* file extension. They provide an elegant way to create HTML output with C#.

Currently the `Index` method returns a string with a message that's hard-coded in the controller class. In the `HelloWorldController` class, replace the `Index` method with the following code:

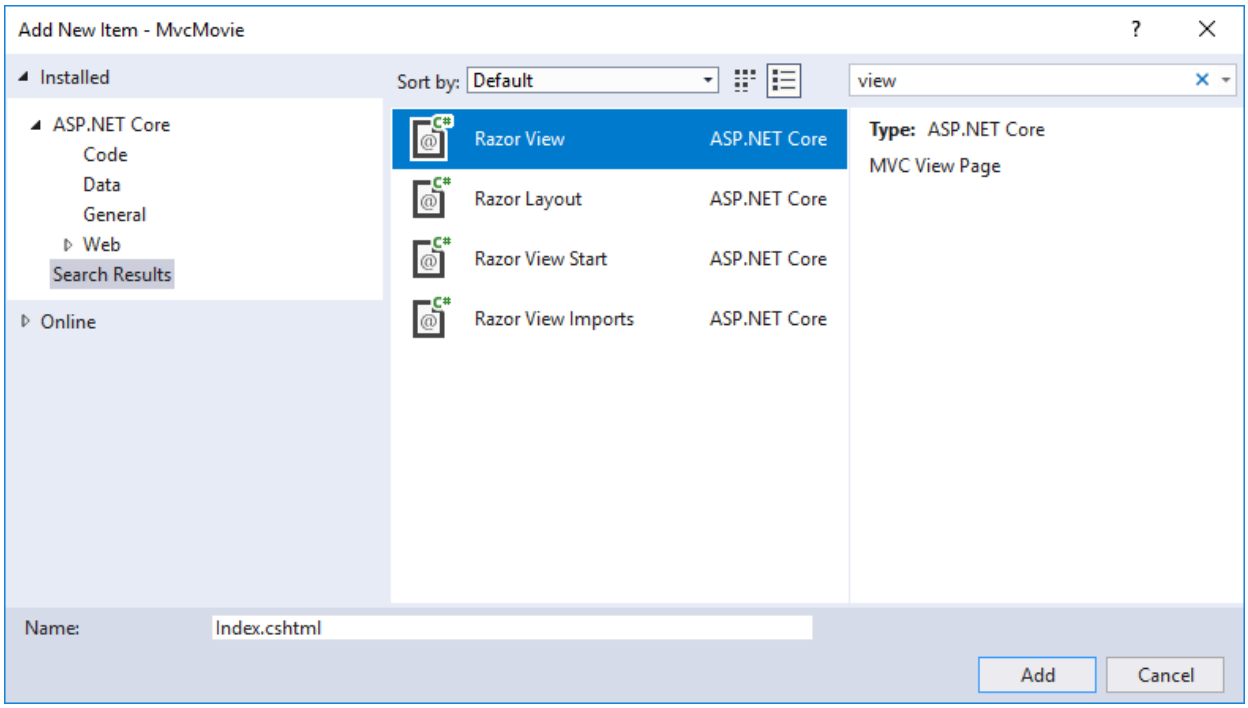
```
public IActionResult Index()
{
    return View();
}
```

The preceding code calls the controller's View method. It uses a view template to generate an HTML response. Controller methods (also known as *action methods*), such as the `Index` method above, generally return an IActionResult (or a class derived from ActionResult), not a type like `string`.

Add a view

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Right click on the *Views* folder, and then **Add > New Folder** and name the folder *HelloWorld*.
- Right click on the *Views/HelloWorld* folder, and then **Add > New Item**.
- In the **Add New Item - MvcMovie** dialog
  - In the search box in the upper-right, enter *view*
  - Select **Razor View**
  - Keep the **Name** box value, *Index.cshtml*.
  - Select **Add**



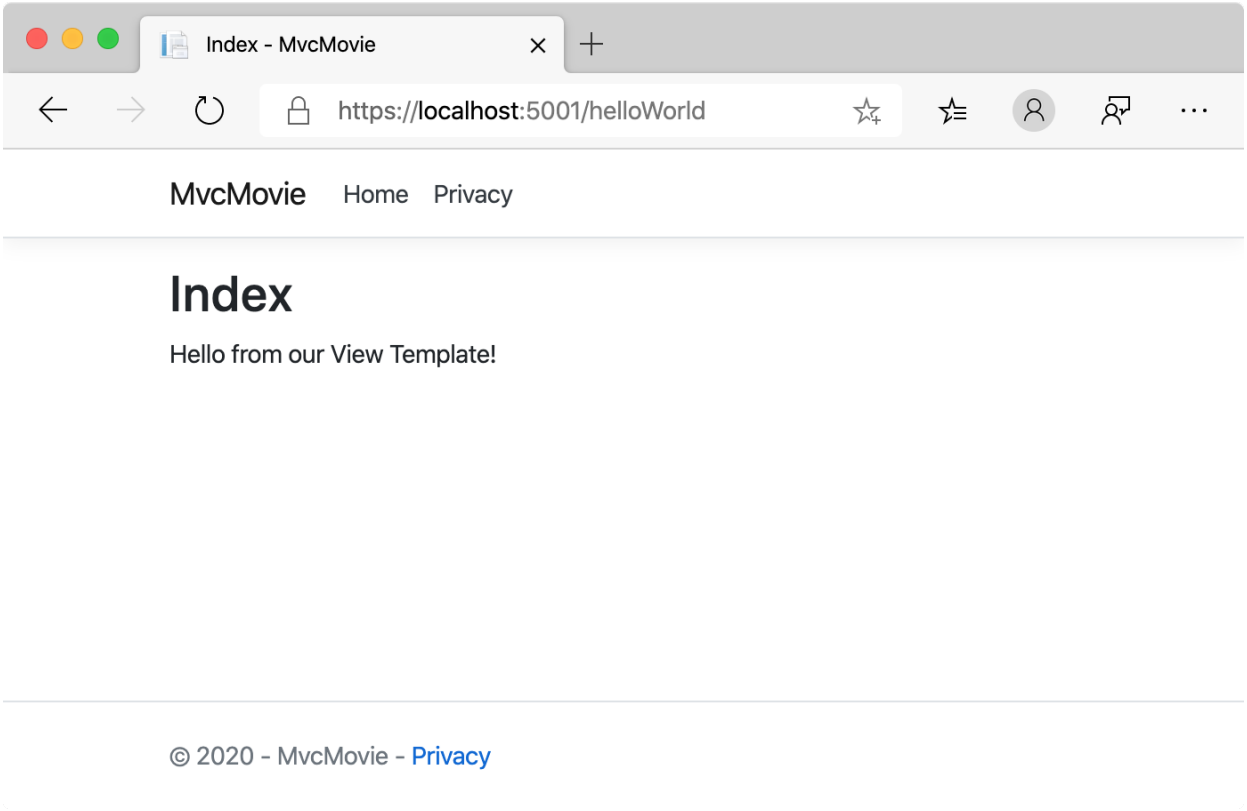
Replace the contents of the *Views/HelloWorld/Index.cshtml* Razor view file with the following:

```
@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>Hello from our View Template!</p>
```

Navigate to `https://localhost:{PORT}/HelloWorld`. The `Index` method in the `HelloWorldController` didn't do much; it ran the statement `return View();`, which specified that the method should use a view template file to render a response to the browser. Because a view template file name wasn't specified, MVC defaulted to using the default view file. The default view file has the same name as the method (`Index`), so the view template in */Views/HelloWorld/Index.cshtml* is used. The image below shows the string "Hello from our View Template!" hard-coded in the view.



Change views and layout pages

Select the menu links (**MvcMovie**, **Home**, and **Privacy**). Each page shows the same menu layout. The menu layout is implemented in the *Views/Shared/_Layout.cshtml* file. Open the *Views/Shared/_Layout.cshtml* file.

Layout templates allow you to specify the HTML container layout of your site in one place and then apply it across multiple pages in your site. Find the `@RenderBody()` line. `RenderBody` is a placeholder where all the view-specific pages you create show up, *wrapped* in the layout page. For example, if you select the **Privacy** link, the **Views/Home/Privacy.cshtml** view is rendered inside the `RenderBody` method.

Change the title, footer, and menu link in the layout file

Replace the content of the *Views/Shared/_Layout.cshtml* file with the following markup. The changes are highlighted:

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Movie App</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.min.css" />
    <link rel="stylesheet" href="~/css/site.css" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-light bg-white border-bottom box-
shadow mb-3">
            <div class="container">
                <a class="navbar-brand" asp-controller="Movies" asp-action="Index">Movie App</a>
                <button class="navbar-toggler" type="button" data-toggle="collapse" data-target=".navbar-
collapse" aria-controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle navigation">
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex flex-sm-row-reverse">
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-controller="Home" asp-
action="Index">Home</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-controller="Home" asp-
action="Privacy">Privacy</a>
                        </li>
                    </ul>
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2020 - Movie App - <a asp-area="" asp-controller="Home" asp-action="Privacy">Privacy</a>
        </div>
    </footer>
    <script src="~/lib/jquery/dist/jquery.min.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.min.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>
    @RenderSection("Scripts", required: false)
</body>
</html>
```

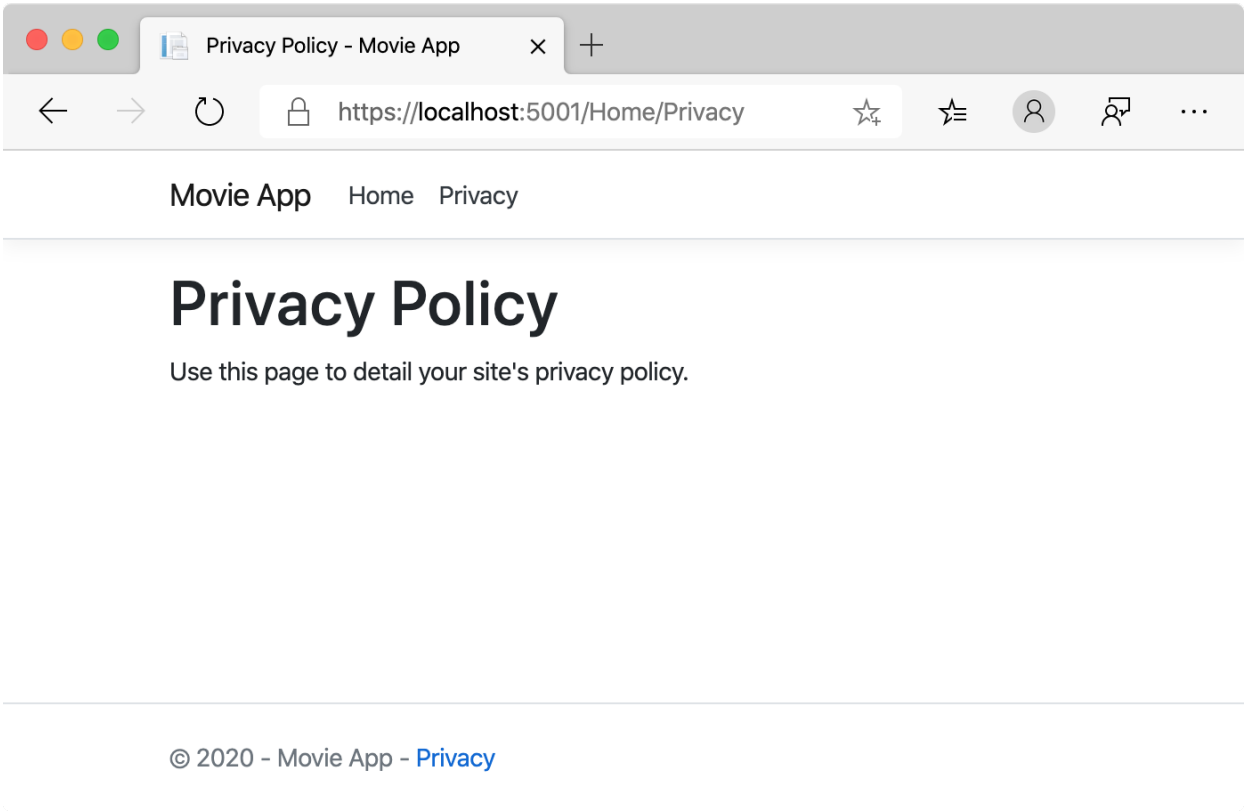
The preceding markup made the following changes:

- 3 occurrences of `MvcMovie` to `Movie App`.
- The anchor element
  `<a class="navbar-brand" asp-area="" asp-controller="Home" asp-action="Index">MvcMovie</a>` to
  `<a class="navbar-brand" asp-controller="Movies" asp-action="Index">Movie App</a>`.

In the preceding markup, the `asp-area=""` anchor Tag Helper attribute and attribute value was omitted because this app is not using Areas.

Note: The `Movies` controller has not been implemented. At this point, the `Movie App` link is not functional.

Save your changes and select the **Privacy** link. Notice how the title on the browser tab displays **Privacy Policy - Movie App** instead of **Privacy Policy - Mvc Movie**:



Select the **Home** link and notice that the title and anchor text also display **Movie App**. We were able to make the change once in the layout template and have all pages on the site reflect the new link text and new title.

Examine the *Views/_ViewStart.cshtml* file:

```
@{
    Layout = "_Layout";
}
```

The *Views/_ViewStart.cshtml* file brings in the *Views/Shared/_Layout.cshtml* file to each view. The `Layout` property can be used to set a different layout view, or set it to `null` so no layout file will be used.

Change the title and `<h2>` element of the *Views/HelloWorld/Index.cshtml* view file:

```
@{
    ViewData["Title"] = "Movie List";
}

<h2>My Movie List</h2>

<p>Hello from our View Template!</p>
```

The title and `<h2>` element are slightly different so you can see which bit of code changes the display.

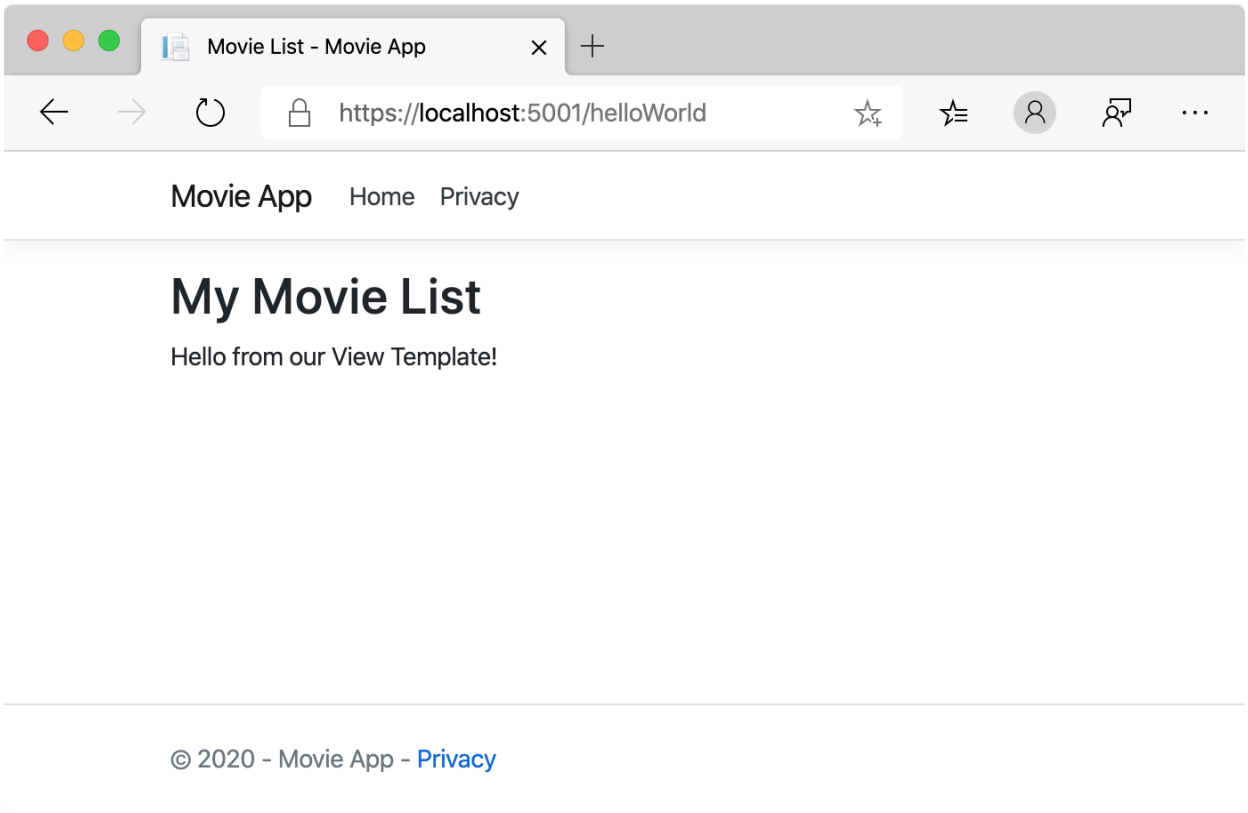
`ViewData["Title"] = "Movie List";` in the code above sets the `Title` property of the `ViewData` dictionary to "Movie List". The `Title` property is used in the `<title>` HTML element in the layout page:

```
<title>@ViewData["Title"] - Movie App</title>
```

Save the change and navigate to `https://localhost:{PORT}/HelloWorld`. Notice that the browser title, the primary

heading, and the secondary headings have changed. (If you don't see changes in the browser, you might be viewing cached content. Press Ctrl+F5 in your browser to force the response from the server to be loaded.) The browser title is created with `ViewData["Title"]` we set in the *Index.cshtml* view template and the additional "- Movie App" added in the layout file.

The content in the *Index.cshtml* view template is merged with the *Views/Shared/_Layout.cshtml* view template. A single HTML response is sent to the browser. Layout templates make it easy to make changes that apply across all of the pages in an app. To learn more, see Layout.



Our little bit of "data" (in this case the "Hello from our View Template!" message) is hard-coded, though. The MVC application has a "V" (view) and you've got a "C" (controller), but no "M" (model) yet.

Passing Data from the Controller to the View

Controller actions are invoked in response to an incoming URL request. A controller class is where the code is written that handles the incoming browser requests. The controller retrieves data from a data source and decides what type of response to send back to the browser. View templates can be used from a controller to generate and format an HTML response to the browser.

Controllers are responsible for providing the data required in order for a view template to render a response. A best practice: View templates should **not** perform business logic or interact with a database directly. Rather, a view template should work only with the data that's provided to it by the controller. Maintaining this "separation of concerns" helps keep the code clean, testable, and maintainable.

Currently, the `Welcome` method in the `HelloWorldController` class takes a `name` and a `ID` parameter and then outputs the values directly to the browser. Rather than have the controller render this response as a string, change the controller to use a view template instead. The view template generates a dynamic response, which means that appropriate bits of data must be passed from the controller to the view in order to generate the response. Do this by having the controller put the dynamic data (parameters) that the view template needs in a `ViewData` dictionary that the view template can then access.

In *HelloWorldController.cs*, change the `Welcome` method to add a `Message` and `NumTimes` value to the `ViewData` dictionary. The `ViewData` dictionary is a dynamic object, which means any type can be used; the `ViewData`

object has no defined properties until you put something inside it. The MVC model binding system automatically maps the named parameters (`name` and `numTimes`) from the query string in the address bar to parameters in your method. The complete *HelloWorldController.cs* file looks like this:

```
using Microsoft.AspNetCore.Mvc;
using System.Text.Encodings.Web;

namespace MvcMovie.Controllers
{
    public class HelloWorldController : Controller
    {
        public IActionResult Index()
        {
            return View();
        }

        public IActionResult Welcome(string name, int numTimes = 1)
        {
            ViewData["Message"] = "Hello " + name;
            ViewData["NumTimes"] = numTimes;

            return View();
        }
    }
}
```

The `ViewData` dictionary object contains data that will be passed to the view.

Create a Welcome view template named *Views/HelloWorld/Welcome.cshtml*.

You'll create a loop in the *Welcome.cshtml* view template that displays "Hello" `NumTimes`. Replace the contents of *Views/HelloWorld/Welcome.cshtml* with the following:

```
@{
    ViewData["Title"] = "Welcome";
}

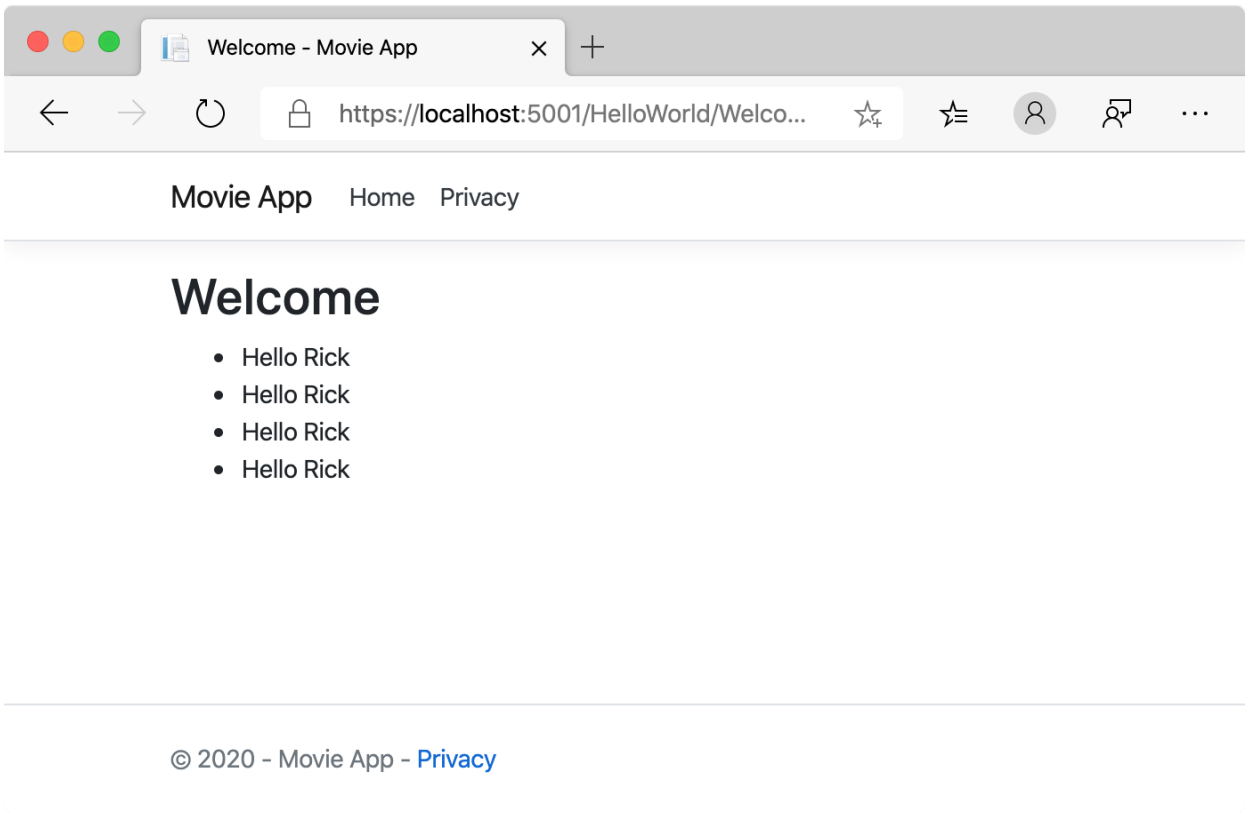
<h2>Welcome</h2>

<ul>
    @for (int i = 0; i < (int)ViewData["NumTimes"]; i++)
    {
        <li>@ViewData["Message"]</li>
    }
</ul>
```

Save your changes and browse to the following URL:

`https://localhost:{PORT}/HelloWorld/Welcome?name=Rick&numtimes=4`

Data is taken from the URL and passed to the controller using the MVC model binder . The controller packages the data into a `ViewData` dictionary and passes that object to the view. The view then renders the data as HTML to the browser.



In the sample above, the `ViewData` dictionary was used to pass data from the controller to a view. Later in the tutorial, a view model is used to pass data from a controller to a view. The view model approach to passing data is generally much preferred over the `ViewData` dictionary approach. See When to use ViewBag, ViewData, or TempData for more information.

In the next tutorial, a database of movies is created.

PREVIOUS NEXT

In this section you modify the `HelloWorldController` class to use Razor view files to cleanly encapsulate the process of generating HTML responses to a client.

You create a view template file using Razor. Razor-based view templates have a *.cshtml* file extension. They provide an elegant way to create HTML output with C#.

Currently the `Index` method returns a string with a message that's hard-coded in the controller class. In the `HelloWorldController` class, replace the `Index` method with the following code:

```
public IActionResult Index()
{
    return View();
}
```

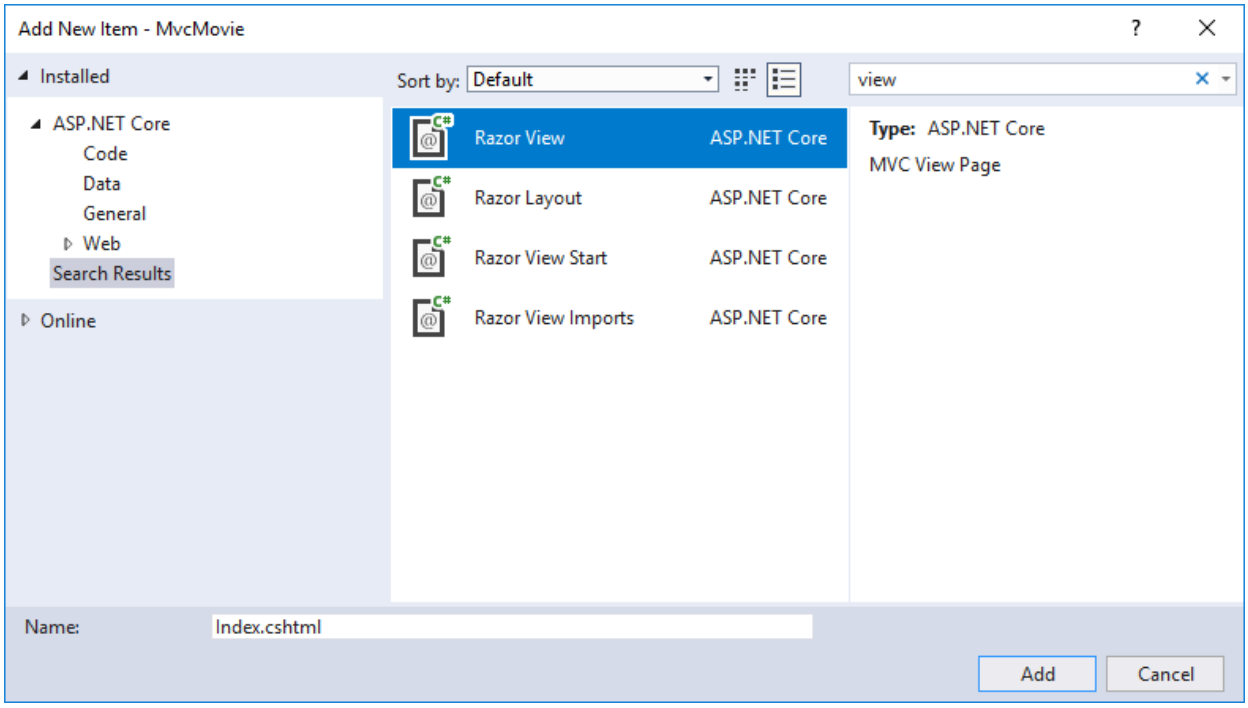
The preceding code calls the controller's View method. It uses a view template to generate an HTML response. Controller methods (also known as *action methods*), such as the `Index` method above, generally return an IActionResult (or a class derived from ActionResult), not a type like `string`.

Add a view

- Visual Studio
- Visual Studio Code

- Visual Studio for Mac

- Right click on the *Views* folder, and then **Add** > **New Folder** and name the folder *HelloWorld*.
- Right click on the *Views/HelloWorld* folder, and then **Add** > **New Item**.
- In the **Add New Item - MvcMovie** dialog
  - In the search box in the upper-right, enter *view*
  - Select **Razor View**
  - Keep the **Name** box value, *Index.cshtml*.
  - Select **Add**



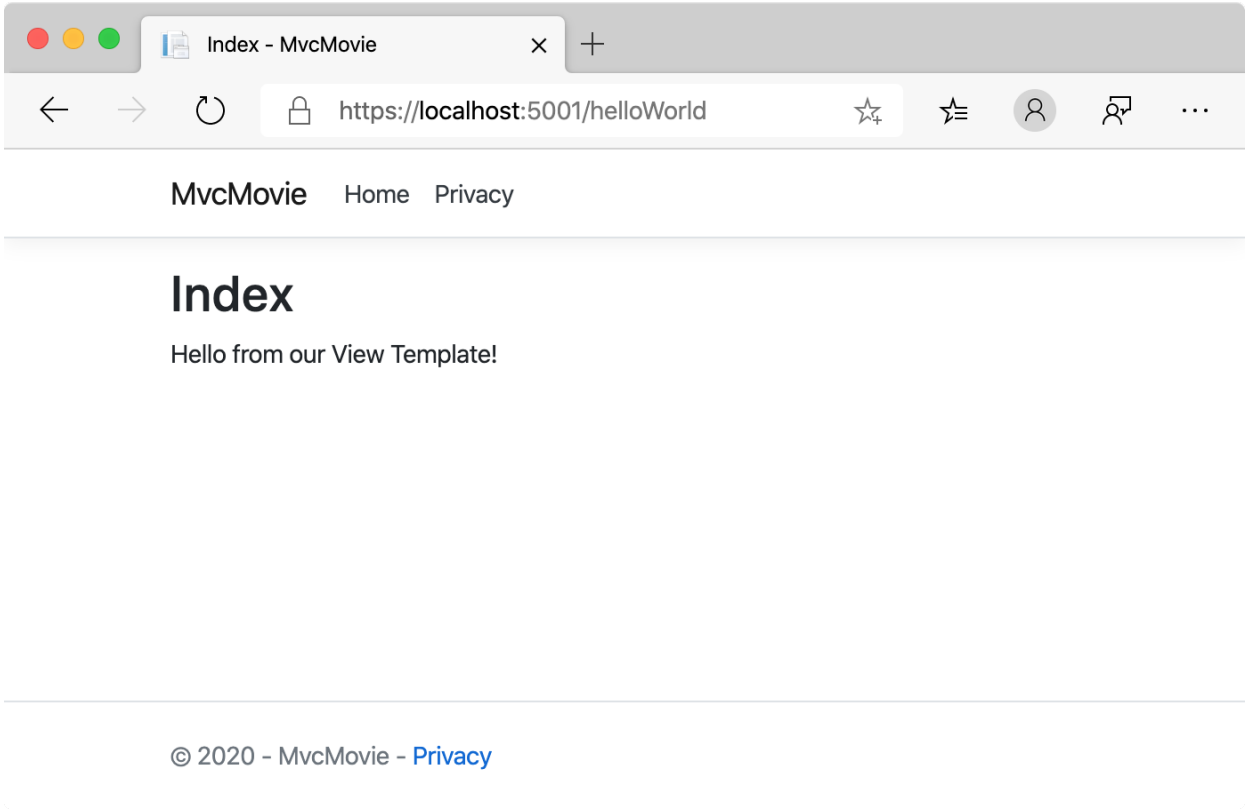
Replace the contents of the *Views/HelloWorld/Index.cshtml* Razor view file with the following:

```
@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>Hello from our View Template!</p>
```

Navigate to `https://localhost:{PORT}/HelloWorld`. The `Index` method in the `HelloWorldController` didn't do much; it ran the statement `return View();`, which specified that the method should use a view template file to render a response to the browser. Because a view template file name wasn't specified, MVC defaulted to using the default view file. The default view file has the same name as the method (`Index`), so in the */Views/HelloWorld/Index.cshtml* is used. The image below shows the string "Hello from our View Template!" hard-coded in the view.



Change views and layout pages

Select the menu links (**MvcMovie**, **Home**, and **Privacy**). Each page shows the same menu layout. The menu layout is implemented in the *Views/Shared/_Layout.cshtml* file. Open the *Views/Shared/_Layout.cshtml* file.

Layout templates allow you to specify the HTML container layout of your site in one place and then apply it across multiple pages in your site. Find the `@RenderBody()` line. `RenderBody` is a placeholder where all the view-specific pages you create show up, *wrapped* in the layout page. For example, if you select the **Privacy** link, the **Views/Home/Privacy.cshtml** view is rendered inside the `RenderBody` method.

Change the title, footer, and menu link in the layout file

- In the title and footer elements, change `MvcMovie` to `Movie App`.
- Change the anchor element
  `<a class="navbar-brand" asp-area="" asp-controller="Home" asp-action="Index">MvcMovie</a>` to
  `<a class="navbar-brand" asp-controller="Movies" asp-action="Index">Movie App</a>`.

The following markup shows the highlighted changes:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Movie App</title>

    <environment include="Development">
        <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    </environment>
    <environment exclude="Development">
        <link rel="stylesheet" href="https://cdnjs.cloudflare.com/ajax/libs/twitter-
bootstrap/4.1.3/css/bootstrap.min.css"
              asp-fallback-href="~/lib/bootstrap/dist/css/bootstrap.min.css"
              asp-fallback-test-class="sr-only" asp-fallback-test-property="position" asp-fallback-test-
value="absolute"
```

```
            crossorigin="anonymous"
            integrity="sha256-eSi1q2PG6J7g7ib17yAaWMcrr5GrtohYChqibrV7PBE="/>
    </environment>
    <link rel="stylesheet" href="~/css/site.css" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-light bg-white border-bottom box-
shadow mb-3">
            <div class="container">
                <a class="navbar-brand" asp-controller="Movies" asp-action="Index">Movie App</a>
                <button class="navbar-toggler" type="button" data-toggle="collapse" data-target=".navbar-
collapse" aria-controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle navigation">
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex flex-sm-row-reverse">
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-controller="Home" asp-
action="Index">Home</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-controller="Home" asp-
action="Privacy">Privacy</a>
                        </li>
                    </ul>
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <partial name="_CookieConsentPartial" />
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2019 - Movie App - <a asp-area="" asp-controller="Home" asp-action="Privacy">Privacy</a>
        </div>
    </footer>

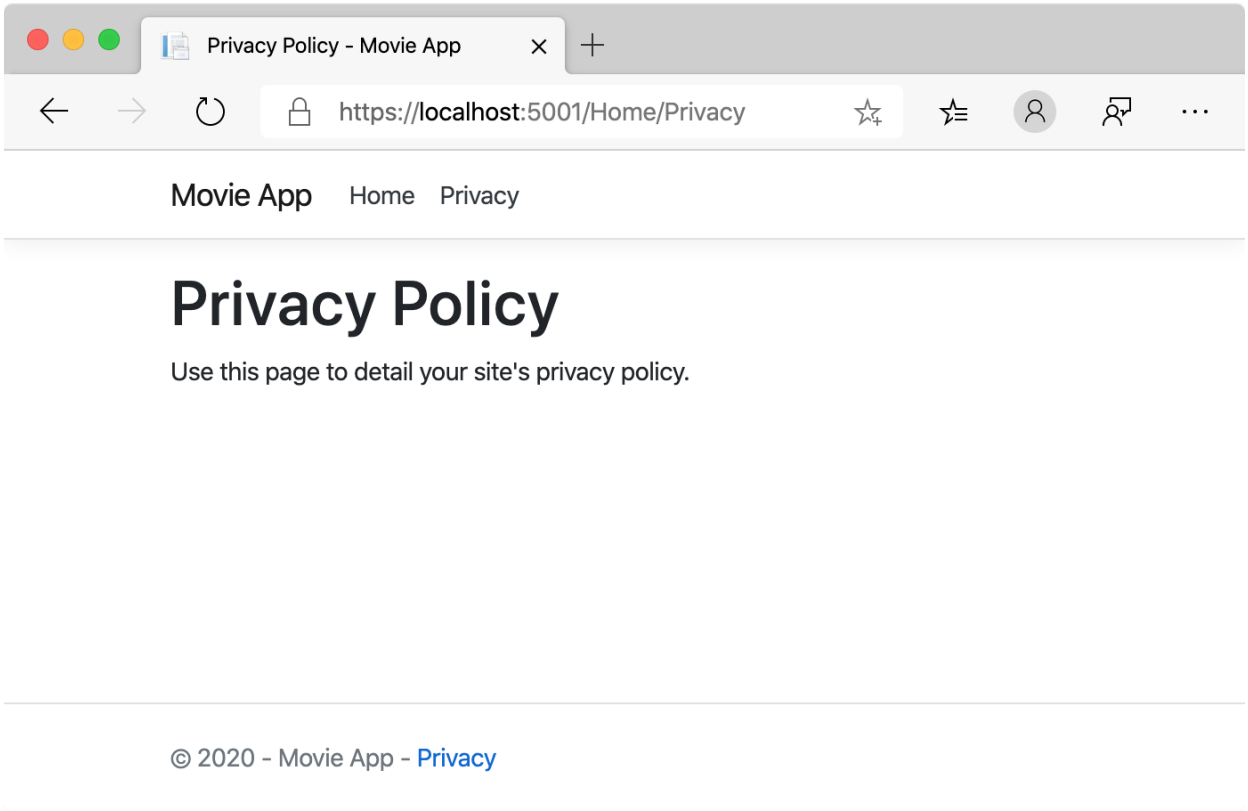
    <environment include="Development">
        <script src="~/lib/jquery/dist/jquery.js"></script>
        <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.js"></script>
    </environment>
    <environment exclude="Development">
        <script src="https://cdnjs.cloudflare.com/ajax/libs/jquery/3.3.1/jquery.min.js"
                asp-fallback-src="~/lib/jquery/dist/jquery.min.js"
                asp-fallback-test="window.jQuery"
                crossorigin="anonymous"
                integrity="sha256-FgpCb/KJQlLNfOu91ta32o/NMZxltwRo8QtmkMRdAu8=">
        </script>
        <script src="https://cdnjs.cloudflare.com/ajax/libs/twitter-
bootstrap/4.1.3/js/bootstrap.bundle.min.js"
                asp-fallback-src="~/lib/bootstrap/dist/js/bootstrap.bundle.min.js"
                asp-fallback-test="window.jQuery && window.jQuery.fn && window.jQuery.fn.modal"
                crossorigin="anonymous"
                integrity="sha256-E/V4cWE4qvAeO5MOhjtGtqDzPndRO1LBk8lJ/PR7CA4=">
        </script>
    </environment>
    <script src="~/js/site.js" asp-append-version="true"></script>

    @RenderSection("Scripts", required: false)
</body>
</html>
```

In the preceding markup, the `asp-area` anchor Tag Helper attribute was omitted because this app is not using Areas.

Note: The `Movies` controller has not been implemented. At this point, the `Movie App` link is not functional.

Save your changes and select the **Privacy** link. Notice how the title on the browser tab displays **Privacy Policy - Movie App** instead of **Privacy Policy - Mvc Movie**:



Select the **Home** link and notice that the title and anchor text also display **Movie App**. We were able to make the change once in the layout template and have all pages on the site reflect the new link text and new title.

Examine the *Views/_ViewStart.cshtml* file:

```
@{
    Layout = "_Layout";
}
```

The *Views/_ViewStart.cshtml* file brings in the *Views/Shared/_Layout.cshtml* file to each view. The `Layout` property can be used to set a different layout view, or set it to `null` so no layout file will be used.

Change the title and `<h2>` element of the *Views/HelloWorld/Index.cshtml* view file:

```
@{
    ViewData["Title"] = "Movie List";
}

<h2>My Movie List</h2>

<p>Hello from our View Template!</p>
```

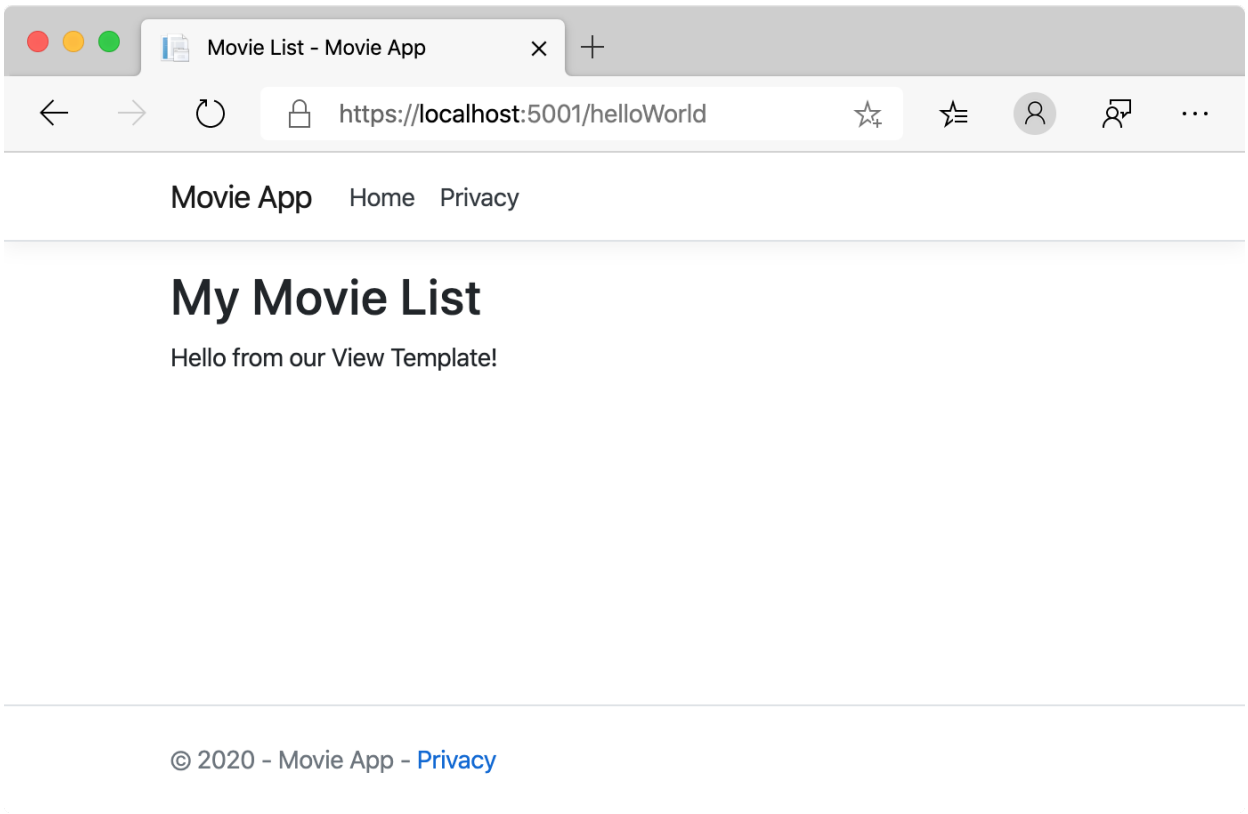
The title and `<h2>` element are slightly different so you can see which bit of code changes the display.

`ViewData["Title"] = "Movie List";` in the code above sets the `Title` property of the `ViewData` dictionary to "Movie List". The `Title` property is used in the `<title>` HTML element in the layout page:

```
<title>@ViewData["Title"] - Movie App</title>
```

Save the change and navigate to `https://localhost:{PORT}/HelloWorld`. Notice that the browser title, the primary heading, and the secondary headings have changed. (If you don't see changes in the browser, you might be viewing cached content. Press Ctrl+F5 in your browser to force the response from the server to be loaded.) The browser title is created with `ViewData["Title"]` we set in the *Index.cshtml* view template and the additional "- Movie App" added in the layout file.

Also notice how the content in the *Index.cshtml* view template was merged with the *Views/Shared/_Layout.cshtml* view template and a single HTML response was sent to the browser. Layout templates make it really easy to make changes that apply across all of the pages in your application. To learn more see Layout.



Our little bit of "data" (in this case the "Hello from our View Template!" message) is hard-coded, though. The MVC application has a "V" (view) and you've got a "C" (controller), but no "M" (model) yet.

Passing Data from the Controller to the View

Controller actions are invoked in response to an incoming URL request. A controller class is where the code is written that handles the incoming browser requests. The controller retrieves data from a data source and decides what type of response to send back to the browser. View templates can be used from a controller to generate and format an HTML response to the browser.

Controllers are responsible for providing the data required in order for a view template to render a response. A best practice: View templates should **not** perform business logic or interact with a database directly. Rather, a view template should work only with the data that's provided to it by the controller. Maintaining this "separation of concerns" helps keep the code clean, testable, and maintainable.

Currently, the `Welcome` method in the `HelloWorldController` class takes a `name` and a `ID` parameter and then outputs the values directly to the browser. Rather than have the controller render this response as a string, change the controller to use a view template instead. The view template generates a dynamic response, which means that appropriate bits of data must be passed from the controller to the view in order to generate the

response. Do this by having the controller put the dynamic data (parameters) that the view template needs in a `ViewData` dictionary that the view template can then access.

In *HelloWorldController.cs*, change the `Welcome` method to add a `Message` and `NumTimes` value to the `ViewData` dictionary. The `ViewData` dictionary is a dynamic object, which means any type can be used; the `ViewData` object has no defined properties until you put something inside it. The MVC model binding system automatically maps the named parameters (`name` and `numTimes`) from the query string in the address bar to parameters in your method. The complete *HelloWorldController.cs* file looks like this:

```
using Microsoft.AspNetCore.Mvc;
using System.Text.Encodings.Web;

namespace MvcMovie.Controllers
{
    public class HelloWorldController : Controller
    {
        public IActionResult Index()
        {
            return View();
        }

        public IActionResult Welcome(string name, int numTimes = 1)
        {
            ViewData["Message"] = "Hello " + name;
            ViewData["NumTimes"] = numTimes;

            return View();
        }
    }
}
```

The `ViewData` dictionary object contains data that will be passed to the view.

Create a Welcome view template named *Views/HelloWorld/Welcome.cshtml*.

You'll create a loop in the *Welcome.cshtml* view template that displays "Hello" `NumTimes`. Replace the contents of *Views/HelloWorld/Welcome.cshtml* with the following:

```
@{
    ViewData["Title"] = "Welcome";
}

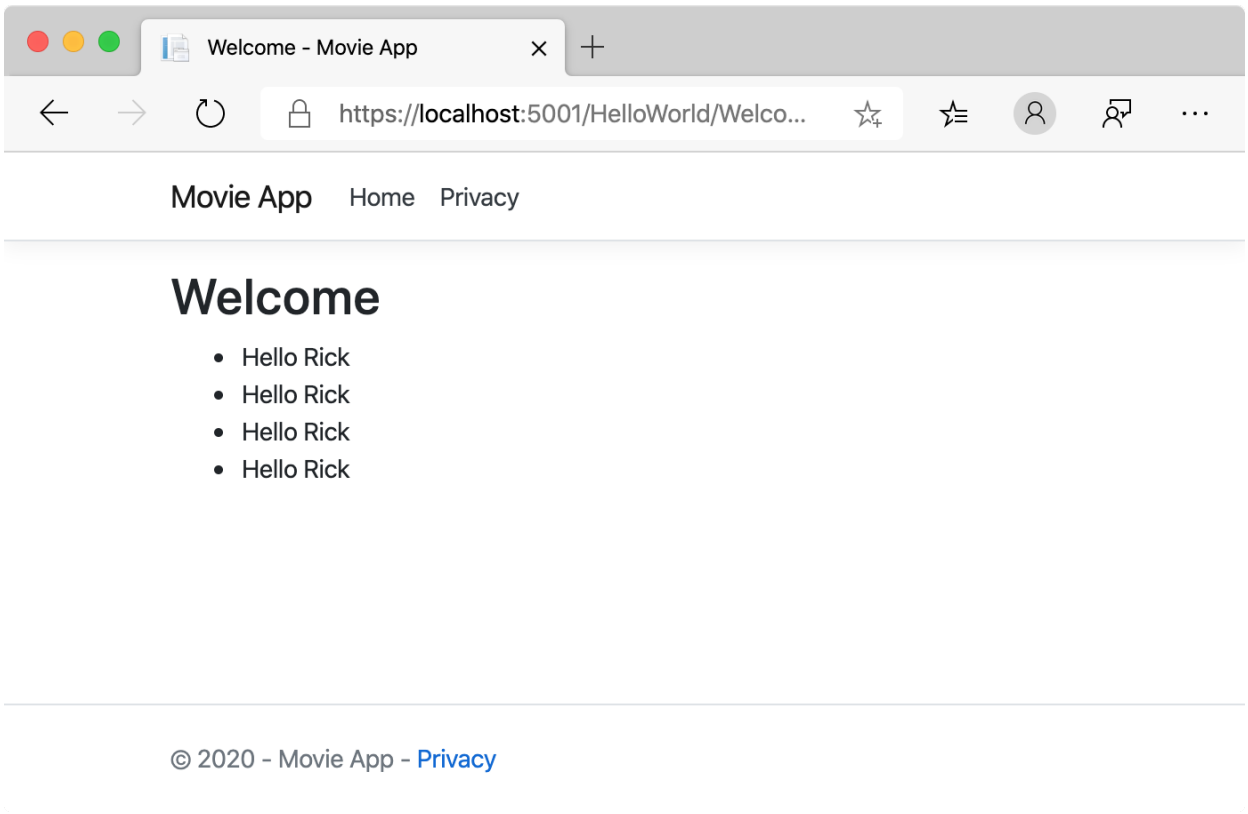
<h2>Welcome</h2>

<ul>
    @for (int i = 0; i < (int)ViewData["NumTimes"]; i++)
    {
        <li>@ViewData["Message"]</li>
    }
</ul>
```

Save your changes and browse to the following URL:

`https://localhost:{PORT}/HelloWorld/Welcome?name=Rick&numtimes=4`

Data is taken from the URL and passed to the controller using the MVC model binder . The controller packages the data into a `ViewData` dictionary and passes that object to the view. The view then renders the data as HTML to the browser.



In the sample above, the `ViewData` dictionary was used to pass data from the controller to a view. Later in the tutorial, a view model is used to pass data from a controller to a view. The view model approach to passing data is generally much preferred over the `ViewData` dictionary approach. See When to use ViewBag, ViewData, or TempData for more information.

In the next tutorial, a database of movies is created.

PREVIOUS NEXT

Part 4, add a model to an ASP.NET Core MVC app

9/22/2020 • 28 minutes to read • Edit Online

By Rick Anderson and Tom Dykstra

In this section, you add classes for managing movies in a database. These classes will be the "**M**odel" part of the **M**VC app.

You use these classes with Entity Framework Core (EF Core) to work with a database. EF Core is an object-relational mapping (ORM) framework that simplifies the data access code that you have to write.

The model classes you create are known as POCO classes (from **P**lain **O**ld **C**LR **O**bjects) because they don't have any dependency on EF Core. They just define the properties of the data that will be stored in the database.

In this tutorial, you write the model classes first, and EF Core creates the database.

Add a data model class

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Right-click the *Models* folder > **Add** > **Class**. Name the file *Movie.cs*.

Update the *Movie.cs* file with the following code:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace MvcMovie.Models
{
    public class Movie
    {
        public int Id { get; set; }
        public string Title { get; set; }

        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }
        public decimal Price { get; set; }
    }
}
```

The `Movie` class contains an `Id` field, which is required by the database for the primary key.

The DataType attribute on `ReleaseDate` specifies the type of the data (`Date`). With this attribute:

- The user is not required to enter time information in the date field.
- Only the date is displayed, not time information.

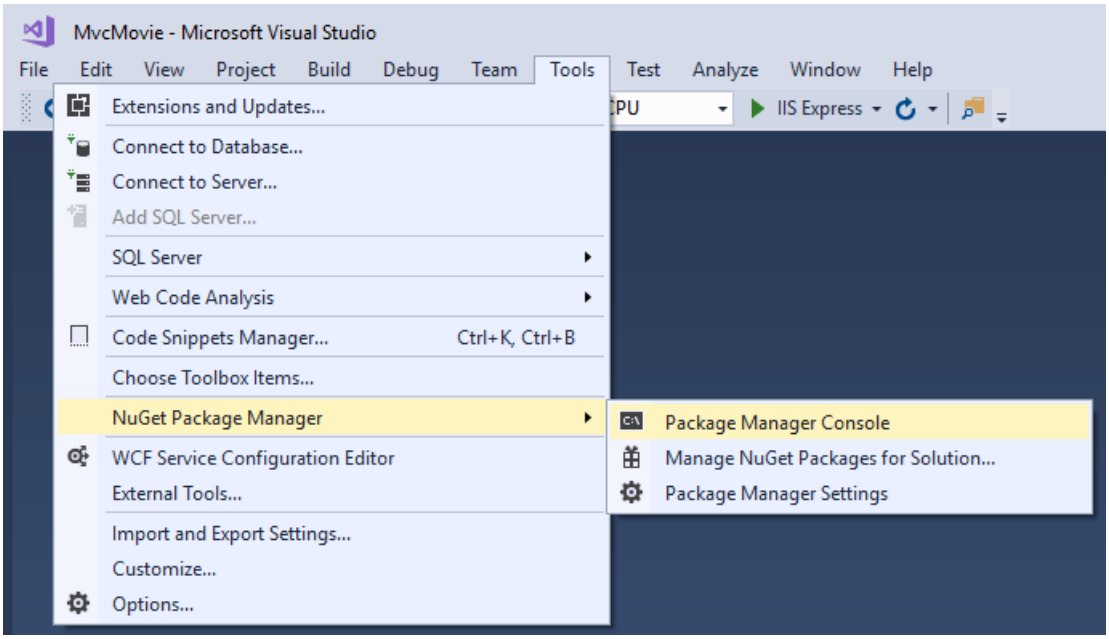
DataAnnotations are covered in a later tutorial.

Add NuGet packages

- Visual Studio

- Visual Studio Code
- Visual Studio for Mac

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console** (PMC).



In the PMC, run the following command:

```
Install-Package Microsoft.EntityFrameworkCore.SqlServer
```

The preceding command adds the EF Core SQL Server provider. The provider package installs the EF Core package as a dependency. Additional packages are installed automatically in the scaffolding step later in the tutorial.

Create a database context class

A database context class is needed to coordinate EF Core functionality (Create, Read, Update, Delete) for the `Movie` model. The database context is derived from Microsoft.EntityFrameworkCore.DbContext and specifies the entities to include in the data model.

Create a *Data* folder.

Add a *Data/MvcMovieContext.cs* file with the following code:

```
using Microsoft.EntityFrameworkCore;
using MvcMovie.Models;

namespace MvcMovie.Data
{
    public class MvcMovieContext : DbContext
    {
        public MvcMovieContext (DbContextOptions<MvcMovieContext> options)
            : base(options)
        {
        }

        public DbSet<Movie> Movie { get; set; }
    }
}
```

The preceding code creates a DbSet<Movie> property for the entity set. In Entity Framework terminology, an

entity set typically corresponds to a database table. An entity corresponds to a row in the table.

Register the database context

ASP.NET Core is built with dependency injection (DI). Services (such as the EF Core DB context) must be registered with DI during application startup. Components that require these services (such as Razor Pages) are provided these services via constructor parameters. The constructor code that gets a DB context instance is shown later in the tutorial. In this section, you register the database context with the DI container.

Add the following `using` statements at the top of *Startup.cs*:

```
using MvcMovie.Data;
using Microsoft.EntityFrameworkCore;
```

Add the following highlighted code in `Startup.ConfigureServices`:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();

    services.AddDbContext<MvcMovieContext>(options =>
            options.UseSqlServer(Configuration.GetConnectionString("MvcMovieContext")));
}
```

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Add a database connection string

Add a connection string to the *appsettings.json* file:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "MvcMovieContext": "Server=(localdb)\\mssqllocaldb;Database=MvcMovieContext-
1;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

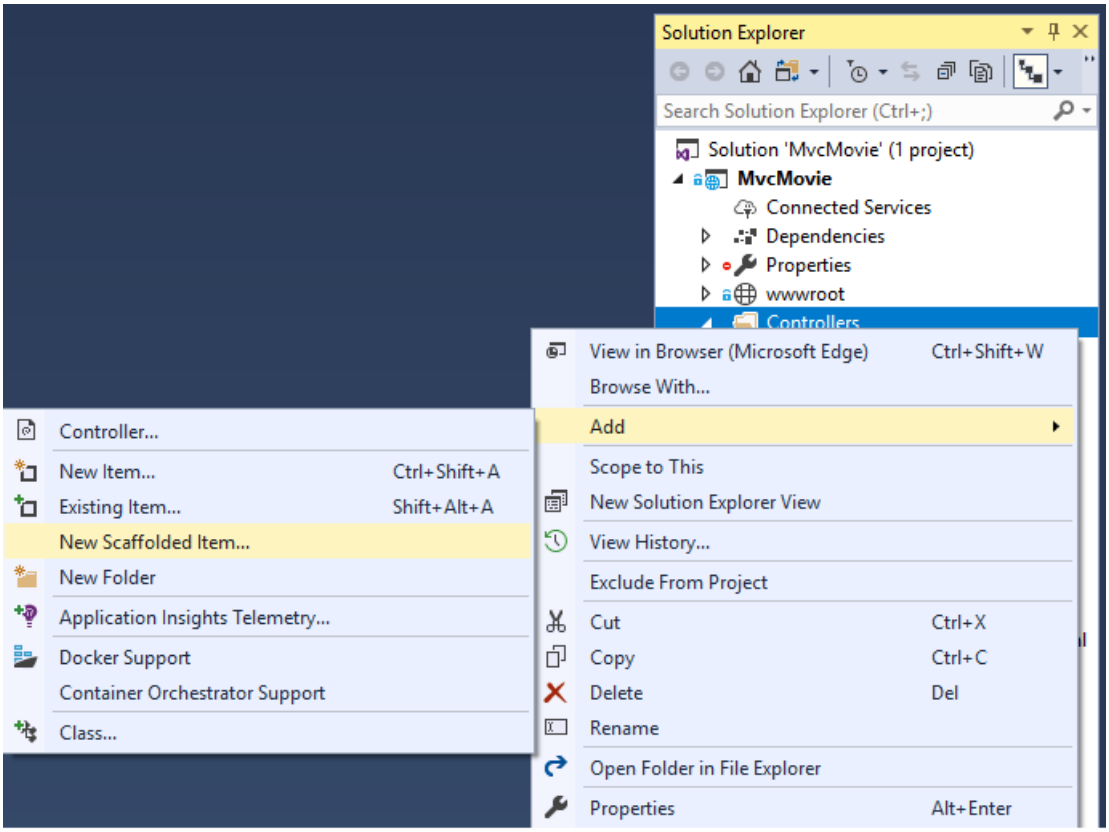
Build the project as a check for compiler errors.

Scaffold movie pages

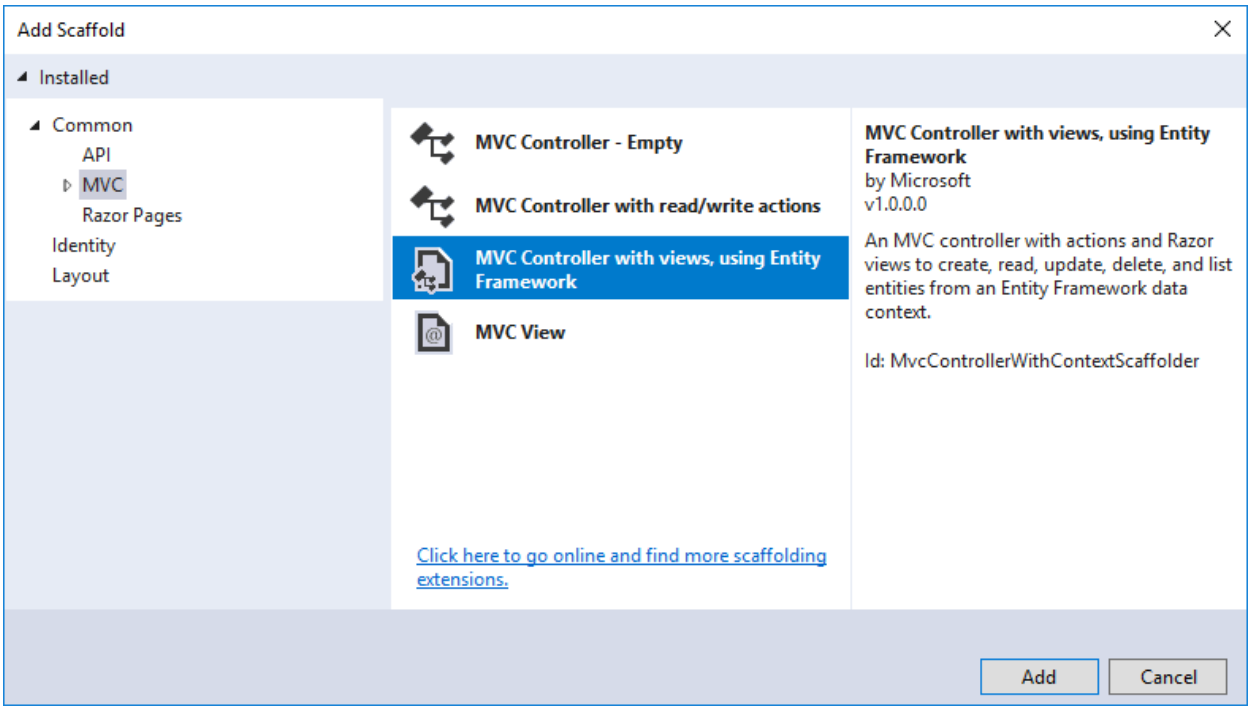
Use the scaffolding tool to produce Create, Read, Update, and Delete (CRUD) pages for the movie model.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

In **Solution Explorer**, right-click the *Controllers* folder > **Add** > **New Scaffolded Item**.

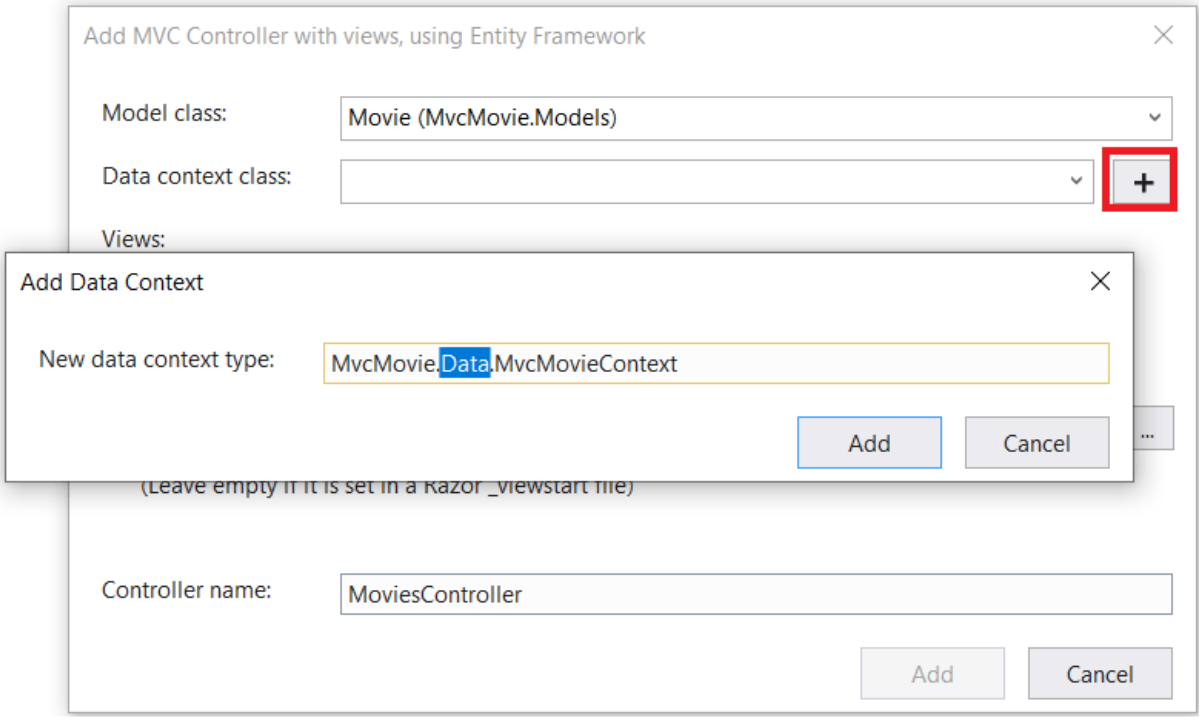


In the **Add Scaffold** dialog, select **MVC Controller with views, using Entity Framework** > **Add**.



Complete the **Add Controller** dialog:

- **Model class:** *Movie (MvcMovie.Models)*
- **Data context class:** *MvcMovieContext (MvcMovie.Data)*



- **Views:** Keep the default of each option checked
- **Controller name:** Keep the default *MoviesController*
- Select **Add**

Visual Studio creates:

- A movies controller (*Controllers/MoviesController.cs*)
- Razor view files for Create, Delete, Details, Edit, and Index pages (*Views/Movies/*.cshtml*)

The automatic creation of these files is known as *scaffolding*.

You can't use the scaffolded pages yet because the database doesn't exist. If you run the app and click on the **Movie App** link, you get a *Cannot open database* or *no such table: Movie* error message.

Initial migration

Use the EF Core Migrations feature to create the database. Migrations is a set of tools that let you create and update a database to match your data model.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console** (PMC).

In the PMC, enter the following commands:

```
Add-Migration InitialCreate
Update-Database
```

- `Add-Migration InitialCreate`: Generates a *Migrations/{timestamp}_InitialCreate.cs* migration file. The `InitialCreate` argument is the migration name. Any name can be used, but by convention, a name is selected that describes the migration. Because this is the first migration, the generated class contains code to create the database schema. The database schema is based on the model specified in the `MvcMovieContext` class.

- `Update-Database`: Updates the database to the latest migration, which the previous command created. This command runs the `Up` method in the *Migrations/{time-stamp}_InitialCreate.cs* file, which creates the database.

  The database update command generates the following warning:

  > No type was specified for the decimal column 'Price' on entity type 'Movie'. This will cause values to be silently truncated if they do not fit in the default precision and scale. Explicitly specify the SQL server column type that can accommodate all the values using 'HasColumnType()'.

  You can ignore that warning, it will be fixed in a later tutorial.

For more information on the PMC tools for EF Core, see EF Core tools reference - PMC in Visual Studio.

The InitialCreate class

Examine the *Migrations/{timestamp}_InitialCreate.cs* migration file:

```
public partial class Initial : Migration
{
    protected override void Up(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.CreateTable(
            name: "Movie",
            columns: table => new
            {
                Id = table.Column<int>(nullable: false)
                    .Annotation("SqlServer:ValueGenerationStrategy",
                                SqlServerValueGenerationStrategy.IdentityColumn),
                Title = table.Column<string>(nullable: true),
                ReleaseDate = table.Column<DateTime>(nullable: false),
                Genre = table.Column<string>(nullable: true),
                Price = table.Column<decimal>(nullable: false)
            },
            constraints: table =>
            {
                table.PrimaryKey("PK_Movie", x => x.Id);
            });
    }

    protected override void Down(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.DropTable(
            name: "Movie");
    }
}
```

The `Up` method creates the Movie table and configures `Id` as the primary key. The `Down` method reverts the schema changes made by the `Up` migration.

Test the app

- Run the app and click the **Movie App** link.

  If you get an exception similar to one of the following:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
SqlException: Cannot open database "MvcMovieContext-1" requested by the login. The login failed.
```

You probably missed the migrations step.

- Test the **Create** page. Enter and submit data.

> **NOTE**
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point and for non US-English date formats, the app must be globalized. For globalization instructions, see this GitHub issue.

- Test the **Edit**, **Details**, and **Delete** pages.

Dependency injection in the controller

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

Open the *Controllers/MoviesController.cs* file and examine the constructor:

```
public class MoviesController : Controller
{
    private readonly MvcMovieContext _context;

    public MoviesController(MvcMovieContext context)
    {
        _context = context;
    }
```

The constructor uses Dependency Injection to inject the database context (`MvcMovieContext`) into the controller. The database context is used in each of the CRUD methods in the controller.

Strongly typed models and the @model keyword

Earlier in this tutorial, you saw how a controller can pass data or objects to a view using the `ViewData` dictionary. The `ViewData` dictionary is a dynamic object that provides a convenient late-bound way to pass information to a view.

MVC also provides the ability to pass strongly typed model objects to a view. This strongly typed approach enables compile time code checking. The scaffolding mechanism used this approach (that is, passing a strongly typed model) with the `MoviesController` class and views.

Examine the generated `Details` method in the *Controllers/MoviesController.cs* file:

```
// GET: Movies/Details/5
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie
        .FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }

    return View(movie);
}
```

The `id` parameter is generally passed as route data. For example `https://localhost:5001/movies/details/1` sets:

- The controller to the `movies` controller (the first URL segment).
- The action to `details` (the second URL segment).
- The id to 1 (the last URL segment).

You can also pass in the `id` with a query string as follows:

`https://localhost:5001/movies/details?id=1`

The `id` parameter is defined as a nullable type (`int?`) in case an ID value isn't provided.

A lambda expression is passed in to `FirstOrDefaultAsync` to select movie entities that match the route data or query string value.

```
var movie = await _context.Movie
    .FirstOrDefaultAsync(m => m.Id == id);
```

If a movie is found, an instance of the `Movie` model is passed to the `Details` view:

```
return View(movie);
```

Examine the contents of the *Views/Movies/Details.cshtml* file:

```
@model MvcMovie.Models.Movie

@{
    ViewData["Title"] = "Details";
}

<h1>Details</h1>

<div>
    <h4>Movie</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.ReleaseDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.ReleaseDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Genre)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Genre)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Price)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Price)
        </dd>
    </dl>
</div>
<div>
    <a asp-action="Edit" asp-route-id="@Model.Id">Edit</a> |
    <a asp-action="Index">Back to List</a>
</div>
```

The `@model` statement at the top of the view file specifies the type of object that the view expects. When the movie controller was created, the following `@model` statement was included:

```
@model MvcMovie.Models.Movie
```

This `@model` directive allows access to the movie that the controller passed to the view. The `Model` object is strongly typed. For example, in the *Details.cshtml* view, the code passes each movie field to the `DisplayNameFor` and `DisplayFor` HTML Helpers with the strongly typed `Model` object. The `Create` and `Edit` methods and views also pass a `Movie` model object.

Examine the *Index.cshtml* view and the `Index` method in the Movies controller. Notice how the code creates a `List` object when it calls the `View` method. The code passes this `Movies` list from the `Index` action method to the view:

```
// GET: Movies
public async Task<IActionResult> Index()
{
    return View(await _context.Movie.ToListAsync());
}
```

When the movies controller was created, scaffolding included the following `@model` statement at the top of the *Index.cshtml* file:

```
@model IEnumerable<MvcMovie.Models.Movie>
```

The `@model` directive allows you to access the list of movies that the controller passed to the view by using a `Model` object that's strongly typed. For example, in the *Index.cshtml* view, the code loops through the movies with a `foreach` statement over the strongly typed `Model` object:

```
@model IEnumerable<MvcMovie.Models.Movie>

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
                <a asp-action="Details" asp-route-id="@item.Id">Details</a> |
                <a asp-action="Delete" asp-route-id="@item.Id">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Because the `Model` object is strongly typed (as an `IEnumerable<Movie>` object), each item in the loop is typed as `Movie`. Among other benefits, this means that you get compile time checking of the code.

Additional resources

- Tag Helpers
- Globalization and localization

Add a data model class

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

Right-click the *Models* folder > **Add** > **Class**. Name the class **Movie**.

Add the following properties to the `Movie` class:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace MvcMovie.Models
{
    public class Movie
    {
        public int Id { get; set; }
        public string Title { get; set; }

        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }
        public decimal Price { get; set; }
    }
}
```

The `Movie` class contains:

- The `Id` field which is required by the database for the primary key.
- `[DataType(DataType.Date)]`: The DataType attribute specifies the type of the data (`Date`). With this attribute:
  - The user is not required to enter time information in the date field.
  - Only the date is displayed, not time information.

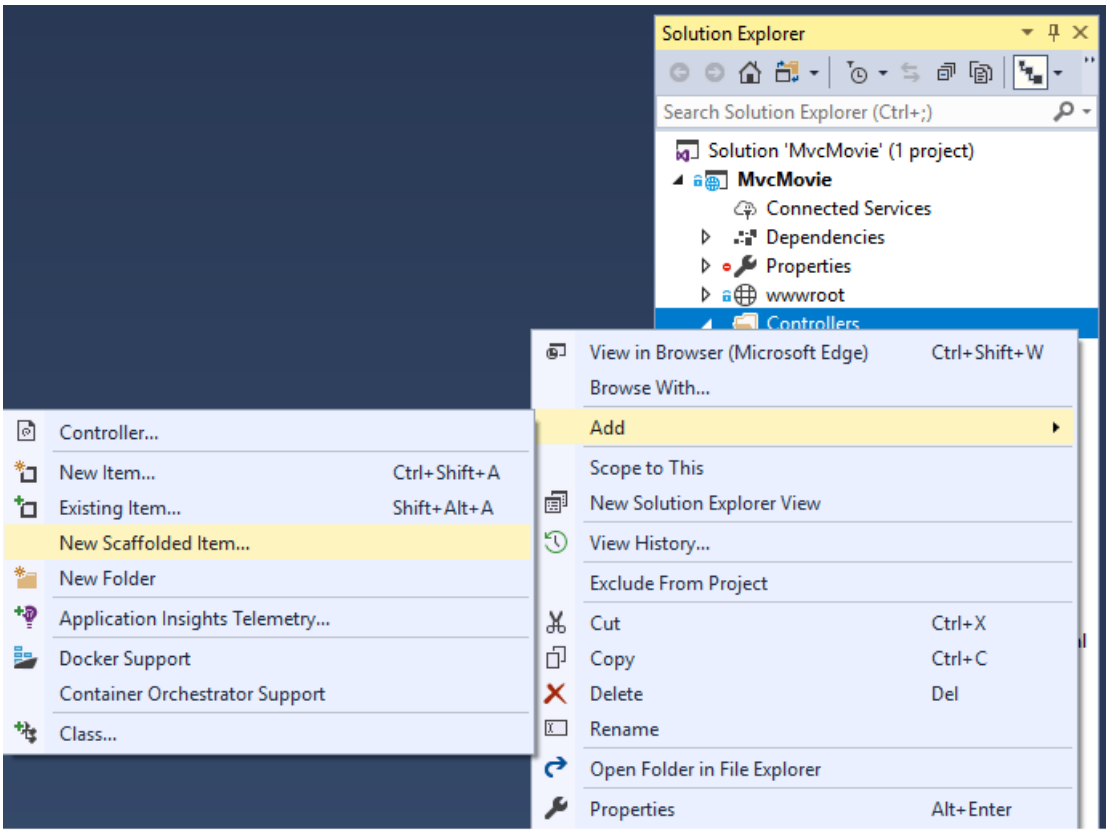
DataAnnotations are covered in a later tutorial.

Scaffold the movie model

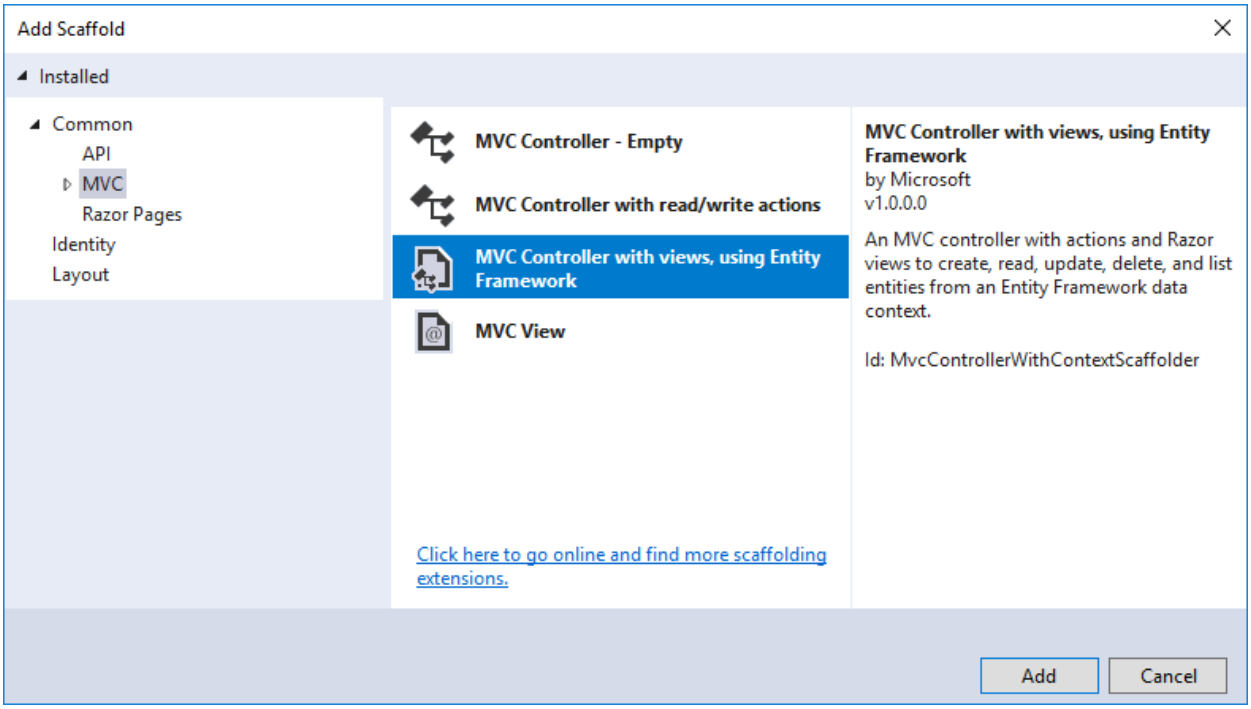
In this section, the movie model is scaffolded. That is, the scaffolding tool produces pages for Create, Read, Update, and Delete (CRUD) operations for the movie model.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

In **Solution Explorer**, right-click the *Controllers* folder > **Add** > **New Scaffolded Item**.

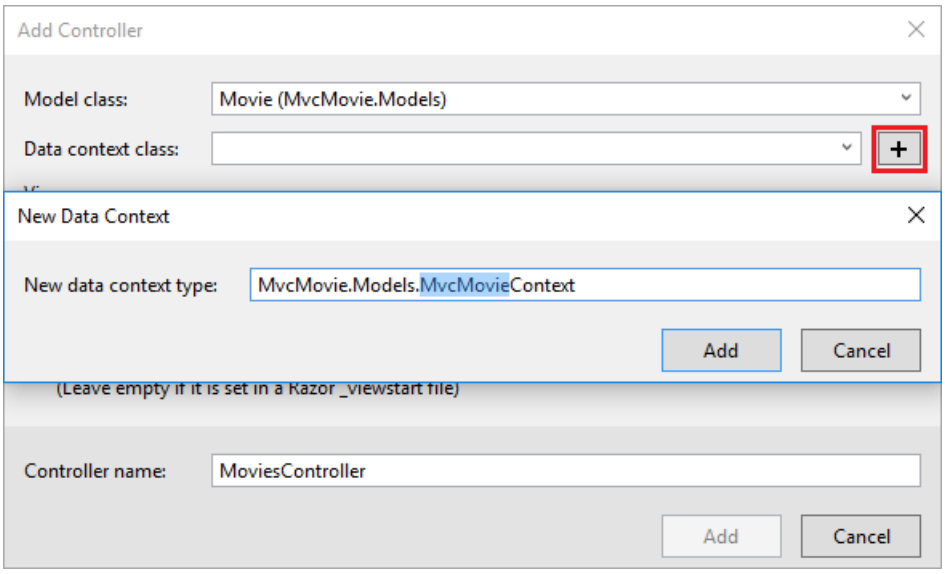


In the **Add Scaffold** dialog, select **MVC Controller with views, using Entity Framework > Add**.

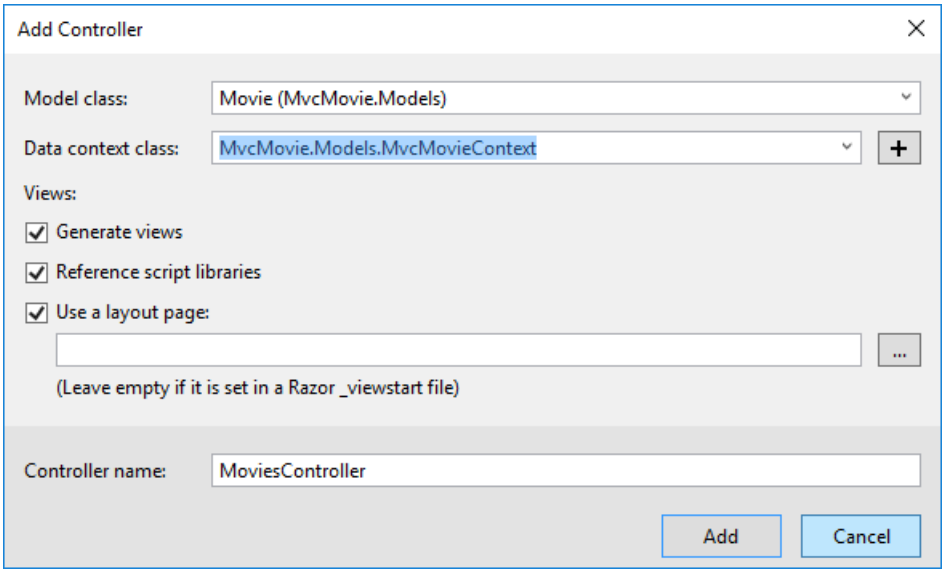


Complete the **Add Controller** dialog:

- **Model class:** *Movie (MvcMovie.Models)*
- **Data context class:** Select the + icon and add the default **MvcMovie.Models.MvcMovieContext**



- **Views:** Keep the default of each option checked
- **Controller name:** Keep the default *MoviesController*
- Select **Add**



Visual Studio creates:

- An Entity Framework Core database context class (*Data/MvcMovieContext.cs*)
- A movies controller (*Controllers/MoviesController.cs*)
- Razor view files for Create, Delete, Details, Edit, and Index pages (*Views/Movies/*.cshtml*)

The automatic creation of the database context and CRUD (create, read, update, and delete) action methods and views is known as *scaffolding*.

If you run the app and click on the **Mvc Movie** link, you get an error similar to the following:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
An unhandled exception occurred while processing the request.

SqlException: Cannot open database "MvcMovieContext-<GUID removed>" requested by the login. The login
failed.
Login failed for user 'Rick'.

System.Data.SqlClient.SqlInternalConnectionTds..ctor(DbConnectionPoolIdentity identity, SqlConnectionString
```

You need to create the database, and you use the EF Core Migrations feature to do that. Migrations lets you create a database that matches your data model and update the database schema when your data model changes.

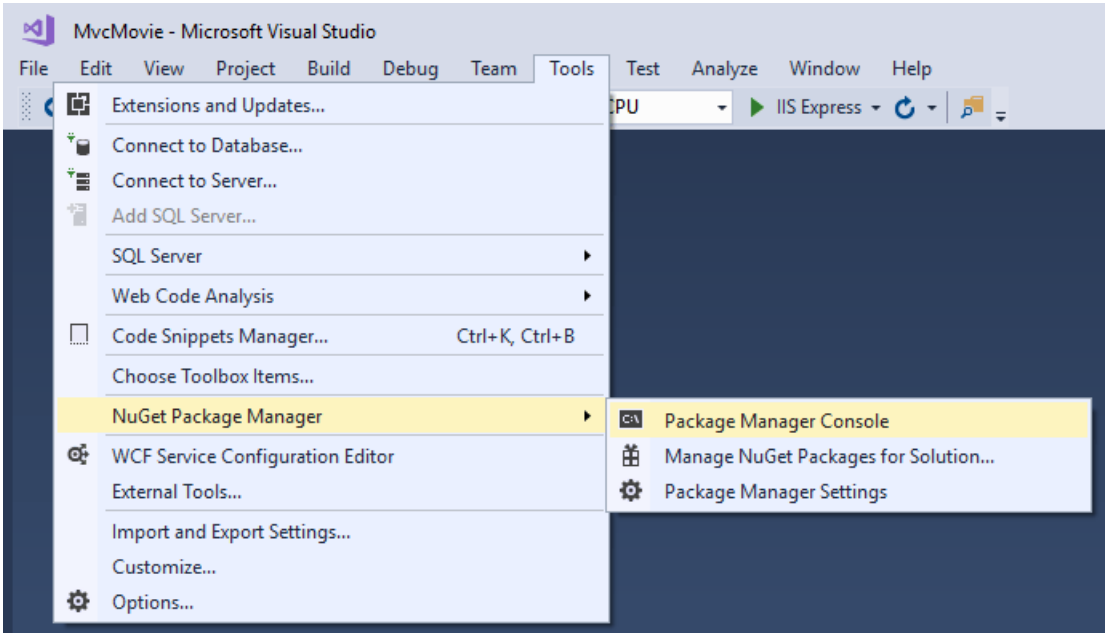
Initial migration

In this section, the following tasks are completed:

- Add an initial migration.
- Update the database with the initial migration.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

1. From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console** (PMC).



2. In the PMC, enter the following commands:

```
Add-Migration Initial
Update-Database
```

The `Add-Migration` command generates code to create the initial database schema.

The database schema is based on the model specified in the `MvcMovieContext` class. The `Initial` argument is the migration name. Any name can be used, but by convention, a name that describes the migration is used. For more information, see Tutorial: Using the migrations feature - ASP.NET MVC with EF Core.

The `Update-Database` command runs the `Up` method in the *Migrations/{time-stamp}_InitialCreate.cs* file, which creates the database.

Examine the context registered with dependency injection

ASP.NET Core is built with dependency injection (DI). Services (such as the EF Core DB context) are registered with DI during application startup. Components that require these services (such as Razor Pages) are provided these services via constructor parameters. The constructor code that gets a DB context instance is shown later in the tutorial.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

The scaffolding tool automatically created a DB context and registered it with the DI container.

Examine the following `Startup.ConfigureServices` method. The highlighted line was added by the scaffolder:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        // This lambda determines whether user consent for non-essential cookies
        // is needed for a given request.
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    services.AddDbContext<MvcMovieContext>(options =>
         options.UseSqlServer(Configuration.GetConnectionString("MvcMovieContext")));
}
```

The `MvcMovieContext` coordinates EF Core functionality (Create, Read, Update, Delete, etc.) for the `Movie` model. The data context (`MvcMovieContext`) is derived from Microsoft.EntityFrameworkCore.DbContext. The data context specifies which entities are included in the data model:

```
// Unused usings removed.
using Microsoft.EntityFrameworkCore;
using MvcMovie.Models;  // Enables public DbSet<Movie> Movie

namespace MvcMovie.Data
{
    public class MvcMovieContext : DbContext
    {
        public MvcMovieContext (DbContextOptions<MvcMovieContext> options)
            : base(options)
        {
        }

        public DbSet<Movie> Movie { get; set; }
    }
}
```

The preceding code creates a DbSet<Movie> property for the entity set. In Entity Framework terminology, an entity set typically corresponds to a database table. An entity corresponds to a row in the table.

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Test the app

- Run the app and append `/Movies` to the URL in the browser (`http://localhost:port/movies`).

If you get a database exception similar to the following:

```
SqlException: Cannot open database "MvcMovieContext-GUID" requested by the login. The login failed.
Login failed for user 'User-name'.
```

You missed the migrations step.

- Test the **Create** link. Enter and submit data.

> **NOTE**
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point and for non US-English date formats, the app must be globalized. For globalization instructions, see this GitHub issue.

- Test the **Edit**, **Details**, and **Delete** links.

Examine the `Startup` class:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        // This lambda determines whether user consent for non-essential cookies
        // is needed for a given request.
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    services.AddDbContext<MvcMovieContext>(options =>
         options.UseSqlServer(Configuration.GetConnectionString("MvcMovieContext")));
}
```

The preceding highlighted code shows the movie database context being added to the Dependency Injection container:

- `services.AddDbContext<MvcMovieContext>(options =>` specifies the database to use and the connection string.
- `=>` is a lambda operator

Open the *Controllers/MoviesController.cs* file and examine the constructor:

```
public class MoviesController : Controller
{
    private readonly MvcMovieContext _context;

    public MoviesController(MvcMovieContext context)
    {
        _context = context;
    }
```

The constructor uses Dependency Injection to inject the database context (`MvcMovieContext`) into the controller. The database context is used in each of the CRUD methods in the controller.

Strongly typed models and the @model keyword

Earlier in this tutorial, you saw how a controller can pass data or objects to a view using the `ViewData` dictionary. The `ViewData` dictionary is a dynamic object that provides a convenient late-bound way to pass information to a view.

MVC also provides the ability to pass strongly typed model objects to a view. This strongly typed approach enables better compile time checking of your code. The scaffolding mechanism used this approach (that is, passing a strongly typed model) with the `MoviesController` class and views when it created the methods and views.

Examine the generated `Details` method in the *Controllers/MoviesController.cs* file:

```
// GET: Movies/Details/5
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie
        .FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }

    return View(movie);
}
```

The `id` parameter is generally passed as route data. For example `https://localhost:5001/movies/details/1` sets:

- The controller to the `movies` controller (the first URL segment).
- The action to `details` (the second URL segment).
- The id to 1 (the last URL segment).

You can also pass in the `id` with a query string as follows:

`https://localhost:5001/movies/details?id=1`

The `id` parameter is defined as a nullable type (`int?`) in case an ID value isn't provided.

A lambda expression is passed in to `FirstOrDefaultAsync` to select movie entities that match the route data or query string value.

```
var movie = await _context.Movie
    .FirstOrDefaultAsync(m => m.Id == id);
```

If a movie is found, an instance of the `Movie` model is passed to the `Details` view:

```
return View(movie);
```

Examine the contents of the *Views/Movies/Details.cshtml* file:

```
@model MvcMovie.Models.Movie

@{
    ViewData["Title"] = "Details";
}

<h1>Details</h1>

<div>
    <h4>Movie</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.ReleaseDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.ReleaseDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Genre)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Genre)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Price)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Price)
        </dd>
    </dl>
</div>
<div>
    <a asp-action="Edit" asp-route-id="@Model.Id">Edit</a> |
    <a asp-action="Index">Back to List</a>
</div>
```

By including a `@model` statement at the top of the view file, you can specify the type of object that the view expects. When you created the movie controller, the following `@model` statement was automatically included at the top of the *Details.cshtml* file:

```
@model MvcMovie.Models.Movie
```

This `@model` directive allows you to access the movie that the controller passed to the view by using a `Model` object that's strongly typed. For example, in the *Details.cshtml* view, the code passes each movie field to the `DisplayNameFor` and `DisplayFor` HTML Helpers with the strongly typed `Model` object. The `Create` and `Edit` methods and views also pass a `Movie` model object.

Examine the *Index.cshtml* view and the `Index` method in the Movies controller. Notice how the code creates a `List` object when it calls the `View` method. The code passes this `Movies` list from the `Index` action method to the view:

```
// GET: Movies
public async Task<IActionResult> Index()
{
    return View(await _context.Movie.ToListAsync());
}
```

When you created the movies controller, scaffolding automatically included the following `@model` statement at the top of the *Index.cshtml* file:

```
@model IEnumerable<MvcMovie.Models.Movie>
```

The `@model` directive allows you to access the list of movies that the controller passed to the view by using a `Model` object that's strongly typed. For example, in the *Index.cshtml* view, the code loops through the movies with a `foreach` statement over the strongly typed `Model` object:

```
@model IEnumerable<MvcMovie.Models.Movie>

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
                <a asp-action="Details" asp-route-id="@item.Id">Details</a> |
                <a asp-action="Delete" asp-route-id="@item.Id">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Because the `Model` object is strongly typed (as an `IEnumerable<Movie>` object), each item in the loop is typed as `Movie`. Among other benefits, this means that you get compile time checking of the code:

- Globalization and localization

PREVIOUS ADDING A VIEW

NEXT WORKING WITH A DATABASE

Part 5, work with a database in an ASP.NET Core MVC app

9/22/2020 • 9 minutes to read • Edit Online

By Rick Anderson

The `MvcMovieContext` object handles the task of connecting to the database and mapping `Movie` objects to database records. The database context is registered with the Dependency Injection container in the `ConfigureServices` method in the *Startup.cs* file:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();

    services.AddDbContext<MvcMovieContext>(options =>
            options.UseSqlServer(Configuration.GetConnectionString("MvcMovieContext")));
}
```

The ASP.NET Core Configuration system reads the `ConnectionString`. For local development, it gets the connection string from the *appsettings.json* file:

```
"ConnectionStrings": {
  "MvcMovieContext": "Server=(localdb)\\mssqllocaldb;Database=MvcMovieContext-
2;Trusted_Connection=True;MultipleActiveResultSets=true"
}
```

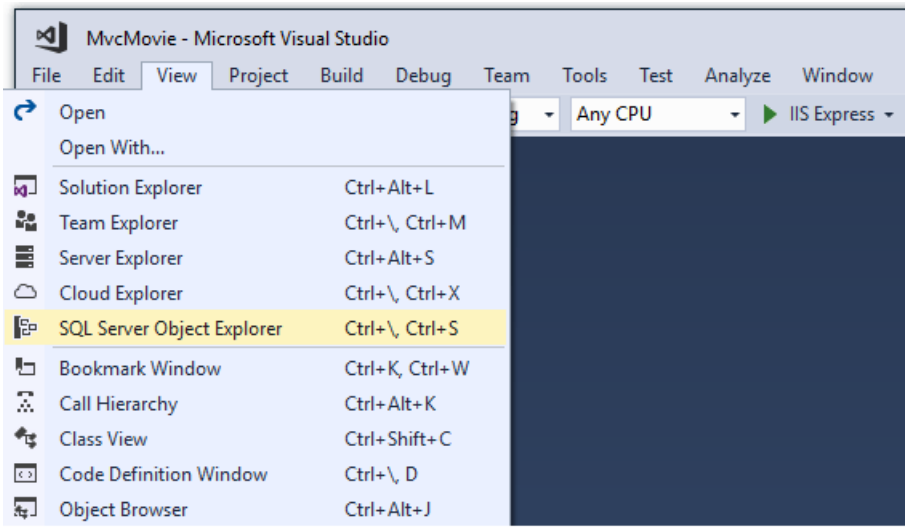
When the app is deployed to a test or production server, an environment variable can be used to set the connection string to a production SQL Server. See Configuration for more information.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

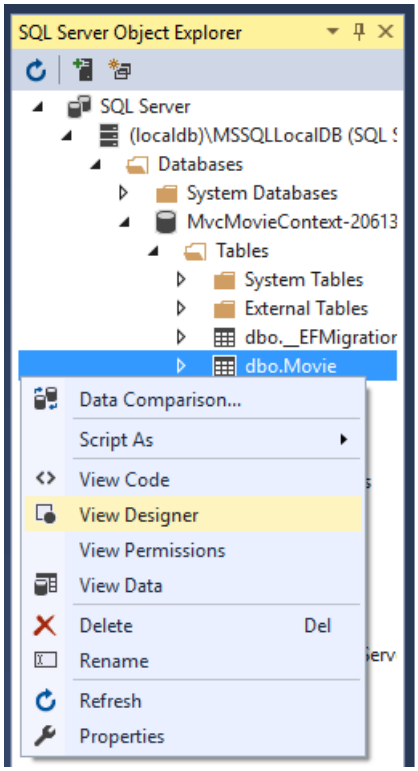
SQL Server Express LocalDB

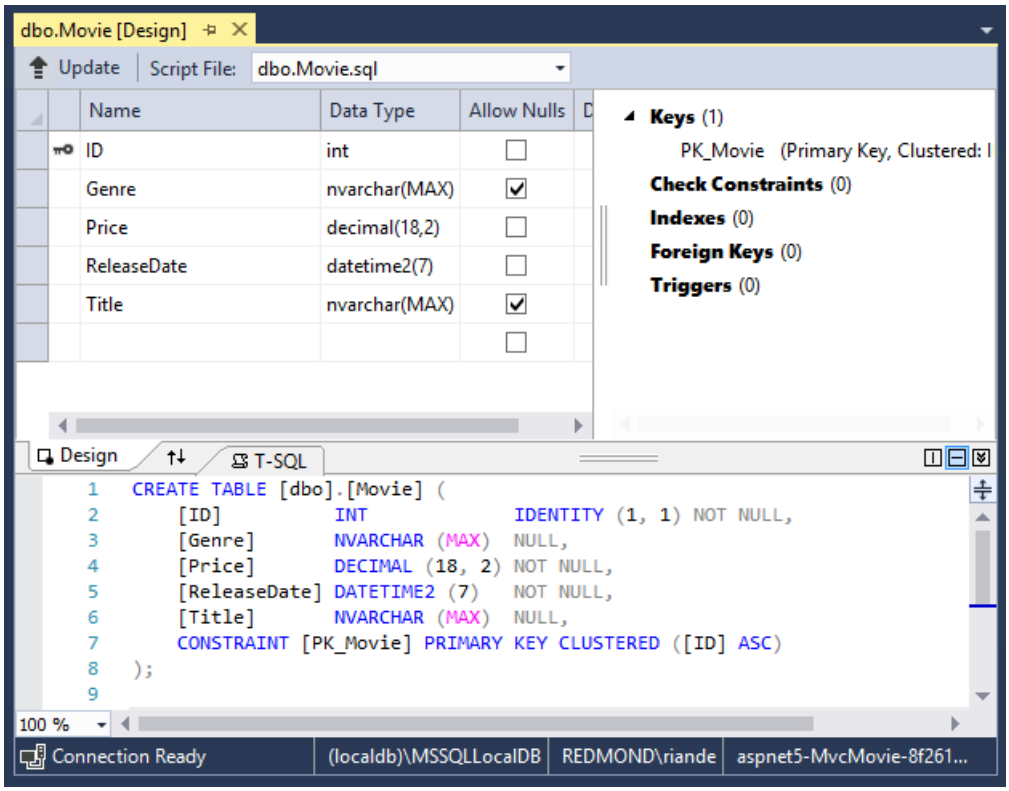
LocalDB is a lightweight version of the SQL Server Express Database Engine that's targeted for program development. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB database creates *.mdf* files in the *C:/Users/{user}* directory.

- From the **View** menu, open **SQL Server Object Explorer** (SSOX).



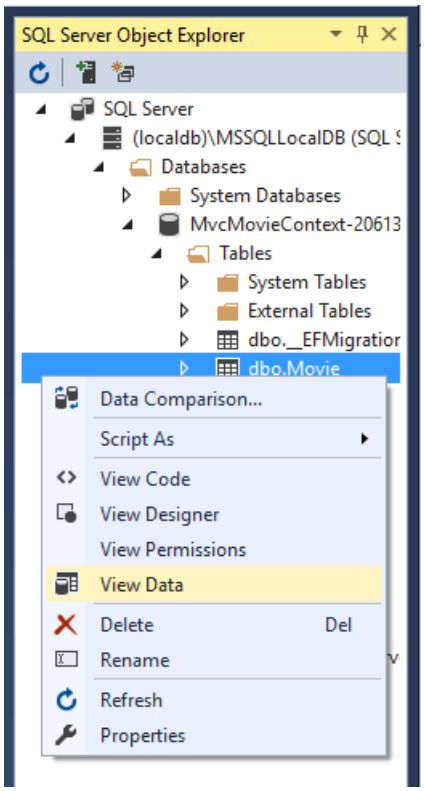
- Right click on the `Movie` table > **View Designer**

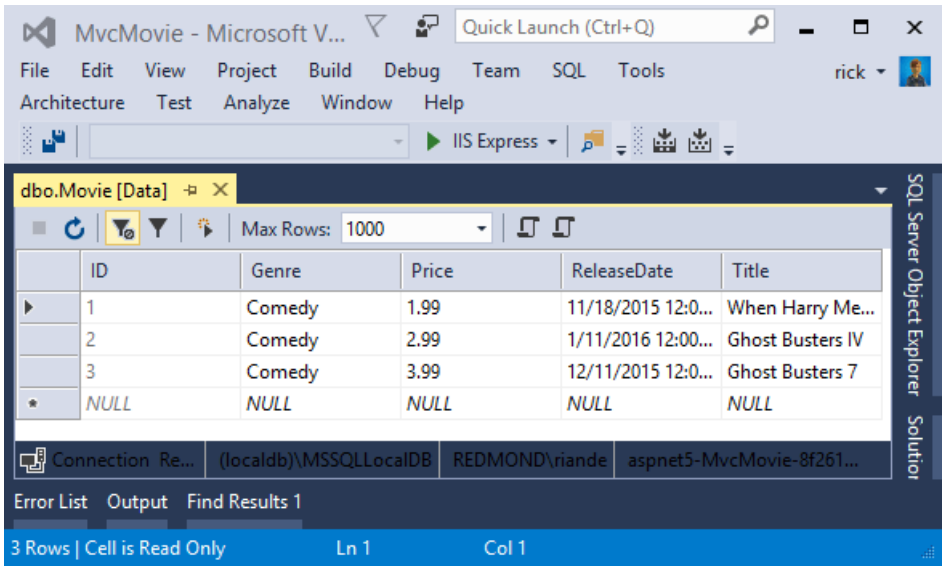




Note the key icon next to `ID`. By default, EF will make a property named `ID` the primary key.

- Right click on the `Movie` table > **View Data**





Seed the database

Create a new class named `SeedData` in the *Models* folder. Replace the generated code with the following:

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using MvcMovie.Data;
using System;
using System.Linq;

namespace MvcMovie.Models
{
    public static class SeedData
    {
        public static void Initialize(IServiceProvider serviceProvider)
        {
            using (var context = new MvcMovieContext(
                serviceProvider.GetRequiredService<
                    DbContextOptions<MvcMovieContext>>()))
            {
                // Look for any movies.
                if (context.Movie.Any())
                {
                    return;   // DB has been seeded
                }

                context.Movie.AddRange(
                    new Movie
                    {
                        Title = "When Harry Met Sally",
                        ReleaseDate = DateTime.Parse("1989-2-12"),
                        Genre = "Romantic Comedy",
                        Price = 7.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters ",
                        ReleaseDate = DateTime.Parse("1984-3-13"),
                        Genre = "Comedy",
                        Price = 8.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters 2",
                        ReleaseDate = DateTime.Parse("1986-2-23"),
                        Genre = "Comedy",
                        Price = 9.99M
                    },

                    new Movie
                    {
                        Title = "Rio Bravo",
                        ReleaseDate = DateTime.Parse("1959-4-15"),
                        Genre = "Western",
                        Price = 3.99M
                    }
                );
                context.SaveChanges();
            }
        }
    }
}
```

If there are any movies in the DB, the seed initializer returns and no movies are added.

```
if (context.Movie.Any())
{
    return;   // DB has been seeded.
}
```

Add the seed initializer

Replace the contents of *Program.cs* with the following code:

```
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
using MvcMovie.Data;
using MvcMovie.Models;
using System;

namespace MvcMovie
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateHostBuilder(args).Build();

            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    SeedData.Initialize(services);
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred seeding the DB.");
                }
            }

            host.Run();

        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureWebHostDefaults(webBuilder =>
                {
                    webBuilder.UseStartup<Startup>();
                });
    }
}
```

Test the app

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Delete all the records in the DB. You can do this with the delete links in the browser or from SSOX.
- Force the app to initialize (call the methods in the `Startup` class) so the seed method runs. To force initialization, IIS Express must be stopped and restarted. You can do this with any of the following approaches:

- Right click the IIS Express system tray icon in the notification area and tap **Exit** or **Stop Site**

  - If you were running VS in non-debug mode, press F5 to run in debug mode
  - If you were running VS in debug mode, stop the debugger and press F5

The app shows the seeded data.

By Rick Anderson

The `MvcMovieContext` object handles the task of connecting to the database and mapping `Movie` objects to

database records. The database context is registered with the Dependency Injection container in the `ConfigureServices` method in the *Startup.cs* file:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        // This lambda determines whether user consent for non-essential cookies
        // is needed for a given request.
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    services.AddDbContext<MvcMovieContext>(options =>
         options.UseSqlServer(Configuration.GetConnectionString("MvcMovieContext")));
}
```

The ASP.NET Core Configuration system reads the `ConnectionString`. For local development, it gets the connection string from the *appsettings.json* file:

```
"ConnectionStrings": {
  "MvcMovieContext": "Server=(localdb)\\mssqllocaldb;Database=MvcMovieContext-
2;Trusted_Connection=True;MultipleActiveResultSets=true"
}
```

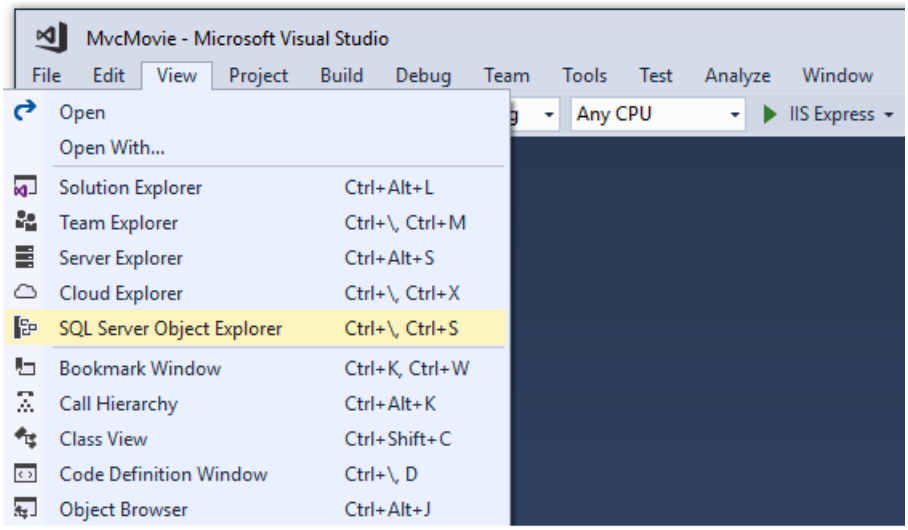
When you deploy the app to a test or production server, you can use an environment variable or another approach to set the connection string to a real SQL Server. See Configuration for more information.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

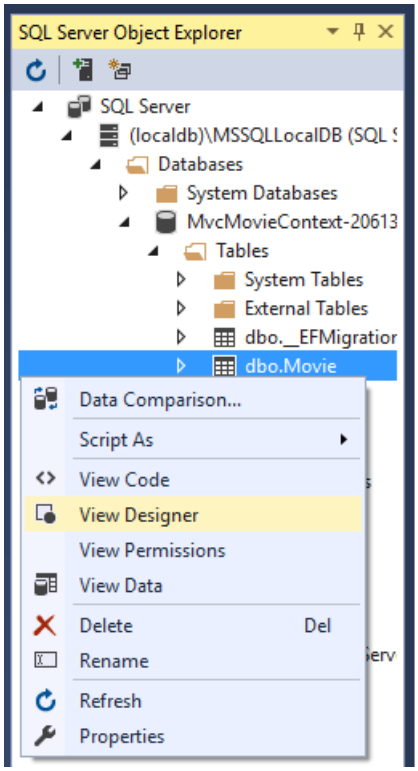
SQL Server Express LocalDB

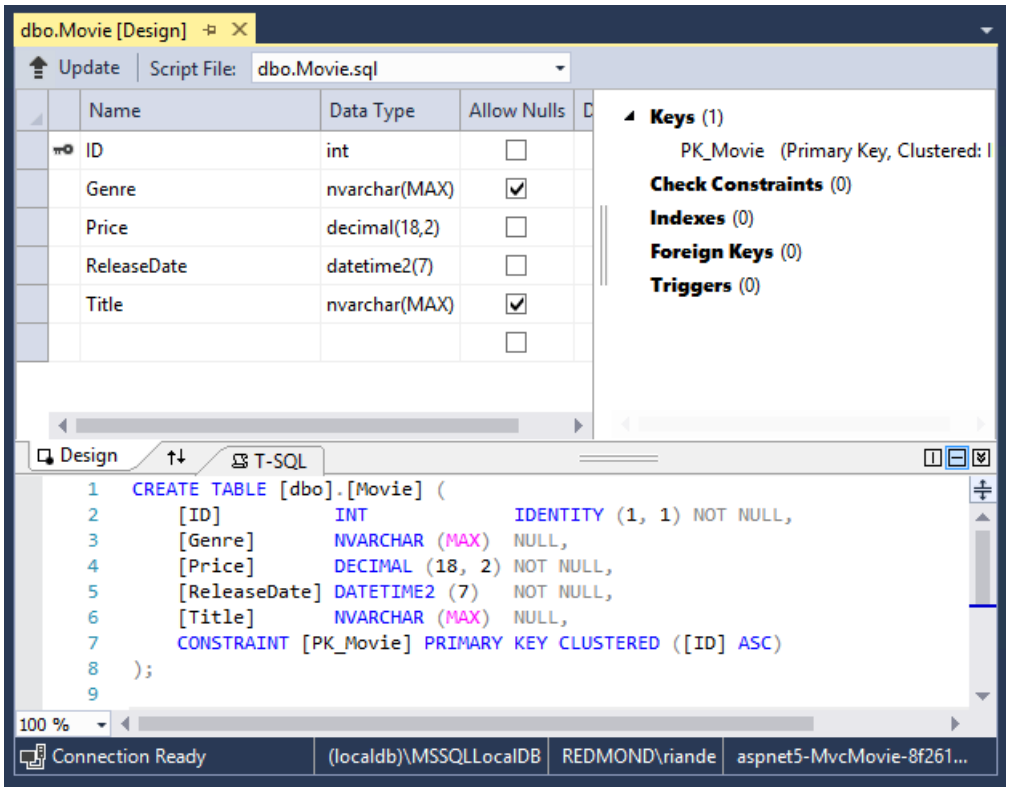
LocalDB is a lightweight version of the SQL Server Express Database Engine that's targeted for program development. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB database creates *.mdf* files in the *C:/Users/{user}* directory.

- From the **View** menu, open **SQL Server Object Explorer** (SSOX).



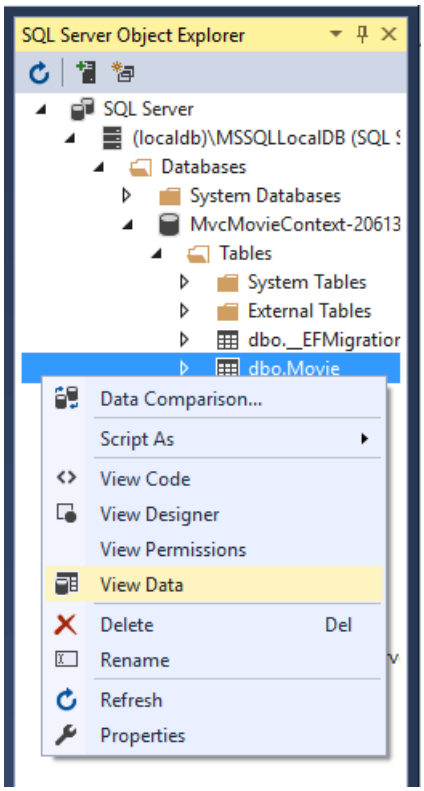
- Right click on the `Movie` table > **View Designer**

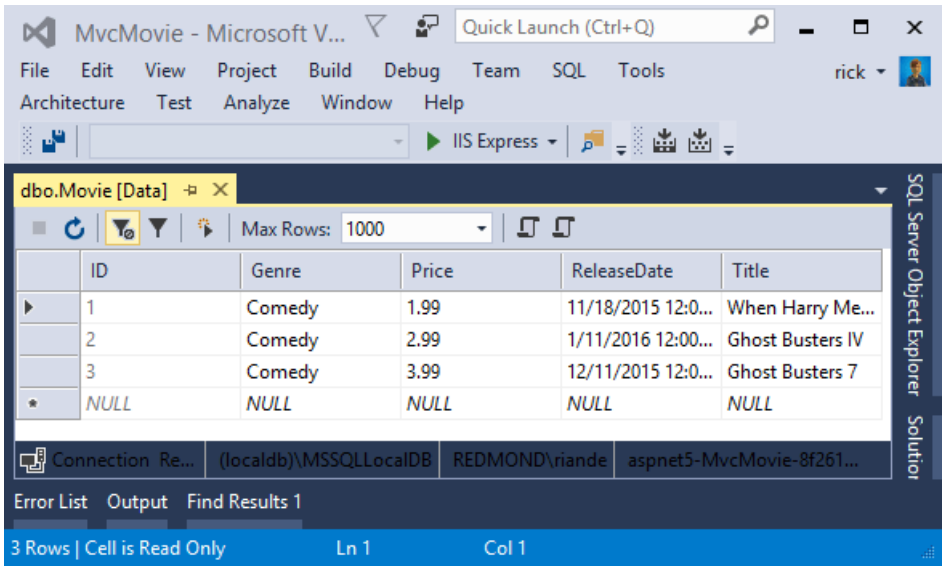




Note the key icon next to `ID`. By default, EF will make a property named `ID` the primary key.

- Right click on the `Movie` table > **View Data**





Seed the database

Create a new class named `SeedData` in the *Models* folder. Replace the generated code with the following:

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using System;
using System.Linq;

namespace MvcMovie.Models
{
    public static class SeedData
    {
        public static void Initialize(IServiceProvider serviceProvider)
        {
            using (var context = new MvcMovieContext(
                serviceProvider.GetRequiredService<
                    DbContextOptions<MvcMovieContext>>()))
            {
                // Look for any movies.
                if (context.Movie.Any())
                {
                    return;   // DB has been seeded
                }

                context.Movie.AddRange(
                    new Movie
                    {
                        Title = "When Harry Met Sally",
                        ReleaseDate = DateTime.Parse("1989-2-12"),
                        Genre = "Romantic Comedy",
                        Price = 7.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters ",
                        ReleaseDate = DateTime.Parse("1984-3-13"),
                        Genre = "Comedy",
                        Price = 8.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters 2",
                        ReleaseDate = DateTime.Parse("1986-2-23"),
                        Genre = "Comedy",
                        Price = 9.99M
                    },

                    new Movie
                    {
                        Title = "Rio Bravo",
                        ReleaseDate = DateTime.Parse("1959-4-15"),
                        Genre = "Western",
                        Price = 3.99M
                    }
                );
                context.SaveChanges();
            }
        }
    }
}
```

If there are any movies in the DB, the seed initializer returns and no movies are added.

```
if (context.Movie.Any())
{
    return;   // DB has been seeded.
}
```

Add the seed initializer

Replace the contents of *Program.cs* with the following code:

```
using Microsoft.AspNetCore;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Logging;
using System;
using Microsoft.EntityFrameworkCore;
using MvcMovie.Models;
using MvcMovie;

namespace MvcMovie
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateWebHostBuilder(args).Build();

            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    var context = services.GetRequiredService<MvcMovieContext>();
                    context.Database.Migrate();
                    SeedData.Initialize(services);
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred seeding the DB.");
                }
            }

            host.Run();
        }

        public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>();
    }
}
```

Test the app

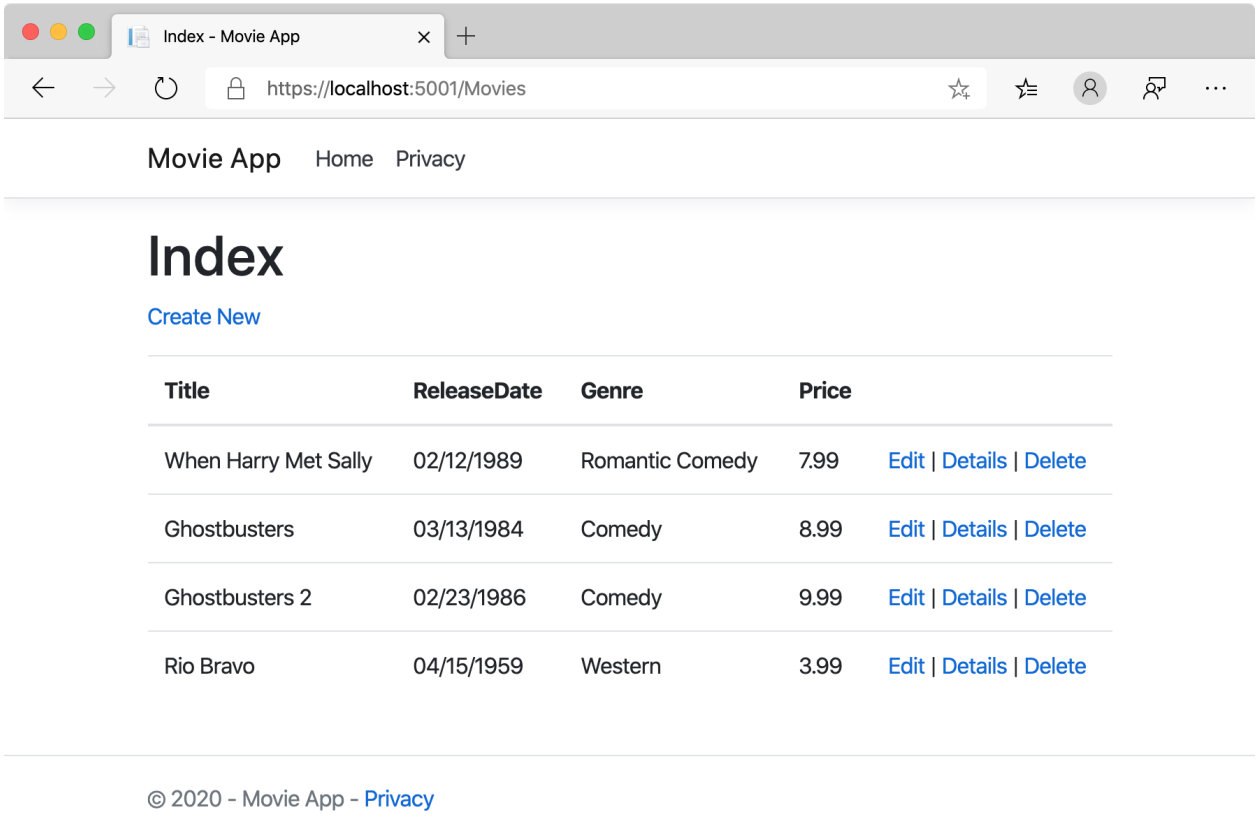
- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Delete all the records in the DB. You can do this with the delete links in the browser or from SSOX.
- Force the app to initialize (call the methods in the `Startup` class) so the seed method runs. To force initialization, IIS Express must be stopped and restarted. You can do this with any of the following approaches:

- Right click the IIS Express system tray icon in the notification area and tap **Exit** or **Stop Site**

  - If you were running VS in non-debug mode, press F5 to run in debug mode
  - If you were running VS in debug mode, stop the debugger and press F5

The app shows the seeded data.

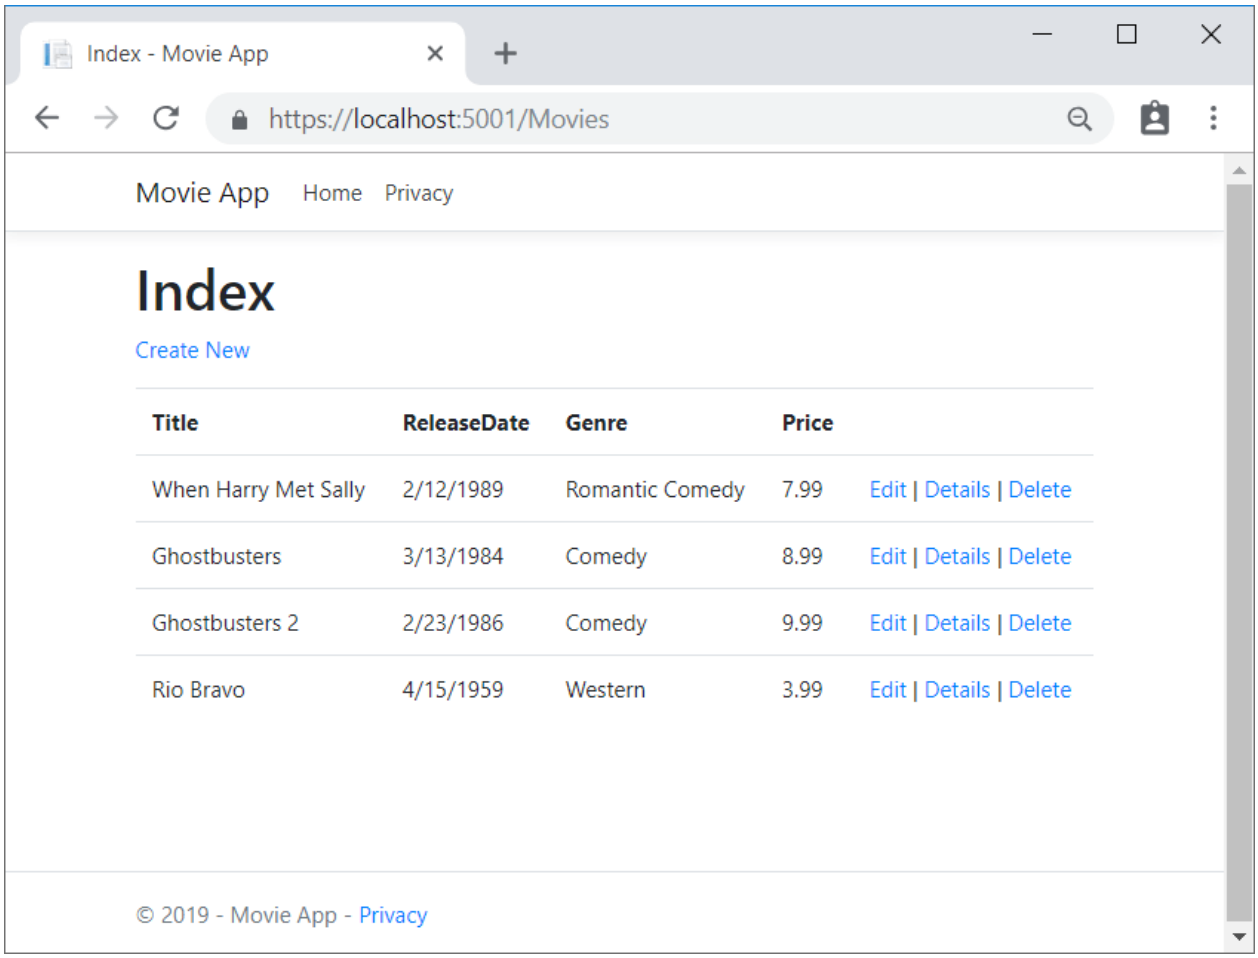


Part 6, controller methods and views in ASP.NET Core

9/22/2020 • 9 minutes to read • Edit Online

By Rick Anderson

We have a good start to the movie app, but the presentation isn't ideal, for example, **ReleaseDate** should be two words.



Open the *Models/Movie.cs* file and add the highlighted lines shown below:

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace MvcMovie.Models
{
    public class Movie
    {
        public int Id { get; set; }
        public string Title { get; set; }

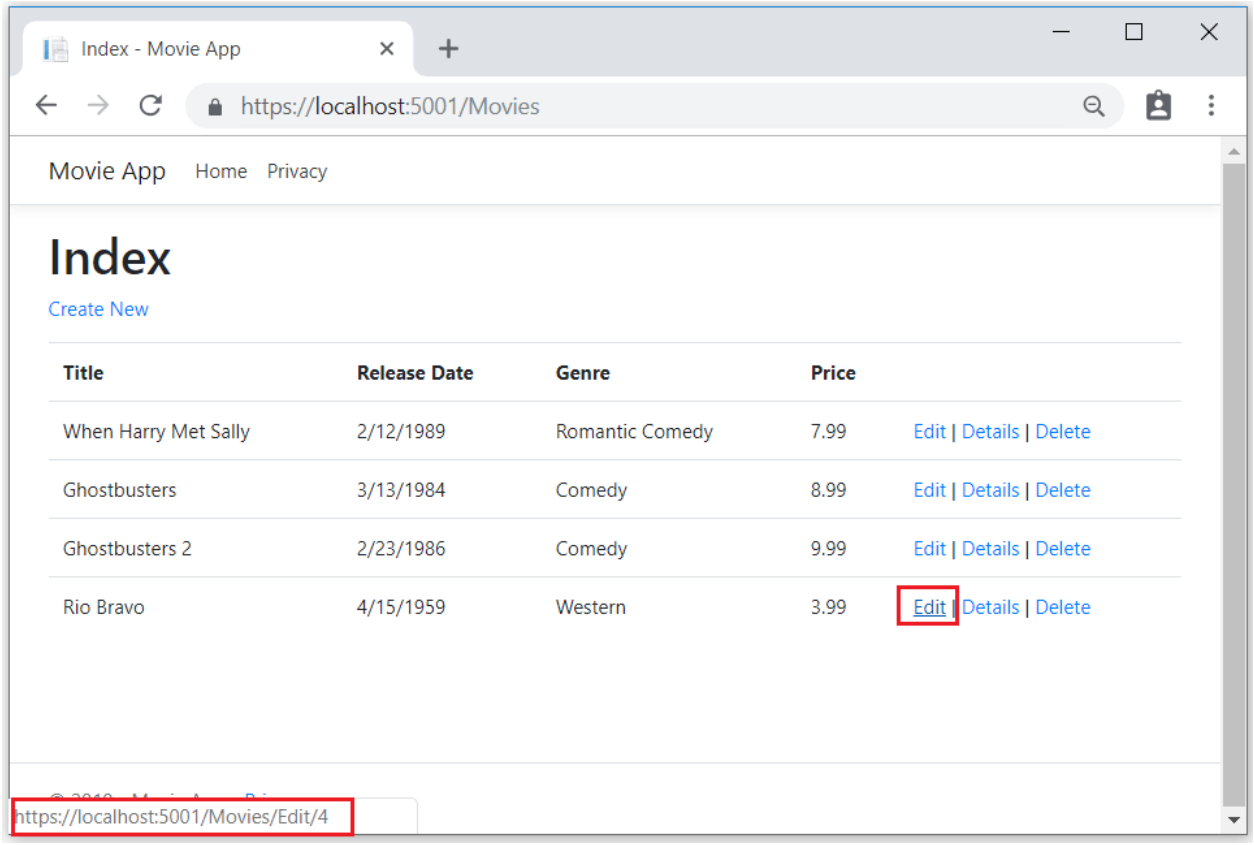
        [Display(Name = "Release Date")]
        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }

        [Column(TypeName = "decimal(18, 2)")]
        public decimal Price { get; set; }
    }
}
```

We cover DataAnnotations in the next tutorial. The Display attribute specifies what to display for the name of a field (in this case "Release Date" instead of "ReleaseDate"). The DataType attribute specifies the type of the data (Date), so the time information stored in the field isn't displayed.

The `[Column(TypeName = "decimal(18, 2)")]` data annotation is required so Entity Framework Core can correctly map `Price` to currency in the database. For more information, see Data Types.

Browse to the `Movies` controller and hold the mouse pointer over an **Edit** link to see the target URL.



The **Edit**, **Details**, and **Delete** links are generated by the Core MVC Anchor Tag Helper in the *Views/Movies/Index.cshtml* file.

```
        <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
        <a asp-action="Details" asp-route-id="@item.ID">Details</a> |
        <a asp-action="Delete" asp-route-id="@item.ID">Delete</a>
    </td>
</tr>
```

Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files. In the code above, the `AnchorTagHelper` dynamically generates the HTML `href` attribute value from the controller action method and route id. You use **View Source** from your favorite browser or use the developer tools to examine the generated markup. A portion of the generated HTML is shown below:

```
 <td>
    <a href="/Movies/Edit/4"> Edit </a> |
    <a href="/Movies/Details/4"> Details </a> |
    <a href="/Movies/Delete/4"> Delete </a>
</td>
```

Recall the format for routing set in the *Startup.cs* file:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(
        name: "default",
        pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

ASP.NET Core translates `https://localhost:5001/Movies/Edit/4` into a request to the `Edit` action method of the `Movies` controller with the parameter `Id` of 4. (Controller methods are also known as action methods.)

Tag Helpers are one of the most popular new features in ASP.NET Core. For more information, see Additional resources.

Open the `Movies` controller and examine the two `Edit` action methods. The following code shows the `HTTP GET Edit` method, which fetches the movie and populates the edit form generated by the *Edit.cshtml* Razor file.

```
// GET: Movies/Edit/5
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie.FindAsync(id);
    if (movie == null)
    {
        return NotFound();
    }
    return View(movie);
}
```

The following code shows the `HTTP POST Edit` method, which processes the posted movie values:

```
// POST: Movies/Edit/5
// To protect from overposting attacks, please enable the specific properties you want to bind to, for
// more details see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id, [Bind("ID,Title,ReleaseDate,Genre,Price")] Movie movie)
{
    if (id != movie.ID)
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

```
// GET: Movies/Edit/5
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie.SingleOrDefaultAsync(m => m.ID == id);
    if (movie == null)
    {
        return NotFound();
    }
    return View(movie);
}
```

The following code shows the `HTTP POST Edit` method, which processes the posted movie values:

```
// POST: Movies/Edit/5
// To protect from overposting attacks, please enable the specific properties you want to bind to, for
// more details see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id, [Bind("ID,Title,ReleaseDate,Genre,Price")] Movie movie)
{
    if (id != movie.ID)
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

The `[Bind]` attribute is one way to protect against over-posting. You should only include properties in the `[Bind]` attribute that you want to change. For more information, see Protect your controller from over-posting. ViewModels provide an alternative approach to prevent over-posting.

Notice the second `Edit` action method is preceded by the `[HttpPost]` attribute.

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id, [Bind("ID,Title,ReleaseDate,Genre,Price")] Movie movie)
{
    if (id != movie.ID)
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction(nameof(Index));
    }
    return View(movie);
}
```

```
// POST: Movies/Edit/5
// To protect from overposting attacks, please enable the specific properties you want to bind to, for
// more details see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id, [Bind("ID,Title,ReleaseDate,Genre,Price")] Movie movie)
{
    if (id != movie.ID)
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

The `HttpPost` attribute specifies that this `Edit` method can be invoked *only* for `POST` requests. You could apply the `[HttpGet]` attribute to the first edit method, but that's not necessary because `[HttpGet]` is the default.

The `ValidateAntiForgeryToken` attribute is used to prevent forgery of a request and is paired up with an anti-forgery token generated in the edit view file (*Views/Movies/Edit.cshtml*). The edit view file generates the anti-forgery token with the Form Tag Helper.

```
<form asp-action="Edit">
```

The Form Tag Helper generates a hidden anti-forgery token that must match the `[ValidateAntiForgeryToken]` generated anti-forgery token in the `Edit` method of the Movies controller. For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

The `HttpGet Edit` method takes the movie `ID` parameter, looks up the movie using the Entity Framework `FindAsync` method, and returns the selected movie to the Edit view. If a movie cannot be found, `NotFound` (HTTP 404) is returned.

```
// GET: Movies/Edit/5
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie.FindAsync(id);
    if (movie == null)
    {
        return NotFound();
    }
    return View(movie);
}
```

When the scaffolding system created the Edit view, it examined the `Movie` class and created code to render `<label>` and `<input>` elements for each property of the class. The following example shows the Edit view that was generated by the Visual Studio scaffolding system:

```
@model MvcMovie.Models.Movie

@{
    ViewData["Title"] = "Edit";
}

<h1>Edit</h1>

<h4>Movie</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Edit">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Id" />
            <div class="form-group">
                <label asp-for="Title" class="control-label"></label>
                <input asp-for="Title" class="form-control" />
                <span asp-validation-for="Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="ReleaseDate" class="control-label"></label>
                <input asp-for="ReleaseDate" class="form-control" />
                <span asp-validation-for="ReleaseDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Genre" class="control-label"></label>
                <input asp-for="Genre" class="form-control" />
                <span asp-validation-for="Genre" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Price" class="control-label"></label>
                <input asp-for="Price" class="form-control" />
                <span asp-validation-for="Price" class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-action="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Notice how the view template has a `@model MvcMovie.Models.Movie` statement at the top of the file. `@model MvcMovie.Models.Movie` specifies that the view expects the model for the view template to be of type `Movie`.

The scaffolded code uses several Tag Helper methods to streamline the HTML markup. The Label Tag Helper displays the name of the field ("Title", "ReleaseDate", "Genre", or "Price"). The Input Tag Helper renders an HTML `<input>` element. The Validation Tag Helper displays any validation messages associated with that property.

Run the application and navigate to the `/Movies` URL. Click an **Edit** link. In the browser, view the source for the page. The generated HTML for the `<form>` element is shown below.

```
<form action="/Movies/Edit/7" method="post">
    <div class="form-horizontal">
        <h4>Movie</h4>
        <hr />
        <div class="text-danger" />
        <input type="hidden" data-val="true" data-val-required="The ID field is required." id="ID" name="ID"
value="7" />
        <div class="form-group">
            <label class="control-label col-md-2" for="Genre" />
            <div class="col-md-10">
                <input class="form-control" type="text" id="Genre" name="Genre" value="Western" />
                <span class="text-danger field-validation-valid" data-valmsg-for="Genre" data-valmsg-
replace="true"></span>
            </div>
        </div>
        <div class="form-group">
            <label class="control-label col-md-2" for="Price" />
            <div class="col-md-10">
                <input class="form-control" type="text" data-val="true" data-val-number="The field Price
must be a number." data-val-required="The Price field is required." id="Price" name="Price" value="3.99" />
                <span class="text-danger field-validation-valid" data-valmsg-for="Price" data-valmsg-
replace="true"></span>
            </div>
        </div>
        <!-- Markup removed for brevity -->
        <div class="form-group">
            <div class="col-md-offset-2 col-md-10">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </div>
    </div>
    <input name="__RequestVerificationToken" type="hidden"
value="CfDJ8Inyxgp63fRFqUePGvuI5jGZsloJu1L7X9le1gy7NCIlSduCRx9jDQClrV9pOTTmqUyXnJBXhmrjcUVDJyDUMm7-
MF_9rK8aAZdRdlOri7FmKVkRe_2v5LIHGKFcTjPrWPYnc9AdSbomkiOSaTEg7RU" />
</form>
```

The `<input>` elements are in an `HTML <form>` element whose `action` attribute is set to post to the `/Movies/Edit/id` URL. The form data will be posted to the server when the `Save` button is clicked. The last line before the closing `</form>` element shows the hidden XSRF token generated by the Form Tag Helper.

Processing the POST Request

The following listing shows the `[HttpPost]` version of the `Edit` action method.

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id, [Bind("ID,Title,ReleaseDate,Genre,Price")] Movie movie)
{
    if (id != movie.ID)
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction(nameof(Index));
    }
    return View(movie);
}
```

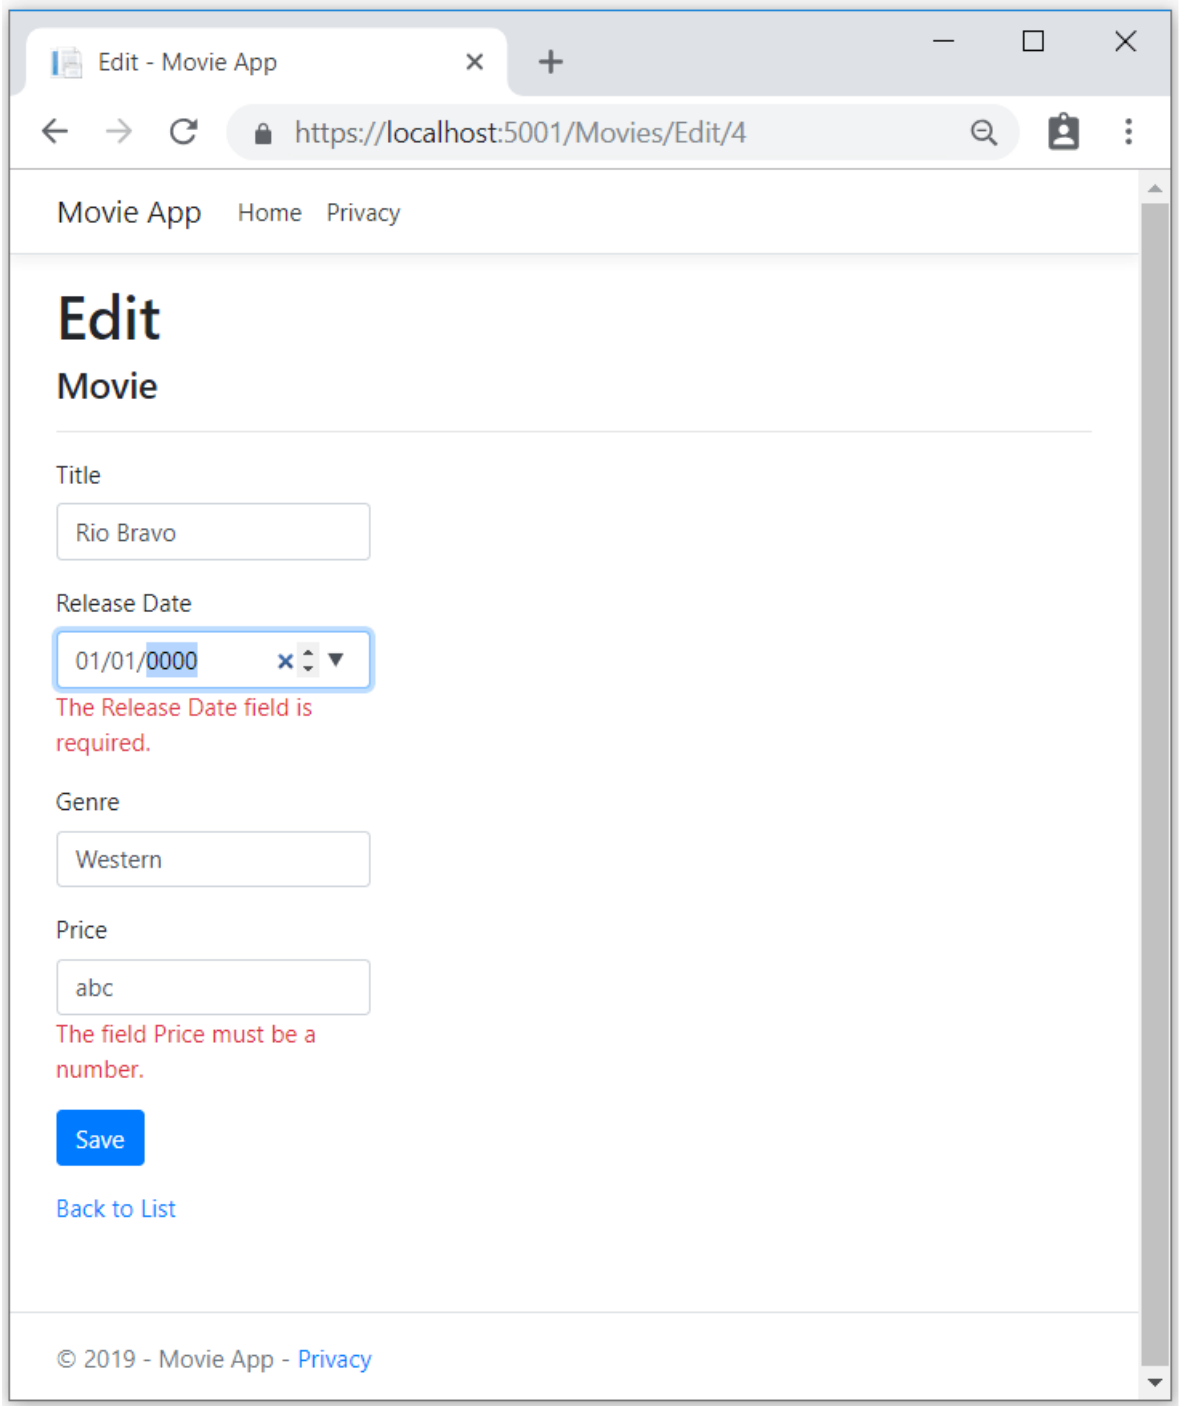
```
// POST: Movies/Edit/5
// To protect from overposting attacks, please enable the specific properties you want to bind to, for
// more details see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id, [Bind("ID,Title,ReleaseDate,Genre,Price")] Movie movie)
{
    if (id != movie.ID)
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

The `[ValidateAntiForgeryToken]` attribute validates the hidden XSRF token generated by the anti-forgery token generator in the Form Tag Helper

The model binding system takes the posted form values and creates a `Movie` object that's passed as the `movie` parameter. The `ModelState.IsValid` method verifies that the data submitted in the form can be used to modify (edit or update) a `Movie` object. If the data is valid, it's saved. The updated (edited) movie data is saved to the database by calling the `SaveChangesAsync` method of database context. After saving the data, the code redirects the user to the `Index` action method of the `MoviesController` class, which displays the movie collection, including the changes just made.

Before the form is posted to the server, client-side validation checks any validation rules on the fields. If there are any validation errors, an error message is displayed and the form isn't posted. If JavaScript is disabled, you won't have client-side validation but the server will detect the posted values that are not valid, and the form values will be redisplayed with error messages. Later in the tutorial we examine Model Validation in more detail. The Validation Tag Helper in the *Views/Movies/Edit.cshtml* view template takes care of displaying appropriate error messages.



All the `HttpGet` methods in the movie controller follow a similar pattern. They get a movie object (or list of objects, in the case of `Index`), and pass the object (model) to the view. The `Create` method passes an empty movie object to the `Create` view. All the methods that create, edit, delete, or otherwise modify data do so in the `[HttpPost]` overload of the method. Modifying data in an `HTTP GET` method is a security risk. Modifying data in an `HTTP GET` method also violates HTTP best practices and the architectural REST pattern, which specifies that GET requests shouldn't change the state of your application. In other words, performing a GET operation should be a safe operation that has no side effects and doesn't modify your persisted data.

Part 7, add search to an ASP.NET Core MVC app

9/22/2020 • 7 minutes to read • Edit Online

By Rick Anderson

In this section, you add search capability to the `Index` action method that lets you search movies by *genre* or *name*.

Update the `Index` method found inside *Controllers/MoviesController.cs* with the following code:

```
public async Task<IActionResult> Index(string searchString)
{
    var movies = from m in _context.Movie
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(await movies.ToListAsync());
}
```

The first line of the `Index` action method creates a LINQ query to select the movies:

```
var movies = from m in _context.Movie
             select m;
```

The query is *only* defined at this point, it has **not** been run against the database.

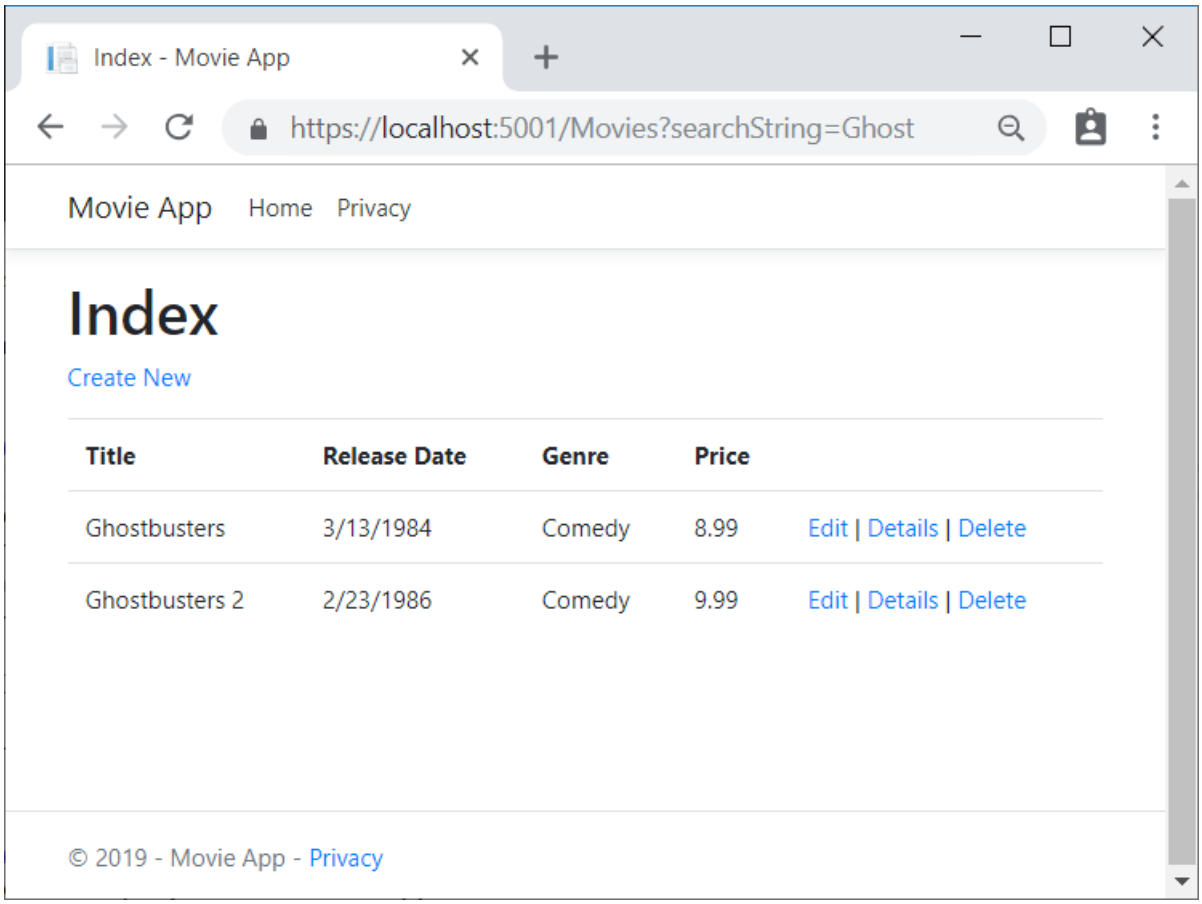
If the `searchString` parameter contains a string, the movies query is modified to filter on the value of the search string:

```
if (!String.IsNullOrEmpty(searchString))
{
    movies = movies.Where(s => s.Title.Contains(searchString));
}
```

The `s => s.Title.Contains()` code above is a Lambda Expression. Lambdas are used in method-based LINQ queries as arguments to standard query operator methods such as the Where method or `Contains` (used in the code above). LINQ queries are not executed when they're defined or when they're modified by calling a method such as `Where`, `Contains`, or `OrderBy`. Rather, query execution is deferred. That means that the evaluation of an expression is delayed until its realized value is actually iterated over or the `ToListAsync` method is called. For more information about deferred query execution, see Query Execution.

Note: The Contains method is run on the database, not in the c# code shown above. The case sensitivity on the query depends on the database and the collation. On SQL Server, Contains maps to SQL LIKE, which is case insensitive. In SQLite, with the default collation, it's case sensitive.

Navigate to `/Movies/Index`. Append a query string such as `?searchString=Ghost` to the URL. The filtered movies are displayed.



If you change the signature of the `Index` method to have a parameter named `id`, the `id` parameter will match the optional `{id}` placeholder for the default routes set in *Startup.cs*.

```
app.UseMvc(routes =>
{
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");
});
```

Change the parameter to `id` and all occurrences of `searchString` change to `id`.

The previous `Index` method:

```
public async Task<IActionResult> Index(string searchString)
{
    var movies = from m in _context.Movie
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(await movies.ToListAsync());
}
```

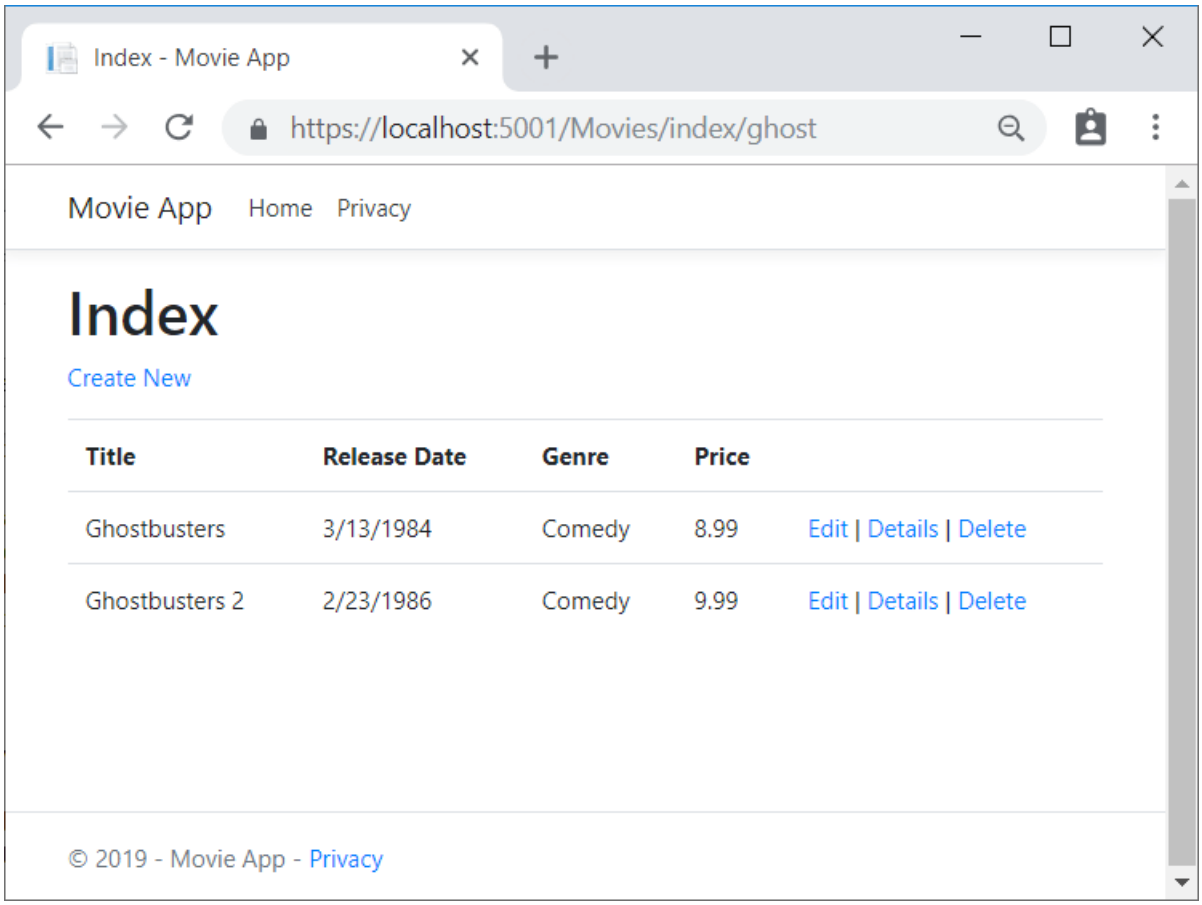
The updated `Index` method with `id` parameter:

```
public async Task<IActionResult> Index(string id)
{
    var movies = from m in _context.Movie
                 select m;

    if (!String.IsNullOrEmpty(id))
    {
        movies = movies.Where(s => s.Title.Contains(id));
    }

    return View(await movies.ToListAsync());
}
```

You can now pass the search title as route data (a URL segment) instead of as a query string value.



However, you can't expect users to modify the URL every time they want to search for a movie. So now you'll add UI elements to help them filter movies. If you changed the signature of the `Index` method to test how to pass the route-bound `ID` parameter, change it back so that it takes a parameter named `searchString`:

```
public async Task<IActionResult> Index(string searchString)
{
    var movies = from m in _context.Movie
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(await movies.ToListAsync());
}
```

Open the *Views/Movies/Index.cshtml* file, and add the `<form>` markup highlighted below:

```
    ViewData["Title"] = "Index";
}

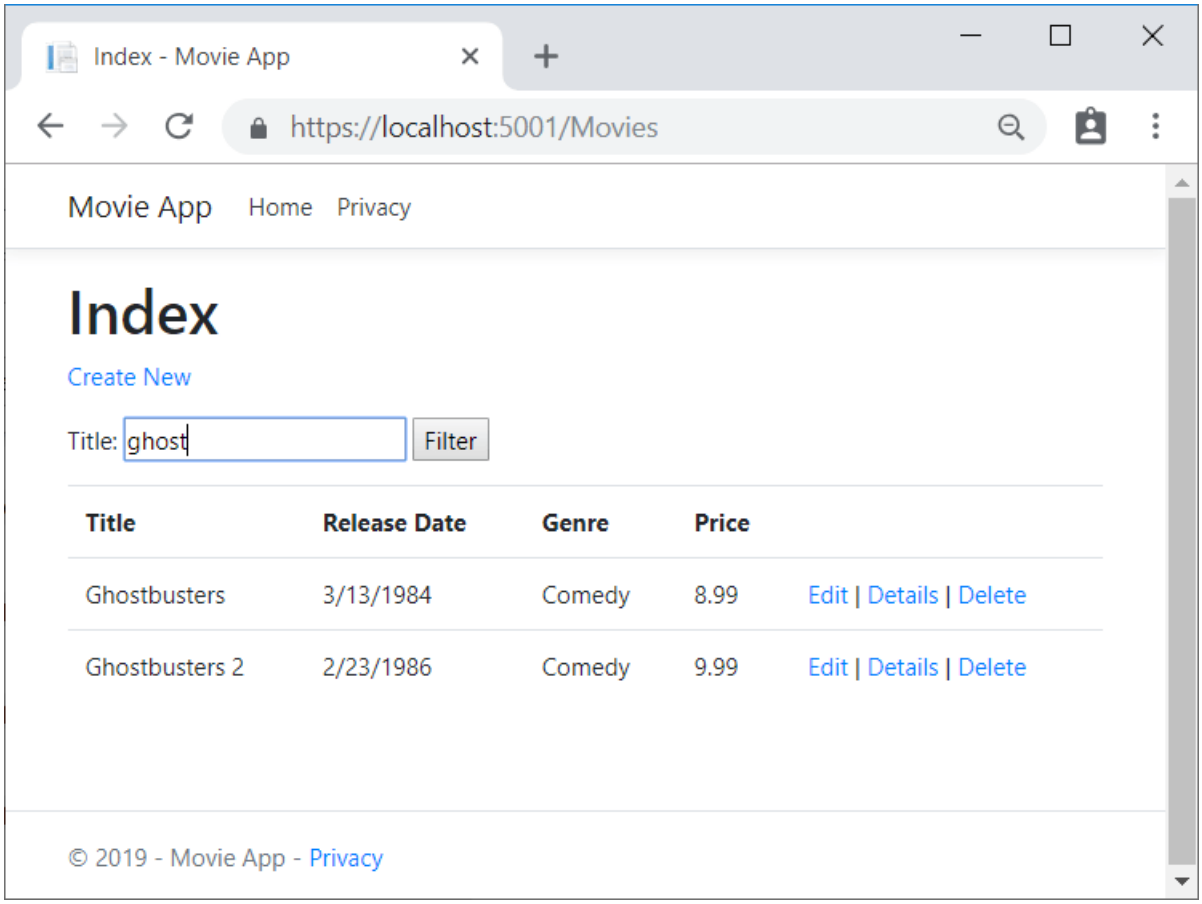
<h2>Index</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>

<form asp-controller="Movies" asp-action="Index">
    <p>
        Title: <input type="text" name="SearchString">
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">
    <thead>
```

The HTML `<form>` tag uses the Form Tag Helper, so when you submit the form, the filter string is posted to the `Index` action of the movies controller. Save your changes and then test the filter.



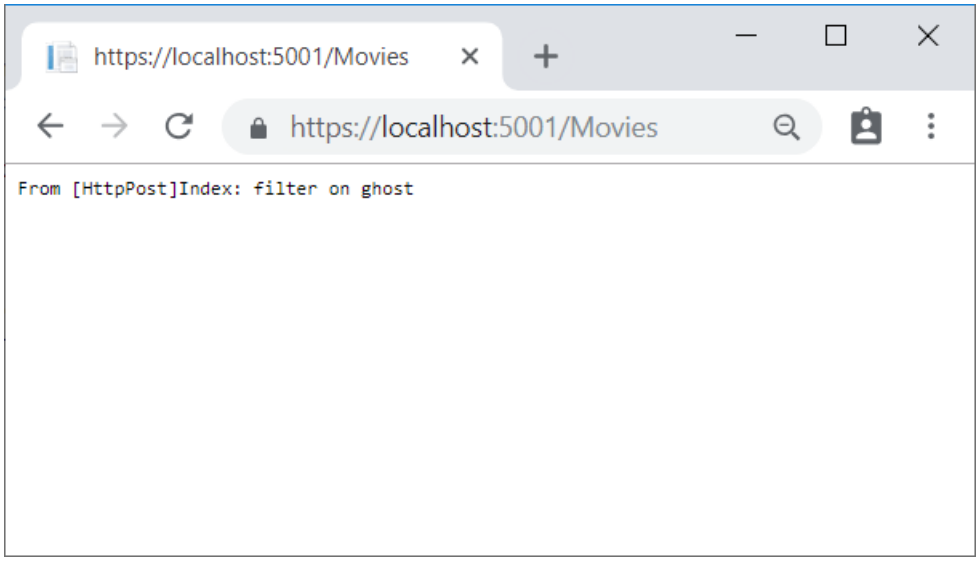
There's no `[HttpPost]` overload of the `Index` method as you might expect. You don't need it, because the method isn't changing the state of the app, just filtering data.

You could add the following `[HttpPost] Index` method.

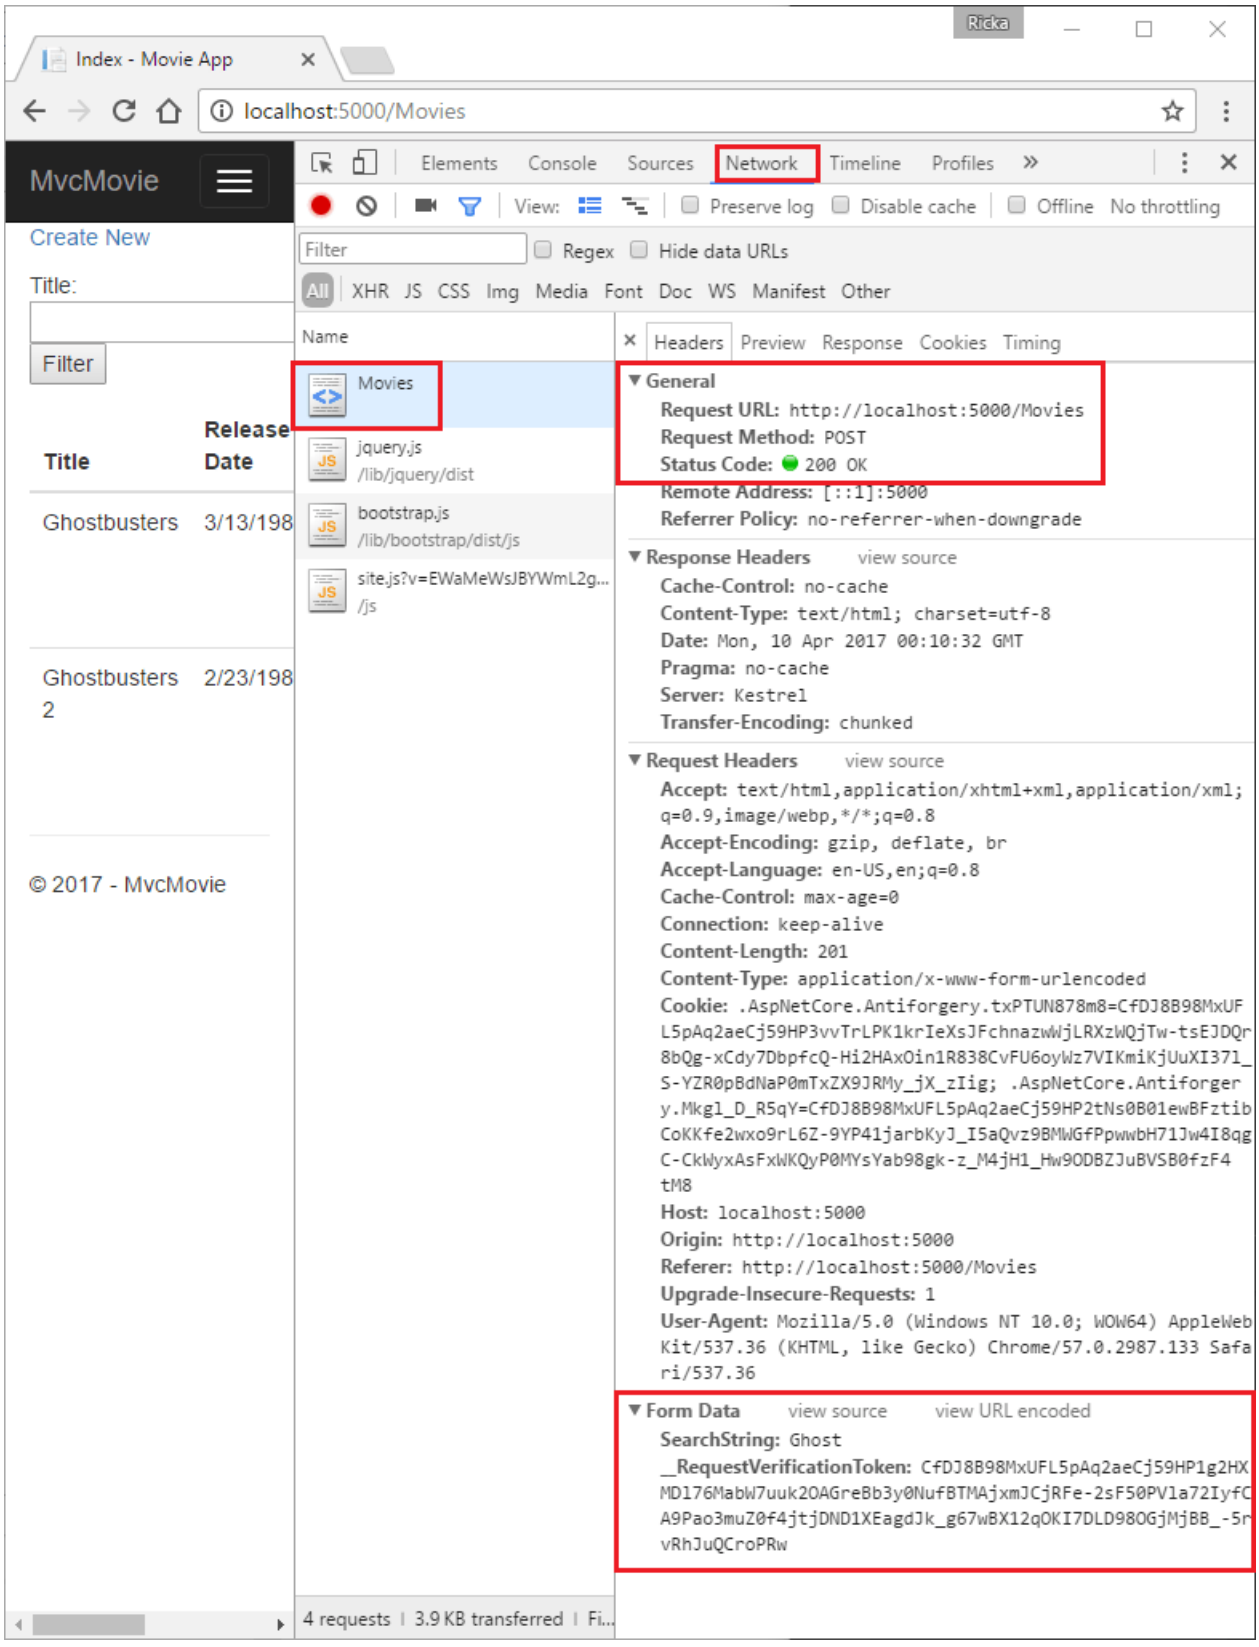
```
[HttpPost]
public string Index(string searchString, bool notUsed)
{
    return "From [HttpPost]Index: filter on " + searchString;
}
```

The `notUsed` parameter is used to create an overload for the `Index` method. We'll talk about that later in the tutorial.

If you add this method, the action invoker would match the `[HttpPost] Index` method, and the `[HttpPost] Index` method would run as shown in the image below.



However, even if you add this `[HttpPost]` version of the `Index` method, there's a limitation in how this has all been implemented. Imagine that you want to bookmark a particular search or you want to send a link to friends that they can click in order to see the same filtered list of movies. Notice that the URL for the HTTP POST request is the same as the URL for the GET request (localhost:{PORT}/Movies/Index) -- there's no search information in the URL. The search string information is sent to the server as a form field value. You can verify that with the browser Developer tools or the excellent Fiddler tool. The image below shows the Chrome browser Developer tools:



You can see the search parameter and XSRF token in the request body. Note, as mentioned in the previous tutorial, the Form Tag Helper generates an XSRF anti-forgery token. We're not modifying data, so we don't need to validate the token in the controller method.

Because the search parameter is in the request body and not the URL, you can't capture that search information to bookmark or share with others. Fix this by specifying the request should be `HTTP GET` found in the *Views/Movies/Index.cshtml* file.

```
@model IEnumerable<MvcMovie.Models.Movie>

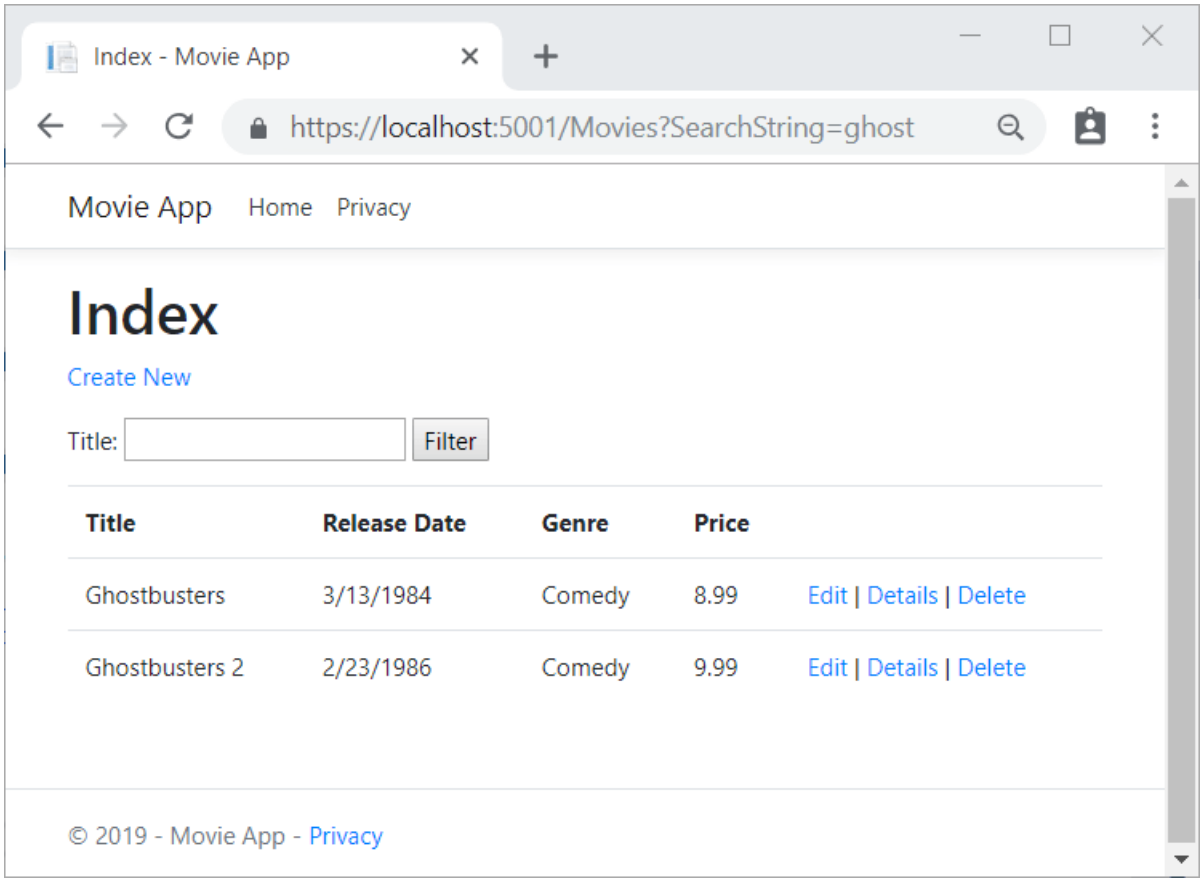
@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>
<form asp-controller="Movies" asp-action="Index" method="get">
    <p>
        Title: <input type="text" name="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Title)
```

Now when you submit a search, the URL contains the search query string. Searching will also go to the `HttpGet Index` action method, even if you have a `HttpPost Index` method.



The following markup shows the change to the `form` tag:

```
<form asp-controller="Movies" asp-action="Index" method="get">
```

Add Search by genre

Add the following `MovieGenreViewModel` class to the *Models* folder:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace MvcMovie.Models
{
    public class MovieGenreViewModel
    {
        public List<Movie> Movies { get; set; }
        public SelectList Genres { get; set; }
        public string MovieGenre { get; set; }
        public string SearchString { get; set; }
    }
}
```

The movie-genre view model will contain:

- A list of movies.
- A `SelectList` containing the list of genres. This allows the user to select a genre from the list.
- `MovieGenre`, which contains the selected genre.
- `SearchString`, which contains the text users enter in the search text box.

Replace the `Index` method in `MoviesController.cs` with the following code:

```
// GET: Movies
public async Task<IActionResult> Index(string movieGenre, string searchString)
{
    // Use LINQ to get list of genres.
    IQueryable<string> genreQuery = from m in _context.Movie
                                    orderby m.Genre
                                    select m.Genre;

    var movies = from m in _context.Movie
                 select m;

    if (!string.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    if (!string.IsNullOrEmpty(movieGenre))
    {
        movies = movies.Where(x => x.Genre == movieGenre);
    }

    var movieGenreVM = new MovieGenreViewModel
    {
        Genres = new SelectList(await genreQuery.Distinct().ToListAsync()),
        Movies = await movies.ToListAsync()
    };

    return View(movieGenreVM);
}
```

The following code is a `LINQ` query that retrieves all the genres from the database.

```
// Use LINQ to get list of genres.
IQueryable<string> genreQuery = from m in _context.Movie
                                orderby m.Genre
                                select m.Genre;
```

The `SelectList` of genres is created by projecting the distinct genres (we don't want our select list to have duplicate genres).

When the user searches for the item, the search value is retained in the search box.

Add search by genre to the Index view

Update `Index.cshtml` found in *Views/Movies/* as follows:

```
@model MvcMovie.Models.MovieGenreViewModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>
<form asp-controller="Movies" asp-action="Index" method="get">
    <p>

        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>

        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

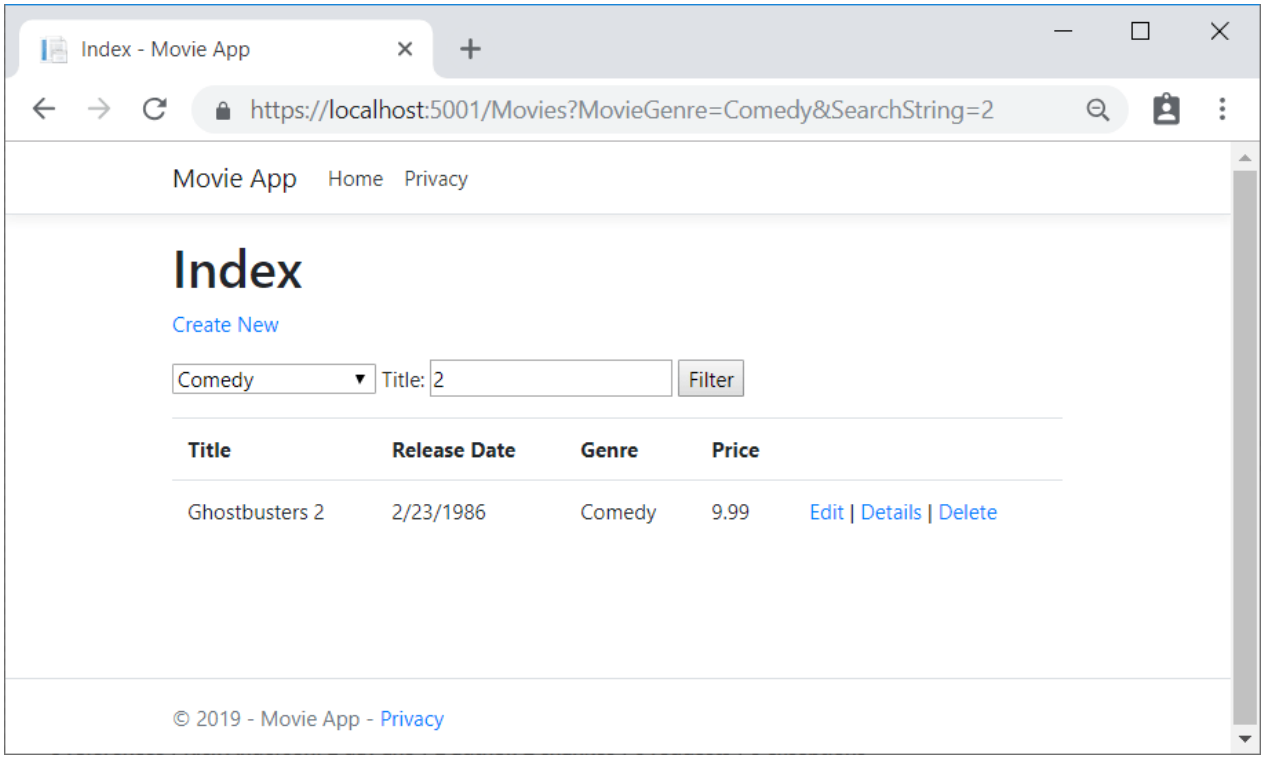
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movies[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies[0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies[0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies[0].Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Movies)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.ReleaseDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Genre)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Price)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
                    <a asp-action="Details" asp-route-id="@item.Id">Details</a> |
                    <a asp-action="Delete" asp-route-id="@item.Id">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

Examine the lambda expression used in the following HTML Helper:

```
@Html.DisplayNameFor(model => model.Movies[0].Title)
```

In the preceding code, the `DisplayNameFor` HTML Helper inspects the `Title` property referenced in the lambda expression to determine the display name. Since the lambda expression is inspected rather than evaluated, you don't receive an access violation when `model`, `model.Movies`, or `model.Movies[0]` are `null` or empty. When the lambda expression is evaluated (for example, `@Html.DisplayFor(modelItem => item.Title)`), the model's property values are evaluated.

Test the app by searching by genre, by movie title, and by both:



Part 8, add a new field to an ASP.NET Core MVC app

9/22/2020 • 4 minutes to read • Edit Online

By Rick Anderson

In this section Entity Framework Code First Migrations is used to:

- Add a new field to the model.
- Migrate the new field to the database.

When EF Code First is used to automatically create a database, Code First:

- Adds a table to the database to track the schema of the database.
- Verifies the database is in sync with the model classes it was generated from. If they aren't in sync, EF throws an exception. This makes it easier to find inconsistent database/code issues.

Add a Rating Property to the Movie Model

Add a `Rating` property to *Models/Movie.cs*:

```
public class Movie
{
    public int Id { get; set; }
    public string Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; }

    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
    public string Rating { get; set; }
}
```

Build the app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Ctrl+Shift+B

Because you've added a new field to the `Movie` class, you need to update the binding white list so this new property will be included. In *MoviesController.cs*, update the `[Bind]` attribute for both the `Create` and `Edit` action methods to include the `Rating` property:

```
[Bind("Id,Title,ReleaseDate,Genre,Price,Rating")]
```

Update the view templates in order to display, create, and edit the new `Rating` property in the browser view.

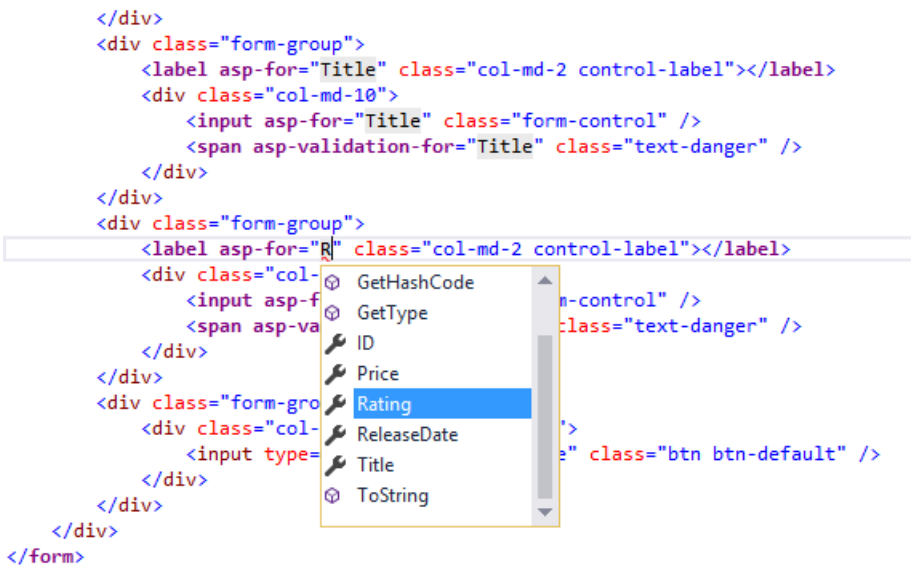
Edit the */Views/Movies/Index.cshtml* file and add a `Rating` field:

```
<thead>
    <tr>
        <th>
            @Html.DisplayNameFor(model => model.Movies[0].Title)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Movies[0].ReleaseDate)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Movies[0].Genre)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Movies[0].Price)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Movies[0].Rating)
        </th>
        <th></th>
    </tr>
</thead>
<tbody>
    @foreach (var item in Model.Movies)
    {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.ReleaseDate)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Genre)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Price)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Rating)
        </td>
        <td>
            <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
```

Update the */Views/Movies/Create.cshtml* with a `Rating` field.

- Visual Studio / Visual Studio for Mac
- Visual Studio Code

You can copy/paste the previous "form group" and let intelliSense help you update the fields. IntelliSense works with Tag Helpers.



Update the remaining templates.

Update the `SeedData` class so that it provides a value for the new column. A sample change is shown below, but you'll want to make this change for each `new Movie`.

```
new Movie
{
    Title = "When Harry Met Sally",
    ReleaseDate = DateTime.Parse("1989-1-11"),
    Genre = "Romantic Comedy",
    Rating = "R",
    Price = 7.99M
},
```

The app won't work until the DB is updated to include the new field. If it's run now, the following `SqlException` is thrown:

```
SqlException: Invalid column name 'Rating'.
```

This error occurs because the updated Movie model class is different than the schema of the Movie table of the existing database. (There's no `Rating` column in the database table.)

There are a few approaches to resolving the error:

1. Have the Entity Framework automatically drop and re-create the database based on the new model class schema. This approach is very convenient early in the development cycle when you're doing active development on a test database; it allows you to quickly evolve the model and database schema together. The downside, though, is that you lose existing data in the database — so you don't want to use this approach on a production database! Using an initializer to automatically seed a database with test data is often a productive way to develop an application. This is a good approach for early development and when using SQLite.

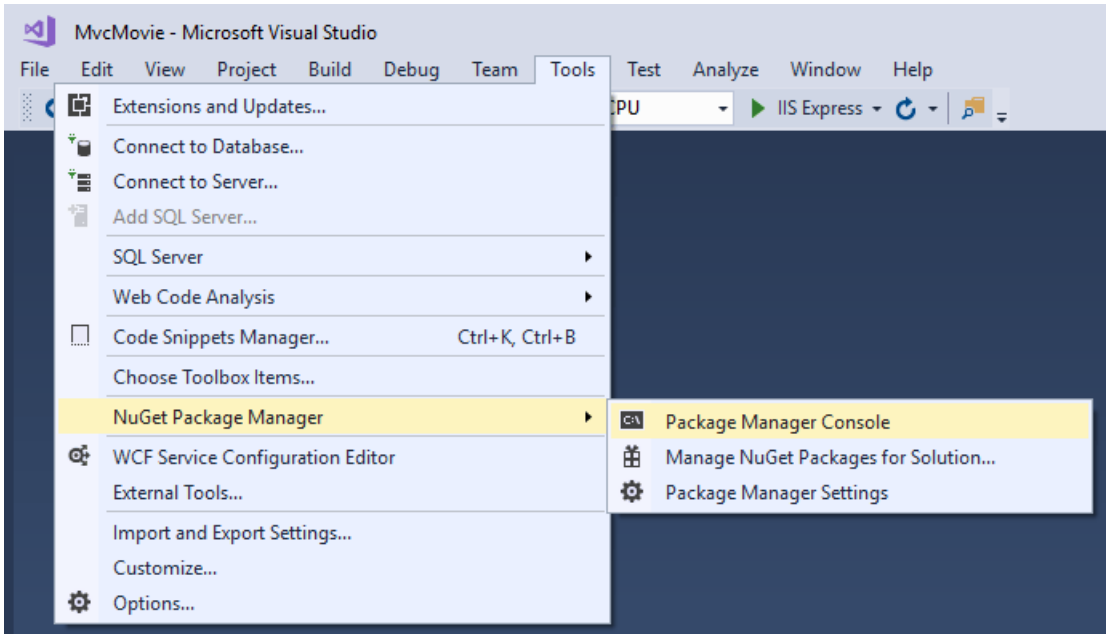
2. Explicitly modify the schema of the existing database so that it matches the model classes. The advantage of this approach is that you keep your data. You can make this change either manually or by creating a database change script.

3. Use Code First Migrations to update the database schema.

For this tutorial, Code First Migrations is used.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**.



In the PMC, enter the following commands:

```
Add-Migration Rating
Update-Database
```

The `Add-Migration` command tells the migration framework to examine the current `Movie` model with the current `Movie` DB schema and create the necessary code to migrate the DB to the new model.

The name "Rating" is arbitrary and is used to name the migration file. It's helpful to use a meaningful name for the migration file.

If all the records in the DB are deleted, the initialize method will seed the DB and include the `Rating` field.

Run the app and verify you can create, edit, and display movies with a `Rating` field.

Part 9, add validation to an ASP.NET Core MVC app

9/22/2020 • 9 minutes to read • Edit Online

By Rick Anderson

In this section:

- Validation logic is added to the `Movie` model.
- You ensure that the validation rules are enforced any time a user creates or edits a movie.

Keeping things DRY

One of the design tenets of MVC is DRY ("Don't Repeat Yourself"). ASP.NET Core MVC encourages you to specify functionality or behavior only once, and then have it be reflected everywhere in an app. This reduces the amount of code you need to write and makes the code you do write less error prone, easier to test, and easier to maintain.

The validation support provided by MVC and Entity Framework Core Code First is a good example of the DRY principle in action. You can declaratively specify validation rules in one place (in the model class) and the rules are enforced everywhere in the app.

Add validation rules to the movie model

The DataAnnotations namespace provides a set of built-in validation attributes that are applied declaratively to a class or property. DataAnnotations also contains formatting attributes like `DataType` that help with formatting and don't provide any validation.

Update the `Movie` class to take advantage of the built-in `Required`, `StringLength`, `RegularExpression`, and `Range` validation attributes.

```
public class Movie
{
    public int Id { get; set; }

    [StringLength(60, MinimumLength = 3)]
    [Required]
    public string Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [Range(1, 100)]
    [DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
    [Required]
    [StringLength(30)]
    public string Genre { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$")]
    [StringLength(5)]
    [Required]
    public string Rating { get; set; }
}
```

The validation attributes specify behavior that you want to enforce on the model properties they're applied to:

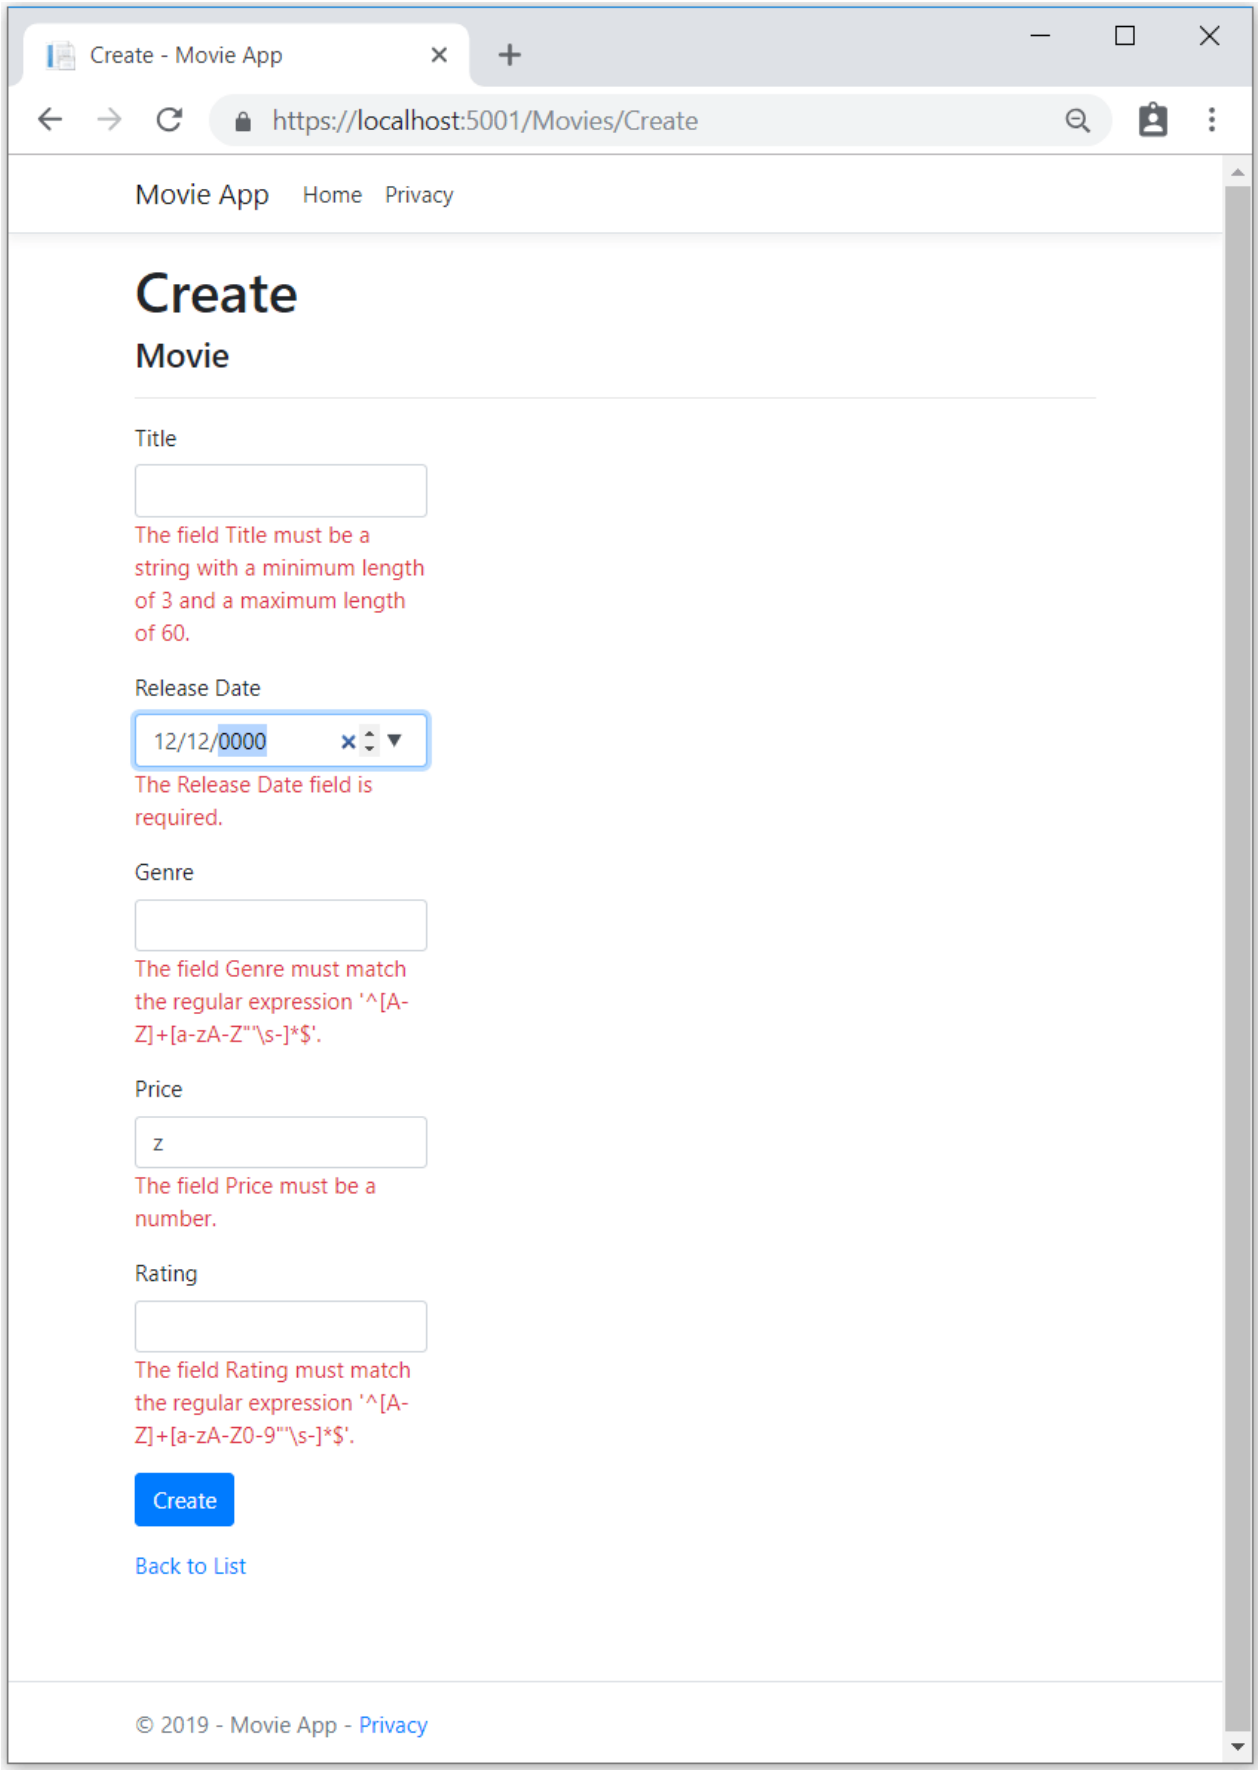
- The `Required` and `MinimumLength` attributes indicate that a property must have a value; but nothing prevents a user from entering white space to satisfy this validation.
- The `RegularExpression` attribute is used to limit what characters can be input. In the preceding code, "Genre":
  - Must only use letters.
  - The first letter is required to be uppercase. White space, numbers, and special characters are not allowed.
- The `RegularExpression` "Rating":
  - Requires that the first character be an uppercase letter.
  - Allows special characters and numbers in subsequent spaces. "PG-13" is valid for a rating, but fails for a "Genre".
- The `Range` attribute constrains a value to within a specified range.
- The `StringLength` attribute lets you set the maximum length of a string property, and optionally its minimum length.
- Value types (such as `decimal`, `int`, `float`, `DateTime`) are inherently required and don't need the `[Required]` attribute.

Having validation rules automatically enforced by ASP.NET Core helps make your app more robust. It also ensures that you can't forget to validate something and inadvertently let bad data into the database.

Validation Error UI

Run the app and navigate to the Movies controller.

Tap the **Create New** link to add a new movie. Fill out the form with some invalid values. As soon as jQuery client side validation detects the error, it displays an error message.



NOTE

You may not be able to enter decimal commas in decimal fields. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. See this GitHub issue 4076 for instructions on adding decimal comma.

Notice how the form has automatically rendered an appropriate validation error message in each field containing

an invalid value. The errors are enforced both client-side (using JavaScript and jQuery) and server-side (in case a user has JavaScript disabled).

A significant benefit is that you didn't need to change a single line of code in the `MoviesController` class or in the *Create.cshtml* view in order to enable this validation UI. The controller and views you created earlier in this tutorial automatically picked up the validation rules that you specified by using validation attributes on the properties of the `Movie` model class. Test validation using the `Edit` action method, and the same validation is applied.

The form data isn't sent to the server until there are no client side validation errors. You can verify this by putting a break point in the `HTTP Post` method, by using the Fiddler tool , or the F12 Developer tools.

How validation works

You might wonder how the validation UI was generated without any updates to the code in the controller or views. The following code shows the two `Create` methods.

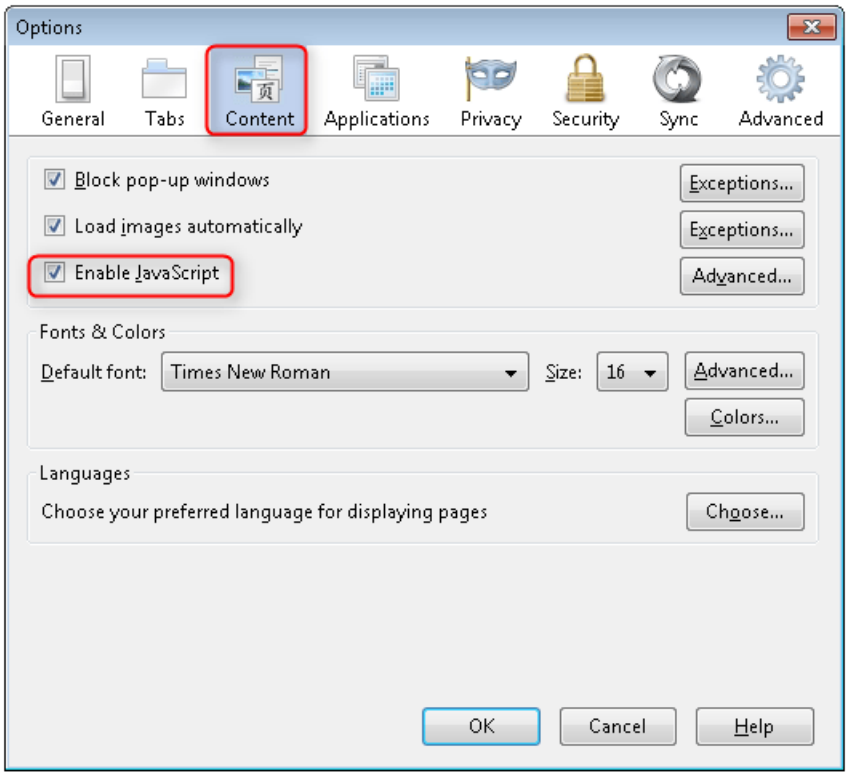
```
// GET: Movies/Create
public IActionResult Create()
{
    return View();
}

// POST: Movies/Create
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Create(
    [Bind("ID,Title,ReleaseDate,Genre,Price, Rating")] Movie movie)
{
    if (ModelState.IsValid)
    {
        _context.Add(movie);
        await _context.SaveChangesAsync();
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

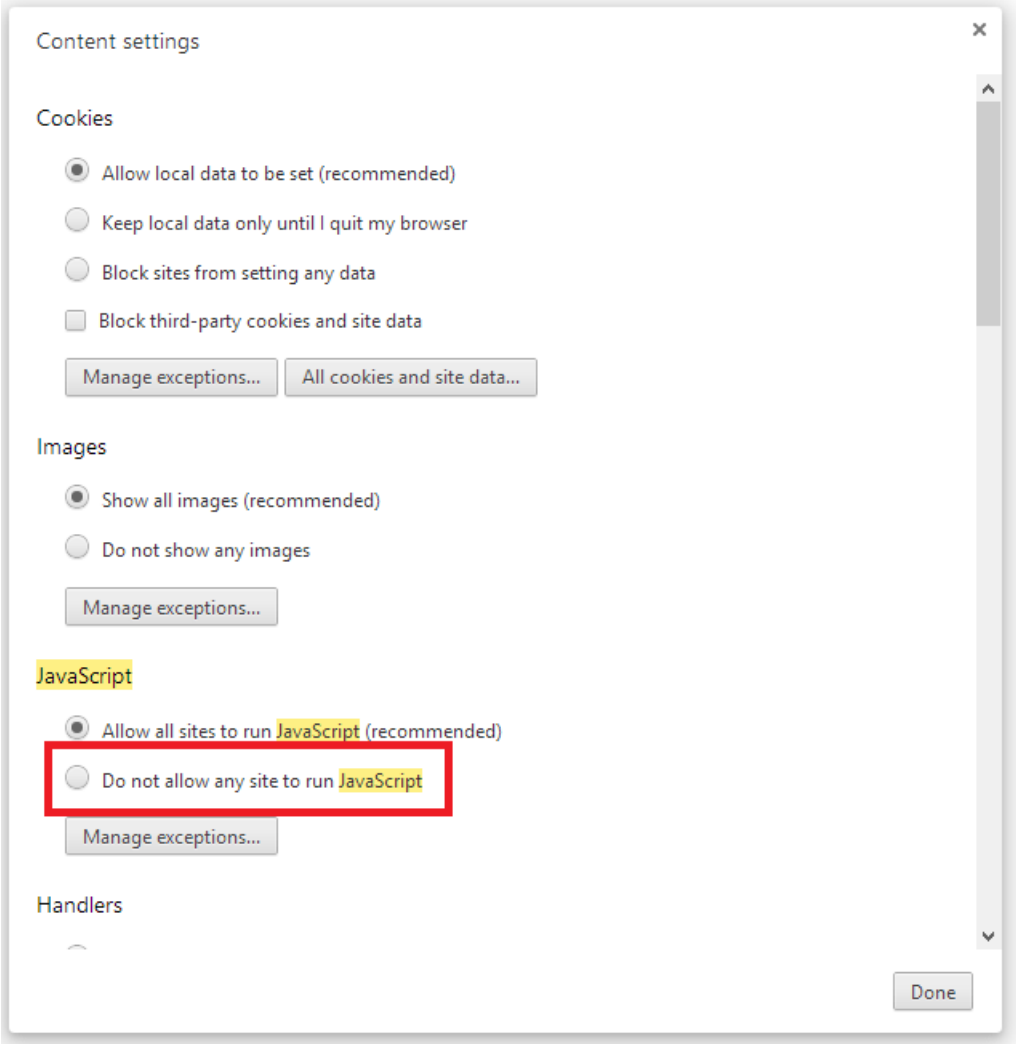
The first (HTTP GET) `Create` action method displays the initial Create form. The second (`[HttpPost]`) version handles the form post. The second `Create` method (The `[HttpPost]` version) calls `ModelState.IsValid` to check whether the movie has any validation errors. Calling this method evaluates any validation attributes that have been applied to the object. If the object has validation errors, the `Create` method re-displays the form. If there are no errors, the method saves the new movie in the database. In our movie example, the form isn't posted to the server when there are validation errors detected on the client side; the second `Create` method is never called when there are client side validation errors. If you disable JavaScript in your browser, client validation is disabled and you can test the HTTP POST `Create` method `ModelState.IsValid` detecting any validation errors.

You can set a break point in the `[HttpPost] Create` method and verify the method is never called, client side validation won't submit the form data when validation errors are detected. If you disable JavaScript in your browser, then submit the form with errors, the break point will be hit. You still get full validation without JavaScript.

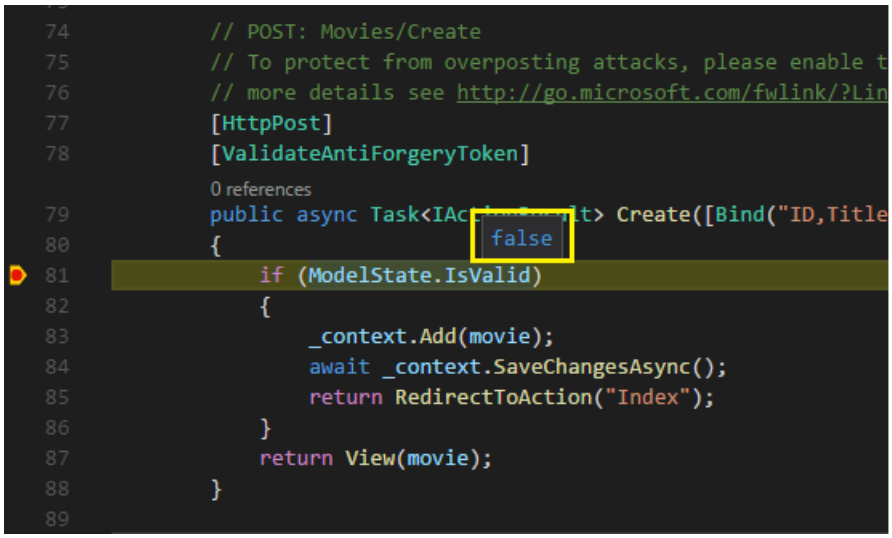
The following image shows how to disable JavaScript in the Firefox browser.



The following image shows how to disable JavaScript in the Chrome browser.



After you disable JavaScript, post invalid data and step through the debugger.



The portion of the *Create.cshtml* view template is shown in the following markup:

```
<h4>Movie</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Create">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Title" class="control-label"></label>
                <input asp-for="Title" class="form-control" />
                <span asp-validation-for="Title" class="text-danger"></span>
            </div>

        @*Markup removed for brevity.*@
```

The preceding markup is used by the action methods to display the initial form and to redisplay it in the event of an error.

The Input Tag Helper uses the DataAnnotations attributes and produces HTML attributes needed for jQuery Validation on the client side. The Validation Tag Helper displays validation errors. See Validation for more information.

What's really nice about this approach is that neither the controller nor the `Create` view template knows anything about the actual validation rules being enforced or about the specific error messages displayed. The validation rules and the error strings are specified only in the `Movie` class. These same validation rules are automatically applied to the `Edit` view and any other views templates you might create that edit your model.

When you need to change validation logic, you can do so in exactly one place by adding validation attributes to the model (in this example, the `Movie` class). You won't have to worry about different parts of the application being inconsistent with how the rules are enforced — all validation logic will be defined in one place and used everywhere. This keeps the code very clean, and makes it easy to maintain and evolve. And it means that you'll be fully honoring the DRY principle.

Using DataType Attributes

Open the *Movie.cs* file and examine the `Movie` class. The `System.ComponentModel.DataAnnotations` namespace provides formatting attributes in addition to the built-in set of validation attributes. We've already applied a `DataType` enumeration value to the release date and to the price fields. The following code shows the `ReleaseDate` and `Price` properties with the appropriate `DataType` attribute.

```
[Display(Name = "Release Date")]
[DataType(DataType.Date)]
public DateTime ReleaseDate { get; set; }

[Range(1, 100)]
[DataType(DataType.Currency)]
public decimal Price { get; set; }
```

The `DataType` attributes only provide hints for the view engine to format the data (and supplies elements/attributes such as `<a>` for URL's and `<a href="mailto:EmailAddress.com">` for email. You can use the `RegularExpression` attribute to validate the format of the data. The `DataType` attribute is used to specify a data type that's more specific than the database intrinsic type, they're not validation attributes. In this case we only want to keep track of the date, not the time. The `DataType` Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress and more. The `DataType` attribute can also enable the application to automatically provide type-specific features. For example, a `mailto:` link can be created for `DataType.EmailAddress`, and a date selector can be provided for `DataType.Date` in browsers that support HTML5. The `DataType` attributes emit HTML 5 `data-` (pronounced data dash) attributes that HTML 5 browsers can understand. The `DataType` attributes do **not** provide any validation.

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the data field is displayed according to the default formats based on the server's `CultureInfo`.

The `DisplayFormat` attribute is used to explicitly specify the date format:

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
public DateTime ReleaseDate { get; set; }
```

The `ApplyFormatInEditMode` setting specifies that the formatting should also be applied when the value is displayed in a text box for editing. (You might not want that for some fields — for example, for currency values, you probably don't want the currency symbol in the text box for editing.)

You can use the `DisplayFormat` attribute by itself, but it's generally a good idea to use the `DataType` attribute. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen, and provides the following benefits that you don't get with DisplayFormat:

- The browser can enable HTML5 features (for example to show a calendar control, the locale-appropriate currency symbol, email links, etc.)
- By default, the browser will render data using the correct format based on your locale.
- The `DataType` attribute can enable MVC to choose the right field template to render the data (the `DisplayFormat` if used by itself uses the string template).

> **NOTE**
> jQuery validation doesn't work with the `Range` attribute and `DateTime`. For example, the following code will always display a client side validation error, even when the date is in the specified range:
>
> `[Range(typeof(DateTime), "1/1/1966", "1/1/2020")]`

You will need to disable jQuery date validation to use the `Range` attribute with `DateTime`. It's generally not a good practice to compile hard dates in your models, so using the `Range` attribute and `DateTime` is discouraged.

The following code shows combining attributes on one line:

```
public class Movie
{
    public int Id { get; set; }

    [StringLength(60, MinimumLength = 3)]
    public string Title { get; set; }

    [Display(Name = "Release Date"), DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z]*$"), Required, StringLength(30)]
    public string Genre { get; set; }

    [Range(1, 100), DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$"), StringLength(5)]
    public string Rating { get; set; }
}
```

In the next part of the series, we review the app and make some improvements to the automatically generated `Details` and `Delete` methods.

Part 10, examine the Details and Delete methods of an ASP.NET Core app

9/22/2020 • 3 minutes to read • Edit Online

By Rick Anderson

Open the Movie controller and examine the `Details` method:

```
// GET: Movies/Details/5
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie
        .FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }

    return View(movie);
}
```

The MVC scaffolding engine that created this action method adds a comment showing an HTTP request that invokes the method. In this case it's a GET request with three URL segments, the `Movies` controller, the `Details` method, and an `id` value. Recall these segments are defined in *Startup.cs*.

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(
        name: "default",
        pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

EF makes it easy to search for data using the `FirstOrDefaultAsync` method. An important security feature built into the method is that the code verifies that the search method has found a movie before it tries to do anything with it. For example, a hacker could introduce errors into the site by changing the URL created by the links from `http://localhost:{PORT}/Movies/Details/1` to something like `http://localhost:{PORT}/Movies/Details/12345` (or some other value that doesn't represent an actual movie). If you didn't check for a null movie, the app would throw an exception.

Examine the `Delete` and `DeleteConfirmed` methods.

```
// GET: Movies/Delete/5
public async Task<IActionResult> Delete(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie
        .FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }

    return View(movie);
}

// POST: Movies/Delete/5
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    var movie = await _context.Movie.FindAsync(id);
    _context.Movie.Remove(movie);
    await _context.SaveChangesAsync();
    return RedirectToAction(nameof(Index));
}
```

Note that the `HTTP GET Delete` method doesn't delete the specified movie, it returns a view of the movie where you can submit (HttpPost) the deletion. Performing a delete operation in response to a GET request (or for that matter, performing an edit operation, create operation, or any other operation that changes data) opens up a security hole.

The `[HttpPost]` method that deletes the data is named `DeleteConfirmed` to give the HTTP POST method a unique signature or name. The two method signatures are shown below:

```
// GET: Movies/Delete/5
public async Task<IActionResult> Delete(int? id)
{
```

```
// POST: Movies/Delete/5
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
```

The common language runtime (CLR) requires overloaded methods to have a unique parameter signature (same method name but different list of parameters). However, here you need two `Delete` methods -- one for GET and one for POST -- that both have the same parameter signature. (They both need to accept a single integer as a parameter.)

There are two approaches to this problem, one is to give the methods different names. That's what the scaffolding mechanism did in the preceding example. However, this introduces a small problem: ASP.NET maps segments of a URL to action methods by name, and if you rename a method, routing normally wouldn't be able to find that method. The solution is what you see in the example, which is to add the `ActionName("Delete")` attribute to the `DeleteConfirmed` method. That attribute performs mapping for the routing system so that a URL that includes /Delete/ for a POST request will find the `DeleteConfirmed` method.

Another common work around for methods that have identical names and signatures is to artificially change the signature of the POST method to include an extra (unused) parameter. That's what we did in a previous post when we added the `notUsed` parameter. You could do the same thing here for the `[HttpPost] Delete` method:

```
// POST: Movies/Delete/6
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Delete(int id, bool notUsed)
```

Views in ASP.NET Core MVC

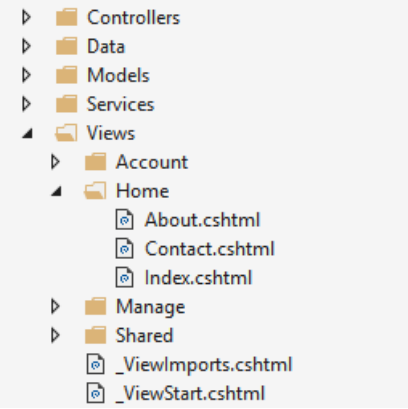
9/22/2020 • 13 minutes to read • Edit Online

By Steve Smith

This document explains views used in ASP.NET Core MVC applications. For information on Razor Pages, see Introduction to Razor Pages.

In the Model-View-Controller (MVC) pattern, the *view* handles the app's data presentation and user interaction. A view is an HTML template with embedded Razor markup. Razor markup is code that interacts with HTML markup to produce a webpage that's sent to the client.

In ASP.NET Core MVC, views are *.cshtml* files that use the C# programming language in Razor markup. Usually, view files are grouped into folders named for each of the app's controllers. The folders are stored in a *Views* folder at the root of the app:



The *Home* controller is represented by a *Home* folder inside the *Views* folder. The *Home* folder contains the views for the *About*, *Contact*, and *Index* (homepage) webpages. When a user requests one of these three webpages, controller actions in the *Home* controller determine which of the three views is used to build and return a webpage to the user.

Use layouts to provide consistent webpage sections and reduce code repetition. Layouts often contain the header, navigation and menu elements, and the footer. The header and footer usually contain boilerplate markup for many metadata elements and links to script and style assets. Layouts help you avoid this boilerplate markup in your views.

Partial views reduce code duplication by managing reusable parts of views. For example, a partial view is useful for an author biography on a blog website that appears in several views. An author biography is ordinary view content and doesn't require code to execute in order to produce the content for the webpage. Author biography content is available to the view by model binding alone, so using a partial view for this type of content is ideal.

View components are similar to partial views in that they allow you to reduce repetitive code, but they're appropriate for view content that requires code to run on the server in order to render the webpage. View components are useful when the rendered content requires database interaction, such as for a website shopping cart. View components aren't limited to model binding in order to produce webpage output.

Benefits of using views

Views help to establish separation of concerns within an MVC app by separating the user interface markup from other parts of the app. Following SoC design makes your app modular, which provides several benefits:

- The app is easier to maintain because it's better organized. Views are generally grouped by app feature. This makes it easier to find related views when working on a feature.
- The parts of the app are loosely coupled. You can build and update the app's views separately from the business logic and data access components. You can modify the views of the app without necessarily having to update other parts of the app.
- It's easier to test the user interface parts of the app because the views are separate units.
- Due to better organization, it's less likely that you'll accidentally repeat sections of the user interface.

Creating a view

Views that are specific to a controller are created in the *Views/[ControllerName]* folder. Views that are shared among controllers are placed in the *Views/Shared* folder. To create a view, add a new file and give it the same name as its associated controller action with the *.cshtml* file extension. To create a view that corresponds with the *About* action in the *Home* controller, create an *About.cshtml* file in the *Views/Home* folder:

```
@{
    ViewData["Title"] = "About";
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<p>Use this area to provide additional information.</p>
```

Razor markup starts with the `@` symbol. Run C# statements by placing C# code within Razor code blocks set off by curly braces (`{ ... }`). For example, see the assignment of "About" to `ViewData["Title"]` shown above. You can display values within HTML by simply referencing the value with the `@` symbol. See the contents of the `<h2>` and `<h3>` elements above.

The view content shown above is only part of the entire webpage that's rendered to the user. The rest of the page's layout and other common aspects of the view are specified in other view files. To learn more, see the Layout topic.

How controllers specify views

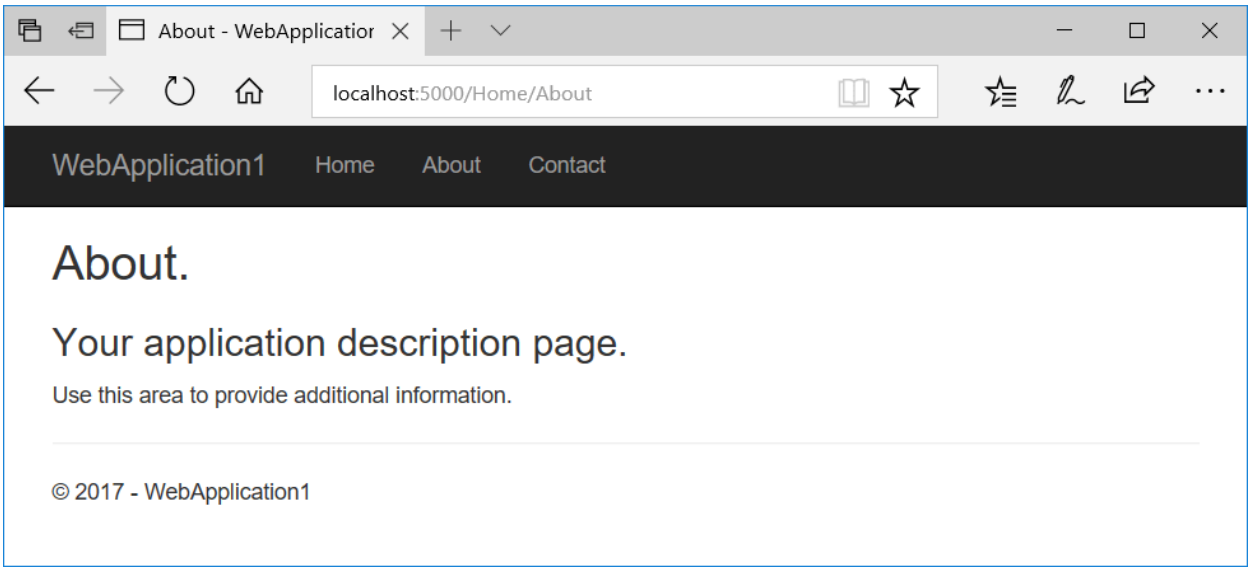
Views are typically returned from actions as a ViewResult, which is a type of ActionResult. Your action method can create and return a `ViewResult` directly, but that isn't commonly done. Since most controllers inherit from Controller, you simply use the `View` helper method to return the `ViewResult`:

HomeController.cs

```
public IActionResult About()
{
    ViewData["Message"] = "Your application description page.";

    return View();
}
```

When this action returns, the *About.cshtml* view shown in the last section is rendered as the following webpage:



The `View` helper method has several overloads. You can optionally specify:

- An explicit view to return:

```
return View("Orders");
```

- A model to pass to the view:

```
return View(Orders);
```

- Both a view and a model:

```
return View("Orders", Orders);
```

View discovery

When an action returns a view, a process called *view discovery* takes place. This process determines which view file is used based on the view name.

The default behavior of the `View` method (`return View();`) is to return a view with the same name as the action method from which it's called. For example, the *About* `ActionResult` method name of the controller is used to search for a view file named *About.cshtml*. First, the runtime looks in the *Views/[ControllerName]* folder for the view. If it doesn't find a matching view there, it searches the *Shared* folder for the view.

It doesn't matter if you implicitly return the `ViewResult` with `return View();` or explicitly pass the view name to the `View` method with `return View("<ViewName>");`. In both cases, view discovery searches for a matching view file in this order:

1. *Views/[ControllerName]/[ViewName].cshtml*
2. *Views/Shared/[ViewName].cshtml*

A view file path can be provided instead of a view name. If using an absolute path starting at the app root (optionally starting with "/" or "~/"), the *.cshtml* extension must be specified:

```
return View("Views/Home/About.cshtml");
```

You can also use a relative path to specify views in different directories without the *.cshtml* extension. Inside the `HomeController`, you can return the *Index* view of your *Manage* views with a relative path:

```
return View("../Manage/Index");
```

Similarly, you can indicate the current controller-specific directory with the "./" prefix:

```
return View("./About");
```

Partial views and view components use similar (but not identical) discovery mechanisms.

You can customize the default convention for how views are located within the app by using a custom IViewLocationExpander.

View discovery relies on finding view files by file name. If the underlying file system is case sensitive, view names are probably case sensitive. For compatibility across operating systems, match case between controller and action names and associated view folders and file names. If you encounter an error that a view file can't be found while working with a case-sensitive file system, confirm that the casing matches between the requested view file and the actual view file name.

Follow the best practice of organizing the file structure for your views to reflect the relationships among controllers, actions, and views for maintainability and clarity.

Passing data to views

Pass data to views using several approaches:

- Strongly typed data: viewmodel
- Weakly typed data
  - `ViewData` (`ViewDataAttribute`)
  - `ViewBag`

Strongly typed data (viewmodel)

The most robust approach is to specify a model type in the view. This model is commonly referred to as a *viewmodel*. You pass an instance of the viewmodel type to the view from the action.

Using a viewmodel to pass data to a view allows the view to take advantage of *strong* type checking. *Strong typing* (or *strongly typed*) means that every variable and constant has an explicitly defined type (for example, `string` , `int` , or `DateTime`). The validity of types used in a view is checked at compile time.

Visual Studio and Visual Studio Code list strongly typed class members using a feature called IntelliSense. When you want to see the properties of a viewmodel, type the variable name for the viewmodel followed by a period (`.`). This helps you write code faster with fewer errors.

Specify a model using the `@model` directive. Use the model with `@Model` :

```
@model WebApplication1.ViewModels.Address

<h2>Contact</h2>
<address>
    @Model.Street<br>
    @Model.City, @Model.State @Model.PostalCode<br>
    <abbr title="Phone">P:</abbr> 425.555.0100
</address>
```

To provide the model to the view, the controller passes it as a parameter:

```
public IActionResult Contact()
{
    ViewData["Message"] = "Your contact page.";

    var viewModel = new Address()
    {
        Name = "Microsoft",
        Street = "One Microsoft Way",
        City = "Redmond",
        State = "WA",
        PostalCode = "98052-6399"
    };

    return View(viewModel);
}
```

There are no restrictions on the model types that you can provide to a view. We recommend using Plain Old CLR Object (POCO) viewmodels with little or no behavior (methods) defined. Usually, viewmodel classes are either stored in the *Models* folder or a separate *ViewModels* folder at the root of the app. The *Address* viewmodel used in the example above is a POCO viewmodel stored in a file named *Address.cs*:

```
namespace WebApplication1.ViewModels
{
    public class Address
    {
        public string Name { get; set; }
        public string Street { get; set; }
        public string City { get; set; }
        public string State { get; set; }
        public string PostalCode { get; set; }
    }
}
```

Nothing prevents you from using the same classes for both your viewmodel types and your business model types. However, using separate models allows your views to vary independently from the business logic and data access parts of your app. Separation of models and viewmodels also offers security benefits when models use model binding and validation for data sent to the app by the user.

Weakly typed data (ViewData, ViewData attribute, and ViewBag)

`ViewBag` *isn't available in Razor Pages.*

In addition to strongly typed views, views have access to a *weakly typed* (also called *loosely typed*) collection of data. Unlike strong types, *weak types* (or *loose types*) means that you don't explicitly declare the type of data you're using. You can use the collection of weakly typed data for passing small amounts of data in and out of controllers and views.

PASSING DATA BETWEEN A ...	EXAMPLE
Controller and a view	Populating a dropdown list with data.
View and a layout view	Setting the **<title>** element content in the layout view from a view file.
Partial view and a view	A widget that displays data based on the webpage that the user requested.

This collection can be referenced through either the `ViewData` or `ViewBag` properties on controllers and views. The `ViewData` property is a dictionary of weakly typed objects. The `ViewBag` property is a wrapper around

`ViewData` that provides dynamic properties for the underlying `ViewData` collection. Note: Key lookups are case-insensitive for both `ViewData` and `ViewBag`.

`ViewData` and `ViewBag` are dynamically resolved at runtime. Since they don't offer compile-time type checking, both are generally more error-prone than using a viewmodel. For that reason, some developers prefer to minimally or never use `ViewData` and `ViewBag`.

ViewData

`ViewData` is a ViewDataDictionary object accessed through `string` keys. String data can be stored and used directly without the need for a cast, but you must cast other `ViewData` object values to specific types when you extract them. You can use `ViewData` to pass data from controllers to views and within views, including partial views and layouts.

The following is an example that sets values for a greeting and an address using `ViewData` in an action:

```
public IActionResult SomeAction()
{
    ViewData["Greeting"] = "Hello";
    ViewData["Address"]  = new Address()
    {
        Name = "Steve",
        Street = "123 Main St",
        City = "Hudson",
        State = "OH",
        PostalCode = "44236"
    };

    return View();
}
```

Work with the data in a view:

```
@{
    // Since Address isn't a string, it requires a cast.
    var address = ViewData["Address"] as Address;
}

@ViewData["Greeting"] World!

<address>
    @address.Name<br>
    @address.Street<br>
    @address.City, @address.State @address.PostalCode
</address>
```

ViewData attribute

Another approach that uses the ViewDataDictionary is ViewDataAttribute. Properties on controllers or Razor Page models marked with the `[ViewData]` attribute have their values stored and loaded from the dictionary.

In the following example, the Home controller contains a `Title` property marked with `[ViewData]`. The `About` method sets the title for the About view:

```
public class HomeController : Controller
{
    [ViewData]
    public string Title { get; set; }

    public IActionResult About()
    {
        Title = "About Us";
        ViewData["Message"] = "Your application description page.";

        return View();
    }
}
```

In the layout, the title is read from the ViewData dictionary:

```
<!DOCTYPE html>
<html lang="en">
<head>
    <title>@ViewData["Title"] - WebApplication</title>
    ...
```

ViewBag

`ViewBag` *isn't available in Razor Pages.*

`ViewBag` is a DynamicViewData object that provides dynamic access to the objects stored in `ViewData`. `ViewBag` can be more convenient to work with, since it doesn't require casting. The following example shows how to use `ViewBag` with the same result as using `ViewData` above:

```
public IActionResult SomeAction()
{
    ViewBag.Greeting = "Hello";
    ViewBag.Address  = new Address()
    {
        Name = "Steve",
        Street = "123 Main St",
        City = "Hudson",
        State = "OH",
        PostalCode = "44236"
    };

    return View();
}
```

```
@ViewBag.Greeting World!

<address>
    @ViewBag.Address.Name<br>
    @ViewBag.Address.Street<br>
    @ViewBag.Address.City, @ViewBag.Address.State @ViewBag.Address.PostalCode
</address>
```

Using ViewData and ViewBag simultaneously

`ViewBag` *isn't available in Razor Pages.*

Since `ViewData` and `ViewBag` refer to the same underlying `ViewData` collection, you can use both `ViewData` and `ViewBag` and mix and match between them when reading and writing values.

Set the title using `ViewBag` and the description using `ViewData` at the top of an *About.cshtml* view:

```
@{
    Layout = "/Views/Shared/_Layout.cshtml";
    ViewBag.Title = "About Contoso";
    ViewData["Description"] = "Let us tell you about Contoso's philosophy and mission.";
}
```

Read the properties but reverse the use of `ViewData` and `ViewBag`. In the *_Layout.cshtml* file, obtain the title using `ViewData` and obtain the description using `ViewBag`:

```
<!DOCTYPE html>
<html lang="en">
<head>
    <title>@ViewData["Title"]</title>
    <meta name="description" content="@ViewBag.Description">
    ...
```

Remember that strings don't require a cast for `ViewData`. You can use `@ViewData["Title"]` without casting.

Using both `ViewData` and `ViewBag` at the same time works, as does mixing and matching reading and writing the properties. The following markup is rendered:

```
<!DOCTYPE html>
<html lang="en">
<head>
    <title>About Contoso</title>
    <meta name="description" content="Let us tell you about Contoso's philosophy and mission.">
    ...
```

Summary of the differences between ViewData and ViewBag

`ViewBag` isn't available in the Razor Pages.

- `ViewData`
  - Derives from ViewDataDictionary, so it has dictionary properties that can be useful, such as `ContainsKey`, `Add`, `Remove`, and `Clear`.
  - Keys in the dictionary are strings, so whitespace is allowed. Example: `ViewData["Some Key With Whitespace"]`
  - Any type other than a `string` must be cast in the view to use `ViewData`.
- `ViewBag`
  - Derives from DynamicViewData, so it allows the creation of dynamic properties using dot notation (`@ViewBag.SomeKey = <value or object>`), and no casting is required. The syntax of `ViewBag` makes it quicker to add to controllers and views.
  - Simpler to check for null values. Example: `@ViewBag.Person?.Name`

When to use ViewData or ViewBag

Both `ViewData` and `ViewBag` are equally valid approaches for passing small amounts of data among controllers and views. The choice of which one to use is based on preference. You can mix and match `ViewData` and `ViewBag` objects, however, the code is easier to read and maintain with one approach used consistently. Both approaches are dynamically resolved at runtime and thus prone to causing runtime errors. Some development teams avoid them.

Dynamic views

Views that don't declare a model type using `@model` but that have a model instance passed to them (for example, `return View(Address);`) can reference the instance's properties dynamically:

```
<address>
    @Model.Street<br>
    @Model.City, @Model.State @Model.PostalCode<br>
    <abbr title="Phone">P:</abbr> 425.555.0100
</address>
```

This feature offers flexibility but doesn't offer compilation protection or IntelliSense. If the property doesn't exist, webpage generation fails at runtime.

More view features

Tag Helpers make it easy to add server-side behavior to existing HTML tags. Using Tag Helpers avoids the need to write custom code or helpers within your views. Tag helpers are applied as attributes to HTML elements and are ignored by editors that can't process them. This allows you to edit and render view markup in a variety of tools.

Generating custom HTML markup can be achieved with many built-in HTML Helpers. More complex user interface logic can be handled by View Components. View components provide the same SoC that controllers and views offer. They can eliminate the need for actions and views that deal with data used by common user interface elements.

Like many other aspects of ASP.NET Core, views support dependency injection, allowing services to be injected into views.

Partial views in ASP.NET Core

9/22/2020 • 8 minutes to read • Edit Online

By Steve Smith, Maher JENDOUBI, Rick Anderson, and Scott Sauber

A partial view is a Razor markup file (*.cshtml*) that renders HTML output *within* another markup file's rendered output.

The term *partial view* is used when developing either an MVC app, where markup files are called *views*, or a Razor Pages app, where markup files are called *pages*. This topic generically refers to MVC views and Razor Pages pages as *markup files*.

View or download sample code (how to download)

When to use partial views

Partial views are an effective way to:

- Break up large markup files into smaller components.

  In a large, complex markup file composed of several logical pieces, there's an advantage to working with each piece isolated into a partial view. The code in the markup file is manageable because the markup only contains the overall page structure and references to partial views.

- Reduce the duplication of common markup content across markup files.

  When the same markup elements are used across markup files, a partial view removes the duplication of markup content into one partial view file. When the markup is changed in the partial view, it updates the rendered output of the markup files that use the partial view.

Partial views shouldn't be used to maintain common layout elements. Common layout elements should be specified in _Layout.cshtml files.

Don't use a partial view where complex rendering logic or code execution is required to render the markup. Instead of a partial view, use a view component.

Declare partial views

A partial view is a *.cshtml* markup file maintained within the *Views* folder (MVC) or *Pages* folder (Razor Pages).

In ASP.NET Core MVC, a controller's ViewResult is capable of returning either a view or a partial view. In Razor Pages, a PageModel can return a partial view represented as a PartialViewResult object. Referencing and rendering partial views is described in the Reference a partial view section.

Unlike MVC view or page rendering, a partial view doesn't run *_ViewStart.cshtml*. For more information on *_ViewStart.cshtml*, see Layout in ASP.NET Core.

Partial view file names often begin with an underscore (`_`). This naming convention isn't required, but it helps to visually differentiate partial views from views and pages.

A partial view is a *.cshtml* markup file maintained within the *Views* folder.

A controller's ViewResult is capable of returning either a view or a partial view. Referencing and rendering partial views is described in the Reference a partial view section.

Unlike MVC view rendering, a partial view doesn't run *_ViewStart.cshtml*. For more information on *_ViewStart.cshtml*, see Layout in ASP.NET Core.

Partial view file names often begin with an underscore (`_`). This naming convention isn't required, but it helps to visually differentiate partial views from views.

Reference a partial view

Use a partial view in a Razor Pages PageModel

In ASP.NET Core 2.0 or 2.1, the following handler method renders the *_AuthorPartialRP.cshtml* partial view to the response:

```
public IActionResult OnGetPartial() =>
    new PartialViewResult
    {
        ViewName = "_AuthorPartialRP",
        ViewData = ViewData,
    };
```

In ASP.NET Core 2.2 or later, a handler method can alternatively call the Partial method to produce a `PartialViewResult` object:

```
public IActionResult OnGetPartial() =>
    Partial("_AuthorPartialRP");
```

Use a partial view in a markup file

Within a markup file, there are several ways to reference a partial view. We recommend that apps use one of the following asynchronous rendering approaches:

- Partial Tag Helper
- Asynchronous HTML Helper

Within a markup file, there are two ways to reference a partial view:

- Asynchronous HTML Helper
- Synchronous HTML Helper

We recommend that apps use the Asynchronous HTML Helper.

Partial Tag Helper

The Partial Tag Helper requires ASP.NET Core 2.1 or later.

The Partial Tag Helper renders content asynchronously and uses an HTML-like syntax:

```
<partial name="_PartialName" />
```

When a file extension is present, the Tag Helper references a partial view that must be in the same folder as the markup file calling the partial view:

```
<partial name="_PartialName.cshtml" />
```

The following example references a partial view from the app root. Paths that start with a tilde-slash (`~/`) or a slash (`/`) refer to the app root:

Razor Pages

```
<partial name="~/Pages/Folder/_PartialName.cshtml" />
<partial name="/Pages/Folder/_PartialName.cshtml" />
```

MVC

```
<partial name="~/Views/Folder/_PartialName.cshtml" />
<partial name="/Views/Folder/_PartialName.cshtml" />
```

The following example references a partial view with a relative path:

```
<partial name="../Account/_PartialName.cshtml" />
```

For more information, see Partial Tag Helper in ASP.NET Core.

Asynchronous HTML Helper

When using an HTML Helper, the best practice is to use PartialAsync. `PartialAsync` returns an IHtmlContent type wrapped in a Task<TResult>. The method is referenced by prefixing the awaited call with an `@` character:

```
@await Html.PartialAsync("_PartialName")
```

When the file extension is present, the HTML Helper references a partial view that must be in the same folder as the markup file calling the partial view:

```
@await Html.PartialAsync("_PartialName.cshtml")
```

The following example references a partial view from the app root. Paths that start with a tilde-slash (`~/`) or a slash (`/`) refer to the app root:

Razor Pages

```
@await Html.PartialAsync("~/Pages/Folder/_PartialName.cshtml")
@await Html.PartialAsync("/Pages/Folder/_PartialName.cshtml")
```

MVC

```
@await Html.PartialAsync("~/Views/Folder/_PartialName.cshtml")
@await Html.PartialAsync("/Views/Folder/_PartialName.cshtml")
```

The following example references a partial view with a relative path:

```
@await Html.PartialAsync("../Account/_LoginPartial.cshtml")
```

Alternatively, you can render a partial view with RenderPartialAsync. This method doesn't return an IHtmlContent. It streams the rendered output directly to the response. Because the method doesn't return a result, it must be called within a Razor code block:

```
@{
    await Html.RenderPartialAsync("_AuthorPartial");
}
```

Since `RenderPartialAsync` streams rendered content, it provides better performance in some scenarios. In performance-critical situations, benchmark the page using both approaches and use the approach that generates a faster response.

Synchronous HTML Helper

Partial and RenderPartial are the synchronous equivalents of `PartialAsync` and `RenderPartialAsync`, respectively. The synchronous equivalents aren't recommended because there are scenarios in which they deadlock. The synchronous methods are targeted for removal in a future release.

> **IMPORTANT**
> If you need to execute code, use a view component instead of a partial view.

Calling `Partial` or `RenderPartial` results in a Visual Studio analyzer warning. For example, the presence of `Partial` yields the following warning message:

> Use of IHtmlHelper.Partial may result in application deadlocks. Consider using <partial> Tag Helper or IHtmlHelper.PartialAsync.

Replace calls to `@Html.Partial` with `@await Html.PartialAsync` or the Partial Tag Helper. For more information on Partial Tag Helper migration, see Migrate from an HTML Helper.

Partial view discovery

When a partial view is referenced by name without a file extension, the following locations are searched in the stated order:

Razor Pages

1. Currently executing page's folder
2. Directory graph above the page's folder
3. `/Shared`
4. `/Pages/Shared`
5. `/Views/Shared`

MVC

1. `/Areas/<Area-Name>/Views/<Controller-Name>`
2. `/Areas/<Area-Name>/Views/Shared`
3. `/Views/Shared`
4. `/Pages/Shared`

1. `/Areas/<Area-Name>/Views/<Controller-Name>`
2. `/Areas/<Area-Name>/Views/Shared`
3. `/Views/Shared`

The following conventions apply to partial view discovery:

- Different partial views with the same file name are allowed when the partial views are in different folders.

- When referencing a partial view by name without a file extension and the partial view is present in both the caller's folder and the *Shared* folder, the partial view in the caller's folder supplies the partial view. If the partial view isn't present in the caller's folder, the partial view is provided from the *Shared* folder. Partial views in the *Shared* folder are called *shared partial views* or *default partial views*.
- Partial views can be *chained*—a partial view can call another partial view if a circular reference isn't formed by the calls. Relative paths are always relative to the current file, not to the root or parent of the file.

> **NOTE**
>
> A Razor `section` defined in a partial view is invisible to parent markup files. The `section` is only visible to the partial view in which it's defined.

Access data from partial views

When a partial view is instantiated, it receives a *copy* of the parent's `ViewData` dictionary. Updates made to the data within the partial view aren't persisted to the parent view. `ViewData` changes in a partial view are lost when the partial view returns.

The following example demonstrates how to pass an instance of ViewDataDictionary to a partial view:

```
@await Html.PartialAsync("_PartialName", customViewData)
```

You can pass a model into a partial view. The model can be a custom object. You can pass a model with `PartialAsync` (renders a block of content to the caller) or `RenderPartialAsync` (streams the content to the output):

```
@await Html.PartialAsync("_PartialName", model)
```

Razor Pages

The following markup in the sample app is from the *Pages/ArticlesRP/ReadRP.cshtml* page. The page contains two partial views. The second partial view passes in a model and `ViewData` to the partial view. The `ViewDataDictionary` constructor overload is used to pass a new `ViewData` dictionary while retaining the existing `ViewData` dictionary.

```
@model ReadRPModel

<h2>@Model.Article.Title</h2>
@* Pass the author's name to Pages\Shared\_AuthorPartialRP.cshtml *@
@await Html.PartialAsync("../Shared/_AuthorPartialRP", Model.Article.AuthorName)
@Model.Article.PublicationDate

@* Loop over the Sections and pass in a section and additional ViewData to
   the strongly typed Pages\ArticlesRP\_ArticleSectionRP.cshtml partial view. *@
@{
    var index = 0;

    foreach (var section in Model.Article.Sections)
    {
        await Html.PartialAsync("_ArticleSectionRP",
                                section,
                                new ViewDataDictionary(ViewData)
                                {
                                    { "index", index }
                                });

        index++;
    }
}
```

Pages/Shared/_AuthorPartialRP.cshtml is the first partial view referenced by the *ReadRP.cshtml* markup file:

```
@model string
<div>
    <h3>@Model</h3>
    This partial view from /Pages/Shared/_AuthorPartialRP.cshtml.
</div>
```

Pages/ArticlesRP/_ArticleSectionRP.cshtml is the second partial view referenced by the *ReadRP.cshtml* markup file:

```
@using PartialViewsSample.ViewModels
@model ArticleSection

<h3>@Model.Title Index: @ViewData["index"]</h3>
<div>
    @Model.Content
</div>
```

MVC

The following markup in the sample app shows the *Views/Articles/Read.cshtml* view. The view contains two partial views. The second partial view passes in a model and `ViewData` to the partial view. The `ViewDataDictionary` constructor overload is used to pass a new `ViewData` dictionary while retaining the existing `ViewData` dictionary.

```
@model PartialViewsSample.ViewModels.Article

<h2>@Model.Title</h2>
@* Pass the author's name to Views\Shared\_AuthorPartial.cshtml *@
@await Html.PartialAsync("_AuthorPartial", Model.AuthorName)
@Model.PublicationDate

@* Loop over the Sections and pass in a section and additional ViewData to
   the strongly typed Views\Articles\_ArticleSection.cshtml partial view. *@
@{
    var index = 0;

    foreach (var section in Model.Sections)
    {
        await Html.PartialAsync("_ArticleSection",
                                section,
                                new ViewDataDictionary(ViewData)
                                {
                                    { "index", index }
                                });

        index++;
    }
}
```

Views/Shared/_AuthorPartial.cshtml is the first partial view referenced by the *Read.cshtml* markup file:

```
@model string
<div>
    <h3>@Model</h3>
    This partial view from /Views/Shared/_AuthorPartial.cshtml.
</div>
```

Views/Articles/_ArticleSection.cshtml is the second partial view referenced by the *Read.cshtml* markup file:

```
@using PartialViewsSample.ViewModels
@model ArticleSection

<h3>@Model.Title Index: @ViewData["index"]</h3>
<div>
    @Model.Content
</div>
```

At runtime, the partials are rendered into the parent markup file's rendered output, which itself is rendered within the shared *_Layout.cshtml*. The first partial view renders the article author's name and publication date:

> Abraham Lincoln
>
> This partial view from <shared partial view file path>. 11/19/1863 12:00:00 AM

The second partial view renders the article's sections:

> Section One Index: 0
>
> Four score and seven years ago ...
>
> Section Two Index: 1
>
> Now we are engaged in a great civil war, testing ...
>
> Section Three Index: 2

> But, in a larger sense, we can not dedicate ...

Handle requests with controllers in ASP.NET Core MVC

9/22/2020 • 4 minutes to read • Edit Online

By Steve Smith and Scott Addie

Controllers, actions, and action results are a fundamental part of how developers build apps using ASP.NET Core MVC.

What is a Controller?

A controller is used to define and group a set of actions. An action (or *action method*) is a method on a controller which handles requests. Controllers logically group similar actions together. This aggregation of actions allows common sets of rules, such as routing, caching, and authorization, to be applied collectively. Requests are mapped to actions through routing.

By convention, controller classes:

- Reside in the project's root-level *Controllers* folder.
- Inherit from `Microsoft.AspNetCore.Mvc.Controller`.

A controller is an instantiable class in which at least one of the following conditions is true:

- The class name is suffixed with `Controller`.
- The class inherits from a class whose name is suffixed with `Controller`.
- The `[Controller]` attribute is applied to the class.

A controller class must not have an associated `[NonController]` attribute.

Controllers should follow the Explicit Dependencies Principle. There are a couple of approaches to implementing this principle. If multiple controller actions require the same service, consider using constructor injection to request those dependencies. If the service is needed by only a single action method, consider using Action Injection to request the dependency.

Within the **M**odel-**V**iew-**C**ontroller pattern, a controller is responsible for the initial processing of the request and instantiation of the model. Generally, business decisions should be performed within the model.

The controller takes the result of the model's processing (if any) and returns either the proper view and its associated view data or the result of the API call. Learn more at Overview of ASP.NET Core MVC and Get started with ASP.NET Core MVC and Visual Studio.

The controller is a *UI-level* abstraction. Its responsibilities are to ensure request data is valid and to choose which view (or result for an API) should be returned. In well-factored apps, it doesn't directly include data access or business logic. Instead, the controller delegates to services handling these responsibilities.

Defining Actions

Public methods on a controller, except those with the `[NonAction]` attribute, are actions. Parameters on actions are bound to request data and are validated using model binding. Model validation occurs for everything that's model-bound. The `ModelState.IsValid` property value indicates whether model binding and validation succeeded.

Action methods should contain logic for mapping a request to a business concern. Business concerns should typically be represented as services that the controller accesses through dependency injection. Actions then map the result of the business action to an application state.

Actions can return anything, but frequently return an instance of `IActionResult` (or `Task<IActionResult>` for async methods) that produces a response. The action method is responsible for choosing *what kind of response*. The action result *does the responding*.

Controller Helper Methods

Controllers usually inherit from Controller, although this isn't required. Deriving from `Controller` provides access to three categories of helper methods:

1. Methods resulting in an empty response body

No `Content-Type` HTTP response header is included, since the response body lacks content to describe.

There are two result types within this category: Redirect and HTTP Status Code.

- HTTP Status Code

  This type returns an HTTP status code. A couple of helper methods of this type are `BadRequest`, `NotFound`, and `Ok`. For example, `return BadRequest();` produces a 400 status code when executed. When methods such as `BadRequest`, `NotFound`, and `Ok` are overloaded, they no longer qualify as HTTP Status Code responders, since content negotiation is taking place.

- Redirect

  This type returns a redirect to an action or destination (using `Redirect`, `LocalRedirect`, `RedirectToAction`, or `RedirectToRoute`). For example, `return RedirectToAction("Complete", new {id = 123});` redirects to `Complete`, passing an anonymous object.

  The Redirect result type differs from the HTTP Status Code type primarily in the addition of a `Location` HTTP response header.

2. Methods resulting in a non-empty response body with a predefined content type

Most helper methods in this category include a `ContentType` property, allowing you to set the `Content-Type` response header to describe the response body.

There are two result types within this category: View and Formatted Response.

- View

  This type returns a view which uses a model to render HTML. For example, `return View(customer);` passes a model to the view for data-binding.

- Formatted Response

  This type returns JSON or a similar data exchange format to represent an object in a specific manner. For example, `return Json(customer);` serializes the provided object into JSON format.

  Other common methods of this type include `File` and `PhysicalFile`. For example, `return PhysicalFile(customerFilePath, "text/xml");` returns PhysicalFileResult.

3. Methods resulting in a non-empty response body formatted in a content type negotiated with the client

This category is better known as **Content Negotiation**. Content negotiation applies whenever an action returns an ObjectResult type or something other than an IActionResult implementation. An action that returns a non-`IActionResult` implementation (for example, `object`) also returns a Formatted Response.

Some helper methods of this type include `BadRequest`, `CreatedAtRoute`, and `Ok`. Examples of these methods include `return BadRequest(modelState);`, `return CreatedAtRoute("routename", values, newobject);`, and

`return Ok(value);`, respectively. Note that `BadRequest` and `Ok` perform content negotiation only when passed a value; without being passed a value, they instead serve as HTTP Status Code result types. The `CreatedAtRoute` method, on the other hand, always performs content negotiation since its overloads all require that a value be passed.

Cross-Cutting Concerns

Applications typically share parts of their workflow. Examples include an app that requires authentication to access the shopping cart, or an app that caches data on some pages. To perform logic before or after an action method, use a *filter*. Using Filters on cross-cutting concerns can reduce duplication.

Most filter attributes, such as `[Authorize]`, can be applied at the controller or action level depending upon the desired level of granularity.

Error handling and response caching are often cross-cutting concerns:

- Handle errors
- Response Caching

Many cross-cutting concerns can be handled using filters or custom middleware.

Routing to controller actions in ASP.NET Core

9/22/2020 • 68 minutes to read • Edit Online

By Ryan Nowak, Kirk Larkin, and Rick Anderson

ASP.NET Core controllers use the Routing middleware to match the URLs of incoming requests and map them to actions. Routes templates:

- Are defined in startup code or attributes.
- Describe how URL paths are matched to actions.
- Are used to generate URLs for links. The generated links are typically returned in responses.

Actions are either conventionally-routed or attribute-routed. Placing a route on the controller or action makes it attribute-routed. See Mixed routing for more information.

This document:

- Explains the interactions between MVC and routing:
  - How typical MVC apps make use of routing features.
  - Covers both:
    - Conventionally routing typically used with controllers and views.
    - *Attribute routing* used with REST APIs. If you're primarily interested in routing for REST APIs, jump to the Attribute routing for REST APIs section.
  - See Routing for advanced routing details.
- Refers to the default routing system added in ASP.NET Core 3.0, called endpoint routing. It's possible to use controllers with the previous version of routing for compatibility purposes. See the 2.2-3.0 migration guide for instructions. Refer to the 2.2 version of this document for reference material on the legacy routing system.

Set up conventional route

`Startup.Configure` typically has code similar to the following when using conventional routing:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(
        name: "default",
        pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

Inside the call to UseEndpoints, MapControllerRoute is used to create a single route. The single route is named `default` route. Most apps with controllers and views use a route template similar to the `default` route. REST APIs should use attribute routing.

The route template `"{controller=Home}/{action=Index}/{id?}"`:

- Matches a URL path like `/Products/Details/5`
- Extracts the route values `{ controller = Products, action = Details, id = 5 }` by tokenizing the path. The extraction of route values results in a match if the app has a controller named `ProductsController` and a `Details` action:

```
public class ProductsController : Controller
{
    public IActionResult Details(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

MyDisplayRouteInfo is provided by the Rick.Docs.Samples.RouteInfo NuGet package and displays route information.

- `/Products/Details/5` model binds the value of `id = 5` to set the `id` parameter to `5`. See Model Binding for more details.
- `{controller=Home}` defines `Home` as the default `controller`.
- `{action=Index}` defines `Index` as the default `action`.
- The `?` character in `{id?}` defines `id` as optional.
- Default and optional route parameters don't need to be present in the URL path for a match. See Route Template Reference for a detailed description of route template syntax.
- Matches the URL path `/`.
- Produces the route values `{ controller = Home, action = Index }`.

The values for `controller` and `action` make use of the default values. `id` doesn't produce a value since there's no corresponding segment in the URL path. `/` only matches if there exists a `HomeController` and `Index` action:

```
public class HomeController : Controller
{
  public IActionResult Index() { ... }
}
```

Using the preceding controller definition and route template, the `HomeController.Index` action is run for the following URL paths:

- `/Home/Index/17`
- `/Home/Index`
- `/Home`
- `/`

The URL path `/` uses the route template default `Home` controllers and `Index` action. The URL path `/Home` uses the route template default `Index` action.

The convenience method MapDefaultControllerRoute:

```
endpoints.MapDefaultControllerRoute();
```

Replaces:

```
endpoints.MapControllerRoute("default", "{controller=Home}/{action=Index}/{id?}");
```

IMPORTANT

Routing is configured using the UseRouting and UseEndpoints middleware. To use controllers:

- Call MapControllers inside `UseEndpoints` to map attribute routed controllers.
- Call MapControllerRoute or MapAreaControllerRoute, to map both conventionally routed controllers and attribute routed controllers.

Conventional routing

Conventional routing is used with controllers and views. The `default` route:

```
endpoints.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");
```

is an example of a *conventional routing*. It's called *conventional routing* because it establishes a *convention* for URL paths:

- The first path segment, `{controller=Home}`, maps to the controller name.
- The second segment, `{action=Index}`, maps to the action name.
- The third segment, `{id?}` is used for an optional `id`. The `?` in `{id?}` makes it optional. `id` is used to map to a model entity.

Using this `default` route, the URL path:

- `/Products/List` maps to the `ProductsController.List` action.
- `/Blog/Article/17` maps to `BlogController.Article` and typically model binds the `id` parameter to 17.

This mapping:

- Is based on the controller and action names **only**.
- Isn't based on namespaces, source file locations, or method parameters.

Using conventional routing with the default route allows creating the app without having to come up with a new URL pattern for each action. For an app with CRUD style actions, having consistency for the URLs across controllers:

- Helps simplify the code.
- Makes the UI more predictable.

WARNING

The `id` in the preceding code is defined as optional by the route template. Actions can execute without the optional ID provided as part of the URL. Generally, when `id` is omitted from the URL:

- `id` is set to `0` by model binding.
- No entity is found in the database matching `id == 0`.

Attribute routing provides fine-grained control to make the ID required for some actions and not for others. By convention, the documentation includes optional parameters like `id` when they're likely to appear in correct usage.

Most apps should choose a basic and descriptive routing scheme so that URLs are readable and meaningful. The default conventional route `{controller=Home}/{action=Index}/{id?}`:

- Supports a basic and descriptive routing scheme.
- Is a useful starting point for UI-based apps.
- Is the only route template needed for many web UI apps. For larger web UI apps, another route using Areas is frequently all that's needed.

MapControllerRoute and MapAreaRoute :

- Automatically assign an **order** value to their endpoints based on the order they are invoked.

Endpoint routing in ASP.NET Core 3.0 and later:

- Doesn't have a concept of routes.
- Doesn't provide ordering guarantees for the execution of extensibility, all endpoints are processed at once.

Enable Logging to see how the built-in routing implementations, such as Route, match requests.

Attribute routing is explained later in this document.

Multiple conventional routes

Multiple conventional routes can be added inside `UseEndpoints` by adding more calls to MapControllerRoute and MapAreaControllerRoute. Doing so allows defining multiple conventions, or to adding conventional routes that are dedicated to a specific action, such as:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(name: "blog",
                pattern: "blog/{*article}",
                defaults: new { controller = "Blog", action = "Article" });
    endpoints.MapControllerRoute(name: "default",
                pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

The `blog` route in the preceding code is a **dedicated conventional route**. It's called a dedicated conventional route because:

- It uses conventional routing.
- It's dedicated to a specific action.

Because `controller` and `action` don't appear in the route template `"blog/{*article}"` as parameters:

- They can only have the default values `{ controller = "Blog", action = "Article" }`.
- This route always maps to the action `BlogController.Article`.

`/Blog`, `/Blog/Article`, and `/Blog/{any-string}` are the only URL paths that match the blog route.

The preceding example:

- `blog` route has a higher priority for matches than the `default` route because it is added first.
- Is an example of Slug style routing where it's typical to have an article name as part of the URL.

WARNING

In ASP.NET Core 3.0 and later, routing doesn't:

- Define a concept called a *route*. `UseRouting` adds route matching to the middleware pipeline. The `UseRouting` middleware looks at the set of endpoints defined in the app, and selects the best endpoint match based on the request.
- Provide guarantees about the execution order of extensibility like IRouteConstraint or IActionConstraint.

See Routing for reference material on routing.

Conventional routing order

Conventional routing only matches a combination of action and controller that are defined by the app. This is intended to simplify cases where conventional routes overlap. Adding routes using MapControllerRoute, MapDefaultControllerRoute, and MapAreaControllerRoute automatically assign an order value to their endpoints based on the order they are invoked. Matches from a route that appears earlier have a higher priority. Conventional routing is order-dependent. In general, routes with areas should be placed earlier as they're more specific than routes without an area. Dedicated conventional routes with catch-all route parameters like `{*article}` can make a route too greedy, meaning that it matches URLs that you intended to be matched by other routes. Put the greedy routes later in the route table to prevent greedy matches.

WARNING

A **catch-all** parameter may match routes incorrectly due to a bug in routing. Apps impacted by this bug have the following characteristics:

- A catch-all route, for example, `{**slug}"`
- The catch-all route fails to match requests it should match.
- Removing other routes makes catch-all route start working.

See GitHub bugs 18677 and 16579 for example cases that hit this bug.

An opt-in fix for this bug is contained in .NET Core 3.1.301 SDK and later. The following code sets an internal switch that fixes this bug:

```
public static void Main(string[] args)
{
   AppContext.SetSwitch("Microsoft.AspNetCore.Routing.UseCorrectCatchAllBehavior",
                        true);
   CreateHostBuilder(args).Build().Run();
}
// Remaining code removed for brevity.
```

Resolving ambiguous actions

When two endpoints match through routing, routing must do one of the following:

- Choose the best candidate.
- Throw an exception.

For example:

```
    public class Products33Controller : Controller
    {
        public IActionResult Edit(int id)
        {
            return ControllerContext.MyDisplayRouteInfo(id);
        }

        [HttpPost]
        public IActionResult Edit(int id, Product product)
        {
            return ControllerContext.MyDisplayRouteInfo(id, product.name);
        }
    }
}
```

The preceding controller defines two actions that match:

- The URL path `/Products33/Edit/17`
- Route data `{ controller = Products33, action = Edit, id = 17 }`.

This is a typical pattern for MVC controllers:

- `Edit(int)` displays a form to edit a product.
- `Edit(int, Product)` processes the posted form.

To resolve the correct route:

- `Edit(int, Product)` is selected when the request is an HTTP `POST`.
- `Edit(int)` is selected when the HTTP verb is anything else. `Edit(int)` is generally called via `GET`.

The HttpPostAttribute, `[HttpPost]`, is provided to routing so that it can choose based on the HTTP method of the request. The `HttpPostAttribute` makes `Edit(int, Product)` a better match than `Edit(int)`.

It's important to understand the role of attributes like `HttpPostAttribute`. Similar attributes are defined for other HTTP verbs. In conventional routing, it's common for actions to use the same action name when they're part of a show form, submit form workflow. For example, see Examine the two Edit action methods.

If routing can't choose a best candidate, an AmbiguousMatchException is thrown, listing the multiple matched endpoints.

Conventional route names

The strings `"blog"` and `"default"` in the following examples are conventional route names:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(name: "blog",
                pattern: "blog/{*article}",
                defaults: new { controller = "Blog", action = "Article" });
    endpoints.MapControllerRoute(name: "default",
                pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

The route names give the route a logical name. The named route can be used for URL generation. Using a named route simplifies URL creation when the ordering of routes could make URL generation complicated. Route names must be unique application wide.

Route names:

- Have no impact on URL matching or handling of requests.
- Are used only for URL generation.

The route name concept is represented in routing as IEndpointNameMetadata. The terms **route name** and **endpoint name**:

- Are interchangeable.
- Which one is used in documentation and code depends on the API being described.

Attribute routing for REST APIs

REST APIs should use attribute routing to model the app's functionality as a set of resources where operations are represented by HTTP verbs.

Attribute routing uses a set of attributes to map actions directly to route templates. The following `StartUp.Configure` code is typical for a REST API and is used in the next sample:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllers();
}

public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    app.UseHttpsRedirection();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
    });
}
```

In the preceding code, MapControllers is called inside `UseEndpoints` to map attribute routed controllers.

In the following example:

- The preceding `Configure` method is used.
- `HomeController` matches a set of URLs similar to what the default conventional route `{controller=Home}/{action=Index}/{id?}` matches.

```
public class HomeController : Controller
{
    [Route("")]
    [Route("Home")]
    [Route("Home/Index")]
    [Route("Home/Index/{id?}")]
    public IActionResult Index(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }

    [Route("Home/About")]
    [Route("Home/About/{id?}")]
    public IActionResult About(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

The `HomeController.Index` action is run for any of the URL paths `/`, `/Home`, `/Home/Index`, or `/Home/Index/3`.

This example highlights a key programming difference between attribute routing and conventional routing. Attribute routing requires more input to specify a route. The conventional default route handles routes more succinctly. However, attribute routing allows and requires precise control of which route templates apply to each action.

With attribute routing, the controller and action names play no part in which action is matched, unless token replacement is used. The following example matches the same URLs as the previous example:

```
public class MyDemoController : Controller
{
    [Route("")]
    [Route("Home")]
    [Route("Home/Index")]
    [Route("Home/Index/{id?}")]
    public IActionResult MyIndex(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }

    [Route("Home/About")]
    [Route("Home/About/{id?}")]
    public IActionResult MyAbout(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

The following code uses token replacement for `action` and `controller`:

```
public class HomeController : Controller
{
    [Route("")]
    [Route("Home")]
    [Route("[controller]/[action]")]
    public IActionResult Index()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [Route("[controller]/[action]")]
    public IActionResult About()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

The following code applies `[Route("[controller]/[action]")]` to the controller:

```
[Route("[controller]/[action]")]
public class HomeController : Controller
{
    [Route("~/")]
    [Route("/Home")]
    [Route("~/Home/Index")]
    public IActionResult Index()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    public IActionResult About()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

In the preceding code, the `Index` method templates must prepend `/` or `~/` to the route templates. Route templates applied to an action that begin with `/` or `~/` don't get combined with route templates applied to the controller.

See Route template precedence for information on route template selection.

Reserved routing names

The following keywords are reserved route parameter names when using Controllers or Razor Pages:

- `action`
- `area`
- `controller`
- `handler`
- `page`

Using `page` as a route parameter with attribute routing is a common error. Doing that results in inconsistent and confusing behavior with URL generation.

```
public class MyDemo2Controller : Controller
{
    [Route("/articles/{page}")]
    public IActionResult ListArticles(int page)
    {
        return ControllerContext.MyDisplayRouteInfo(page);
    }
}
```

The special parameter names are used by the URL generation to determine if a URL generation operation refers to a Razor Page or to a Controller.

HTTP verb templates

ASP.NET Core has the following HTTP verb templates:

- [HttpGet]
- [HttpPost]
- [HttpPut]
- [HttpDelete]
- [HttpHead]
- [HttpPatch]

Route templates

ASP.NET Core has the following route templates:

- All the HTTP verb templates are route templates.
- [Route]

Attribute routing with Http verb attributes

Consider the following controller:

```
[Route("api/[controller]")]
[ApiController]
public class Test2Controller : ControllerBase
{
    [HttpGet]   // GET /api/test2
    public IActionResult ListProducts()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [HttpGet("{id}")]   // GET /api/test2/xyz
    public IActionResult GetProduct(string id)
    {
       return ControllerContext.MyDisplayRouteInfo(id);
    }

    [HttpGet("int/{id:int}")] // GET /api/test2/int/3
    public IActionResult GetIntProduct(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }

    [HttpGet("int2/{id}")]  // GET /api/test2/int2/3
    public IActionResult GetInt2Product(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

In the preceding code:

- Each action contains the `[HttpGet]` attribute, which constrains matching to HTTP GET requests only.
- The `GetProduct` action includes the `"{id}"` template, therefore `id` is appended to the `"api/[controller]"` template on the controller. The methods template is `"api/[controller]/"{id}""`. Therefore this action only matches GET requests of for the form `/api/test2/xyz`, `/api/test2/123`, `/api/test2/{any string}`, etc.

  ```
  [HttpGet("{id}")]   // GET /api/test2/xyz
  public IActionResult GetProduct(string id)
  {
     return ControllerContext.MyDisplayRouteInfo(id);
  }
  ```

- The `GetIntProduct` action contains the `"int/{id:int}")` template. The `:int` portion of the template constrains the `id` route values to strings that can be converted to an integer. A GET request to `/api/test2/int/abc`:
  - Doesn't match this action.
  - Returns a 404 Not Found error.

  ```
  [HttpGet("int/{id:int}")] // GET /api/test2/int/3
  public IActionResult GetIntProduct(int id)
  {
      return ControllerContext.MyDisplayRouteInfo(id);
  }
  ```

- The `GetInt2Product` action contains `{id}` in the template, but doesn't constrain `id` to values that can be converted to an integer. A GET request to `/api/test2/int2/abc`:
  - Matches this route.

- Model binding fails to convert `abc` to an integer. The `id` parameter of the method is integer.
- Returns a 400 Bad Request because model binding failed to convert `abc` to an integer.

```
[HttpGet("int2/{id}")]  // GET /api/test2/int2/3
public IActionResult GetInt2Product(int id)
{
    return ControllerContext.MyDisplayRouteInfo(id);
}
```

Attribute routing can use HttpMethodAttribute attributes such as HttpPostAttribute, HttpPutAttribute, and HttpDeleteAttribute. All of the HTTP verb attributes accept a route template. The following example shows two actions that match the same route template:

```
[ApiController]
public class MyProductsController : ControllerBase
{
    [HttpGet("/products3")]
    public IActionResult ListProducts()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [HttpPost("/products3")]
    public IActionResult CreateProduct(MyProduct myProduct)
    {
        return ControllerContext.MyDisplayRouteInfo(myProduct.Name);
    }
}
```

Using the URL path `/products3`:

- The `MyProductsController.ListProducts` action runs when the HTTP verb is `GET`.
- The `MyProductsController.CreateProduct` action runs when the HTTP verb is `POST`.

When building a REST API, it's rare that you'll need to use `[Route(...)]` on an action method because the action accepts all HTTP methods. It's better to use the more specific HTTP verb attribute to be precise about what your API supports. Clients of REST APIs are expected to know what paths and HTTP verbs map to specific logical operations.

REST APIs should use attribute routing to model the app's functionality as a set of resources where operations are represented by HTTP verbs. This means that many operations, for example, GET and POST on the same logical resource use the same URL. Attribute routing provides a level of control that's needed to carefully design an API's public endpoint layout.

Since an attribute route applies to a specific action, it's easy to make parameters required as part of the route template definition. In the following example, `id` is required as part of the URL path:

```
[ApiController]
public class Products2ApiController : ControllerBase
{
    [HttpGet("/products2/{id}", Name = "Products_List")]
    public IActionResult GetProduct(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

The `Products2ApiController.GetProduct(int)` action:

- Is run with URL path like `/products2/3`
- Isn't run with the URL path `/products2`.

The [Consumes] attribute allows an action to limit the supported request content types. For more information, see Define supported request content types with the Consumes attribute.

See Routing for a full description of route templates and related options.

For more information on `[ApiController]`, see ApiController attribute.

Route name

The following code defines a route name of `Products_List`:

```
[ApiController]
public class Products2ApiController : ControllerBase
{
    [HttpGet("/products2/{id}", Name = "Products_List")]
    public IActionResult GetProduct(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

Route names can be used to generate a URL based on a specific route. Route names:

- Have no impact on the URL matching behavior of routing.
- Are only used for URL generation.

Route names must be unique application-wide.

Contrast the preceding code with the conventional default route, which defines the `id` parameter as optional (`{id?}`). The ability to precisely specify APIs has advantages, such as allowing `/products` and `/products/5` to be dispatched to different actions.

Combining attribute routes

To make attribute routing less repetitive, route attributes on the controller are combined with route attributes on the individual actions. Any route templates defined on the controller are prepended to route templates on the actions. Placing a route attribute on the controller makes **all** actions in the controller use attribute routing.

```
[ApiController]
[Route("products")]
public class ProductsApiController : ControllerBase
{
    [HttpGet]
    public IActionResult ListProducts()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [HttpGet("{id}")]
    public IActionResult GetProduct(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

In the preceding example:

- The URL path `/products` can match `ProductsApi.ListProducts`
- The URL path `/products/5` can match `ProductsApi.GetProduct(int)`.

Both of these actions only match HTTP `GET` because they're marked with the `[HttpGet]` attribute.

Route templates applied to an action that begin with `/` or `~/` don't get combined with route templates applied to the controller. The following example matches a set of URL paths similar to the default route.

```
[Route("Home")]
public class HomeController : Controller
{
    [Route("")]
    [Route("Index")]
    [Route("/")]
    public IActionResult Index()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [Route("About")]
    public IActionResult About()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

The following table explains the `[Route]` attributes in the preceding code:

ATTRIBUTE	COMBINES WITH `[ROUTE("HOME")]`	DEFINES ROUTE TEMPLATE
`[Route("")]`	Yes	`"Home"`
`[Route("Index")]`	Yes	`"Home/Index"`
`[Route("/")]`	No	`""`
`[Route("About")]`	Yes	`"Home/About"`

Attribute route order

Routing builds a tree and matches all endpoints simultaneously:

- The route entries behave as if placed in an ideal ordering.
- The most specific routes have a chance to execute before the more general routes.

For example, an attribute route like `blog/search/{topic}` is more specific than an attribute route like `blog/{*article}`. The `blog/search/{topic}` route has higher priority, by default, because it's more specific. Using conventional routing, the developer is responsible for placing routes in the desired order.

Attribute routes can configure an order using the Order property. All of the framework provided route attributes include `Order` . Routes are processed according to an ascending sort of the `Order` property. The default order is `0`. Setting a route using `Order = -1` runs before routes that don't set an order. Setting a route using `Order = 1` runs after default route ordering.

Avoid depending on `Order`. If an app's URL-space requires explicit order values to route correctly, then it's likely confusing to clients as well. In general, attribute routing selects the correct route with URL matching. If the default order used for URL generation isn't working, using a route name as an override is usually simpler than applying the `Order` property.

Consider the following two controllers which both define the route matching `/home`:

```
public class HomeController : Controller
{
    [Route("")]
    [Route("Home")]
    [Route("Home/Index")]
    [Route("Home/Index/{id?}")]
    public IActionResult Index(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }

    [Route("Home/About")]
    [Route("Home/About/{id?}")]
    public IActionResult About(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

```
public class MyDemoController : Controller
{
    [Route("")]
    [Route("Home")]
    [Route("Home/Index")]
    [Route("Home/Index/{id?}")]
    public IActionResult MyIndex(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }

    [Route("Home/About")]
    [Route("Home/About/{id?}")]
    public IActionResult MyAbout(int? id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

Requesting `/home` with the preceding code throws an exception similar to the following:

```
AmbiguousMatchException: The request matched multiple endpoints. Matches:

 WebMvcRouting.Controllers.HomeController.Index
 WebMvcRouting.Controllers.MyDemoController.MyIndex
```

Adding `Order` to one of the route attributes resolves the ambiguity:

```
[Route("")]
[Route("Home", Order = 2)]
[Route("Home/MyIndex")]
public IActionResult MyIndex()
{
    return ControllerContext.MyDisplayRouteInfo();
}
```

With the preceding code, `/home` runs the `HomeController.Index` endpoint. To get to the `MyDemoController.MyIndex`, request `/home/MyIndex`. **Note**:

- The preceding code is an example or poor routing design. It was used to illustrate the `Order` property.
- The `Order` property only resolves the ambiguity, that template cannot be matched. It would be better to remove the `[Route("Home")]` template.

See Razor Pages route and app conventions: Route order for information on route order with Razor Pages.

In some cases, an HTTP 500 error is returned with ambiguous routes. Use logging to see which endpoints caused the `AmbiguousMatchException`.

Token replacement in route templates [controller], [action], [area]

For convenience, attribute routes support token replacement for reserved route parameters by enclosing a token in one of the following:

- Square brackets: `[]`
- Curly braces: `{}`

The tokens `[action]`, `[area]`, and `[controller]` are replaced with the values of the action name, area name, and controller name from the action where the route is defined:

```
[Route("[controller]/[action]")]
public class Products0Controller : Controller
{
    [HttpGet]
    public IActionResult List()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [HttpGet("{id}")]
    public IActionResult Edit(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

In the preceding code:

```
[HttpGet]
public IActionResult List()
{
    return ControllerContext.MyDisplayRouteInfo();
}
```

- Matches `/Products0/List`

```
[HttpGet("{id}")]
public IActionResult Edit(int id)
{
    return ControllerContext.MyDisplayRouteInfo(id);
}
```

- Matches `/Products0/Edit/{id}`

Token replacement occurs as the last step of building the attribute routes. The preceding example behaves the same as the following code:

```
public class Products20Controller : Controller
{
    [HttpGet("[controller]/[action]")]  // Matches '/Products20/List'
    public IActionResult List()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [HttpGet("[controller]/[action]/{id}")]   // Matches '/Products20/Edit/{id}'
    public IActionResult Edit(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

If you are reading this in a language other than English, let us know in this GitHub discussion issue if you'd like to see the code comments in your native language.

Attribute routes can also be combined with inheritance. This is powerful combined with token replacement. Token replacement also applies to route names defined by attribute routes. `[Route("[controller]/[action]", Name="[controller]_[action]")]` generates a unique route name for each action:

```
[ApiController]
[Route("api/[controller]/[action]", Name = "[controller]_[action]")]
public abstract class MyBase2Controller : ControllerBase
{
}

public class Products11Controller : MyBase2Controller
{
    [HttpGet]                       // /api/products11/
    public IActionResult List()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    [HttpGet("{id}")]             //    /api/products11/edit/3
    public IActionResult Edit(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

Token replacement also applies to route names defined by attribute routes. `[Route("[controller]/[action]", Name="[controller]_[action]")]` generates a unique route name for each action.

To match the literal token replacement delimiter `[` or `]`, escape it by repeating the character (`[[` or `]]`).

Use a parameter transformer to customize token replacement

Token replacement can be customized using a parameter transformer. A parameter transformer implements IOutboundParameterTransformer and transforms the value of parameters. For example, a custom `SlugifyParameterTransformer` parameter transformer changes the `SubscriptionManagement` route value to `subscription-management`:

```
public class SlugifyParameterTransformer : IOutboundParameterTransformer
{
    public string TransformOutbound(object value)
    {
        if (value == null) { return null; }

        return Regex.Replace(value.ToString(),
                             "([a-z])([A-Z])",
                             "$1-$2",
                             RegexOptions.CultureInvariant,
                             TimeSpan.FromMilliseconds(100)).ToLowerInvariant();
    }
}
```

The RouteTokenTransformerConvention is an application model convention that:

- Applies a parameter transformer to all attribute routes in an application.
- Customizes the attribute route token values as they are replaced.

```
public class SubscriptionManagementController : Controller
{
    [HttpGet("[controller]/[action]")]
    public IActionResult ListAll()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

The preceding `ListAll` method matches `/subscription-management/list-all`.

The `RouteTokenTransformerConvention` is registered as an option in `ConfigureServices`.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews(options =>
    {
        options.Conventions.Add(new RouteTokenTransformerConvention(
                                    new SlugifyParameterTransformer()));
    });
}
```

See MDN web docs on Slug for the definition of Slug.

> **WARNING**
>
> When using System.Text.RegularExpressions to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions` causing a Denial-of-Service attack. ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

Multiple attribute routes

Attribute routing supports defining multiple routes that reach the same action. The most common usage of this is to mimic the behavior of the default conventional route as shown in the following example:

```
[Route("[controller]")]
public class Products13Controller : Controller
{
    [Route("")]     // Matches 'Products13'
    [Route("Index")] // Matches 'Products13/Index'
    public IActionResult Index()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
```

Putting multiple route attributes on the controller means that each one combines with each of the route attributes on the action methods:

```
[Route("Store")]
[Route("[controller]")]
public class Products6Controller : Controller
{
    [HttpPost("Buy")]       // Matches 'Products6/Buy' and 'Store/Buy'
    [HttpPost("Checkout")]  // Matches 'Products6/Checkout' and 'Store/Checkout'
    public IActionResult Buy()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

All the HTTP verb route constraints implement `IActionConstraint`.

When multiple route attributes that implement IActionConstraint are placed on an action:

- Each action constraint combines with the route template applied to the controller.

```
[Route("api/[controller]")]
public class Products7Controller : ControllerBase
{
    [HttpPut("Buy")]        // Matches PUT 'api/Products7/Buy'
    [HttpPost("Checkout")]  // Matches POST 'api/Products7/Checkout'
    public IActionResult Buy()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

Using multiple routes on actions might seem useful and powerful, it's better to keep your app's URL space basic and well defined. Use multiple routes on actions **only** where needed, for example, to support existing clients.

Specifying attribute route optional parameters, default values, and constraints

Attribute routes support the same inline syntax as conventional routes to specify optional parameters, default values, and constraints.

```
public class Products14Controller : Controller
{
    [HttpPost("product14/{id:int}")]
    public IActionResult ShowProduct(int id)
    {
        return ControllerContext.MyDisplayRouteInfo(id);
    }
}
```

In the preceding code, `[HttpPost("product/{id:int}")]` applies a route constraint. The `ProductsController.ShowProduct` action is matched only by URL paths like `/product/3`. The route template portion `{id:int}` constrains that segment to only integers.

See Route Template Reference for a detailed description of route template syntax.

Custom route attributes using IRouteTemplateProvider

All of the route attributes implement IRouteTemplateProvider. The ASP.NET Core runtime:

- Looks for attributes on controller classes and action methods when the app starts.
- Uses the attributes that implement `IRouteTemplateProvider` to build the initial set of routes.

Implement `IRouteTemplateProvider` to define custom route attributes. Each `IRouteTemplateProvider` allows you to define a single route with a custom route template, order, and name:

```
public class MyApiControllerAttribute : Attribute, IRouteTemplateProvider
{
    public string Template => "api/[controller]";
    public int? Order => 2;
    public string Name { get; set; }
}

[MyApiController]
[ApiController]
public class MyTestApiController : ControllerBase
{
    // GET /api/MyTestApi
    [HttpGet]
    public IActionResult Get()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

The preceding `Get` method returns `Order = 2, Template = api/MyTestApi`.

Use application model to customize attribute routes

The application model:

- Is an object model created at startup.
- Contains all of the metadata used by ASP.NET Core to route and execute the actions in an app.

The application model includes all of the data gathered from route attributes. The data from route attributes is provided by the `IRouteTemplateProvider` implementation. Conventions:

- Can be written to modify the application model to customize how routing behaves.
- Are read at app startup.

This section shows a basic example of customizing routing using application model. The following code makes routes roughly line up with the folder structure of the project.

```
public class NamespaceRoutingConvention : Attribute, IControllerModelConvention
{
    private readonly string _baseNamespace;

    public NamespaceRoutingConvention(string baseNamespace)
    {
        _baseNamespace = baseNamespace;
    }

    public void Apply(ControllerModel controller)
    {
        var hasRouteAttributes = controller.Selectors.Any(selector =>
                                                selector.AttributeRouteModel != null);
        if (hasRouteAttributes)
        {
            return;
        }

        var namespc = controller.ControllerType.Namespace;
        if (namespc == null)
            return;
        var template = new StringBuilder();
        template.Append(namespc, _baseNamespace.Length + 1,
                        namespc.Length - _baseNamespace.Length - 1);
        template.Replace('.', '/');
        template.Append("/[controller]/[action]/{id?}");

        foreach (var selector in controller.Selectors)
        {
            selector.AttributeRouteModel = new AttributeRouteModel()
            {
                Template = template.ToString()
            };
        }
    }
}
```

The following code prevents the `namespace` convention from being applied to controllers that are attribute routed:

```
public void Apply(ControllerModel controller)
{
    var hasRouteAttributes = controller.Selectors.Any(selector =>
                                            selector.AttributeRouteModel != null);
    if (hasRouteAttributes)
    {
        return;
    }
```

For example, the following controller doesn't use `NamespaceRoutingConvention`:

```
[Route("[controller]/[action]/{id?}")]
public class ManagersController : Controller
{
    // /managers/index
    public IActionResult Index()
    {
        var template = ControllerContext.ActionDescriptor.AttributeRouteInfo?.Template;
        return Content($"Index- template:{template}");
    }

    public IActionResult List(int? id)
    {
        var path = Request.Path.Value;
        return Content($"List- Path:{path}");
    }
}
```

The `NamespaceRoutingConvention.Apply` method:

- Does nothing if the controller is attribute routed.
- Sets the controllers template based on the `namespace`, with the base `namespace` removed.

The `NamespaceRoutingConvention` can be applied in `Startup.ConfigureServices`:

```
namespace My.Application
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        public void ConfigureServices(IServiceCollection services)
        {
            services.AddControllersWithViews(options =>
            {
                options.Conventions.Add(
                    new NamespaceRoutingConvention(typeof(Startup).Namespace));
            });
        }
        // Remaining code ommitted for brevity.
```

For example, consider the following controller:

```
using Microsoft.AspNetCore.Mvc;

namespace My.Application.Admin.Controllers
{
    public class UsersController : Controller
    {
        // GET /admin/controllers/users/index
        public IActionResult Index()
        {
            var fullname = typeof(UsersController).FullName;
            var template =
                ControllerContext.ActionDescriptor.AttributeRouteInfo?.Template;
            var path = Request.Path.Value;

            return Content($"Path: {path} fullname: {fullname}  template:{template}");
        }

        public IActionResult List(int? id)
        {
            var path = Request.Path.Value;
            return Content($"Path: {path} ID:{id}");
        }
    }
}
```

In the preceding code:

- The base `namespace` is `My.Application`.
- The full name of the preceding controller is `My.Application.Admin.Controllers.UsersController`.
- The `NamespaceRoutingConvention` sets the controllers template to `Admin/Controllers/Users/[action]/{id?`.

The `NamespaceRoutingConvention` can also be applied as an attribute on a controller:

```
[NamespaceRoutingConvention("My.Application")]
public class TestController : Controller
{
    // /admin/controllers/test/index
    public IActionResult Index()
    {
        var template = ControllerContext.ActionDescriptor.AttributeRouteInfo?.Template;
        var actionname = ControllerContext.ActionDescriptor.ActionName;
        return Content($"Action- {actionname} template:{template}");
    }

    public IActionResult List(int? id)
    {
        var path = Request.Path.Value;
        return Content($"List- Path:{path}");
    }
}
```

Mixed routing: Attribute routing vs conventional routing

ASP.NET Core apps can mix the use of conventional routing and attribute routing. It's typical to use conventional routes for controllers serving HTML pages for browsers, and attribute routing for controllers serving REST APIs.

Actions are either conventionally routed or attribute routed. Placing a route on the controller or the action makes it attribute routed. Actions that define attribute routes cannot be reached through the conventional routes and vice-versa. **Any** route attribute on the controller makes **all** actions in the controller attribute routed.

Attribute routing and conventional routing use the same routing engine.

URL Generation and ambient values

Apps can use routing URL generation features to generate URL links to actions. Generating URLs eliminates hardcoding URLs, making code more robust and maintainable. This section focuses on the URL generation features provided by MVC and only cover basics of how URL generation works. See Routing for a detailed description of URL generation.

The IUrlHelper interface is the underlying element of infrastructure between MVC and routing for URL generation. An instance of `IUrlHelper` is available through the `Url` property in controllers, views, and view components.

In the following example, the `IUrlHelper` interface is used through the `Controller.Url` property to generate a URL to another action.

```
public class UrlGenerationController : Controller
{
    public IActionResult Source()
    {
        // Generates /UrlGeneration/Destination
        var url = Url.Action("Destination");
        return ControllerContext.MyDisplayRouteInfo("", $" URL = {url}");
    }

    public IActionResult Destination()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
}
```

If the app is using the default conventional route, the value of the `url` variable is the URL path string `/UrlGeneration/Destination`. This URL path is created by routing by combining:

- The route values from the current request, which are called **ambient values**.
- The values passed to `Url.Action` and substituting those values into the route template:

```
ambient values: { controller = "UrlGeneration", action = "Source" }
values passed to Url.Action: { controller = "UrlGeneration", action = "Destination" }
route template: {controller}/{action}/{id?}

result: /UrlGeneration/Destination
```

Each route parameter in the route template has its value substituted by matching names with the values and ambient values. A route parameter that doesn't have a value can:

- Use a default value if it has one.
- Be skipped if it's optional. For example, the `id` from the route template `{controller}/{action}/{id?}`.

URL generation fails if any required route parameter doesn't have a corresponding value. If URL generation fails for a route, the next route is tried until all routes have been tried or a match is found.

The preceding example of `Url.Action` assumes conventional routing. URL generation works similarly with attribute routing, though the concepts are different. With conventional routing:

- The route values are used to expand a template.
- The route values for `controller` and `action` usually appear in that template. This works because the

URLs matched by routing adhere to a convention.

The following example uses attribute routing:

```
public class UrlGenerationAttrController : Controller
{
    [HttpGet("custom")]
    public IActionResult Source()
    {
        var url = Url.Action("Destination");
        return ControllerContext.MyDisplayRouteInfo("", $" URL = {url}");
    }

    [HttpGet("custom/url/to/destination")]
    public IActionResult Destination()
    {
       return ControllerContext.MyDisplayRouteInfo();
    }
}
```

The `Source` action in the preceding code generates `custom/url/to/destination`.

LinkGenerator was added in ASP.NET Core 3.0 as an alternative to `IUrlHelper`. `LinkGenerator` offers similar but more flexible functionality. Each method on `IUrlHelper` has a corresponding family of methods on `LinkGenerator` as well.

Generating URLs by action name

Url.Action, LinkGenerator.GetPathByAction, and all related overloads all are designed to generate the target endpoint by specifying a controller name and action name.

When using `Url.Action`, the current route values for `controller` and `action` are provided by the runtime:

- The value of `controller` and `action` are part of both ambient values and values. The method `Url.Action` always uses the current values of `action` and `controller` and generates a URL path that routes to the current action.

Routing attempts to use the values in ambient values to fill in information that wasn't provided when generating a URL. Consider a route like `{a}/{b}/{c}/{d}` with ambient values `{ a = Alice, b = Bob, c = Carol, d = David }`:

- Routing has enough information to generate a URL without any additional values.
- Routing has enough information because all route parameters have a value.

If the value `{ d = Donovan }` is added:

- The value `{ d = David }` is ignored.
- The generated URL path is `Alice/Bob/Carol/Donovan`.

Warning: URL paths are hierarchical. In the preceding example, if the value `{ c = Cheryl }` is added:

- Both of the values `{ c = Carol, d = David }` are ignored.
- There is no longer a value for `d` and URL generation fails.
- The desired values of `c` and `d` must be specified to generate a URL.

You might expect to hit this problem with the default route `{controller}/{action}/{id?}`. This problem is rare in practice because `Url.Action` always explicitly specifies a `controller` and `action` value.

Several overloads of Url.Action take a route values object to provide values for route parameters other than `controller` and `action`. The route values object is frequently used with `id`. For example,

`Url.Action("Buy", "Products", new { id = 17 })`. The route values object:

- By convention is usually an object of anonymous type.
- Can be an `IDictionary<>` or a POCO).

Any additional route values that don't match route parameters are put in the query string.

```
public IActionResult Index()
{
    var url = Url.Action("Buy", "Products", new { id = 17, color = "red" });
    return Content(url);
}
```

The preceding code generates `/Products/Buy/17?color=red`.

The following code generates an absolute URL:

```
public IActionResult Index2()
{
    var url = Url.Action("Buy", "Products", new { id = 17 }, protocol: Request.Scheme);
    // Returns https://localhost:5001/Products/Buy/17
    return Content(url);
}
```

To create an absolute URL, use one of the following:

- An overload that accepts a `protocol`. For example, the preceding code.
- LinkGenerator.GetUriByAction, which generates absolute URIs by default.

Generate URLs by route

The preceding code demonstrated generating a URL by passing in the controller and action name. `IUrlHelper` also provides the Url.RouteUrl family of methods. These methods are similar to Url.Action, but they don't copy the current values of `action` and `controller` to the route values. The most common usage of `Url.RouteUrl`:

- Specifies a route name to generate the URL.
- Generally doesn't specify a controller or action name.

```
public class UrlGeneration2Controller : Controller
{
    [HttpGet("")]
    public IActionResult Source()
    {
        var url = Url.RouteUrl("Destination_Route");
        return ControllerContext.MyDisplayRouteInfo("", $" URL = {url}");
    }

    [HttpGet("custom/url/to/destination2", Name = "Destination_Route")]
    public IActionResult Destination()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }
```

The following Razor file generates an HTML link to the `Destination_Route`:

```
<h1>Test Links</h1>

<ul>
    <li><a href="@Url.RouteUrl("Destination_Route")">Test Destination_Route</a></li>
</ul>
```

Generate URLs in HTML and Razor

IHtmlHelper provides the HtmlHelper methods Html.BeginForm and Html.ActionLink to generate `<form>` and `<a>` elements respectively. These methods use the Url.Action method to generate a URL and they accept similar arguments. The `Url.RouteUrl` companions for `HtmlHelper` are `Html.BeginRouteForm` and `Html.RouteLink` which have similar functionality.

TagHelpers generate URLs through the `form` TagHelper and the `<a>` TagHelper. Both of these use `IUrlHelper` for their implementation. See Tag Helpers in forms for more information.

Inside views, the `IUrlHelper` is available through the `Url` property for any ad-hoc URL generation not covered by the above.

URL generation in Action Results

The preceding examples showed using `IUrlHelper` in a controller. The most common usage in a controller is to generate a URL as part of an action result.

The ControllerBase and Controller base classes provide convenience methods for action results that reference another action. One typical usage is to redirect after accepting user input:

```
[HttpPost]
[ValidateAntiForgeryToken]
public IActionResult Edit(int id, Customer customer)
{
    if (ModelState.IsValid)
    {
        // Update DB with new details.
        ViewData["Message"] = $"Successful edit of customer {id}";
        return RedirectToAction("Index");
    }
    return View(customer);
}
```

The action results factory methods such as RedirectToAction and CreatedAtAction follow a similar pattern to the methods on `IUrlHelper`.

Special case for dedicated conventional routes

Conventional routing can use a special kind of route definition called a dedicated conventional route. In the following example, the route named `blog` is a dedicated conventional route:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(name: "blog",
                pattern: "blog/{*article}",
                defaults: new { controller = "Blog", action = "Article" });
    endpoints.MapControllerRoute(name: "default",
                pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

Using the preceding route definitions, `Url.Action("Index", "Home")` generates the URL path `/` using the `default` route, but why? You might guess the route values `{ controller = Home, action = Index }` would be

enough to generate a URL using `blog`, and the result would be `/blog?action=Index&controller=Home`.

Dedicated conventional routes rely on a special behavior of default values that don't have a corresponding route parameter that prevents the route from being too greedy with URL generation. In this case the default values are `{ controller = Blog, action = Article }`, and neither `controller` nor `action` appears as a route parameter. When routing performs URL generation, the values provided must match the default values. URL generation using `blog` fails because the values `{ controller = Home, action = Index }` don't match `{ controller = Blog, action = Article }`. Routing then falls back to try `default`, which succeeds.

Areas

Areas are an MVC feature used to organize related functionality into a group as a separate:

- Routing namespace for controller actions.
- Folder structure for views.

Using areas allows an app to have multiple controllers with the same name, as long as they have different areas. Using areas creates a hierarchy for the purpose of routing by adding another route parameter, `area` to `controller` and `action`. This section discusses how routing interacts with areas. See Areas for details about how areas are used with views.

The following example configures MVC to use the default conventional route and an `area` route for an `area` named `Blog`:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapAreaControllerRoute("blog_route", "Blog",
        "Manage/{controller}/{action}/{id?}");
    endpoints.MapControllerRoute("default_route", "{controller}/{action}/{id?}");
});
```

In the preceding code, MapAreaControllerRoute is called to create the `"blog_route"`. The second parameter, `"Blog"`, is the area name.

When matching a URL path like `/Manage/Users/AddUser`, the `"blog_route"` route generates the route values `{ area = Blog, controller = Users, action = AddUser }`. The `area` route value is produced by a default value for `area`. The route created by `MapAreaControllerRoute` is equivalent to the following:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute("blog_route", "Manage/{controller}/{action}/{id?}",
        defaults: new { area = "Blog" }, constraints: new { area = "Blog" });
    endpoints.MapControllerRoute("default_route", "{controller}/{action}/{id?}");
});
```

`MapAreaControllerRoute` creates a route using both a default value and constraint for `area` using the provided area name, in this case `Blog`. The default value ensures that the route always produces `{ area = Blog, ... }`, the constraint requires the value `{ area = Blog, ... }` for URL generation.

Conventional routing is order-dependent. In general, routes with areas should be placed earlier as they're more specific than routes without an area.

Using the preceding example, the route values `{ area = Blog, controller = Users, action = AddUser }` match the following action:

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace1
{
    [Area("Blog")]
    public class UsersController : Controller
    {
        // GET /manage/users/adduser
        public IActionResult AddUser()
        {
            var area = ControllerContext.ActionDescriptor.RouteValues["area"];
            var actionName = ControllerContext.ActionDescriptor.ActionName;
            var controllerName = ControllerContext.ActionDescriptor.ControllerName;

            return Content($"area name:{area}" +
                $" controller:{controllerName}  action name: {actionName}");
        }
    }
}
```

The [Area] attribute is what denotes a controller as part of an area. This controller is in the `Blog` area. Controllers without an `[Area]` attribute are not members of any area, and do **not** match when the `area` route value is provided by routing. In the following example, only the first controller listed can match the route values `{ area = Blog, controller = Users, action = AddUser }`.

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace1
{
    [Area("Blog")]
    public class UsersController : Controller
    {
        // GET /manage/users/adduser
        public IActionResult AddUser()
        {
            var area = ControllerContext.ActionDescriptor.RouteValues["area"];
            var actionName = ControllerContext.ActionDescriptor.ActionName;
            var controllerName = ControllerContext.ActionDescriptor.ControllerName;

            return Content($"area name:{area}" +
                $" controller:{controllerName}  action name: {actionName}");
        }
    }
}
```

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace2
{
    // Matches { area = Zebra, controller = Users, action = AddUser }
    [Area("Zebra")]
    public class UsersController : Controller
    {
        // GET /zebra/users/adduser
        public IActionResult AddUser()
        {
            var area = ControllerContext.ActionDescriptor.RouteValues["area"];
            var actionName = ControllerContext.ActionDescriptor.ActionName;
            var controllerName = ControllerContext.ActionDescriptor.ControllerName;

            return Content($"area name:{area}" +
                $" controller:{controllerName}  action name: {actionName}");
        }
    }
}
```

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace3
{
    // Matches { area = string.Empty, controller = Users, action = AddUser }
    // Matches { area = null, controller = Users, action = AddUser }
    // Matches { controller = Users, action = AddUser }
    public class UsersController : Controller
    {
        // GET /users/adduser
        public IActionResult AddUser()
        {
            var area = ControllerContext.ActionDescriptor.RouteValues["area"];
            var actionName = ControllerContext.ActionDescriptor.ActionName;
            var controllerName = ControllerContext.ActionDescriptor.ControllerName;

            return Content($"area name:{area}" +
                $" controller:{controllerName}  action name: {actionName}");
        }
    }
}
```

The namespace of each controller is shown here for completeness. If the preceding controllers uses the same namespace, a compiler error would be generated. Class namespaces have no effect on MVC's routing.

The first two controllers are members of areas, and only match when their respective area name is provided by the `area` route value. The third controller isn't a member of any area, and can only match when no value for `area` is provided by routing.

In terms of matching *no value*, the absence of the `area` value is the same as if the value for `area` were null or the empty string.

When executing an action inside an area, the route value for `area` is available as an ambient value for routing to use for URL generation. This means that by default areas act *sticky* for URL generation as demonstrated by the following sample.

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapAreaControllerRoute(name: "duck_route",
                                     areaName: "Duck",
                                     pattern: "Manage/{controller}/{action}/{id?}");
    endpoints.MapControllerRoute(name: "default",
                                 pattern: "Manage/{controller=Home}/{action=Index}/{id?}");
});
```

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace4
{
    [Area("Duck")]
    public class UsersController : Controller
    {
        // GET /Manage/users/GenerateURLInArea
        public IActionResult GenerateURLInArea()
        {
            // Uses the 'ambient' value of area.
            var url = Url.Action("Index", "Home");
            // Returns /Manage/Home/Index
            return Content(url);
        }

        // GET /Manage/users/GenerateURLOutsideOfArea
        public IActionResult GenerateURLOutsideOfArea()
        {
            // Uses the empty value for area.
            var url = Url.Action("Index", "Home", new { area = "" });
            // Returns /Manage
            return Content(url);
        }
    }
}
```

The following code generates a URL to `/Zebra/Users/AddUser`:

```
public class HomeController : Controller
{
    public IActionResult About()
    {
        var url = Url.Action("AddUser", "Users", new { Area = "Zebra" });
        return Content($"URL: {url}");
    }
```

Action definition

Public methods on a controller, except those with the NonAction attribute, are actions.

Sample code

- The MyDisplayRouteInfo method is included in the sample download and is used to display routing information.
- View or download sample code (how to download)

Debug diagnostics

For detailed routing diagnostic output, set `Logging:LogLevel:Microsoft` to `Debug`. In the development

environment, set the log level in *appsettings.Development.json*:

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Debug",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  }
}
```

ASP.NET Core MVC uses the Routing middleware to match the URLs of incoming requests and map them to actions. Routes are defined in startup code or attributes. Routes describe how URL paths should be matched to actions. Routes are also used to generate URLs (for links) sent out in responses.

Actions are either conventionally routed or attribute routed. Placing a route on the controller or the action makes it attribute routed. See Mixed routing for more information.

This document will explain the interactions between MVC and routing, and how typical MVC apps make use of routing features. See Routing for details on advanced routing.

Setting up Routing Middleware

In your *Configure* method you may see code similar to:

```
app.UseMvc(routes =>
{
   routes.MapRoute("default", "{controller=Home}/{action=Index}/{id?}");
});
```

Inside the call to `UseMvc`, `MapRoute` is used to create a single route, which we'll refer to as the `default` route. Most MVC apps will use a route with a template similar to the `default` route.

The route template `"{controller=Home}/{action=Index}/{id?}"` can match a URL path like `/Products/Details/5` and will extract the route values `{ controller = Products, action = Details, id = 5 }` by tokenizing the path. MVC will attempt to locate a controller named `ProductsController` and run the action `Details`:

```
public class ProductsController : Controller
{
   public IActionResult Details(int id) { ... }
}
```

Note that in this example, model binding would use the value of `id = 5` to set the `id` parameter to `5` when invoking this action. See the Model Binding for more details.

Using the `default` route:

```
routes.MapRoute("default", "{controller=Home}/{action=Index}/{id?}");
```

The route template:

- `{controller=Home}` defines `Home` as the default `controller`
- `{action=Index}` defines `Index` as the default `action`

- `{id?}` defines `id` as optional

Default and optional route parameters don't need to be present in the URL path for a match. See Route Template Reference for a detailed description of route template syntax.

`"{controller=Home}/{action=Index}/{id?}"` can match the URL path `/` and will produce the route values `{ controller = Home, action = Index }`. The values for `controller` and `action` make use of the default values, `id` doesn't produce a value since there's no corresponding segment in the URL path. MVC would use these route values to select the `HomeController` and `Index` action:

```
public class HomeController : Controller
{
  public IActionResult Index() { ... }
}
```

Using this controller definition and route template, the `HomeController.Index` action would be executed for any of the following URL paths:

- `/Home/Index/17`
- `/Home/Index`
- `/Home`
- `/`

The convenience method `UseMvcWithDefaultRoute`:

```
app.UseMvcWithDefaultRoute();
```

Can be used to replace:

```
app.UseMvc(routes =>
{
   routes.MapRoute("default", "{controller=Home}/{action=Index}/{id?}");
});
```

`UseMvc` and `UseMvcWithDefaultRoute` add an instance of `RouterMiddleware` to the middleware pipeline. MVC doesn't interact directly with middleware, and uses routing to handle requests. MVC is connected to the routes through an instance of `MvcRouteHandler`. The code inside of `UseMvc` is similar to the following:

```
var routes = new RouteBuilder(app);

// Add connection to MVC, will be hooked up by calls to MapRoute.
routes.DefaultHandler = new MvcRouteHandler(...);

// Execute callback to register routes.
// routes.MapRoute("default", "{controller=Home}/{action=Index}/{id?}");

// Create route collection and add the middleware.
app.UseRouter(routes.Build());
```

`UseMvc` doesn't directly define any routes, it adds a placeholder to the route collection for the `attribute` route. The overload `UseMvc(Action<IRouteBuilder>)` lets you add your own routes and also supports attribute routing. `UseMvc` and all of its variations add a placeholder for the attribute route - attribute routing is always available regardless of how you configure `UseMvc`. `UseMvcWithDefaultRoute` defines a default route and

supports attribute routing. The Attribute Routing section includes more details on attribute routing.

Conventional routing

The `default` route:

```
routes.MapRoute("default", "{controller=Home}/{action=Index}/{id?}");
```

The preceding code is an example of a conventional routing. This style is called conventional routing because it establishes a *convention* for URL paths:

- The first path segment maps to the controller name.
- The second maps to the action name.
- The third segment is used for an optional `id`. `id` maps to a model entity.

Using this `default` route, the URL path `/Products/List` maps to the `ProductsController.List` action, and `/Blog/Article/17` maps to `BlogController.Article`. This mapping is based on the controller and action names **only** and isn't based on namespaces, source file locations, or method parameters.

> **TIP**
> Using conventional routing with the default route allows you to build the application quickly without having to come up with a new URL pattern for each action you define. For an application with CRUD style actions, having consistency for the URLs across your controllers can help simplify your code and make your UI more predictable.

> **WARNING**
> The `id` is defined as optional by the route template, meaning that your actions can execute without the ID provided as part of the URL. Usually what will happen if `id` is omitted from the URL is that it will be set to `0` by model binding, and as a result no entity will be found in the database matching `id == 0`. Attribute routing can give you fine-grained control to make the ID required for some actions and not for others. By convention the documentation will include optional parameters like `id` when they're likely to appear in correct usage.

Multiple routes

You can add multiple routes inside `UseMvc` by adding more calls to `MapRoute`. Doing so allows you to define multiple conventions, or to add conventional routes that are dedicated to a specific action, such as:

```
app.UseMvc(routes =>
{
   routes.MapRoute("blog", "blog/{*article}",
            defaults: new { controller = "Blog", action = "Article" });
   routes.MapRoute("default", "{controller=Home}/{action=Index}/{id?}");
});
```

The `blog` route here is a *dedicated conventional route*, meaning that it uses the conventional routing system, but is dedicated to a specific action. Since `controller` and `action` don't appear in the route template as parameters, they can only have the default values, and thus this route will always map to the action `BlogController.Article`.

Routes in the route collection are ordered, and will be processed in the order they're added. So in this example, the `blog` route will be tried before the `default` route.

> **NOTE**
>
> *Dedicated conventional routes* often use **catch-all** route parameters like `{*article}` to capture the remaining portion of the URL path. This can make a route 'too greedy' meaning that it matches URLs that you intended to be matched by other routes. Put the 'greedy' routes later in the route table to solve this.

Fallback

As part of request processing, MVC will verify that the route values can be used to find a controller and action in your application. If the route values don't match an action then the route isn't considered a match, and the next route will be tried. This is called *fallback*, and it's intended to simplify cases where conventional routes overlap.

Disambiguating actions

When two actions match through routing, MVC must disambiguate to choose the 'best' candidate or else throw an exception. For example:

```
public class ProductsController : Controller
{
   public IActionResult Edit(int id) { ... }

   [HttpPost]
   public IActionResult Edit(int id, Product product) { ... }
}
```

This controller defines two actions that would match the URL path `/Products/Edit/17` and route data `{ controller = Products, action = Edit, id = 17 }`. This is a typical pattern for MVC controllers where `Edit(int)` shows a form to edit a product, and `Edit(int, Product)` processes the posted form. To make this possible MVC would need to choose `Edit(int, Product)` when the request is an HTTP `POST` and `Edit(int)` when the HTTP verb is anything else.

The `HttpPostAttribute` (`[HttpPost]`) is an implementation of `IActionConstraint` that will only allow the action to be selected when the HTTP verb is `POST`. The presence of an `IActionConstraint` makes the `Edit(int, Product)` a 'better' match than `Edit(int)`, so `Edit(int, Product)` will be tried first.

You will only need to write custom `IActionConstraint` implementations in specialized scenarios, but it's important to understand the role of attributes like `HttpPostAttribute` - similar attributes are defined for other HTTP verbs. In conventional routing it's common for actions to use the same action name when they're part of a `show form -> submit form` workflow. The convenience of this pattern will become more apparent after reviewing the Understanding IActionConstraint section.

If multiple routes match, and MVC can't find a 'best' route, it will throw an `AmbiguousActionException`.

Route names

The strings `"blog"` and `"default"` in the following examples are route names:

```
app.UseMvc(routes =>
{
   routes.MapRoute("blog", "blog/{*article}",
               defaults: new { controller = "Blog", action = "Article" });
   routes.MapRoute("default", "{controller=Home}/{action=Index}/{id?}");
});
```

The route names give the route a logical name so that the named route can be used for URL generation. This greatly simplifies URL creation when the ordering of routes could make URL generation complicated. Route

names must be unique application-wide.

Route names have no impact on URL matching or handling of requests; they're used only for URL generation. Routing has more detailed information on URL generation including URL generation in MVC-specific helpers.

Attribute routing

Attribute routing uses a set of attributes to map actions directly to route templates. In the following example, `app.UseMvc();` is used in the `Configure` method and no route is passed. The `HomeController` will match a set of URLs similar to what the default route `{controller=Home}/{action=Index}/{id?}` would match:

```
public class HomeController : Controller
{
   [Route("")]
   [Route("Home")]
   [Route("Home/Index")]
   public IActionResult Index()
   {
      return View();
   }
   [Route("Home/About")]
   public IActionResult About()
   {
      return View();
   }
   [Route("Home/Contact")]
   public IActionResult Contact()
   {
      return View();
   }
}
```

The `HomeController.Index()` action will be executed for any of the URL paths `/`, `/Home`, or `/Home/Index`.

> **NOTE**
> This example highlights a key programming difference between attribute routing and conventional routing. Attribute routing requires more input to specify a route; the conventional default route handles routes more succinctly. However, attribute routing allows (and requires) precise control of which route templates apply to each action.

With attribute routing the controller name and action names play **no** role in which action is selected. This example will match the same URLs as the previous example.

```
public class MyDemoController : Controller
{
   [Route("")]
   [Route("Home")]
   [Route("Home/Index")]
   public IActionResult MyIndex()
   {
      return View("Index");
   }
   [Route("Home/About")]
   public IActionResult MyAbout()
   {
      return View("About");
   }
   [Route("Home/Contact")]
   public IActionResult MyContact()
   {
      return View("Contact");
   }
}
```

NOTE

The route templates above don't define route parameters for `action`, `area`, and `controller`. In fact, these route parameters are not allowed in attribute routes. Since the route template is already associated with an action, it wouldn't make sense to parse the action name from the URL.

Attribute routing with Http[Verb] attributes

Attribute routing can also make use of the `Http[Verb]` attributes such as `HttpPostAttribute`. All of these attributes can accept a route template. This example shows two actions that match the same route template:

```
[HttpGet("/products")]
public IActionResult ListProducts()
{
   // ...
}

[HttpPost("/products")]
public IActionResult CreateProduct(...)
{
   // ...
}
```

For a URL path like `/products` the `ProductsApi.ListProducts` action will be executed when the HTTP verb is `GET` and `ProductsApi.CreateProduct` will be executed when the HTTP verb is `POST`. Attribute routing first matches the URL against the set of route templates defined by route attributes. Once a route template matches, `IActionConstraint` constraints are applied to determine which actions can be executed.

TIP

When building a REST API, it's rare that you will want to use `[Route(...)]` on an action method as the action will accept all HTTP methods. It's better to use the more specific `Http*Verb*Attributes` to be precise about what your API supports. Clients of REST APIs are expected to know what paths and HTTP verbs map to specific logical operations.

Since an attribute route applies to a specific action, it's easy to make parameters required as part of the route template definition. In this example, `id` is required as part of the URL path.

```
public class ProductsApiController : Controller
{
   [HttpGet("/products/{id}", Name = "Products_List")]
   public IActionResult GetProduct(int id) { ... }
}
```

The `ProductsApi.GetProduct(int)` action will be executed for a URL path like `/products/3` but not for a URL path like `/products`. See Routing for a full description of route templates and related options.

Route Name

The following code defines a *route name* of `Products_List`:

```
public class ProductsApiController : Controller
{
   [HttpGet("/products/{id}", Name = "Products_List")]
   public IActionResult GetProduct(int id) { ... }
}
```

Route names can be used to generate a URL based on a specific route. Route names have no impact on the URL matching behavior of routing and are only used for URL generation. Route names must be unique application-wide.

> **NOTE**
> Contrast this with the conventional *default route*, which defines the `id` parameter as optional (`{id?}`). This ability to precisely specify APIs has advantages, such as allowing `/products` and `/products/5` to be dispatched to different actions.

Combining routes

To make attribute routing less repetitive, route attributes on the controller are combined with route attributes on the individual actions. Any route templates defined on the controller are prepended to route templates on the actions. Placing a route attribute on the controller makes **all** actions in the controller use attribute routing.

```
[Route("products")]
public class ProductsApiController : Controller
{
   [HttpGet]
   public IActionResult ListProducts() { ... }

   [HttpGet("{id}")]
   public ActionResult GetProduct(int id) { ... }
}
```

In this example the URL path `/products` can match `ProductsApi.ListProducts`, and the URL path `/products/5` can match `ProductsApi.GetProduct(int)`. Both of these actions only match HTTP `GET` because they're marked with the `HttpGetAttribute`.

Route templates applied to an action that begin with `/` or `~/` don't get combined with route templates applied to the controller. This example matches a set of URL paths similar to the *default route*.

```
[Route("Home")]
public class HomeController : Controller
{
    [Route("")]      // Combines to define the route template "Home"
    [Route("Index")] // Combines to define the route template "Home/Index"
    [Route("/")]     // Doesn't combine, defines the route template ""
    public IActionResult Index()
    {
        ViewData["Message"] = "Home index";
        var url = Url.Action("Index", "Home");
        ViewData["Message"] = "Home index" + "var url = Url.Action; =  " + url;
        return View();
    }

    [Route("About")] // Combines to define the route template "Home/About"
    public IActionResult About()
    {
        return View();
    }
}
```

Ordering attribute routes

In contrast to conventional routes, which execute in a defined order, attribute routing builds a tree and matches all routes simultaneously. This behaves as-if the route entries were placed in an ideal ordering; the most specific routes have a chance to execute before the more general routes.

For example, a route like `blog/search/{topic}` is more specific than a route like `blog/{*article}`. Logically speaking the `blog/search/{topic}` route 'runs' first, by default, because that's the only sensible ordering. Using conventional routing, the developer is responsible for placing routes in the desired order.

Attribute routes can configure an order, using the `Order` property of all of the framework provided route attributes. Routes are processed according to an ascending sort of the `Order` property. The default order is `0`. Setting a route using `Order = -1` will run before routes that don't set an order. Setting a route using `Order = 1` will run after default route ordering.

> **TIP**
>
> Avoid depending on `Order`. If your URL-space requires explicit order values to route correctly, then it's likely confusing to clients as well. In general attribute routing will select the correct route with URL matching. If the default order used for URL generation isn't working, using route name as an override is usually simpler than applying the `Order` property.

Razor Pages routing and MVC controller routing share an implementation. Information on route order in the Razor Pages topics is available at Razor Pages route and app conventions: Route order.

Token replacement in route templates ([controller], [action], [area])

For convenience, attribute routes support *token replacement* by enclosing a token in square-brackets (`[`, `]`). The tokens `[action]`, `[area]`, and `[controller]` are replaced with the values of the action name, area name, and controller name from the action where the route is defined. In the following example, the actions match URL paths as described in the comments:

```
[Route("[controller]/[action]")]
public class ProductsController : Controller
{
    [HttpGet] // Matches '/Products/List'
    public IActionResult List() {
        // ...
    }

    [HttpGet("{id}")] // Matches '/Products/Edit/{id}'
    public IActionResult Edit(int id) {
        // ...
    }
}
```

Token replacement occurs as the last step of building the attribute routes. The above example will behave the same as the following code:

```
public class ProductsController : Controller
{
    [HttpGet("[controller]/[action]")] // Matches '/Products/List'
    public IActionResult List() {
        // ...
    }

    [HttpGet("[controller]/[action]/{id}")] // Matches '/Products/Edit/{id}'
    public IActionResult Edit(int id) {
        // ...
    }
}
```

Attribute routes can also be combined with inheritance. This is particularly powerful combined with token replacement.

```
[Route("api/[controller]")]
public abstract class MyBaseController : Controller { ... }

public class ProductsController : MyBaseController
{
   [HttpGet] // Matches '/api/Products'
   public IActionResult List() { ... }

   [HttpPut("{id}")] // Matches '/api/Products/{id}'
   public IActionResult Edit(int id) { ... }
}
```

Token replacement also applies to route names defined by attribute routes. `[Route("[controller]/[action]", Name="[controller]_[action]")]` generates a unique route name for each action.

To match the literal token replacement delimiter `[` or `]`, escape it by repeating the character (`[[` or `]]`).

Use a parameter transformer to customize token replacement

Token replacement can be customized using a parameter transformer. A parameter transformer implements `IOutboundParameterTransformer` and transforms the value of parameters. For example, a custom `SlugifyParameterTransformer` parameter transformer changes the `SubscriptionManagement` route value to `subscription-management`.

The `RouteTokenTransformerConvention` is an application model convention that:

- Applies a parameter transformer to all attribute routes in an application.
- Customizes the attribute route token values as they are replaced.

```
public class SubscriptionManagementController : Controller
{
    [HttpGet("[controller]/[action]")] // Matches '/subscription-management/list-all'
    public IActionResult ListAll() { ... }
}
```

The `RouteTokenTransformerConvention` is registered as an option in `ConfigureServices`.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc(options =>
    {
        options.Conventions.Add(new RouteTokenTransformerConvention(
                                    new SlugifyParameterTransformer()));
    });
}

public class SlugifyParameterTransformer : IOutboundParameterTransformer
{
    public string TransformOutbound(object value)
    {
        if (value == null) { return null; }

        // Slugify value
        return Regex.Replace(value.ToString(), "([a-z])([A-Z])", "$1-$2").ToLower();
    }
}
```

Multiple Routes

Attribute routing supports defining multiple routes that reach the same action. The most common usage of this is to mimic the behavior of the *default conventional route* as shown in the following example:

```
[Route("[controller]")]
public class ProductsController : Controller
{
   [Route("")]     // Matches 'Products'
   [Route("Index")] // Matches 'Products/Index'
   public IActionResult Index()
}
```

Putting multiple route attributes on the controller means that each one will combine with each of the route attributes on the action methods.

```
[Route("Store")]
[Route("[controller]")]
public class ProductsController : Controller
{
   [HttpPost("Buy")]     // Matches 'Products/Buy' and 'Store/Buy'
   [HttpPost("Checkout")] // Matches 'Products/Checkout' and 'Store/Checkout'
   public IActionResult Buy()
}
```

When multiple route attributes (that implement `IActionConstraint`) are placed on an action, then each action constraint combines with the route template from the attribute that defined it.

```
[Route("api/[controller]")]
public class ProductsController : Controller
{
   [HttpPut("Buy")]      // Matches PUT 'api/Products/Buy'
   [HttpPost("Checkout")] // Matches POST 'api/Products/Checkout'
   public IActionResult Buy()
}
```

TIP

While using multiple routes on actions can seem powerful, it's better to keep your application's URL space simple and well-defined. Use multiple routes on actions only where needed, for example to support existing clients.

Specifying attribute route optional parameters, default values, and constraints

Attribute routes support the same inline syntax as conventional routes to specify optional parameters, default values, and constraints.

```
[HttpPost("product/{id:int}")]
public IActionResult ShowProduct(int id)
{
   // ...
}
```

See Route Template Reference for a detailed description of route template syntax.

Custom route attributes using `IRouteTemplateProvider`

All of the route attributes provided in the framework (`[Route(...)]` , `[HttpGet(...)]` , etc.) implement the `IRouteTemplateProvider` interface. MVC looks for attributes on controller classes and action methods when the app starts and uses the ones that implement `IRouteTemplateProvider` to build the initial set of routes.

You can implement `IRouteTemplateProvider` to define your own route attributes. Each `IRouteTemplateProvider` allows you to define a single route with a custom route template, order, and name:

```
public class MyApiControllerAttribute : Attribute, IRouteTemplateProvider
{
   public string Template => "api/[controller]";

   public int? Order { get; set; }

   public string Name { get; set; }
}
```

The attribute from the above example automatically sets the `Template` to `"api/[controller]"` when `[MyApiController]` is applied.

Using Application Model to customize attribute routes

The *application model* is an object model created at startup with all of the metadata used by MVC to route and execute your actions. The *application model* includes all of the data gathered from route attributes (through `IRouteTemplateProvider`). You can write *conventions* to modify the application model at startup time to customize how routing behaves. This section shows a simple example of customizing routing using application model.

```
using Microsoft.AspNetCore.Mvc.ApplicationModels;
using System.Linq;
using System.Text;
public class NamespaceRoutingConvention : IControllerModelConvention
{
    private readonly string _baseNamespace;

    public NamespaceRoutingConvention(string baseNamespace)
    {
        _baseNamespace = baseNamespace;
    }

    public void Apply(ControllerModel controller)
    {
        var hasRouteAttributes = controller.Selectors.Any(selector =>
                                                selector.AttributeRouteModel != null);
        if (hasRouteAttributes)
        {
            // This controller manually defined some routes, so treat this
            // as an override and not apply the convention here.
            return;
        }

        // Use the namespace and controller name to infer a route for the controller.
        //
        // Example:
        //
        //  controller.ControllerTypeInfo ->    "My.Application.Admin.UsersController"
        //  baseNamespace ->                    "My.Application"
        //
        //  template =>                         "Admin/[controller]"
        //
        // This makes your routes roughly line up with the folder structure of your project.
        //
        var namespc = controller.ControllerType.Namespace;
        if (namespc == null)
            return;
        var template = new StringBuilder();
        template.Append(namespc, _baseNamespace.Length + 1,
                        namespc.Length - _baseNamespace.Length - 1);
        template.Replace('.', '/');
        template.Append("/[controller]");

        foreach (var selector in controller.Selectors)
        {
            selector.AttributeRouteModel = new AttributeRouteModel()
            {
                Template = template.ToString()
            };
        }
    }
}
```

Mixed routing: Attribute routing vs conventional routing

MVC applications can mix the use of conventional routing and attribute routing. It's typical to use conventional routes for controllers serving HTML pages for browsers, and attribute routing for controllers serving REST APIs.

Actions are either conventionally routed or attribute routed. Placing a route on the controller or the action makes it attribute routed. Actions that define attribute routes cannot be reached through the conventional routes and vice-versa. **Any** route attribute on the controller makes all actions in the controller attribute routed.

NOTE

What distinguishes the two types of routing systems is the process applied after a URL matches a route template. In conventional routing, the route values from the match are used to choose the action and controller from a lookup table of all conventional routed actions. In attribute routing, each template is already associated with an action, and no further lookup is needed.

Complex segments

Complex segments (for example, `[Route("/dog{token}cat")]`), are processed by matching up literals from right to left in a non-greedy way. See the source code for a description. For more information, see this issue.

URL Generation

MVC applications can use routing's URL generation features to generate URL links to actions. Generating URLs eliminates hardcoding URLs, making your code more robust and maintainable. This section focuses on the URL generation features provided by MVC and will only cover basics of how URL generation works. See Routing for a detailed description of URL generation.

The `IUrlHelper` interface is the underlying piece of infrastructure between MVC and routing for URL generation. You'll find an instance of `IUrlHelper` available through the `Url` property in controllers, views, and view components.

In this example, the `IUrlHelper` interface is used through the `Controller.Url` property to generate a URL to another action.

```
using Microsoft.AspNetCore.Mvc;

public class UrlGenerationController : Controller
{
    public IActionResult Source()
    {
        // Generates /UrlGeneration/Destination
        var url = Url.Action("Destination");
        return Content($"Go check out {url}, it's really great.");
    }

    public IActionResult Destination()
    {
        return View();
    }
}
```

If the application is using the default conventional route, the value of the `url` variable will be the URL path string `/UrlGeneration/Destination`. This URL path is created by routing by combining the route values from the current request (ambient values), with the values passed to `Url.Action` and substituting those values into the route template:

```
ambient values: { controller = "UrlGeneration", action = "Source" }
values passed to Url.Action: { controller = "UrlGeneration", action = "Destination" }
route template: {controller}/{action}/{id?}

result: /UrlGeneration/Destination
```

Each route parameter in the route template has its value substituted by matching names with the values and ambient values. A route parameter that doesn't have a value can use a default value if it has one, or be

skipped if it's optional (as in the case of `id` in this example). URL generation will fail if any required route parameter doesn't have a corresponding value. If URL generation fails for a route, the next route is tried until all routes have been tried or a match is found.

The example of `Url.Action` above assumes conventional routing, but URL generation works similarly with attribute routing, though the concepts are different. With conventional routing, the route values are used to expand a template, and the route values for `controller` and `action` usually appear in that template - this works because the URLs matched by routing adhere to a *convention*. In attribute routing, the route values for `controller` and `action` are not allowed to appear in the template - they're instead used to look up which template to use.

This example uses attribute routing:

```
// In Startup class
public void Configure(IApplicationBuilder app)
{
    app.UseMvc();
}
```

```
using Microsoft.AspNetCore.Mvc;

public class UrlGenerationController : Controller
{
    [HttpGet("")]
    public IActionResult Source()
    {
        var url = Url.Action("Destination"); // Generates /custom/url/to/destination
        return Content($"Go check out {url}, it's really great.");
    }

    [HttpGet("custom/url/to/destination")]
    public IActionResult Destination() {
        return View();
    }
}
```

MVC builds a lookup table of all attribute routed actions and will match the `controller` and `action` values to select the route template to use for URL generation. In the sample above, `custom/url/to/destination` is generated.

Generating URLs by action name

`Url.Action` (`IUrlHelper` . `Action`) and all related overloads all are based on that idea that you want to specify what you're linking to by specifying a controller name and action name.

> **NOTE**
>
> When using `Url.Action`, the current route values for `controller` and `action` are specified for you - the value of `controller` and `action` are part of both *ambient values* **and** *values*. The method `Url.Action`, always uses the current values of `action` and `controller` and will generate a URL path that routes to the current action.

Routing attempts to use the values in ambient values to fill in information that you didn't provide when generating a URL. Using a route like `{a}/{b}/{c}/{d}` and ambient values `{ a = Alice, b = Bob, c = Carol, d = David }`, routing has enough information to generate a URL without any additional values - since all route parameters have a value. If you added the value `{ d = Donovan }`, the value `{ d = David }` would be ignored, and the generated URL path would be `Alice/Bob/Carol/Donovan`.

WARNING

URL paths are hierarchical. In the example above, if you added the value `{ c = Cheryl }`, both of the values `{ c = Carol, d = David }` would be ignored. In this case we no longer have a value for `d` and URL generation will fail. You would need to specify the desired value of `c` and `d`. You might expect to hit this problem with the default route (`{controller}/{action}/{id?}`) - but you will rarely encounter this behavior in practice as `Url.Action` will always explicitly specify a `controller` and `action` value.

Longer overloads of `Url.Action` also take an additional *route values* object to provide values for route parameters other than `controller` and `action`. You will most commonly see this used with `id` like `Url.Action("Buy", "Products", new { id = 17 })`. By convention the *route values* object is usually an object of anonymous type, but it can also be an `IDictionary<>` or a *plain old .NET object*. Any additional route values that don't match route parameters are put in the query string.

```
using Microsoft.AspNetCore.Mvc;

public class TestController : Controller
{
    public IActionResult Index()
    {
        // Generates /Products/Buy/17?color=red
        var url = Url.Action("Buy", "Products", new { id = 17, color = "red" });
        return Content(url);
    }
}
```

TIP

To create an absolute URL, use an overload that accepts a `protocol`:
`Url.Action("Buy", "Products", new { id = 17 }, protocol: Request.Scheme)`

Generating URLs by route

The code above demonstrated generating a URL by passing in the controller and action name. `IUrlHelper` also provides the `Url.RouteUrl` family of methods. These methods are similar to `Url.Action`, but they don't copy the current values of `action` and `controller` to the route values. The most common usage is to specify a route name to use a specific route to generate the URL, generally *without* specifying a controller or action name.

```
using Microsoft.AspNetCore.Mvc;

public class UrlGenerationController : Controller
{
    [HttpGet("")]
    public IActionResult Source()
    {
        var url = Url.RouteUrl("Destination_Route"); // Generates /custom/url/to/destination
        return Content($"See {url}, it's really great.");
    }

    [HttpGet("custom/url/to/destination", Name = "Destination_Route")]
    public IActionResult Destination() {
        return View();
    }
}
```

Generating URLs in HTML

`IHtmlHelper` provides the `HtmlHelper` methods `Html.BeginForm` and `Html.ActionLink` to generate `<form>` and `<a>` elements respectively. These methods use the `Url.Action` method to generate a URL and they accept similar arguments. The `Url.RouteUrl` companions for `HtmlHelper` are `Html.BeginRouteForm` and `Html.RouteLink` which have similar functionality.

TagHelpers generate URLs through the `form` TagHelper and the `<a>` TagHelper. Both of these use `IUrlHelper` for their implementation. See Working with Forms for more information.

Inside views, the `IUrlHelper` is available through the `Url` property for any ad-hoc URL generation not covered by the above.

Generating URLS in Action Results

The examples above have shown using `IUrlHelper` in a controller, while the most common usage in a controller is to generate a URL as part of an action result.

The `ControllerBase` and `Controller` base classes provide convenience methods for action results that reference another action. One typical usage is to redirect after accepting user input.

```
public IActionResult Edit(int id, Customer customer)
{
    if (ModelState.IsValid)
    {
        // Update DB with new details.
        return RedirectToAction("Index");
    }
    return View(customer);
}
```

The action results factory methods follow a similar pattern to the methods on `IUrlHelper`.

Special case for dedicated conventional routes

Conventional routing can use a special kind of route definition called a *dedicated conventional route*. In the example below, the route named `blog` is a dedicated conventional route.

```
app.UseMvc(routes =>
{
    routes.MapRoute("blog", "blog/{*article}",
        defaults: new { controller = "Blog", action = "Article" });
    routes.MapRoute("default", "{controller=Home}/{action=Index}/{id?}");
});
```

Using these route definitions, `Url.Action("Index", "Home")` will generate the URL path `/` with the `default` route, but why? You might guess the route values `{ controller = Home, action = Index }` would be enough to generate a URL using `blog`, and the result would be `/blog?action=Index&controller=Home`.

Dedicated conventional routes rely on a special behavior of default values that don't have a corresponding route parameter that prevents the route from being "too greedy" with URL generation. In this case the default values are `{ controller = Blog, action = Article }`, and neither `controller` nor `action` appears as a route parameter. When routing performs URL generation, the values provided must match the default values. URL generation using `blog` will fail because the values `{ controller = Home, action = Index }` don't match `{ controller = Blog, action = Article }`. Routing then falls back to try `default`, which succeeds.

Areas

Areas are an MVC feature used to organize related functionality into a group as a separate routing-namespace (for controller actions) and folder structure (for views). Using areas allows an application to have

multiple controllers with the same name - as long as they have different *areas*. Using areas creates a hierarchy for the purpose of routing by adding another route parameter, `area` to `controller` and `action`. This section will discuss how routing interacts with areas - see Areas for details about how areas are used with views.

The following example configures MVC to use the default conventional route and an *area route* for an area named `Blog`:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapAreaControllerRoute("blog_route", "Blog",
        "Manage/{controller}/{action}/{id?}");
    endpoints.MapControllerRoute("default_route", "{controller}/{action}/{id?}");
});
```

When matching a URL path like `/Manage/Users/AddUser`, the first route will produce the route values `{ area = Blog, controller = Users, action = AddUser }`. The `area` route value is produced by a default value for `area`, in fact the route created by `MapAreaRoute` is equivalent to the following:

```

```

`MapAreaRoute` creates a route using both a default value and constraint for `area` using the provided area name, in this case `Blog`. The default value ensures that the route always produces `{ area = Blog, ... }`, the constraint requires the value `{ area = Blog, ... }` for URL generation.

> **TIP**
> Conventional routing is order-dependent. In general, routes with areas should be placed earlier in the route table as they're more specific than routes without an area.

Using the above example, the route values would match the following action:

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace1
{
    [Area("Blog")]
    public class UsersController : Controller
    {
        // GET /manage/users/adduser
        public IActionResult AddUser()
        {
            var area = ControllerContext.ActionDescriptor.RouteValues["area"];
            var actionName = ControllerContext.ActionDescriptor.ActionName;
            var controllerName = ControllerContext.ActionDescriptor.ControllerName;

            return Content($"area name:{area}" +
                $" controller:{controllerName}  action name: {actionName}");
        }
    }
}
```

The `AreaAttribute` is what denotes a controller as part of an area, we say that this controller is in the `Blog` area. Controllers without an `[Area]` attribute are not members of any area, and will **not** match when the `area` route value is provided by routing. In the following example, only the first controller listed can match the route values `{ area = Blog, controller = Users, action = AddUser }`.

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace1
{
    [Area("Blog")]
    public class UsersController : Controller
    {
        // GET /manage/users/adduser
        public IActionResult AddUser()
        {
            var area = ControllerContext.ActionDescriptor.RouteValues["area"];
            var actionName = ControllerContext.ActionDescriptor.ActionName;
            var controllerName = ControllerContext.ActionDescriptor.ControllerName;

            return Content($"area name:{area}" +
                $" controller:{controllerName}  action name: {actionName}");
        }
    }
}
```

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace2
{
    // Matches { area = Zebra, controller = Users, action = AddUser }
    [Area("Zebra")]
    public class UsersController : Controller
    {
        // GET /zebra/users/adduser
        public IActionResult AddUser()
        {
            var area = ControllerContext.ActionDescriptor.RouteValues["area"];
            var actionName = ControllerContext.ActionDescriptor.ActionName;
            var controllerName = ControllerContext.ActionDescriptor.ControllerName;

            return Content($"area name:{area}" +
                $" controller:{controllerName}  action name: {actionName}");
        }
    }
}
```

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace3
{
    // Matches { area = string.Empty, controller = Users, action = AddUser }
    // Matches { area = null, controller = Users, action = AddUser }
    // Matches { controller = Users, action = AddUser }
    public class UsersController : Controller
    {
        // GET /users/adduser
        public IActionResult AddUser()
        {
            var area = ControllerContext.ActionDescriptor.RouteValues["area"];
            var actionName = ControllerContext.ActionDescriptor.ActionName;
            var controllerName = ControllerContext.ActionDescriptor.ControllerName;

            return Content($"area name:{area}" +
                $" controller:{controllerName}  action name: {actionName}");
        }
    }
}
```

NOTE

The namespace of each controller is shown here for completeness - otherwise the controllers would have a naming conflict and generate a compiler error. Class namespaces have no effect on MVC's routing.

The first two controllers are members of areas, and only match when their respective area name is provided by the `area` route value. The third controller isn't a member of any area, and can only match when no value for `area` is provided by routing.

NOTE

In terms of matching *no value*, the absence of the `area` value is the same as if the value for `area` were null or the empty string.

When executing an action inside an area, the route value for `area` will be available as an *ambient value* for routing to use for URL generation. This means that by default areas act *sticky* for URL generation as demonstrated by the following sample.

```
using Microsoft.AspNetCore.Mvc;

namespace MyApp.Namespace4
{
    [Area("Duck")]
    public class UsersController : Controller
    {
        // GET /Manage/users/GenerateURLInArea
        public IActionResult GenerateURLInArea()
        {
            // Uses the 'ambient' value of area.
            var url = Url.Action("Index", "Home");
            // Returns /Manage/Home/Index
            return Content(url);
        }

        // GET /Manage/users/GenerateURLOutsideOfArea
        public IActionResult GenerateURLOutsideOfArea()
        {
            // Uses the empty value for area.
            var url = Url.Action("Index", "Home", new { area = "" });
            // Returns /Manage
            return Content(url);
        }
    }
}
```

Understanding IActionConstraint

NOTE

This section is a deep-dive on framework internals and how MVC chooses an action to execute. A typical application won't need a custom `IActionConstraint`

You have likely already used `IActionConstraint` even if you're not familiar with the interface. The `[HttpGet]` Attribute and similar `[Http-VERB]` attributes implement `IActionConstraint` in order to limit the execution of

an action method.

```
public class ProductsController : Controller
{
    [HttpGet]
    public IActionResult Edit() { }

    public IActionResult Edit(...) { }
}
```

Assuming the default conventional route, the URL path `/Products/Edit` would produce the values `{ controller = Products, action = Edit }`, which would match **both** of the actions shown here. In `IActionConstraint` terminology we would say that both of these actions are considered candidates - as they both match the route data.

When the `HttpGetAttribute` executes, it will say that *Edit()* is a match for *GET* and isn't a match for any other HTTP verb. The `Edit(...)` action doesn't have any constraints defined, and so will match any HTTP verb. So assuming a `POST` - only `Edit(...)` matches. But, for a `GET` both actions can still match - however, an action with an `IActionConstraint` is always considered *better* than an action without. So because `Edit()` has `[HttpGet]` it's considered more specific, and will be selected if both actions can match.

Conceptually, `IActionConstraint` is a form of *overloading*, but instead of overloading methods with the same name, it's overloading between actions that match the same URL. Attribute routing also uses `IActionConstraint` and can result in actions from different controllers both being considered candidates.

Implementing IActionConstraint

The simplest way to implement an `IActionConstraint` is to create a class derived from `System.Attribute` and place it on your actions and controllers. MVC will automatically discover any `IActionConstraint` that are applied as attributes. You can use the application model to apply constraints, and this is probably the most flexible approach as it allows you to metaprogram how they're applied.

In the following example, a constraint chooses an action based on a *country code* from the route data. The full sample on GitHub.

```
public class CountrySpecificAttribute : Attribute, IActionConstraint
{
    private readonly string _countryCode;

    public CountrySpecificAttribute(string countryCode)
    {
        _countryCode = countryCode;
    }

    public int Order
    {
        get
        {
            return 0;
        }
    }

    public bool Accept(ActionConstraintContext context)
    {
        return string.Equals(
            context.RouteContext.RouteData.Values["country"].ToString(),
            _countryCode,
            StringComparison.OrdinalIgnoreCase);
    }
}
```

You are responsible for implementing the `Accept` method and choosing an 'Order' for the constraint to execute. In this case, the `Accept` method returns `true` to denote the action is a match when the `country` route value matches. This is different from a `RouteValueAttribute` in that it allows fallback to a non-attributed action. The sample shows that if you define an `en-US` action then a country code like `fr-FR` will fall back to a more generic controller that doesn't have `[CountrySpecific(...)]` applied.

The `Order` property decides which *stage* the constraint is part of. Action constraints run in groups based on the `Order`. For example, all of the framework provided HTTP method attributes use the same `Order` value so that they run in the same stage. You can have as many stages as you need to implement your desired policies.

> **TIP**
> To decide on a value for `Order` think about whether or not your constraint should be applied before HTTP methods. Lower numbers run first.

Dependency injection into controllers in ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

By Shadi Namrouti, Rick Anderson, and Steve Smith

ASP.NET Core MVC controllers request dependencies explicitly via constructors. ASP.NET Core has built-in support for dependency injection (DI). DI makes apps easier to test and maintain.

View or download sample code (how to download)

Constructor Injection

Services are added as a constructor parameter, and the runtime resolves the service from the service container. Services are typically defined using interfaces. For example, consider an app that requires the current time. The following interface exposes the `IDateTime` service:

```
public interface IDateTime
{
    DateTime Now { get; }
}
```

The following code implements the `IDateTime` interface:

```
public class SystemDateTime : IDateTime
{
    public DateTime Now
    {
        get { return DateTime.Now; }
    }
}
```

Add the service to the service container:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSingleton<IDateTime, SystemDateTime>();

    services.AddControllersWithViews();
}
```

For more information on AddSingleton, see DI service lifetimes.

The following code displays a greeting to the user based on the time of day:

```
public class HomeController : Controller
{
    private readonly IDateTime _dateTime;

    public HomeController(IDateTime dateTime)
    {
        _dateTime = dateTime;
    }

    public IActionResult Index()
    {
        var serverTime = _dateTime.Now;
        if (serverTime.Hour < 12)
        {
            ViewData["Message"] = "It's morning here - Good Morning!";
        }
        else if (serverTime.Hour < 17)
        {
            ViewData["Message"] = "It's afternoon here - Good Afternoon!";
        }
        else
        {
            ViewData["Message"] = "It's evening here - Good Evening!";
        }
        return View();
    }
```

Run the app and a message is displayed based on the time.

Action injection with FromServices

The FromServicesAttribute enables injecting a service directly into an action method without using constructor injection:

```
public IActionResult About([FromServices] IDateTime dateTime)
{
    return Content( $"Current server time: {dateTime.Now}");
}
```

Access settings from a controller

Accessing app or configuration settings from within a controller is a common pattern. The *options pattern* described in Options pattern in ASP.NET Core is the preferred approach to manage settings. Generally, don't directly inject IConfiguration into a controller.

Create a class that represents the options. For example:

```
public class SampleWebSettings
{
    public string Title { get; set; }
    public int Updates { get; set; }
}
```

Add the configuration class to the services collection:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSingleton<IDateTime, SystemDateTime>();
    services.Configure<SampleWebSettings>(Configuration);

    services.AddControllersWithViews();
}
```

Configure the app to read the settings from a JSON-formatted file:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddJsonFile("samplewebsettings.json",
                    optional: false,
                    reloadOnChange: true);
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The following code requests the `IOptions<SampleWebSettings>` settings from the service container and uses them in the `Index` method:

```
public class SettingsController : Controller
{
    private readonly SampleWebSettings _settings;

    public SettingsController(IOptions<SampleWebSettings> settingsOptions)
    {
        _settings = settingsOptions.Value;
    }

    public IActionResult Index()
    {
        ViewData["Title"] = _settings.Title;
        ViewData["Updates"] = _settings.Updates;
        return View();
    }
}
```

Additional resources

- See Test controller logic in ASP.NET Core to learn how to make code easier to test by explicitly requesting dependencies in controllers.
- Replace the default dependency injection container with a third party implementation.

By Shadi Namrouti, Rick Anderson, and Steve Smith

ASP.NET Core MVC controllers request dependencies explicitly via constructors. ASP.NET Core has built-in support

for dependency injection (DI). DI makes apps easier to test and maintain.

View or download sample code (how to download)

Constructor Injection

Services are added as a constructor parameter, and the runtime resolves the service from the service container. Services are typically defined using interfaces. For example, consider an app that requires the current time. The following interface exposes the `IDateTime` service:

```
public interface IDateTime
{
    DateTime Now { get; }
}
```

The following code implements the `IDateTime` interface:

```
public class SystemDateTime : IDateTime
{
    public DateTime Now
    {
        get { return DateTime.Now; }
    }
}
```

Add the service to the service container:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSingleton<IDateTime, SystemDateTime>();

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

For more information on AddSingleton, see DI service lifetimes.

The following code displays a greeting to the user based on the time of day:

```
public class HomeController : Controller
{
    private readonly IDateTime _dateTime;

    public HomeController(IDateTime dateTime)
    {
        _dateTime = dateTime;
    }

    public IActionResult Index()
    {
        var serverTime = _dateTime.Now;
        if (serverTime.Hour < 12)
        {
            ViewData["Message"] = "It's morning here - Good Morning!";
        }
        else if (serverTime.Hour < 17)
        {
            ViewData["Message"] = "It's afternoon here - Good Afternoon!";
        }
        else
        {
            ViewData["Message"] = "It's evening here - Good Evening!";
        }
        return View();
    }
```

Run the app and a message is displayed based on the time.

Action injection with FromServices

The FromServicesAttribute enables injecting a service directly into an action method without using constructor injection:

```
public IActionResult About([FromServices] IDateTime dateTime)
{
    ViewData["Message"] = $"Current server time: {dateTime.Now}";

    return View();
}
```

Access settings from a controller

Accessing app or configuration settings from within a controller is a common pattern. The *options pattern* described in Options pattern in ASP.NET Core is the preferred approach to manage settings. Generally, don't directly inject IConfiguration into a controller.

Create a class that represents the options. For example:

```
public class SampleWebSettings
{
    public string Title { get; set; }
    public int Updates { get; set; }
}
```

Add the configuration class to the services collection:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSingleton<IDateTime, SystemDateTime>();
    services.Configure<SampleWebSettings>(Configuration);

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

Configure the app to read the settings from a JSON-formatted file:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
        .ConfigureAppConfiguration((hostingContext, config) =>
        {
            config.AddJsonFile("samplewebsettings.json",
                               optional: false,        // File is not optional.
                               reloadOnChange: false);
        })
        .UseStartup<Startup>();
}
```

The following code requests the `IOptions<SampleWebSettings>` settings from the service container and uses them in the `Index` method:

```
public class SettingsController : Controller
{
    private readonly SampleWebSettings _settings;

    public SettingsController(IOptions<SampleWebSettings> settingsOptions)
    {
        _settings = settingsOptions.Value;
    }

    public IActionResult Index()
    {
        ViewData["Title"] = _settings.Title;
        ViewData["Updates"] = _settings.Updates;
        return View();
    }
}
```

- See Test controller logic in ASP.NET Core to learn how to make code easier to test by explicitly requesting dependencies in controllers.
- Replace the default dependency injection container with a third party implementation.

Dependency injection into views in ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

By Steve Smith

ASP.NET Core supports dependency injection into views. This can be useful for view-specific services, such as localization or data required only for populating view elements. You should try to maintain separation of concerns between your controllers and views. Most of the data your views display should be passed in from the controller.

View or download sample code (how to download)

Configuration injection

appsettings.json values can be injected directly into a view.

Example of an *appsettings.json* file:

```
{
   "root": {
      "parent": {
         "child": "myvalue"
      }
   }
}
```

The syntax for `@inject`: `@inject <type> <name>`

An example using `@inject`:

```
@using Microsoft.Extensions.Configuration
@inject IConfiguration Configuration
@{
   string myValue = Configuration["root:parent:child"];
   ...
}
```

Service injection

A service can be injected into a view using the `@inject` directive. You can think of `@inject` as adding a property to the view, and populating the property using DI.

```
@using System.Threading.Tasks
@using ViewInjectSample.Model
@using ViewInjectSample.Model.Services
@model IEnumerable<ToDoItem>
@inject StatisticsService StatsService
<!DOCTYPE html>
<html>
<head>
    <title>To Do Items</title>
</head>
<body>
    <div>
        <h1>To Do Items</h1>
        <ul>
            <li>Total Items: @StatsService.GetCount()</li>
            <li>Completed: @StatsService.GetCompletedCount()</li>
            <li>Avg. Priority: @StatsService.GetAveragePriority()</li>
        </ul>
        <table>
            <tr>
                <th>Name</th>
                <th>Priority</th>
                <th>Is Done?</th>
            </tr>
            @foreach (var item in Model)
            {
                <tr>
                    <td>@item.Name</td>
                    <td>@item.Priority</td>
                    <td>@item.IsDone</td>
                </tr>
            }
        </table>
    </div>
</body>
</html>
```

This view displays a list of `ToDoItem` instances, along with a summary showing overall statistics. The summary is populated from the injected `StatisticsService`. This service is registered for dependency injection in `ConfigureServices` in *Startup.cs*:

```
// For more information on how to configure your application, visit http://go.microsoft.com/fwlink/?
LinkID=398940
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc();

    services.AddTransient<IToDoItemRepository, ToDoItemRepository>();
    services.AddTransient<StatisticsService>();
    services.AddTransient<ProfileOptionsService>();
```

The `StatisticsService` performs some calculations on the set of `ToDoItem` instances, which it accesses via a repository:

```
using System.Linq;
using ViewInjectSample.Interfaces;

namespace ViewInjectSample.Model.Services
{
    public class StatisticsService
    {
        private readonly IToDoItemRepository _toDoItemRepository;

        public StatisticsService(IToDoItemRepository toDoItemRepository)
        {
            _toDoItemRepository = toDoItemRepository;
        }

        public int GetCount()
        {
            return _toDoItemRepository.List().Count();
        }

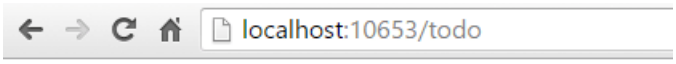
        public int GetCompletedCount()
        {
            return _toDoItemRepository.List().Count(x => x.IsDone);
        }

        public double GetAveragePriority()
        {
            if (_toDoItemRepository.List().Count() == 0)
            {
                return 0.0;
            }

            return _toDoItemRepository.List().Average(x => x.Priority);
        }
    }
}
```

The sample repository uses an in-memory collection. The implementation shown above (which operates on all of the data in memory) isn't recommended for large, remotely accessed data sets.

The sample displays data from the model bound to the view and the service injected into the view:



To Do Items

- Total Items: 50
- Completed: 17
- Avg. Priority: 3

Name	Priority	Is Done?
Task 1	1	True
Task 2	2	False
Task 3	3	False
Task 4	4	True
Task 5	5	False

Populating Lookup Data

View injection can be useful to populate options in UI elements, such as dropdown lists. Consider a user profile form that includes options for specifying gender, state, and other preferences. Rendering such a form using a standard MVC approach would require the controller to request data access services for each of these sets of

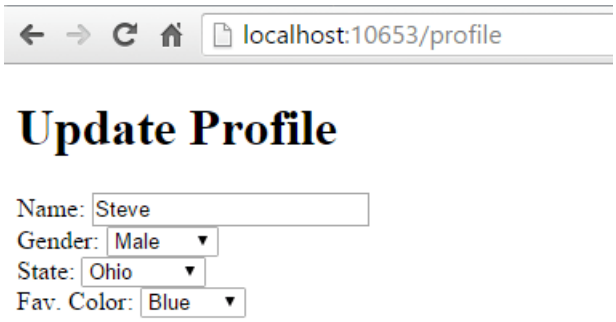
options, and then populate a model or `ViewBag` with each set of options to be bound.

An alternative approach injects services directly into the view to obtain the options. This minimizes the amount of code required by the controller, moving this view element construction logic into the view itself. The controller action to display a profile editing form only needs to pass the form the profile instance:

```
using Microsoft.AspNetCore.Mvc;
using ViewInjectSample.Model;

namespace ViewInjectSample.Controllers
{
    public class ProfileController : Controller
    {
        [Route("Profile")]
        public IActionResult Index()
        {
            // TODO: look up profile based on logged-in user
            var profile = new Profile()
            {
                Name = "Steve",
                FavColor = "Blue",
                Gender = "Male",
                State = new State("Ohio","OH")
            };
            return View(profile);
        }
    }
}
```

The HTML form used to update these preferences includes dropdown lists for three of the properties:



These lists are populated by a service that has been injected into the view:

```
@using System.Threading.Tasks
@using ViewInjectSample.Model.Services
@model ViewInjectSample.Model.Profile
@inject ProfileOptionsService Options
<!DOCTYPE html>
<html>
<head>
    <title>Update Profile</title>
</head>
<body>
<div>
    <h1>Update Profile</h1>
    Name: @Html.TextBoxFor(m => m.Name)
    <br/>
    Gender: @Html.DropDownList("Gender",
           Options.ListGenders().Select(g =>
                new SelectListItem() { Text = g, Value = g }))
    <br/>

    State: @Html.DropDownListFor(m => m.State.Code,
           Options.ListStates().Select(s =>
                new SelectListItem() { Text = s.Name, Value = s.Code}))
    <br />

    Fav. Color: @Html.DropDownList("FavColor",
           Options.ListColors().Select(c =>
                new SelectListItem() { Text = c, Value = c }))
    </div>
</body>
</html>
```

The `ProfileOptionsService` is a UI-level service designed to provide just the data needed for this form:

```
using System.Collections.Generic;

namespace ViewInjectSample.Model.Services
{
    public class ProfileOptionsService
    {
        public List<string> ListGenders()
        {
            // keeping this simple
            return new List<string>() {"Female", "Male"};
        }

        public List<State> ListStates()
        {
            // a few states from USA
            return new List<State>()
            {
                new State("Alabama", "AL"),
                new State("Alaska", "AK"),
                new State("Ohio", "OH")
            };
        }

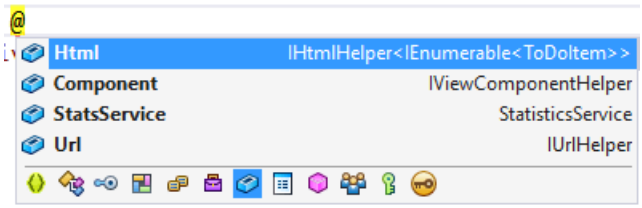
        public List<string> ListColors()
        {
            return new List<string>() { "Blue","Green","Red","Yellow" };
        }
    }
}
```

IMPORTANT

Don't forget to register types you request through dependency injection in `Startup.ConfigureServices`. An unregistered type throws an exception at runtime because the service provider is internally queried via GetRequiredService.

Overriding Services

In addition to injecting new services, this technique can also be used to override previously injected services on a page. The figure below shows all of the fields available on the page used in the first example:



As you can see, the default fields include `Html`, `Component`, and `Url` (as well as the `StatsService` that we injected). If for instance you wanted to replace the default HTML Helpers with your own, you could easily do so using `@inject`:

```
@using System.Threading.Tasks
@using ViewInjectSample.Helpers
@inject MyHtmlHelper Html
<!DOCTYPE html>
<html>
<head>
    <title>My Helper</title>
</head>
<body>
    <div>
        Test: @Html.Value
    </div>
</body>
</html>
```

If you want to extend existing services, you can simply use this technique while inheriting from or wrapping the existing implementation with your own.

Unit test controller logic in ASP.NET Core

9/22/2020 • 25 minutes to read • Edit Online

By Steve Smith

Unit tests involve testing a part of an app in isolation from its infrastructure and dependencies. When unit testing controller logic, only the contents of a single action are tested, not the behavior of its dependencies or of the framework itself.

Unit testing controllers

Set up unit tests of controller actions to focus on the controller's behavior. A controller unit test avoids scenarios such as filters, routing, and model binding. Tests that cover the interactions among components that collectively respond to a request are handled by *integration tests*. For more information on integration tests, see Integration tests in ASP.NET Core.

If you're writing custom filters and routes, unit test them in isolation, not as part of tests on a particular controller action.

To demonstrate controller unit tests, review the following controller in the sample app.

View or download sample code (how to download)

The Home controller displays a list of brainstorming sessions and allows the creation of new brainstorming sessions with a POST request:

```
public class HomeController : Controller
{
    private readonly IBrainstormSessionRepository _sessionRepository;

    public HomeController(IBrainstormSessionRepository sessionRepository)
    {
        _sessionRepository = sessionRepository;
    }

    public async Task<IActionResult> Index()
    {
        var sessionList = await _sessionRepository.ListAsync();

        var model = sessionList.Select(session => new StormSessionViewModel()
        {
            Id = session.Id,
            DateCreated = session.DateCreated,
            Name = session.Name,
            IdeaCount = session.Ideas.Count
        });

        return View(model);
    }

    public class NewSessionModel
    {
        [Required]
        public string SessionName { get; set; }
    }

    [HttpPost]
    public async Task<IActionResult> Index(NewSessionModel model)
    {
        if (!ModelState.IsValid)
        {
            return BadRequest(ModelState);
        }
        else
        {
            await _sessionRepository.AddAsync(new BrainstormSession()
            {
                DateCreated = DateTimeOffset.Now,
                Name = model.SessionName
            });
        }

        return RedirectToAction(actionName: nameof(Index));
    }
}
```

The preceding controller:

- Follows the Explicit Dependencies Principle.
- Expects dependency injection (DI) to provide an instance of `IBrainstormSessionRepository`.
- Can be tested with a mocked `IBrainstormSessionRepository` service using a mock object framework, such as Moq. A *mocked object* is a fabricated object with a predetermined set of property and method behaviors used for testing. For more information, see Introduction to integration tests.

The `HTTP GET Index` method has no looping or branching and only calls one method. The unit test for this action:

- Mocks the `IBrainstormSessionRepository` service using the `GetTestSessions` method. `GetTestSessions` creates two mock brainstorm sessions with dates and session names.
- Executes the `Index` method.

- Makes assertions on the result returned by the method:
  - A ViewResult is returned.
  - The ViewDataDictionary.Model is a `StormSessionViewModel`.
  - There are two brainstorming sessions stored in the `ViewDataDictionary.Model`.

```
[Fact]
public async Task Index_ReturnsAViewResult_WithAListOfBrainstormSessions()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.ListAsync())
        .ReturnsAsync(GetTestSessions());
    var controller = new HomeController(mockRepo.Object);

    // Act
    var result = await controller.Index();

    // Assert
    var viewResult = Assert.IsType<ViewResult>(result);
    var model = Assert.IsAssignableFrom<IEnumerable<StormSessionViewModel>>(
        viewResult.ViewData.Model);
    Assert.Equal(2, model.Count());
}
```

```
private List<BrainstormSession> GetTestSessions()
{
    var sessions = new List<BrainstormSession>();
    sessions.Add(new BrainstormSession()
    {
        DateCreated = new DateTime(2016, 7, 2),
        Id = 1,
        Name = "Test One"
    });
    sessions.Add(new BrainstormSession()
    {
        DateCreated = new DateTime(2016, 7, 1),
        Id = 2,
        Name = "Test Two"
    });
    return sessions;
}
```

The Home controller's `HTTP POST Index` method tests verifies that:

- When ModelState.IsValid is `false`, the action method returns a *400 Bad Request* ViewResult with the appropriate data.
- When `ModelState.IsValid` is `true`:
  - The `Add` method on the repository is called.
  - A RedirectToActionResult is returned with the correct arguments.

An invalid model state is tested by adding errors using AddModelError as shown in the first test below:

```
[Fact]
public async Task IndexPost_ReturnsBadRequestResult_WhenModelStateIsInvalid()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.ListAsync())
        .ReturnsAsync(GetTestSessions());
    var controller = new HomeController(mockRepo.Object);
    controller.ModelState.AddModelError("SessionName", "Required");
    var newSession = new HomeController.NewSessionModel();

    // Act
    var result = await controller.Index(newSession);

    // Assert
    var badRequestResult = Assert.IsType<BadRequestObjectResult>(result);
    Assert.IsType<SerializableError>(badRequestResult.Value);
}

[Fact]
public async Task IndexPost_ReturnsARedirectAndAddsSession_WhenModelStateIsValid()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.AddAsync(It.IsAny<BrainstormSession>()))
        .Returns(Task.CompletedTask)
        .Verifiable();
    var controller = new HomeController(mockRepo.Object);
    var newSession = new HomeController.NewSessionModel()
    {
        SessionName = "Test Name"
    };

    // Act
    var result = await controller.Index(newSession);

    // Assert
    var redirectToActionResult = Assert.IsType<RedirectToActionResult>(result);
    Assert.Null(redirectToActionResult.ControllerName);
    Assert.Equal("Index", redirectToActionResult.ActionName);
    mockRepo.Verify();
}
```

When ModelState isn't valid, the same `ViewResult` is returned as for a GET request. The test doesn't attempt to pass in an invalid model. Passing an invalid model isn't a valid approach, since model binding isn't running (although an integration test does use model binding). In this case, model binding isn't tested. These unit tests are only testing the code in the action method.

The second test verifies that when the `ModelState` is valid:

- A new `BrainstormSession` is added (via the repository).
- The method returns a `RedirectToActionResult` with the expected properties.

Mocked calls that aren't called are normally ignored, but calling `Verifiable` at the end of the setup call allows mock validation in the test. This is performed with the call to `mockRepo.Verify`, which fails the test if the expected method wasn't called.

> **NOTE**
>
> The Moq library used in this sample makes it possible to mix verifiable, or "strict", mocks with non-verifiable mocks (also called "loose" mocks or stubs). Learn more about customizing Mock behavior with Moq.

SessionController in the sample app displays information related to a particular brainstorming session. The controller includes logic to deal with invalid `id` values (there are two `return` scenarios in the following example to cover these scenarios). The final `return` statement returns a new `StormSessionViewModel` to the view (*Controllers/SessionController.cs*):

```
public class SessionController : Controller
{
    private readonly IBrainstormSessionRepository _sessionRepository;

    public SessionController(IBrainstormSessionRepository sessionRepository)
    {
        _sessionRepository = sessionRepository;
    }

    public async Task<IActionResult> Index(int? id)
    {
        if (!id.HasValue)
        {
            return RedirectToAction(actionName: nameof(Index),
                controllerName: "Home");
        }

        var session = await _sessionRepository.GetByIdAsync(id.Value);
        if (session == null)
        {
            return Content("Session not found.");
        }

        var viewModel = new StormSessionViewModel()
        {
            DateCreated = session.DateCreated,
            Name = session.Name,
            Id = session.Id
        };

        return View(viewModel);
    }
}
```

The unit tests include one test for each `return` scenario in the Session controller `Index` action:

```
[Fact]
public async Task IndexReturnsARedirectToIndexHomeWhenIdIsNull()
{
    // Arrange
    var controller = new SessionController(sessionRepository: null);

    // Act
    var result = await controller.Index(id: null);

    // Assert
    var redirectToActionResult =
        Assert.IsType<RedirectToActionResult>(result);
    Assert.Equal("Home", redirectToActionResult.ControllerName);
    Assert.Equal("Index", redirectToActionResult.ActionName);
}

[Fact]
public async Task IndexReturnsContentWithSessionNotFoundWhenSessionNotFound()
{
    // Arrange
    int testSessionId = 1;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new SessionController(mockRepo.Object);

    // Act
    var result = await controller.Index(testSessionId);

    // Assert
    var contentResult = Assert.IsType<ContentResult>(result);
    Assert.Equal("Session not found.", contentResult.Content);
}

[Fact]
public async Task IndexReturnsViewResultWithStormSessionViewModel()
{
    // Arrange
    int testSessionId = 1;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSessions().FirstOrDefault(
            s => s.Id == testSessionId));
    var controller = new SessionController(mockRepo.Object);

    // Act
    var result = await controller.Index(testSessionId);

    // Assert
    var viewResult = Assert.IsType<ViewResult>(result);
    var model = Assert.IsType<StormSessionViewModel>(
        viewResult.ViewData.Model);
    Assert.Equal("Test One", model.Name);
    Assert.Equal(2, model.DateCreated.Day);
    Assert.Equal(testSessionId, model.Id);
}
```

Moving to the Ideas controller, the app exposes functionality as a web API on the `api/ideas` route:

- A list of ideas (`IdeaDTO`) associated with a brainstorming session is returned by the `ForSession` method.
- The `Create` method adds new ideas to a session.

```
[HttpGet("forsession/{sessionId}")]
public async Task<IActionResult> ForSession(int sessionId)
{
    var session = await _sessionRepository.GetByIdAsync(sessionId);
    if (session == null)
    {
        return NotFound(sessionId);
    }

    var result = session.Ideas.Select(idea => new IdeaDTO()
    {
        Id = idea.Id,
        Name = idea.Name,
        Description = idea.Description,
        DateCreated = idea.DateCreated
    }).ToList();

    return Ok(result);
}

[HttpPost("create")]
public async Task<IActionResult> Create([FromBody]NewIdeaModel model)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }

    var session = await _sessionRepository.GetByIdAsync(model.SessionId);
    if (session == null)
    {
        return NotFound(model.SessionId);
    }

    var idea = new Idea()
    {
        DateCreated = DateTimeOffset.Now,
        Description = model.Description,
        Name = model.Name
    };
    session.AddIdea(idea);

    await _sessionRepository.UpdateAsync(session);

    return Ok(session);
}
```

Avoid returning business domain entities directly via API calls. Domain entities:

- Often include more data than the client requires.
- Unnecessarily couple the app's internal domain model with the publicly exposed API.

Mapping between domain entities and the types returned to the client can be performed:

- Manually with a LINQ `Select`, as the sample app uses. For more information, see LINQ (Language Integrated Query).
- Automatically with a library, such as AutoMapper.

Next, the sample app demonstrates unit tests for the `Create` and `ForSession` API methods of the Ideas controller.

The sample app contains two `ForSession` tests. The first test determines if `ForSession` returns a NotFoundObjectResult (HTTP Not Found) for an invalid session:

```
[Fact]
public async Task ForSession_ReturnsHttpNotFound_ForInvalidSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSession(testSessionId);

    // Assert
    var notFoundObjectResult = Assert.IsType<NotFoundObjectResult>(result);
    Assert.Equal(testSessionId, notFoundObjectResult.Value);
}
```

The second `ForSession` test determines if `ForSession` returns a list of session ideas (`<List<IdeaDTO>>`) for a valid session. The checks also examine the first idea to confirm its `Name` property is correct:

```
[Fact]
public async Task ForSession_ReturnsIdeasForSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSession());
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSession(testSessionId);

    // Assert
    var okResult = Assert.IsType<OkObjectResult>(result);
    var returnValue = Assert.IsType<List<IdeaDTO>>(okResult.Value);
    var idea = returnValue.FirstOrDefault();
    Assert.Equal("One", idea.Name);
}
```

To test the behavior of the `Create` method when the `ModelState` is invalid, the sample app adds a model error to the controller as part of the test. Don't try to test model validation or model binding in unit tests—just test the action method's behavior when confronted with an invalid `ModelState`:

```
[Fact]
public async Task Create_ReturnsBadRequest_GivenInvalidModel()
{
    // Arrange & Act
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    controller.ModelState.AddModelError("error", "some error");

    // Act
    var result = await controller.Create(model: null);

    // Assert
    Assert.IsType<BadRequestObjectResult>(result);
}
```

The second test of `Create` depends on the repository returning `null`, so the mock repository is configured to

return `null`. There's no need to create a test database (in memory or otherwise) and construct a query that returns this result. The test can be accomplished in a single statement, as the sample code illustrates:

```
[Fact]
public async Task Create_ReturnsHttpNotFound_ForInvalidSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.Create(new NewIdeaModel());

    // Assert
    Assert.IsType<NotFoundObjectResult>(result);
}
```

The third `Create` test, `Create_ReturnsNewlyCreatedIdeaForSession`, verifies that the repository's `UpdateAsync` method is called. The mock is called with `Verifiable`, and the mocked repository's `Verify` method is called to confirm the verifiable method is executed. It's not the unit test's responsibility to ensure that the `UpdateAsync` method saved the data—that can be performed with an integration test.

```
[Fact]
public async Task Create_ReturnsNewlyCreatedIdeaForSession()
{
    // Arrange
    int testSessionId = 123;
    string testName = "test name";
    string testDescription = "test description";
    var testSession = GetTestSession();
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(testSession);
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = testSessionId
    };
    mockRepo.Setup(repo => repo.UpdateAsync(testSession))
        .Returns(Task.CompletedTask)
        .Verifiable();

    // Act
    var result = await controller.Create(newIdea);

    // Assert
    var okResult = Assert.IsType<OkObjectResult>(result);
    var returnSession = Assert.IsType<BrainstormSession>(okResult.Value);
    mockRepo.Verify();
    Assert.Equal(2, returnSession.Ideas.Count());
    Assert.Equal(testName, returnSession.Ideas.LastOrDefault().Name);
    Assert.Equal(testDescription, returnSession.Ideas.LastOrDefault().Description);
}
```

Test ActionResult<T>

In ASP.NET Core 2.1 or later, ActionResult<T> (ActionResult<TValue>) enables you to return a type deriving from `ActionResult` or return a specific type.

The sample app includes a method that returns a `List<IdeaDTO>` for a given session `id`. If the session `id` doesn't exist, the controller returns NotFound:

```
[HttpGet("forsessionactionresult/{sessionId}")]
[ProducesResponseType(200)]
[ProducesResponseType(404)]
public async Task<ActionResult<List<IdeaDTO>>> ForSessionActionResult(int sessionId)
{
    var session = await _sessionRepository.GetByIdAsync(sessionId);

    if (session == null)
    {
        return NotFound(sessionId);
    }

    var result = session.Ideas.Select(idea => new IdeaDTO()
    {
        Id = idea.Id,
        Name = idea.Name,
        Description = idea.Description,
        DateCreated = idea.DateCreated
    }).ToList();

    return result;
}
```

Two tests of the `ForSessionActionResult` controller are included in the `ApiIdeasControllerTests`.

The first test confirms that the controller returns an `ActionResult` but not a nonexistent list of ideas for a nonexistent session `id`:

- The `ActionResult` type is `ActionResult<List<IdeaDTO>>`.
- The Result is a NotFoundObjectResult.

```
[Fact]
public async Task ForSessionActionResult_ReturnsNotFoundObjectResultForNonexistentSession()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    var nonExistentSessionId = 999;

    // Act
    var result = await controller.ForSessionActionResult(nonExistentSessionId);

    // Assert
    var actionResult = Assert.IsType<ActionResult<List<IdeaDTO>>>(result);
    Assert.IsType<NotFoundObjectResult>(actionResult.Result);
}
```

For a valid session `id`, the second test confirms that the method returns:

- An `ActionResult` with a `List<IdeaDTO>` type.
- The ActionResult<T>.Value is a `List<IdeaDTO>` type.
- The first item in the list is a valid idea matching the idea stored in the mock session (obtained by calling `GetTestSession`).

```
[Fact]
public async Task ForSessionActionResult_ReturnsIdeasForSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSession());
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSessionActionResult(testSessionId);

    // Assert
    var actionResult = Assert.IsType<ActionResult<List<IdeaDTO>>>(result);
    var returnValue = Assert.IsType<List<IdeaDTO>>(actionResult.Value);
    var idea = returnValue.FirstOrDefault();
    Assert.Equal("One", idea.Name);
}
```

The sample app also includes a method to create a new `Idea` for a given session. The controller returns:

- BadRequest for an invalid model.
- NotFound if the session doesn't exist.
- CreatedAtAction when the session is updated with the new idea.

```
[HttpPost("createactionresult")]
[ProducesResponseType(201)]
[ProducesResponseType(400)]
[ProducesResponseType(404)]
public async Task<ActionResult<BrainstormSession>> CreateActionResult([FromBody]NewIdeaModel model)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }

    var session = await _sessionRepository.GetByIdAsync(model.SessionId);

    if (session == null)
    {
        return NotFound(model.SessionId);
    }

    var idea = new Idea()
    {
        DateCreated = DateTimeOffset.Now,
        Description = model.Description,
        Name = model.Name
    };
    session.AddIdea(idea);

    await _sessionRepository.UpdateAsync(session);

    return CreatedAtAction(nameof(CreateActionResult), new { id = session.Id }, session);
}
```

Three tests of `CreateActionResult` are included in the `ApiIdeasControllerTests`.

The first text confirms that a BadRequest is returned for an invalid model.

```
[Fact]
public async Task CreateActionResult_ReturnsBadRequest_GivenInvalidModel()
{
    // Arrange & Act
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    controller.ModelState.AddModelError("error", "some error");

    // Act
    var result = await controller.CreateActionResult(model: null);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>(result);
    Assert.IsType<BadRequestObjectResult>(actionResult.Result);
}
```

The second test checks that a NotFound is returned if the session doesn't exist.

```
[Fact]
public async Task CreateActionResult_ReturnsNotFoundObjectResultForNonexistentSession()
{
    // Arrange
    var nonExistentSessionId = 999;
    string testName = "test name";
    string testDescription = "test description";
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = nonExistentSessionId
    };

    // Act
    var result = await controller.CreateActionResult(newIdea);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>(result);
    Assert.IsType<NotFoundObjectResult>(actionResult.Result);
}
```

For a valid session `id`, the final test confirms that:

- The method returns an `ActionResult` with a `BrainstormSession` type.
- The ActionResult<T>.Result is a CreatedAtActionResult. `CreatedAtActionResult` is analogous to a *201 Created* response with a `Location` header.
- The ActionResult<T>.Value is a `BrainstormSession` type.
- The mock call to update the session, `UpdateAsync(testSession)`, was invoked. The `Verifiable` method call is checked by executing `mockRepo.Verify()` in the assertions.
- Two `Idea` objects are returned for the session.
- The last item (the `Idea` added by the mock call to `UpdateAsync`) matches the `newIdea` added to the session in the test.

```
[Fact]
public async Task CreateActionResult_ReturnsNewlyCreatedIdeaForSession()
{
    // Arrange
    int testSessionId = 123;
    string testName = "test name";
    string testDescription = "test description";
    var testSession = GetTestSession();
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(testSession);
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = testSessionId
    };
    mockRepo.Setup(repo => repo.UpdateAsync(testSession))
        .Returns(Task.CompletedTask)
        .Verifiable();

    // Act
    var result = await controller.CreateActionResult(newIdea);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>(result);
    var createdAtActionResult = Assert.IsType<CreatedAtActionResult>(actionResult.Result);
    var returnValue = Assert.IsType<BrainstormSession>(createdAtActionResult.Value);
    mockRepo.Verify();
    Assert.Equal(2, returnValue.Ideas.Count());
    Assert.Equal(testName, returnValue.Ideas.LastOrDefault().Name);
    Assert.Equal(testDescription, returnValue.Ideas.LastOrDefault().Description);
}
```

Controllers play a central role in any ASP.NET Core MVC app. As such, you should have confidence that controllers behave as intended. Automated tests can detect errors before the app is deployed to a production environment.

View or download sample code (how to download)

Unit tests of controller logic

Unit tests involve testing a part of an app in isolation from its infrastructure and dependencies. When unit testing controller logic, only the contents of a single action are tested, not the behavior of its dependencies or of the framework itself.

Set up unit tests of controller actions to focus on the controller's behavior. A controller unit test avoids scenarios such as filters, routing, and model binding. Tests that cover the interactions among components that collectively respond to a request are handled by *integration tests*. For more information on integration tests, see Integration tests in ASP.NET Core.

If you're writing custom filters and routes, unit test them in isolation, not as part of tests on a particular controller action.

To demonstrate controller unit tests, review the following controller in the sample app. The Home controller displays a list of brainstorming sessions and allows the creation of new brainstorming sessions with a POST request:

```
public class HomeController : Controller
{
    private readonly IBrainstormSessionRepository _sessionRepository;

    public HomeController(IBrainstormSessionRepository sessionRepository)
    {
        _sessionRepository = sessionRepository;
    }

    public async Task<IActionResult> Index()
    {
        var sessionList = await _sessionRepository.ListAsync();

        var model = sessionList.Select(session => new StormSessionViewModel()
        {
            Id = session.Id,
            DateCreated = session.DateCreated,
            Name = session.Name,
            IdeaCount = session.Ideas.Count
        });

        return View(model);
    }

    public class NewSessionModel
    {
        [Required]
        public string SessionName { get; set; }
    }

    [HttpPost]
    public async Task<IActionResult> Index(NewSessionModel model)
    {
        if (!ModelState.IsValid)
        {
            return BadRequest(ModelState);
        }
        else
        {
            await _sessionRepository.AddAsync(new BrainstormSession()
            {
                DateCreated = DateTimeOffset.Now,
                Name = model.SessionName
            });
        }

        return RedirectToAction(actionName: nameof(Index));
    }
}
```

The preceding controller:

- Follows the Explicit Dependencies Principle.
- Expects dependency injection (DI) to provide an instance of `IBrainstormSessionRepository`.
- Can be tested with a mocked `IBrainstormSessionRepository` service using a mock object framework, such as Moq. A *mocked object* is a fabricated object with a predetermined set of property and method behaviors used for testing. For more information, see Introduction to integration tests.

The `HTTP GET Index` method has no looping or branching and only calls one method. The unit test for this action:

- Mocks the `IBrainstormSessionRepository` service using the `GetTestSessions` method. `GetTestSessions` creates two mock brainstorm sessions with dates and session names.
- Executes the `Index` method.

- Makes assertions on the result returned by the method:
  - A ViewResult is returned.
  - The ViewDataDictionary.Model is a `StormSessionViewModel`.
  - There are two brainstorming sessions stored in the `ViewDataDictionary.Model`.

```
[Fact]
public async Task Index_ReturnsAViewResult_WithAListOfBrainstormSessions()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.ListAsync())
        .ReturnsAsync(GetTestSessions());
    var controller = new HomeController(mockRepo.Object);

    // Act
    var result = await controller.Index();

    // Assert
    var viewResult = Assert.IsType<ViewResult>(result);
    var model = Assert.IsAssignableFrom<IEnumerable<StormSessionViewModel>>(
        viewResult.ViewData.Model);
    Assert.Equal(2, model.Count());
}
```

```
private List<BrainstormSession> GetTestSessions()
{
    var sessions = new List<BrainstormSession>();
    sessions.Add(new BrainstormSession()
    {
        DateCreated = new DateTime(2016, 7, 2),
        Id = 1,
        Name = "Test One"
    });
    sessions.Add(new BrainstormSession()
    {
        DateCreated = new DateTime(2016, 7, 1),
        Id = 2,
        Name = "Test Two"
    });
    return sessions;
}
```

The Home controller's `HTTP POST Index` method tests verifies that:

- When ModelState.IsValid is `false`, the action method returns a *400 Bad Request* ViewResult with the appropriate data.
- When `ModelState.IsValid` is `true`:
  - The `Add` method on the repository is called.
  - A RedirectToActionResult is returned with the correct arguments.

An invalid model state is tested by adding errors using AddModelError as shown in the first test below:

```
[Fact]
public async Task IndexPost_ReturnsBadRequestResult_WhenModelStateIsInvalid()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.ListAsync())
        .ReturnsAsync(GetTestSessions());
    var controller = new HomeController(mockRepo.Object);
    controller.ModelState.AddModelError("SessionName", "Required");
    var newSession = new HomeController.NewSessionModel();

    // Act
    var result = await controller.Index(newSession);

    // Assert
    var badRequestResult = Assert.IsType<BadRequestObjectResult>(result);
    Assert.IsType<SerializableError>(badRequestResult.Value);
}

[Fact]
public async Task IndexPost_ReturnsARedirectAndAddsSession_WhenModelStateIsValid()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.AddAsync(It.IsAny<BrainstormSession>()))
        .Returns(Task.CompletedTask)
        .Verifiable();
    var controller = new HomeController(mockRepo.Object);
    var newSession = new HomeController.NewSessionModel()
    {
        SessionName = "Test Name"
    };

    // Act
    var result = await controller.Index(newSession);

    // Assert
    var redirectToActionResult = Assert.IsType<RedirectToActionResult>(result);
    Assert.Null(redirectToActionResult.ControllerName);
    Assert.Equal("Index", redirectToActionResult.ActionName);
    mockRepo.Verify();
}
```

When ModelState isn't valid, the same `ViewResult` is returned as for a GET request. The test doesn't attempt to pass in an invalid model. Passing an invalid model isn't a valid approach, since model binding isn't running (although an integration test does use model binding). In this case, model binding isn't tested. These unit tests are only testing the code in the action method.

The second test verifies that when the `ModelState` is valid:

- A new `BrainstormSession` is added (via the repository).
- The method returns a `RedirectToActionResult` with the expected properties.

Mocked calls that aren't called are normally ignored, but calling `Verifiable` at the end of the setup call allows mock validation in the test. This is performed with the call to `mockRepo.Verify`, which fails the test if the expected method wasn't called.

> **NOTE**
>
> The Moq library used in this sample makes it possible to mix verifiable, or "strict", mocks with non-verifiable mocks (also called "loose" mocks or stubs). Learn more about customizing Mock behavior with Moq.

SessionController in the sample app displays information related to a particular brainstorming session. The controller includes logic to deal with invalid `id` values (there are two `return` scenarios in the following example to cover these scenarios). The final `return` statement returns a new `StormSessionViewModel` to the view (*Controllers/SessionController.cs*):

```
public class SessionController : Controller
{
    private readonly IBrainstormSessionRepository _sessionRepository;

    public SessionController(IBrainstormSessionRepository sessionRepository)
    {
        _sessionRepository = sessionRepository;
    }

    public async Task<IActionResult> Index(int? id)
    {
        if (!id.HasValue)
        {
            return RedirectToAction(actionName: nameof(Index),
                controllerName: "Home");
        }

        var session = await _sessionRepository.GetByIdAsync(id.Value);
        if (session == null)
        {
            return Content("Session not found.");
        }

        var viewModel = new StormSessionViewModel()
        {
            DateCreated = session.DateCreated,
            Name = session.Name,
            Id = session.Id
        };

        return View(viewModel);
    }
}
```

The unit tests include one test for each `return` scenario in the Session controller `Index` action:

```
[Fact]
public async Task IndexReturnsARedirectToIndexHomeWhenIdIsNull()
{
    // Arrange
    var controller = new SessionController(sessionRepository: null);

    // Act
    var result = await controller.Index(id: null);

    // Assert
    var redirectToActionResult =
        Assert.IsType<RedirectToActionResult>(result);
    Assert.Equal("Home", redirectToActionResult.ControllerName);
    Assert.Equal("Index", redirectToActionResult.ActionName);
}

[Fact]
public async Task IndexReturnsContentWithSessionNotFoundWhenSessionNotFound()
{
    // Arrange
    int testSessionId = 1;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new SessionController(mockRepo.Object);

    // Act
    var result = await controller.Index(testSessionId);

    // Assert
    var contentResult = Assert.IsType<ContentResult>(result);
    Assert.Equal("Session not found.", contentResult.Content);
}

[Fact]
public async Task IndexReturnsViewResultWithStormSessionViewModel()
{
    // Arrange
    int testSessionId = 1;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSessions().FirstOrDefault(
            s => s.Id == testSessionId));
    var controller = new SessionController(mockRepo.Object);

    // Act
    var result = await controller.Index(testSessionId);

    // Assert
    var viewResult = Assert.IsType<ViewResult>(result);
    var model = Assert.IsType<StormSessionViewModel>(
        viewResult.ViewData.Model);
    Assert.Equal("Test One", model.Name);
    Assert.Equal(2, model.DateCreated.Day);
    Assert.Equal(testSessionId, model.Id);
}
```

Moving to the Ideas controller, the app exposes functionality as a web API on the `api/ideas` route:

- A list of ideas (`IdeaDTO`) associated with a brainstorming session is returned by the `ForSession` method.
- The `Create` method adds new ideas to a session.

```
[HttpGet("forsession/{sessionId}")]
public async Task<IActionResult> ForSession(int sessionId)
{
    var session = await _sessionRepository.GetByIdAsync(sessionId);
    if (session == null)
    {
        return NotFound(sessionId);
    }

    var result = session.Ideas.Select(idea => new IdeaDTO()
    {
        Id = idea.Id,
        Name = idea.Name,
        Description = idea.Description,
        DateCreated = idea.DateCreated
    }).ToList();

    return Ok(result);
}

[HttpPost("create")]
public async Task<IActionResult> Create([FromBody]NewIdeaModel model)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }

    var session = await _sessionRepository.GetByIdAsync(model.SessionId);
    if (session == null)
    {
        return NotFound(model.SessionId);
    }

    var idea = new Idea()
    {
        DateCreated = DateTimeOffset.Now,
        Description = model.Description,
        Name = model.Name
    };
    session.AddIdea(idea);

    await _sessionRepository.UpdateAsync(session);

    return Ok(session);
}
```

Avoid returning business domain entities directly via API calls. Domain entities:

- Often include more data than the client requires.
- Unnecessarily couple the app's internal domain model with the publicly exposed API.

Mapping between domain entities and the types returned to the client can be performed:

- Manually with a LINQ `Select`, as the sample app uses. For more information, see LINQ (Language Integrated Query).
- Automatically with a library, such as AutoMapper.

Next, the sample app demonstrates unit tests for the `Create` and `ForSession` API methods of the Ideas controller.

The sample app contains two `ForSession` tests. The first test determines if `ForSession` returns a NotFoundObjectResult (HTTP Not Found) for an invalid session:

```
[Fact]
public async Task ForSession_ReturnsHttpNotFound_ForInvalidSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSession(testSessionId);

    // Assert
    var notFoundObjectResult = Assert.IsType<NotFoundObjectResult>(result);
    Assert.Equal(testSessionId, notFoundObjectResult.Value);
}
```

The second `ForSession` test determines if `ForSession` returns a list of session ideas (`<List<IdeaDTO>>`) for a valid session. The checks also examine the first idea to confirm its `Name` property is correct:

```
[Fact]
public async Task ForSession_ReturnsIdeasForSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSession());
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSession(testSessionId);

    // Assert
    var okResult = Assert.IsType<OkObjectResult>(result);
    var returnValue = Assert.IsType<List<IdeaDTO>>(okResult.Value);
    var idea = returnValue.FirstOrDefault();
    Assert.Equal("One", idea.Name);
}
```

To test the behavior of the `Create` method when the `ModelState` is invalid, the sample app adds a model error to the controller as part of the test. Don't try to test model validation or model binding in unit tests—just test the action method's behavior when confronted with an invalid `ModelState`:

```
[Fact]
public async Task Create_ReturnsBadRequest_GivenInvalidModel()
{
    // Arrange & Act
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    controller.ModelState.AddModelError("error", "some error");

    // Act
    var result = await controller.Create(model: null);

    // Assert
    Assert.IsType<BadRequestObjectResult>(result);
}
```

The second test of `Create` depends on the repository returning `null`, so the mock repository is configured to

return `null`. There's no need to create a test database (in memory or otherwise) and construct a query that returns this result. The test can be accomplished in a single statement, as the sample code illustrates:

```
[Fact]
public async Task Create_ReturnsHttpNotFound_ForInvalidSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.Create(new NewIdeaModel());

    // Assert
    Assert.IsType<NotFoundObjectResult>(result);
}
```

The third `Create` test, `Create_ReturnsNewlyCreatedIdeaForSession`, verifies that the repository's `UpdateAsync` method is called. The mock is called with `Verifiable`, and the mocked repository's `Verify` method is called to confirm the verifiable method is executed. It's not the unit test's responsibility to ensure that the `UpdateAsync` method saved the data—that can be performed with an integration test.

```
[Fact]
public async Task Create_ReturnsNewlyCreatedIdeaForSession()
{
    // Arrange
    int testSessionId = 123;
    string testName = "test name";
    string testDescription = "test description";
    var testSession = GetTestSession();
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(testSession);
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = testSessionId
    };
    mockRepo.Setup(repo => repo.UpdateAsync(testSession))
        .Returns(Task.CompletedTask)
        .Verifiable();

    // Act
    var result = await controller.Create(newIdea);

    // Assert
    var okResult = Assert.IsType<OkObjectResult>(result);
    var returnSession = Assert.IsType<BrainstormSession>(okResult.Value);
    mockRepo.Verify();
    Assert.Equal(2, returnSession.Ideas.Count());
    Assert.Equal(testName, returnSession.Ideas.LastOrDefault().Name);
    Assert.Equal(testDescription, returnSession.Ideas.LastOrDefault().Description);
}
```

Test ActionResult<T>

In ASP.NET Core 2.1 or later, ActionResult<T> (ActionResult<TValue>) enables you to return a type deriving from `ActionResult` or return a specific type.

The sample app includes a method that returns a `List<IdeaDTO>` for a given session `id`. If the session `id` doesn't exist, the controller returns NotFound:

```
[HttpGet("forsessionactionresult/{sessionId}")]
[ProducesResponseType(200)]
[ProducesResponseType(404)]
public async Task<ActionResult<List<IdeaDTO>>> ForSessionActionResult(int sessionId)
{
    var session = await _sessionRepository.GetByIdAsync(sessionId);

    if (session == null)
    {
        return NotFound(sessionId);
    }

    var result = session.Ideas.Select(idea => new IdeaDTO()
    {
        Id = idea.Id,
        Name = idea.Name,
        Description = idea.Description,
        DateCreated = idea.DateCreated
    }).ToList();

    return result;
}
```

Two tests of the `ForSessionActionResult` controller are included in the `ApiIdeasControllerTests`.

The first test confirms that the controller returns an `ActionResult` but not a nonexistent list of ideas for a nonexistent session `id`:

- The `ActionResult` type is `ActionResult<List<IdeaDTO>>`.
- The Result is a NotFoundObjectResult.

```
[Fact]
public async Task ForSessionActionResult_ReturnsNotFoundObjectResultForNonexistentSession()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    var nonExistentSessionId = 999;

    // Act
    var result = await controller.ForSessionActionResult(nonExistentSessionId);

    // Assert
    var actionResult = Assert.IsType<ActionResult<List<IdeaDTO>>>(result);
    Assert.IsType<NotFoundObjectResult>(actionResult.Result);
}
```

For a valid session `id`, the second test confirms that the method returns:

- An `ActionResult` with a `List<IdeaDTO>` type.
- The ActionResult<T>.Value is a `List<IdeaDTO>` type.
- The first item in the list is a valid idea matching the idea stored in the mock session (obtained by calling `GetTestSession`).

```
[Fact]
public async Task ForSessionActionResult_ReturnsIdeasForSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSession());
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSessionActionResult(testSessionId);

    // Assert
    var actionResult = Assert.IsType<ActionResult<List<IdeaDTO>>>(result);
    var returnValue = Assert.IsType<List<IdeaDTO>>(actionResult.Value);
    var idea = returnValue.FirstOrDefault();
    Assert.Equal("One", idea.Name);
}
```

The sample app also includes a method to create a new `Idea` for a given session. The controller returns:

- BadRequest for an invalid model.
- NotFound if the session doesn't exist.
- CreatedAtAction when the session is updated with the new idea.

```
[HttpPost("createactionresult")]
[ProducesResponseType(201)]
[ProducesResponseType(400)]
[ProducesResponseType(404)]
public async Task<ActionResult<BrainstormSession>> CreateActionResult([FromBody]NewIdeaModel model)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }

    var session = await _sessionRepository.GetByIdAsync(model.SessionId);

    if (session == null)
    {
        return NotFound(model.SessionId);
    }

    var idea = new Idea()
    {
        DateCreated = DateTimeOffset.Now,
        Description = model.Description,
        Name = model.Name
    };
    session.AddIdea(idea);

    await _sessionRepository.UpdateAsync(session);

    return CreatedAtAction(nameof(CreateActionResult), new { id = session.Id }, session);
}
```

Three tests of `CreateActionResult` are included in the `ApiIdeasControllerTests`.

The first text confirms that a BadRequest is returned for an invalid model.

```
[Fact]
public async Task CreateActionResult_ReturnsBadRequest_GivenInvalidModel()
{
    // Arrange & Act
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    controller.ModelState.AddModelError("error", "some error");

    // Act
    var result = await controller.CreateActionResult(model: null);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>(result);
    Assert.IsType<BadRequestObjectResult>(actionResult.Result);
}
```

The second test checks that a NotFound is returned if the session doesn't exist.

```
[Fact]
public async Task CreateActionResult_ReturnsNotFoundObjectResultForNonexistentSession()
{
    // Arrange
    var nonExistentSessionId = 999;
    string testName = "test name";
    string testDescription = "test description";
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = nonExistentSessionId
    };

    // Act
    var result = await controller.CreateActionResult(newIdea);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>(result);
    Assert.IsType<NotFoundObjectResult>(actionResult.Result);
}
```

For a valid session `id`, the final test confirms that:

- The method returns an `ActionResult` with a `BrainstormSession` type.
- The ActionResult<T>.Result is a CreatedAtActionResult. `CreatedAtActionResult` is analogous to a *201 Created* response with a `Location` header.
- The ActionResult<T>.Value is a `BrainstormSession` type.
- The mock call to update the session, `UpdateAsync(testSession)`, was invoked. The `Verifiable` method call is checked by executing `mockRepo.Verify()` in the assertions.
- Two `Idea` objects are returned for the session.
- The last item (the `Idea` added by the mock call to `UpdateAsync`) matches the `newIdea` added to the session in the test.

```
[Fact]
public async Task CreateActionResult_ReturnsNewlyCreatedIdeaForSession()
{
    // Arrange
    int testSessionId = 123;
    string testName = "test name";
    string testDescription = "test description";
    var testSession = GetTestSession();
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(testSession);
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = testSessionId
    };
    mockRepo.Setup(repo => repo.UpdateAsync(testSession))
        .Returns(Task.CompletedTask)
        .Verifiable();

    // Act
    var result = await controller.CreateActionResult(newIdea);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>(result);
    var createdAtActionResult = Assert.IsType<CreatedAtActionResult>(actionResult.Result);
    var returnValue = Assert.IsType<BrainstormSession>(createdAtActionResult.Value);
    mockRepo.Verify();
    Assert.Equal(2, returnValue.Ideas.Count());
    Assert.Equal(testName, returnValue.Ideas.LastOrDefault().Name);
    Assert.Equal(testDescription, returnValue.Ideas.LastOrDefault().Description);
}
```

Introduction to ASP.NET Core Blazor

9/22/2020 • 5 minutes to read • Edit Online

By Daniel Roth and Luke Latham

Welcome to Blazor!

Blazor is a framework for building interactive client-side web UI with .NET:

- Create rich interactive UIs using C# instead of JavaScript.
- Share server-side and client-side app logic written in .NET.
- Render the UI as HTML and CSS for wide browser support, including mobile browsers.
- Integrate with modern hosting platforms, such as Docker.

Using .NET for client-side web development offers the following advantages:

- Write code in C# instead of JavaScript.
- Leverage the existing .NET ecosystem of .NET libraries.
- Share app logic across server and client.
- Benefit from .NET's performance, reliability, and security.
- Stay productive with Visual Studio on Windows, Linux, and macOS.
- Build on a common set of languages, frameworks, and tools that are stable, feature-rich, and easy to use.

Components

Blazor apps are based on *components*. A component in Blazor is an element of UI, such as a page, dialog, or data entry form.

Components are .NET classes built into .NET assemblies that:

- Define flexible UI rendering logic.
- Handle user events.
- Can be nested and reused.
- Can be shared and distributed as Razor class libraries or NuGet packages.

The component class is usually written in the form of a Razor markup page with a `.razor` file extension. Components in Blazor are formally referred to as *Razor components*. Razor is a syntax for combining HTML markup with C# code designed for developer productivity. Razor allows you to switch between HTML markup and C# in the same file with IntelliSense support. Razor Pages and MVC also use Razor. Unlike Razor Pages and MVC, which are built around a request/response model, components are used specifically for client-side UI logic and composition.

The following Razor markup demonstrates a component (`Dialog.razor`), which can be nested within another component:

```
<div>
    <h1>@Title</h1>

    @ChildContent

    <button @onclick="OnYes">Yes!</button>
</div>

@code {
    [Parameter]
    public string Title { get; set; }

    [Parameter]
    public RenderFragment ChildContent { get; set; }

    private void OnYes()
    {
        Console.WriteLine("Write to the console in C#! 'Yes' button was selected.");
    }
}
```

The dialog's body content (`ChildContent`) and title (`Title`) are provided by the component that uses this component in its UI. `OnYes` is a C# method triggered by the button's `onclick` event.

Blazor uses natural HTML tags for UI composition. HTML elements specify components, and a tag's attributes pass values to a component's properties.

In the following example, the `Index` component uses the `Dialog` component. `ChildContent` and `Title` are set by the attributes and content of the `<Dialog>` element.

`Pages/Index.razor`:

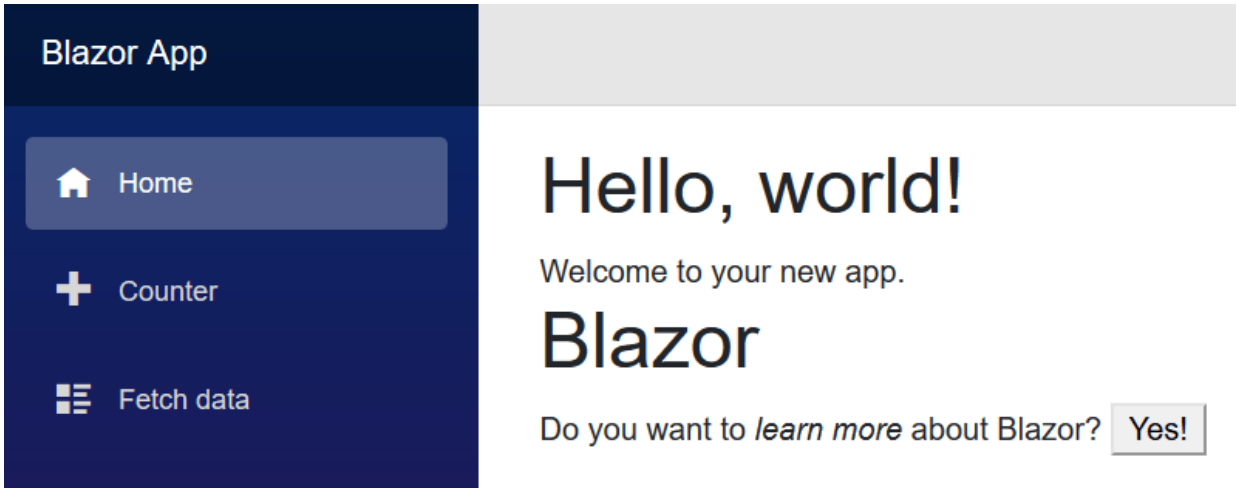
```
@page "/"

<h1>Hello, world!</h1>

Welcome to your new app.

<Dialog Title="Blazor">
    Do you want to <i>learn more</i> about Blazor?
</Dialog>
```

The dialog is rendered when the parent (`Pages/Index.razor`) is accessed in a browser:



When this component is used in the app, IntelliSense in Visual Studio and Visual Studio Code speeds development with syntax and parameter completion.

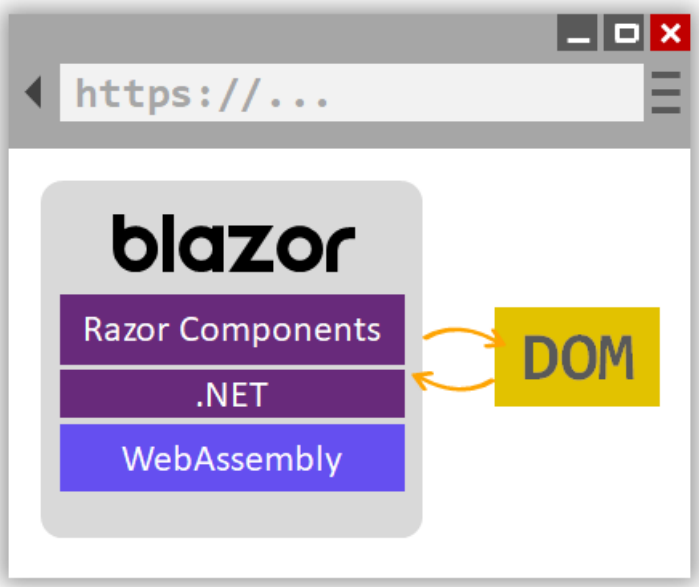
Components render into an in-memory representation of the browser's Document Object Model (DOM) called a *render tree*, which is used to update the UI in a flexible and efficient way.

Blazor WebAssembly

Blazor WebAssembly is a single-page app framework for building interactive client-side web apps with .NET. Blazor WebAssembly uses open web standards without plugins or code transpilation and works in all modern web browsers, including mobile browsers.

Running .NET code inside web browsers is made possible by WebAssembly (abbreviated `wasm`). WebAssembly is a compact bytecode format optimized for fast download and maximum execution speed. WebAssembly is an open web standard and supported in web browsers without plugins.

WebAssembly code can access the full functionality of the browser via JavaScript, called *JavaScript interoperability* (or *JavaScript interop*). .NET code executed via WebAssembly in the browser runs in the browser's JavaScript sandbox with the protections that the sandbox provides against malicious actions on the client machine.



When a Blazor WebAssembly app is built and run in a browser:

- C# code files and Razor files are compiled into .NET assemblies.
- The assemblies and the .NET runtime are downloaded to the browser.
- Blazor WebAssembly bootstraps the .NET runtime and configures the runtime to load the assemblies for the app. The Blazor WebAssembly runtime uses JavaScript interop to handle DOM manipulation and browser API calls.

The size of the published app, its *payload size*, is a critical performance factor for an app's useability. A large app takes a relatively long time to download to a browser, which diminishes the user experience. Blazor WebAssembly optimizes payload size to reduce download times:

- Unused code is stripped out of the app when it's published by the Intermediate Language (IL) Trimmer.
- HTTP responses are compressed.
- The .NET runtime and assemblies are cached in the browser.

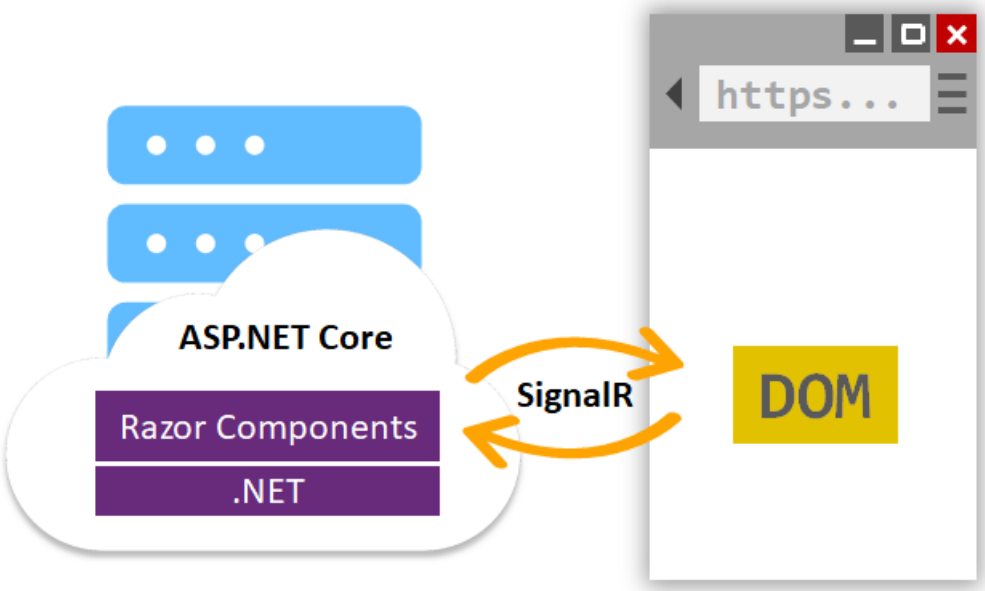
- Unused code is stripped out of the app when it's published by the Intermediate Language (IL) Linker.
- HTTP responses are compressed.
- The .NET runtime and assemblies are cached in the browser.

Blazor Server

Blazor decouples component rendering logic from how UI updates are applied. Blazor Server provides support for hosting Razor components on the server in an ASP.NET Core app. UI updates are handled over a SignalR connection.

The runtime handles sending UI events from the browser to the server and applies UI updates sent by the server back to the browser after running the components.

The connection used by Blazor Server to communicate with the browser is also used to handle JavaScript interop calls.



JavaScript interop

For apps that require third-party JavaScript libraries and access to browser APIs, components interoperate with JavaScript. Components are capable of using any library or API that JavaScript is able to use. C# code can call into JavaScript code, and JavaScript code can call into C# code. For more information, see the following articles:

- Call JavaScript functions from .NET methods in ASP.NET Core Blazor
- Call .NET methods from JavaScript functions in ASP.NET Core Blazor

Code sharing and .NET Standard

Blazor implements .NET Standard 2.1, which enables Blazor projects to reference libraries that conform to .NET Standard 2.1 or earlier specifications. .NET Standard is a formal specification of .NET APIs that are common across .NET implementations. .NET Standard class libraries can be shared across different .NET platforms, such as Blazor, .NET Framework, .NET Core, Xamarin, Mono, and Unity.

APIs that aren't applicable inside of a web browser (for example, accessing the file system, opening a socket, and threading) throw a PlatformNotSupportedException.

ASP.NET Core Blazor supported platforms

9/22/2020 • 2 minutes to read • Edit Online

By Luke Latham

Browser requirements

Blazor WebAssembly

BROWSER	VERSION
Microsoft Edge	Current
Mozilla Firefox	Current
Google Chrome, including Android	Current
Safari, including iOS	Current
Microsoft Internet Explorer	Not Supported†

†Microsoft Internet Explorer doesn't support WebAssembly.

Blazor Server

BROWSER	VERSION
Microsoft Edge	Current
Mozilla Firefox	Current
Google Chrome, including Android	Current
Safari, including iOS	Current
Microsoft Internet Explorer	11†

†Additional polyfills are required (for example, promises can be added via a `Polyfill.io` bundle).

Tooling for ASP.NET Core Blazor

9/22/2020 • 2 minutes to read • Edit Online

By Daniel Roth and Luke Latham

1. Install the latest version of Visual Studio 2019 with the **ASP.NET and web development** workload.
2. Create a new project.
3. Select **Blazor App**. Select **Next**.
4. Provide a project name in the **Project name** field or accept the default project name. Confirm the **Location** entry is correct or provide a location for the project. Select **Create**.
5. For a Blazor WebAssembly experience, choose the **Blazor WebAssembly App** template. For a Blazor Server experience, choose the **Blazor Server App** template. Select **Create**.

   For information on the two Blazor hosting models, *Blazor WebAssembly* and *Blazor Server*, see ASP.NET Core Blazor hosting models.
6. Press `Ctrl+F5` to run the app.

For more information on trusting the ASP.NET Core HTTPS development certificate, see Enforce HTTPS in ASP.NET Core.

1. Install the latest version of the .NET Core 3.1 SDK. If you previously installed the SDK, you can determine your installed version by executing the following command in a command shell:

   ```
   dotnet --version
   ```
2. Install the latest version of Visual Studio Code.
3. Install the latest C# for Visual Studio Code extension.
4. For a Blazor WebAssembly experience, execute the following command in a command shell:

   ```
   dotnet new blazorwasm -o WebApplication1
   ```

   For a Blazor Server experience, execute the following command in a command shell:

   ```
   dotnet new blazorserver -o WebApplication1
   ```

   For information on the two Blazor hosting models, *Blazor WebAssembly* and *Blazor Server*, see ASP.NET Core Blazor hosting models.
5. Open the `WebApplication1` folder in Visual Studio Code.
6. The IDE requests that you add assets to build and debug the project. Select **Yes**.
7. Press `Ctrl+F5` to run the app.

Trust a development certificate

There's no centralized way to trust a certificate on Linux. Typically, one of the following approaches is adopted:

- Exclude the app's URL in browser's exclude list.
- Trust all self-signed certificates for `localhost`.
- Add the certificate to the list of trusted certificates in the browser.

For more information, see the guidance provided by your browser and Linux distribution.

1. Install Visual Studio for Mac.
2. Select **File** > **New Solution** or create a **New** project from the **Start Window**.
3. In the sidebar, select **Web and Console** > **App**.

   For a Blazor WebAssembly experience, choose the **Blazor WebAssembly App** template. For a Blazor Server experience, choose the **Blazor Server App** template. Select **Next**.

   For information on the two Blazor hosting models, *Blazor WebAssembly* and *Blazor Server*, see ASP.NET Core Blazor hosting models.
4. Confirm that **Authentication** is set to **No Authentication**. Select **Next**.
5. In the **Project Name** field, name the app `WebApplication1`. Select **Create**.
6. Select **Run** > **Start Without Debugging** to run the app *without the debugger*. Run the app with **Run** > **Start Debugging** or the Run (▶) button to run the app *with the debugger*.

If a prompt appears to trust the development certificate, trust the certificate and continue. The user and keychain passwords are required to trust the certificate. For more information on trusting the ASP.NET Core HTTPS development certificate, see Enforce HTTPS in ASP.NET Core.

ASP.NET Core Blazor hosting models

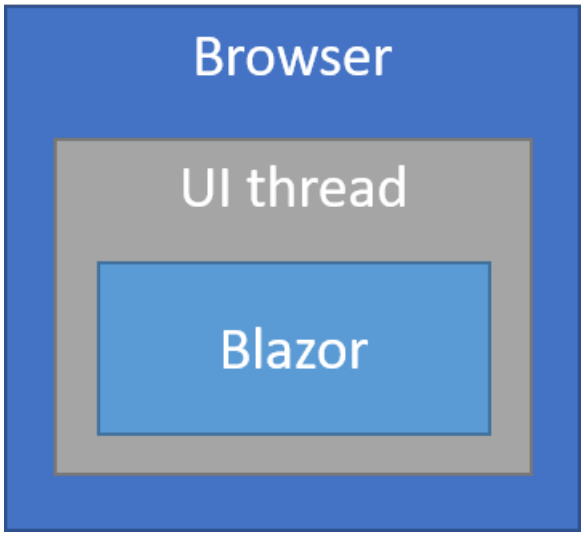
9/22/2020 • 9 minutes to read • Edit Online

By Daniel Roth

Blazor is a web framework designed to run client-side in the browser on a WebAssembly-based .NET runtime (*Blazor WebAssembly*) or server-side in ASP.NET Core (*Blazor Server*). Regardless of the hosting model, the app and component models *are the same*.

Blazor WebAssembly

The principal hosting model for Blazor is running client-side in the browser on WebAssembly. The Blazor app, its dependencies, and the .NET runtime are downloaded to the browser. The app is executed directly on the browser UI thread. UI updates and event handling occur within the same process. The app's assets are deployed as static files to a web server or service capable of serving static content to clients. Because the app is created for deployment without a backend ASP.NET Core app, it's called a *standalone Blazor WebAssembly app*.



To create a Blazor app using the client-side hosting model, use the **Blazor WebAssembly App** template (`dotnet new blazorwasm`).

After selecting the **Blazor WebAssembly App** template, you have the option of configuring the app to use an ASP.NET Core backend by selecting the **ASP.NET Core hosted** check box (`dotnet new blazorwasm --hosted`). The ASP.NET Core app serves the Blazor app to clients. An app with an ASP.NET Core backend is called a *hosted Blazor WebAssembly app*. The Blazor WebAssembly app can interact with the server over the network using web API calls or SignalR (Use ASP.NET Core SignalR with Blazor WebAssembly).

The `blazor.webassembly.js` script is provided by the framework and handles:

- Downloading the .NET runtime, the app, and the app's dependencies.
- Initialization of the runtime to run the app.

The Blazor WebAssembly hosting model offers several benefits:

- There's no .NET server-side dependency. The app is fully functioning after it's downloaded to the client.
- Client resources and capabilities are fully leveraged.
- Work is offloaded from the server to the client.
- An ASP.NET Core web server isn't required to host the app. Serverless deployment scenarios are possible (for

example, serving the app from a CDN).

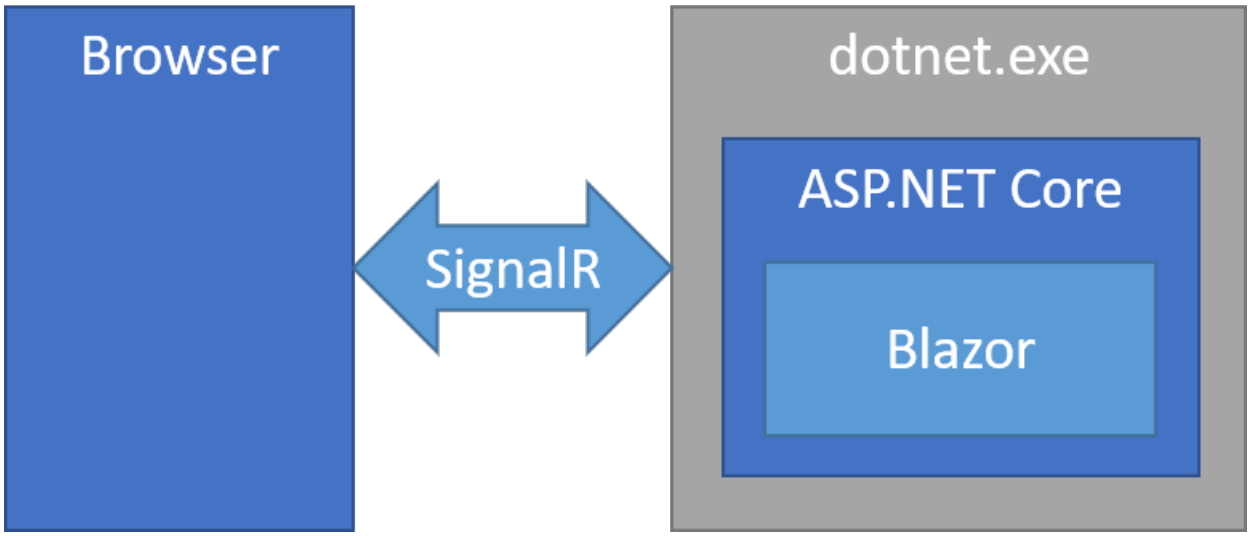
There are downsides to Blazor WebAssembly hosting:

- The app is restricted to the capabilities of the browser.
- Capable client hardware and software (for example, WebAssembly support) is required.
- Download size is larger, and apps take longer to load.
- .NET runtime and tooling support is less mature. For example, limitations exist in .NET Standard support and debugging.

The hosted Blazor app model supports Docker containers. Right-click on the Server project in Visual Studio and select **Add** > **Docker Support**.

Blazor Server

With the Blazor Server hosting model, the app is executed on the server from within an ASP.NET Core app. UI updates, event handling, and JavaScript calls are handled over a SignalR connection.



To create a Blazor app using the Blazor Server hosting model, use the ASP.NET Core **Blazor Server App** template (`dotnet new blazorserver`). The ASP.NET Core app hosts the Blazor Server app and creates the SignalR endpoint where clients connect.

The ASP.NET Core app references the app's `Startup` class to add:

- Server-side services.
- The app to the request handling pipeline.

On the client, the `blazor.server.js` script establishes the SignalR connection with the server. The script is served to the client-side app from an embedded resource in the ASP.NET Core shared framework. The client-side app is responsible for persisting and restoring app state as required.

The Blazor Server hosting model offers several benefits:

- Download size is significantly smaller than a Blazor WebAssembly app, and the app loads much faster.
- The app takes full advantage of server capabilities, including use of any .NET Core compatible APIs.
- .NET Core on the server is used to run the app, so existing .NET tooling, such as debugging, works as expected.
- Thin clients are supported. For example, Blazor Server apps work with browsers that don't support WebAssembly and on resource-constrained devices.
- The app's .NET/C# code base, including the app's component code, isn't served to clients.

> **IMPORTANT**
>
> A Blazor Server app prerenders in response to the first client request, which sets up the UI state on the server. When the client attempts to create a SignalR connection, **the client must reconnect to the same server**. Blazor Server apps that use more than one backend server should implement *sticky sessions* for SignalR connections. For more information, see the Connection to the server section.

There are downsides to Blazor Server hosting:

- Higher latency usually exists. Every user interaction involves a network hop.
- There's no offline support. If the client connection fails, the app stops working.
- Scalability is challenging for apps with many users. The server must manage multiple client connections and handle client state.
- An ASP.NET Core server is required to serve the app. Serverless deployment scenarios aren't possible (for example, serving the app from a CDN).

The Blazor Server app model supports Docker containers. Right-click on the project in Visual Studio and select **Add** > **Docker Support**.

Comparison to server-rendered UI

One way to understand Blazor Server apps is to understand how it differs from traditional models for rendering UI in ASP.NET Core apps using Razor views or Razor Pages. Both models use the Razor language to describe HTML content, but they significantly differ in how markup is rendered.

When a Razor Page or view is rendered, every line of Razor code emits HTML in text form. After rendering, the server disposes of the page or view instance, including any state that was produced. When another request for the page occurs, for instance when server validation fails and the validation summary is displayed:

- The entire page is rerendered to HTML text again.
- The page is sent to the client.

A Blazor app is composed of reusable elements of UI called *components*. A component contains C# code, markup, and other components. When a component is rendered, Blazor produces a graph of the included components similar to an HTML or XML Document Object Model (DOM). This graph includes component state held in properties and fields. Blazor evaluates the component graph to produce a binary representation of the markup. The binary format can be:

- Turned into HTML text (during prerendering†).
- Used to efficiently update the markup during regular rendering.

†*Prerendering*: The requested Razor component is compiled on the server into static HTML and sent to the client, where it's rendered to the user. After the connection is made between the client and the server, the component's static prerendered elements are replaced with interactive elements. Prerendering makes the app feel more responsive to the user.

A UI update in Blazor is triggered by:

- User interaction, such as selecting a button.
- App triggers, such as a timer.

The graph is rerendered, and a UI *diff* (difference) is calculated. This diff is the smallest set of DOM edits required to update the UI on the client. The diff is sent to the client in a binary format and applied by the browser.

A component is disposed after the user navigates away from it on the client. While a user is interacting with a component, the component's state (services, resources) must be held in the server's memory. Because the state of many components might be maintained by the server concurrently, memory exhaustion is a concern that must be

addressed. For guidance on how to author a Blazor Server app to ensure the best use of server memory, see Threat mitigation guidance for ASP.NET Core Blazor Server.

Circuits

A Blazor Server app is built on top of ASP.NET Core SignalR. Each client communicates to the server over one or more SignalR connections called a *circuit*. A circuit is Blazor's abstraction over SignalR connections that can tolerate temporary network interruptions. When a Blazor client sees that the SignalR connection is disconnected, it attempts to reconnect to the server using a new SignalR connection.

Each browser screen (browser tab or iframe) that is connected to a Blazor Server app uses a SignalR connection. This is yet another important distinction compared to typical server-rendered apps. In a server-rendered app, opening the same app in multiple browser screens typically doesn't translate into additional resource demands on the server. In a Blazor Server app, each browser screen requires a separate circuit and separate instances of component state to be managed by the server.

Blazor considers closing a browser tab or navigating to an external URL a *graceful* termination. In the event of a graceful termination, the circuit and associated resources are immediately released. A client may also disconnect non-gracefully, for instance due to a network interruption. Blazor Server stores disconnected circuits for a configurable interval to allow the client to reconnect.

Blazor Server allows code to define a *circuit handler*, which allows running code on changes to the state of a user's circuit. For more information, see ASP.NET Core Blazor advanced scenarios.

UI Latency

UI latency is the time it takes from an initiated action to the time the UI is updated. Smaller values for UI latency are imperative for an app to feel responsive to a user. In a Blazor Server app, each action is sent to the server, processed, and a UI diff is sent back. Consequently, UI latency is the sum of network latency and the server latency in processing the action.

For a line of business app that's limited to a private corporate network, the effect on user perceptions of latency due to network latency are usually imperceptible. For an app deployed over the Internet, latency may become noticeable to users, particularly if users are widely distributed geographically.

Memory usage can also contribute to app latency. Increased memory usage results in frequent garbage collection or paging memory to disk, both of which degrade app performance and consequently increase UI latency.

Blazor Server apps should be optimized to minimize UI latency by reducing network latency and memory usage. For an approach to measuring network latency, see Host and deploy ASP.NET Core Blazor Server. For more information on SignalR and Blazor, see:

- Host and deploy ASP.NET Core Blazor Server
- Threat mitigation guidance for ASP.NET Core Blazor Server

Connection to the server

Blazor Server apps require an active SignalR connection to the server. If the connection is lost, the app attempts to reconnect to the server. As long as the client's state is still in memory, the client session resumes without losing state.

A Blazor Server app prerenders in response to the first client request, which sets up the UI state on the server. When the client attempts to create a SignalR connection, the client must reconnect to the same server. Blazor Server apps that use more than one backend server should implement *sticky sessions* for SignalR connections.

We recommend using the Azure SignalR Service for Blazor Server apps. The service allows for scaling up a Blazor Server app to a large number of concurrent SignalR connections. Sticky sessions are enabled for the Azure SignalR Service by setting the service's `ServerStickyMode` option or configuration value to `Required`. For more information, see Host and deploy ASP.NET Core Blazor Server.

When using IIS, sticky sessions are enabled with Application Request Routing. For more information, see HTTP Load Balancing using Application Request Routing.

Build a Blazor todo list app

9/22/2020 • 4 minutes to read • Edit Online

By Daniel Roth and Luke Latham

This tutorial shows you how to build and modify a Blazor app. You learn how to:

- Create a todo list Blazor app project
- Modify Razor components
- Use event handling and data binding in components
- Use routing in a Blazor app

At the end of this tutorial, you'll have a working todo list app.

Prerequisites

.NET Core 3.1 SDK or later

Create a todo list Blazor app

1. Create a new Blazor app named `TodoList` in a command shell:

   ```
   dotnet new blazorserver -o TodoList
   ```

   The preceding command creates a folder named `TodoList` to hold the app. The `TodoList` folder is the *root folder* of the project. Change directories to the `TodoList` folder with the following command:

   ```
   cd TodoList
   ```

2. Add a new `Todo` Razor component to the app in the `Pages` folder using the following command:

   ```
   dotnet new razorcomponent -n Todo -o Pages
   ```

   IMPORTANT

   Razor component file names require a capitalized first letter. Open the `Pages` folder and confirm that the `Todo` component file name starts with a capital letter `T`. The file name should be `Todo.razor`.

3. In `Pages/Todo.razor` provide the initial markup for the component:

   ```
   @page "/todo"

   <h3>Todo</h3>
   ```

4. Add the `Todo` component to the navigation bar.

   The `NavMenu` component (`Shared/NavMenu.razor`) is used in the app's layout. Layouts are components that allow you to avoid duplication of content in the app.

Add a `<NavLink>` element for the `Todo` component by adding the following list item markup below the existing list items in the `Shared/NavMenu.razor` file:

```
<li class="nav-item px-3">
    <NavLink class="nav-link" href="todo">
        <span class="oi oi-list-rich" aria-hidden="true"></span> Todo
    </NavLink>
</li>
```

5. Build and run the app by executing the `dotnet run` command in the command shell from the `TodoList` folder. Visit the new Todo page to confirm that the link to the `Todo` component works.

6. Add a `TodoItem.cs` file to the root of the project (the `TodoList` folder) to hold a class that represents a todo item. Use the following C# code for the `TodoItem` class:

```
public class TodoItem
{
    public string Title { get; set; }
    public bool IsDone { get; set; }
}
```

7. Return to the `Todo` component (`Pages/Todo.razor`):

   - Add a field for the todo items in an `@code` block. The `Todo` component uses this field to maintain the state of the todo list.
   - Add unordered list markup and a `foreach` loop to render each todo item as a list item (`<li>`).

```
@page "/todo"

<h3>Todo</h3>

<ul>
    @foreach (var todo in todos)
    {
        <li>@todo.Title</li>
    }
</ul>

@code {
    private IList<TodoItem> todos = new List<TodoItem>();
}
```

8. The app requires UI elements for adding todo items to the list. Add a text input (`<input>`) and a button (`<button>`) below the unordered list (`<ul>...</ul>`):

```
@page "/todo"

<h3>Todo</h3>

<ul>
    @foreach (var todo in todos)
    {
        <li>@todo.Title</li>
    }
</ul>

<input placeholder="Something todo" />
<button>Add todo</button>

@code {
    private IList<TodoItem> todos = new List<TodoItem>();
}
```

9. Stop the running app in the command shell. Many command shells accept the keyboard command `Ctrl+c` to stop an app. Rebuild and run the app with the `dotnet run` command. When the `Add todo` button is selected, nothing happens because an event handler isn't wired up to the button.

10. Add an `AddTodo` method to the `Todo` component and register it for button selections using the `@onclick` attribute. The `AddTodo` C# method is called when the button is selected:

```
<input placeholder="Something todo" />
<button @onclick="AddTodo">Add todo</button>

@code {
    private IList<TodoItem> todos = new List<TodoItem>();

    private void AddTodo()
    {
        // Todo: Add the todo
    }
}
```

11. To get the title of the new todo item, add a `newTodo` string field at the top of the `@code` block and bind it to the value of the text input using the `bind` attribute in the `<input>` element:

```
private IList<TodoItem> todos = new List<TodoItem>();
private string newTodo;
```

```
<input placeholder="Something todo" @bind="newTodo" />
```

12. Update the `AddTodo` method to add the `TodoItem` with the specified title to the list. Clear the value of the text input by setting `newTodo` to an empty string:

```
@page "/todo"

<h3>Todo</h3>

<ul>
    @foreach (var todo in todos)
    {
        <li>@todo.Title</li>
    }
</ul>

<input placeholder="Something todo" @bind="newTodo" />
<button @onclick="AddTodo">Add todo</button>

@code {
    private IList<TodoItem> todos = new List<TodoItem>();
    private string newTodo;

    private void AddTodo()
    {
        if (!string.IsNullOrWhiteSpace(newTodo))
        {
            todos.Add(new TodoItem { Title = newTodo });
            newTodo = string.Empty;
        }
    }
}
```

13. Stop the running app in the command shell. Rebuild and run the app with the `dotnet run` command. Add some todo items to the todo list to test the new code.

14. The title text for each todo item can be made editable, and a check box can help the user keep track of completed items. Add a check box input for each todo item and bind its value to the `IsDone` property. Change `@todo.Title` to an `<input>` element bound to `@todo.Title`:

```
<ul>
    @foreach (var todo in todos)
    {
        <li>
            <input type="checkbox" @bind="todo.IsDone" />
            <input @bind="todo.Title" />
        </li>
    }
</ul>
```

15. To verify that these values are bound, update the `<h3>` header to show a count of the number of todo items that aren't complete (`IsDone` is `false`).

```
<h3>Todo (@todos.Count(todo => !todo.IsDone))</h3>
```

16. The completed `Todo` component (`Pages/Todo.razor`):

```
@page "/todo"

<h3>Todo (@todos.Count(todo => !todo.IsDone))</h3>

<ul>
    @foreach (var todo in todos)
    {
        <li>
            <input type="checkbox" @bind="todo.IsDone" />
            <input @bind="todo.Title" />
        </li>
    }
</ul>

<input placeholder="Something todo" @bind="newTodo" />
<button @onclick="AddTodo">Add todo</button>

@code {
    private IList<TodoItem> todos = new List<TodoItem>();
    private string newTodo;

    private void AddTodo()
    {
        if (!string.IsNullOrWhiteSpace(newTodo))
        {
            todos.Add(new TodoItem { Title = newTodo });
            newTodo = string.Empty;
        }
    }
}
```

17. Stop the running app in the command shell. Rebuild and run the app with the `dotnet run` command. Add todo items to test the new code.

Next steps

In this tutorial, you learned how to:

- Create a todo list Blazor app project
- Modify Razor components
- Use event handling and data binding in components
- Use routing in a Blazor app

Learn about tooling for ASP.NET Core Blazor:

Tooling for ASP.NET Core Blazor

Use ASP.NET Core SignalR with Blazor WebAssembly

9/22/2020 • 7 minutes to read • Edit Online

By Daniel Roth and Luke Latham

This tutorial teaches the basics of building a real-time app using SignalR with Blazor WebAssembly. You learn how to:

- Create a Blazor WebAssembly Hosted app project
- Add the SignalR client library
- Add a SignalR hub
- Add SignalR services and an endpoint for the SignalR hub
- Add Razor component code for chat

At the end of this tutorial, you'll have a working chat app.

View or download sample code (how to download)

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac
- .NET Core CLI

- Visual Studio 2019 16.6 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

Create a hosted Blazor WebAssembly app project

Follow the guidance for your choice of tooling:

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac
- .NET Core CLI

> **NOTE**
> Visual Studio 16.6 or later and .NET Core SDK 3.1.300 or later are required.

1. Create a new project.
2. Select **Blazor App** and select **Next**.
3. Type `BlazorSignalRApp` in the **Project name** field. Confirm the **Location** entry is correct or provide a location for the project. Select **Create**.
4. Choose the **Blazor WebAssembly App** template.
5. Under **Advanced**, select the **ASP.NET Core hosted** check box.

6. Select **Create**.

Add the SignalR client library

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac
- .NET Core CLI

1. In **Solution Explorer**, right-click the `BlazorSignalRApp.Client` project and select **Manage NuGet Packages**.
2. In the **Manage NuGet Packages** dialog, confirm that the **Package source** is set to `nuget.org`.
3. With **Browse** selected, type `Microsoft.AspNetCore.SignalR.Client` in the search box.
4. In the search results, select the `Microsoft.AspNetCore.SignalR.Client` package and select **Install**.
5. If the **Preview Changes** dialog appears, select **OK**.
6. If the **License Acceptance** dialog appears, select **I Accept** if you agree with the license terms.

Add a SignalR hub

In the `BlazorSignalRApp.Server` project, create a `Hubs` (plural) folder and add the following `ChatHub` class (`Hubs/ChatHub.cs`):

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.SignalR;

namespace BlazorSignalRApp.Server.Hubs
{
    public class ChatHub : Hub
    {
        public async Task SendMessage(string user, string message)
        {
            await Clients.All.SendAsync("ReceiveMessage", user, message);
        }
    }
}
```

Add services and an endpoint for the SignalR hub

1. In the `BlazorSignalRApp.Server` project, open the `Startup.cs` file.
2. Add the namespace for the `ChatHub` class to the top of the file:

   ```
   using BlazorSignalRApp.Server.Hubs;
   ```

3. Add SignalR and Response Compression Middleware services to `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSignalR();
    services.AddControllersWithViews();
    services.AddResponseCompression(opts =>
    {
        opts.MimeTypes = ResponseCompressionDefaults.MimeTypes.Concat(
            new[] { "application/octet-stream" });
    });
}
```

4. In `Startup.Configure`:

   - Use Response Compression Middleware at the top of the processing pipeline's configuration.
   - Between the endpoints for controllers and the client-side fallback, add an endpoint for the hub.

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    app.UseResponseCompression();

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseWebAssemblyDebugging();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseBlazorFrameworkFiles();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
        endpoints.MapHub<ChatHub>("/chathub");
        endpoints.MapFallbackToFile("index.html");
    });
}
```

Add Razor component code for chat

1. In the `BlazorSignalRApp.Client` project, open the `Pages/Index.razor` file.

2. Replace the markup with the following code:

```
@page "/"
@using Microsoft.AspNetCore.SignalR.Client
@inject NavigationManager NavigationManager
@implements IDisposable

<div class="form-group">
    <label>
        User:
        <input @bind="userInput" />
    </label>
</div>
<div class="form-group">
    <label>
        Message:
        <input @bind="messageInput" size="50" />
    </label>
</div>
<button @onclick="Send" disabled="@(!IsConnected)">Send</button>

<hr>

<ul id="messagesList">
    @foreach (var message in messages)
    {
        <li>@message</li>
    }
</ul>

@code {
    private HubConnection hubConnection;
    private List<string> messages = new List<string>();
    private string userInput;
    private string messageInput;

    protected override async Task OnInitializedAsync()
    {
        hubConnection = new HubConnectionBuilder()
            .WithUrl(NavigationManager.ToAbsoluteUri("/chathub"))
            .Build();

        hubConnection.On<string, string>("ReceiveMessage", (user, message) =>
        {
            var encodedMsg = $"{user}: {message}";
            messages.Add(encodedMsg);
            StateHasChanged();
        });

        await hubConnection.StartAsync();
    }

    Task Send() =>
        hubConnection.SendAsync("SendMessage", userInput, messageInput);

    public bool IsConnected =>
        hubConnection.State == HubConnectionState.Connected;

    public void Dispose()
    {
        _ = hubConnection.DisposeAsync();
    }
}
```

Run the app

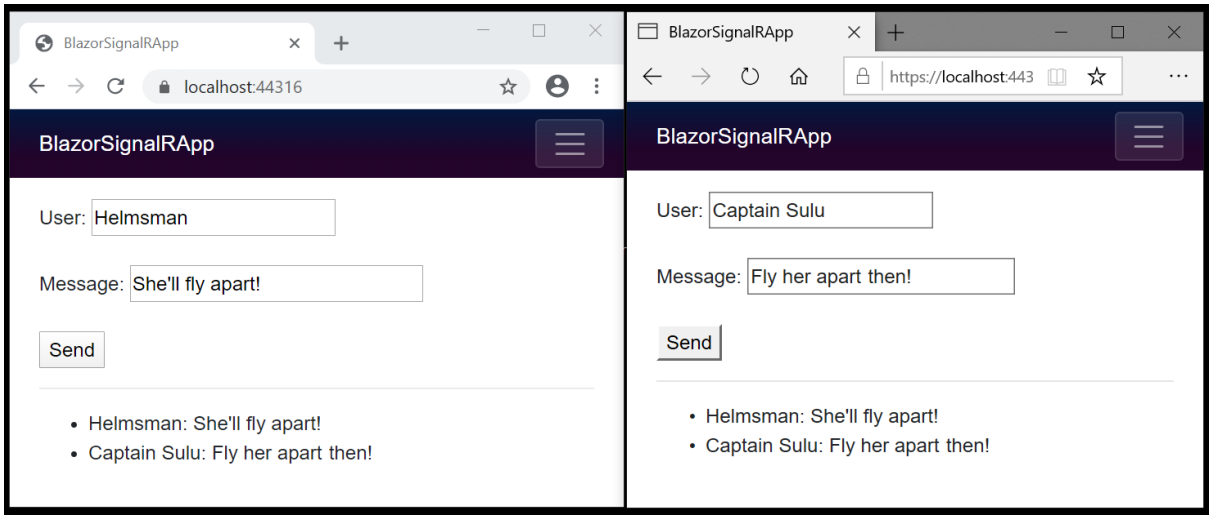
1. Follow the guidance for your tooling:

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac
- .NET Core CLI

1. In **Solution Explorer**, select the `BlazorSignalRApp.Server` project. Press `F5` to run the app with debugging or `Ctrl+F5` to run the app without debugging.

2. Copy the URL from the address bar, open another browser instance or tab, and paste the URL in the address bar.

3. Choose either browser, enter a name and message, and select the button to send the message. The name and message are displayed on both pages instantly:



Quotes: *Star Trek VI: The Undiscovered Country* © 1991 Paramount

Next steps

In this tutorial, you learned how to:

- Create a Blazor WebAssembly Hosted app project
- Add the SignalR client library
- Add a SignalR hub
- Add SignalR services and an endpoint for the SignalR hub
- Add Razor component code for chat

To learn more about building Blazor apps, see the Blazor documentation:

Introduction to ASP.NET Core Blazor

Additional resources

- Introduction to ASP.NET Core SignalR
- SignalR cross-origin negotiation for authentication

ASP.NET Core Blazor templates

9/22/2020 • 3 minutes to read • Edit Online

By Daniel Roth and Luke Latham

The Blazor framework provides templates to develop apps for each of the Blazor hosting models:

- Blazor WebAssembly (`blazorwasm`)
- Blazor Server (`blazorserver`)

For more information on Blazor's hosting models, see ASP.NET Core Blazor hosting models.

Template options are available by passing the `--help` option to the `dotnet new` CLI command:

```
dotnet new blazorwasm --help
dotnet new blazorserver --help
```

Blazor project structure

The following files and folders make up a Blazor app generated from a Blazor project template:

- `Program.cs` : The app's entry point that sets up the:
  - ASP.NET Core host (Blazor Server)
  - WebAssembly host (Blazor WebAssembly): The code in this file is unique to apps created from the Blazor WebAssembly template (`blazorwasm`).
    - The `App` component is the root component of the app. The `App` component is specified as the `app` DOM element (`<app>...</app>`) to the root component collection (`builder.RootComponents.Add<App>("app")`).
    - Services are added and configured (for example, `builder.Services.AddSingleton<IMyDependency, MyDependency>()`).
- `Startup.cs` (Blazor Server): Contains the app's startup logic. The `Startup` class defines two methods:
  - `ConfigureServices` : Configures the app's dependency injection (DI) services. In Blazor Server apps, services are added by calling AddServerSideBlazor, and the `WeatherForecastService` is added to the service container for use by the example `FetchData` component.
  - `Configure` : Configures the app's request handling pipeline:
    - MapBlazorHub is called to set up an endpoint for the real-time connection with the browser. The connection is created with SignalR, which is a framework for adding real-time web functionality to apps.
    - `MapFallbackToPage("/_Host")` is called to set up the root page of the app (`Pages/_Host.cshtml`) and enable navigation.
- `wwwroot/index.html` (Blazor WebAssembly): The root page of the app implemented as an HTML page:
  - When any page of the app is initially requested, this page is rendered and returned in the response.
  - The page specifies where the root `App` component is rendered. The component is rendered at the location of the `app` DOM element (`<app>...</app>`).
  - The `_framework/blazor.webassembly.js` JavaScript file is loaded, which:
    - Downloads the .NET runtime, the app, and the app's dependencies.

    - Initializes the runtime to run the app.
- `App.razor`: The root component of the app that sets up client-side routing using the Router component. The Router component intercepts browser navigation and renders the page that matches the requested address.
- `Pages` folder: Contains the routable components/pages (`.razor`) that make up the Blazor app and the root Razor page of a Blazor Server app. The route for each page is specified using the `@page` directive. The template includes the following:
    - `_Host.cshtml` (Blazor Server): The root page of the app implemented as a Razor Page:
        - When any page of the app is initially requested, this page is rendered and returned in the response.
        - The `_framework/blazor.server.js` JavaScript file is loaded, which sets up the real-time SignalR connection between the browser and the server.
        - The Host page specifies where the root `App` component (`App.razor`) is rendered.
    - `Counter` (`Pages/Counter.razor`): Implements the Counter page.
    - `Error` (`Error.razor`, Blazor Server app only): Rendered when an unhandled exception occurs in the app.
    - `FetchData` (`Pages/FetchData.razor`): Implements the Fetch data page.
    - `Index` (`Pages/Index.razor`): Implements the Home page.
- `Properties/launchSettings.json`: Holds development environment configuration.
- `Shared` folder: Contains other UI components (`.razor`) used by the app:
    - `MainLayout` (`MainLayout.razor`): The app's layout component.
    - `NavMenu` (`NavMenu.razor`): Implements sidebar navigation. Includes the `NavLink` component (NavLink), which renders navigation links to other Razor components. The NavLink component automatically indicates a selected state when its component is loaded, which helps the user understand which component is currently displayed.
- `_Imports.razor`: Includes common Razor directives to include in the app's components (`.razor`), such as `@using` directives for namespaces.
- `Data` folder (Blazor Server): Contains the `WeatherForecast` class and implementation of the `WeatherForecastService` that provide example weather data to the app's `FetchData` component.
- `wwwroot`: The Web Root folder for the app containing the app's public static assets.
- `appsettings.json`: Holds configuration settings for the app. In a Blazor WebAssembly app, the app settings file is located in the `wwwroot` folder. In a Blazor Server app, the app settings file is located at the project root.

ASP.NET Core Blazor routing

9/22/2020 • 9 minutes to read • Edit Online

By Luke Latham

Learn how to route requests and how to use the NavLink component to create navigation links in Blazor apps.

ASP.NET Core endpoint routing integration

Blazor Server is integrated into ASP.NET Core Endpoint Routing. An ASP.NET Core app is configured to accept incoming connections for interactive components with MapBlazorHub in `Startup.Configure`:

```
app.UseRouting();

app.UseEndpoints(endpoints =>
{
    endpoints.MapBlazorHub();
    endpoints.MapFallbackToPage("/_Host");
});
```

The most typical configuration is to route all requests to a Razor page, which acts as the host for the server-side part of the Blazor Server app. By convention, the *host* page is usually named `_Host.cshtml`. The route specified in the host file is called a *fallback route* because it operates with a low priority in route matching. The fallback route is considered when other routes don't match. This allows the app to use others controllers and pages without interfering with the Blazor Server app.

For information on configuring MapFallbackToPage for non-root URL server hosting, see Host and deploy ASP.NET Core Blazor.

Route templates

The Router component enables routing to each component with a specified route. The Router component appears in the `App.razor` file:

```
<Router AppAssembly="@typeof(Startup).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="@routeData" DefaultLayout="@typeof(MainLayout)" />
    </Found>
    <NotFound>
        <p>Sorry, there's nothing at this address.</p>
    </NotFound>
</Router>
```

When a `.razor` file with an `@page` directive is compiled, the generated class is provided a RouteAttribute specifying the route template.

At runtime, the RouteView component:

- Receives the RouteData from the Router along with any desired parameters.
- Renders the specified component with its layout (or an optional default layout) using the specified parameters.

You can optionally specify a DefaultLayout parameter with a layout class to use for components that don't specify a layout. The default Blazor templates specify the `MainLayout` component. `MainLayout.razor` is in the template

project's `Shared` folder. For more information on layouts, see ASP.NET Core Blazor layouts.

Multiple route templates can be applied to a component. The following component responds to requests for `/BlazorRoute` and `/DifferentBlazorRoute`:

```
@page "/BlazorRoute"
@page "/DifferentBlazorRoute"

<h1>Blazor routing</h1>
```

IMPORTANT

For URLs to resolve correctly, the app must include a `<base>` tag in its `wwwroot/index.html` file (Blazor WebAssembly) or `Pages/_Host.cshtml` file (Blazor Server) with the app base path specified in the `href` attribute (`<base href="/">`). For more information, see Host and deploy ASP.NET Core Blazor.

Provide custom content when content isn't found

The Router component allows the app to specify custom content if content isn't found for the requested route.

In the `App.razor` file, set custom content in the NotFound template parameter of the Router component:

```
<Router AppAssembly="typeof(Startup).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="@routeData" DefaultLayout="@typeof(MainLayout)" />
    </Found>
    <NotFound>
        <h1>Sorry</h1>
        <p>Sorry, there's nothing at this address.</p> b
    </NotFound>
</Router>
```

The content of `<NotFound>` tags can include arbitrary items, such as other interactive components. To apply a default layout to NotFound content, see ASP.NET Core Blazor layouts.

Route to components from multiple assemblies

Use the AdditionalAssemblies parameter to specify additional assemblies for the Router component to consider when searching for routable components. Specified assemblies are considered in addition to the `AppAssembly`-specified assembly. In the following example, `Component1` is a routable component defined in a referenced class library. The following AdditionalAssemblies example results in routing support for `Component1`:

```
<Router
    AppAssembly="@typeof(Program).Assembly"
    AdditionalAssemblies="new[] { typeof(Component1).Assembly }">
    ...
</Router>
```

Route parameters

The router uses route parameters to populate the corresponding component parameters with the same name (case insensitive):

```
@page "/RouteParameter"
@page "/RouteParameter/{text}"

<h1>Blazor is @Text!</h1>

@code {
    [Parameter]
    public string Text { get; set; }

    protected override void OnInitialized()
    {
        Text = Text ?? "fantastic";
    }
}
```

Optional parameters aren't supported. Two `@page` directives are applied in the previous example. The first permits navigation to the component without a parameter. The second `@page` directive takes the `{text}` route parameter and assigns the value to the `Text` property.

Route constraints

A route constraint enforces type matching on a route segment to a component.

In the following example, the route to the `Users` component only matches if:

- An `Id` route segment is present on the request URL.
- The `Id` segment is an integer (`int`).

```
@page "/Users/{Id:int}"

<h1>The user Id is @Id!</h1>

@code {
    [Parameter]
    public int Id { get; set; }
}
```

The route constraints shown in the following table are available. For the route constraints that match with the invariant culture, see the warning below the table for more information.

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	INVARIANT CULTURE MATCHING
`bool`	`{active:bool}`	`true`, `FALSE`	No
`datetime`	`{dob:datetime}`	`2016-12-31`, `2016-12-31 7:32pm`	Yes
`decimal`	`{price:decimal}`	`49.99`, `-1,000.01`	Yes
`double`	`{weight:double}`	`1.234`, `-1,001.01e8`	Yes
`float`	`{weight:float}`	`1.234`, `-1,001.01e8`	Yes

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	INVARIANT CULTURE MATCHING
`guid`	`{id:guid}`	`CD2C1638-1638-72D5-1638-DEADBEEF1638`, `{CD2C1638-1638-72D5-1638-DEADBEEF1638}`	No
`int`	`{id:int}`	`123456789`, `-123456789`	Yes
`long`	`{ticks:long}`	`123456789`, `-123456789`	Yes

WARNING

Route constraints that verify the URL and are converted to a CLR type (such as `int` or DateTime) always use the invariant culture. These constraints assume that the URL is non-localizable.

Routing with URLs that contain dots

For hosted Blazor WebAssembly and Blazor Server apps, the server-side default route template assumes that if the last segment of a request URL contains a dot (`.`) that a file is requested (for example, `https://localhost.com:5001/example/some.thing`). Without additional configuration, an app returns a *404 - Not Found* response if this was meant to route to a component. To use a route with one or more parameters that contains a dot, the app must configure the route with a custom template.

Consider the following `Example` component that can receive a route parameter from the last segment of the URL:

```
@page "/example"
@page "/example/{param}"

<p>
    Param: @Param
</p>

@code {
    [Parameter]
    public string Param { get; set; }
}
```

To permit the *Server* app of a hosted Blazor WebAssembly solution to route the request with a dot in the `param` parameter, add a fallback file route template with the optional parameter in `Startup.Configure` (`Startup.cs`):

```
endpoints.MapFallbackToFile("/example/{param?}", "index.html");
```

To configure a Blazor Server app to route the request with a dot in the `param` parameter, add a fallback page route template with the optional parameter in `Startup.Configure` (`Startup.cs`):

```
endpoints.MapFallbackToPage("/example/{param?}", "/_Host");
```

For more information, see Routing in ASP.NET Core.

Catch-all route parameters

This section applies to ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.

Catch-all route parameters, which capture paths across multiple folder boundaries, are supported in components. The catch-all route parameter must be:

- Named to match the route segment name. Naming isn't case sensitive.
- A `string` type. The framework doesn't provide automatic casting.
- At the end of the URL.

```
@page "/page/{*pageRoute}"

@code {
    [Parameter]
    public string PageRoute { get; set; }
}
```

For the URL `/page/this/is/a/test` with a route template of `/page/{*pageRoute}`, the value of `PageRoute` is set to `this/is/a/test`.

Slashes and segments of the captured path are decoded. For a route template of `/page/{*pageRoute}`, the URL `/page/this/is/a%2Ftest%2A` yields `this/is/a/test*`.

Catch-all route parameters are supported in ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.*

NavLink component

Use a NavLink component in place of HTML hyperlink elements (`<a>`) when creating navigation links. A NavLink component behaves like an `<a>` element, except it toggles an `active` CSS class based on whether its `href` matches the current URL. The `active` class helps a user understand which page is the active page among the navigation links displayed. Optionally, assign a CSS class name to NavLink.ActiveClass to apply a custom CSS class to the rendered link when the current route matches the `href`.

The following `NavMenu` component creates a `Bootstrap` navigation bar that demonstrates how to use NavLink components:

```
<div class="@NavMenuCssClass" @onclick="@ToggleNavMenu">
    <ul class="nav flex-column">
        <li class="nav-item px-3">
            <NavLink class="nav-link" href="" Match="NavLinkMatch.All">
                <span class="oi oi-home" aria-hidden="true"></span> Home
            </NavLink>
        </li>
        <li class="nav-item px-3">
            <NavLink class="nav-link" href="MyComponent" Match="NavLinkMatch.Prefix">
                <span class="oi oi-plus" aria-hidden="true"></span> My Component
            </NavLink>
        </li>
    </ul>
</div>
```

There are two NavLinkMatch options that you can assign to the `Match` attribute of the `<NavLink>` element:

- NavLinkMatch.All: The NavLink is active when it matches the entire current URL.
- NavLinkMatch.Prefix (*default*): The NavLink is active when it matches any prefix of the current URL.

In the preceding example, the Home NavLink `href=""` matches the home URL and only receives the `active` CSS class at the app's default base path URL (for example, `https://localhost:5001/`). The second NavLink receives the `active` class when the user visits any URL with a `MyComponent` prefix (for example,

`https://localhost:5001/MyComponent` and `https://localhost:5001/MyComponent/AnotherSegment`).

Additional NavLink component attributes are passed through to the rendered anchor tag. In the following example, the NavLink component includes the `target` attribute:

```
<NavLink href="my-page" target="_blank">My page</NavLink>
```

The following HTML markup is rendered:

```
<a href="my-page" target="_blank">My page</a>
```

WARNING

Due to the way that Blazor renders child content, rendering `NavLink` components inside a `for` loop requires a local index variable if the incrementing loop variable is used in the `NavLink` (child) component's content:

```
@for (int c = 0; c < 10; c++)
{
    var current = c;
    <li ...>
        <NavLink ... href="@c">
            <span ...></span> @current
        </NavLink>
    </li>
}
```

Using an index variable in this scenario is a requirement for **any** child component that uses a loop variable in its child content, not just the `NavLink` component.

Alternatively, use a `foreach` loop with Enumerable.Range:

```
@foreach(var c in Enumerable.Range(0,10))
{
    <li ...>
        <NavLink ... href="@c">
            <span ...></span> @c
        </NavLink>
    </li>
}
```

URI and navigation state helpers

Use NavigationManager to work with URIs and navigation in C# code. NavigationManager provides the event and methods shown in the following table.

MEMBER	DESCRIPTION
Uri	Gets the current absolute URI.
BaseUri	Gets the base URI (with a trailing slash) that can be prepended to relative URI paths to produce an absolute URI. Typically, BaseUri corresponds to the `href` attribute on the document's `<base>` element in `wwwroot/index.html` (Blazor WebAssembly) or `Pages/_Host.cshtml` (Blazor Server).

MEMBER	DESCRIPTION
NavigateTo	Navigates to the specified URI. If `forceLoad` is `true`: • Client-side routing is bypassed. • The browser is forced to load the new page from the server, whether or not the URI is normally handled by the client-side router.
LocationChanged	An event that fires when the navigation location has changed.
ToAbsoluteUri	Converts a relative URI into an absolute URI.
ToBaseRelativePath	Given a base URI (for example, a URI previously returned by BaseUri), converts an absolute URI into a URI relative to the base URI prefix.

The following component navigates to the app's `Counter` component when the button is selected:

```
@page "/navigate"
@inject NavigationManager NavigationManager

<h1>Navigate in Code Example</h1>

<button class="btn btn-primary" @onclick="NavigateToCounterComponent">
    Navigate to the Counter component
</button>

@code {
    private void NavigateToCounterComponent()
    {
        NavigationManager.NavigateTo("counter");
    }
}
```

The following component handles a location changed event by subscribing to NavigationManager.LocationChanged. The `HandleLocationChanged` method is unhooked when `Dispose` is called by the framework. Unhooking the method permits garbage collection of the component.

```
@implements IDisposable
@inject NavigationManager NavigationManager

...

protected override void OnInitialized()
{
    NavigationManager.LocationChanged += HandleLocationChanged;
}

private void HandleLocationChanged(object sender, LocationChangedEventArgs e)
{
    ...
}

public void Dispose()
{
    NavigationManager.LocationChanged -= HandleLocationChanged;
}
```

LocationChangedEventArgs provides the following information about the event:

- Location: The URL of the new location.
- IsNavigationIntercepted: If `true`, Blazor intercepted the navigation from the browser. If `false`, NavigationManager.NavigateTo caused the navigation to occur.

For more information on component disposal, see ASP.NET Core Blazor lifecycle.

Query string and parse parameters

The query string of a request can be obtained from the NavigationManager's Uri property:

```
@inject NavigationManager Navigation

...

var query = new Uri(Navigation.Uri).Query;
```

To parse a query string's parameters:

- Add a package reference for Microsoft.AspNetCore.WebUtilities.
- Obtain the value after parsing the query string with QueryHelpers.ParseQuery.

```
@page "/"
@using Microsoft.AspNetCore.WebUtilities
@inject NavigationManager NavigationManager

<h1>Query string parse example</h1>

<p>Value: @queryValue</p>

@code {
    private string queryValue = "Not set";

    protected override void OnInitialized()
    {
        var query = new Uri(NavigationManager.Uri).Query;

        if (QueryHelpers.ParseQuery(query).TryGetValue("{KEY}", out var value))
        {
            queryValue = value;
        }
    }
}
```

The placeholder `{KEY}` in the preceding example is the query string parameter key. For example, the URL key-value pair `?ship=Tardis` uses a key of `ship`.

ASP.NET Core Blazor configuration

9/22/2020 • 3 minutes to read • Edit Online

> **NOTE**
> This topic applies to Blazor WebAssembly. For general guidance on ASP.NET Core app configuration, see Configuration in ASP.NET Core.

Blazor WebAssembly loads configuration from app settings files by default:

- `wwwroot/appsettings.json`
- `wwwroot/appsettings.{ENVIRONMENT}.json`

Other configuration providers registered by the app can also provide configuration.

Not all providers or provider features are appropriate for Blazor WebAssembly apps:

- Azure Key Vault configuration provider: The provider isn't supported for managed identity and application ID (client ID) with client secret scenarios. Application ID with a client secret isn't recommended for any ASP.NET Core app, especially Blazor WebAssembly apps because the client secret can't be secured client-side to access to the service.
- Azure App configuration provider: The provider isn't appropriate for Blazor WebAssembly apps because Blazor WebAssembly apps don't run on a server in Azure.

> **WARNING**
> Configuration in a Blazor WebAssembly app is visible to users. **Don't store app secrets or credentials in configuration.**

For more information on configuration providers, see Configuration in ASP.NET Core.

App settings configuration

`wwwroot/appsettings.json`:

```
{
  "message": "Hello from config!"
}
```

Inject an IConfiguration instance into a component to access the configuration data:

```
@page "/"
@using Microsoft.Extensions.Configuration
@inject IConfiguration Configuration

<h1>Configuration example</h1>

<p>Message: @Configuration["message"]</p>
```

Custom configuration provider with EF Core

The custom configuration provider with EF Core demonstrated in Configuration in ASP.NET Core works with Blazor WebAssembly apps.

Add the example's configuration provider with the following code in `Program.Main` (`Program.cs`):

```
builder.Configuration.AddEFConfiguration(
    options => options.UseInMemoryDatabase("InMemoryDb"));
```

Inject an IConfiguration instance into a component to access the configuration data:

```
@using Microsoft.Extensions.Configuration
@inject IConfiguration Configuration

<ul>
    <li>@Configuration["quote1"]</li>
    <li>@Configuration["quote2"]</li>
    <li>@Configuration["quote3"]</li>
</ul>
```

Memory Configuration Source

The following example uses a MemoryConfigurationSource to supply additional configuration:

`Program.Main`:

```
using Microsoft.Extensions.Configuration.Memory;

...

var vehicleData = new Dictionary<string, string>()
{
    { "color", "blue" },
    { "type", "car" },
    { "wheels:count", "3" },
    { "wheels:brand", "Blazin" },
    { "wheels:brand:type", "rally" },
    { "wheels:year", "2008" },
};

var memoryConfig = new MemoryConfigurationSource { InitialData = vehicleData };

...

builder.Configuration.Add(memoryConfig);
```

Inject an IConfiguration instance into a component to access the configuration data:

```
@page "/"
@using Microsoft.Extensions.Configuration
@inject IConfiguration Configuration

<h1>Configuration example</h1>

<h2>Wheels</h2>

<ul>
    <li>Count: @Configuration["wheels:count"]</li>
    <li>Brand: @Configuration["wheels:brand"]</li>
    <li>Type: @Configuration["wheels:brand:type"]</li>
    <li>Year: @Configuration["wheels:year"]</li>
</ul>

@code {
    protected override void OnInitialized()
    {
        var wheelsSection = Configuration.GetSection("wheels");

        ...
    }
}
```

To read other configuration files from the `wwwroot` folder into configuration, use an HttpClient to obtain the file's content. When using this approach, the existing HttpClient service registration can use the local client created to read the file, as the following example shows:

`wwwroot/cars.json`:

```
{
    "size": "tiny"
}
```

`Program.Main`:

```
using Microsoft.Extensions.Configuration;

...

var client = new HttpClient()
{
    BaseAddress = new Uri(builder.HostEnvironment.BaseAddress)
};

builder.Services.AddScoped(sp => client);

using var response = await client.GetAsync("cars.json");
using var stream = await response.Content.ReadAsStreamAsync();

builder.Configuration.AddJsonStream(stream);
```

Authentication configuration

`wwwroot/appsettings.json`:

```
{
  "Local": {
    "Authority": "{AUTHORITY}",
    "ClientId": "{CLIENT ID}"
  }
}
```

`Program.Main`:

```
builder.Services.AddOidcAuthentication(options =>
    builder.Configuration.Bind("Local", options.ProviderOptions));
```

Logging configuration

Add a package reference for `Microsoft.Extensions.Logging.Configuration`:

```
<PackageReference Include="Microsoft.Extensions.Logging.Configuration" Version="{VERSION}" />
```

For the placeholder `{VERSION}`, the latest stable version of the package that matches the app's shared framework version can be found in the package's **Version History** at NuGet.org.

`wwwroot/appsettings.json`:

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  }
}
```

`Program.Main`:

```
using Microsoft.Extensions.Logging;

...

builder.Logging.AddConfiguration(
    builder.Configuration.GetSection("Logging"));
```

Host builder configuration

`Program.Main`:

```
var hostname = builder.Configuration["HostName"];
```

Cached configuration

Configuration files are cached for offline use. With Progressive Web Applications (PWAs), you can only update configuration files when creating a new deployment. Editing configuration files between deployments has no effect because:

- Users have cached versions of the files that they continue to use.
- The PWA's `service-worker.js` and `service-worker-assets.js` files must be rebuilt on compilation, which signal to the app on the user's next online visit that the app has been redeployed.

For more information on how background updates are handled by PWAs, see Build Progressive Web Applications with ASP.NET Core Blazor WebAssembly.

ASP.NET Core Blazor dependency injection

9/22/2020 • 11 minutes to read • Edit Online

By Rainer Stropek and Mike Rousos

Blazor supports dependency injection (DI). Apps can use built-in services by injecting them into components. Apps can also define and register custom services and make them available throughout the app via DI.

DI is a technique for accessing services configured in a central location. This can be useful in Blazor apps to:

- Share a single instance of a service class across many components, known as a *singleton* service.
- Decouple components from concrete service classes by using reference abstractions. For example, consider an interface `IDataAccess` for accessing data in the app. The interface is implemented by a concrete `DataAccess` class and registered as a service in the app's service container. When a component uses DI to receive an `IDataAccess` implementation, the component isn't coupled to the concrete type. The implementation can be swapped, perhaps for a mock implementation in unit tests.

Default services

Default services are automatically added to the app's service collection.

SERVICE	LIFETIME	DESCRIPTION
HttpClient	Scoped	Provides methods for sending HTTP requests and receiving HTTP responses from a resource identified by a URI. The instance of HttpClient in a Blazor WebAssembly app uses the browser for handling the HTTP traffic in the background. Blazor Server apps don't include an HttpClient configured as a service by default. Provide an HttpClient to a Blazor Server app. For more information, see Call a web API from ASP.NET Core Blazor WebAssembly.
IJSRuntime	Singleton (Blazor WebAssembly) Scoped (Blazor Server)	Represents an instance of a JavaScript runtime where JavaScript calls are dispatched. For more information, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.
NavigationManager	Singleton (Blazor WebAssembly) Scoped (Blazor Server)	Contains helpers for working with URIs and navigation state. For more information, see URI and navigation state helpers.

A custom service provider doesn't automatically provide the default services listed in the table. If you use a custom service provider and require any of the services shown in the table, add the required services to the new service provider.

Add services to an app

Blazor WebAssembly

Configure services for the app's service collection in the `Main` method of `Program.cs`. In the following example, the `MyDependency` implementation is registered for `IMyDependency`:

```
using System;
using System.Net.Http;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Components.WebAssembly.Hosting;
using Microsoft.Extensions.DependencyInjection;

public class Program
{
    public static async Task Main(string[] args)
    {
        var builder = WebAssemblyHostBuilder.CreateDefault(args);
        builder.Services.AddSingleton<IMyDependency, MyDependency>();
        builder.RootComponents.Add<App>("app");

        builder.Services.AddScoped(sp =>
            new HttpClient
            {
                BaseAddress = new Uri(builder.HostEnvironment.BaseAddress)
            });

        await builder.Build().RunAsync();
    }
}
```

Once the host is built, services can be accessed from the root DI scope before any components are rendered. This can be useful for running initialization logic before rendering content:

```
public class Program
{
    public static async Task Main(string[] args)
    {
        var builder = WebAssemblyHostBuilder.CreateDefault(args);
        builder.Services.AddSingleton<WeatherService>();
        builder.RootComponents.Add<App>("app");

        builder.Services.AddScoped(sp =>
            new HttpClient
            {
                BaseAddress = new Uri(builder.HostEnvironment.BaseAddress)
            });

        var host = builder.Build();

        var weatherService = host.Services.GetRequiredService<WeatherService>();
        await weatherService.InitializeWeatherAsync();

        await host.RunAsync();
    }
}
```

The host also provides a central configuration instance for the app. Building on the preceding example, the weather service's URL is passed from a default configuration source (for example, `appsettings.json`) to `InitializeWeatherAsync`:

```
public class Program
{
    public static async Task Main(string[] args)
    {
        var builder = WebAssemblyHostBuilder.CreateDefault(args);
        builder.Services.AddSingleton<WeatherService>();
        builder.RootComponents.Add<App>("app");

        builder.Services.AddScoped(sp =>
            new HttpClient
            {
                BaseAddress = new Uri(builder.HostEnvironment.BaseAddress)
            });

        var host = builder.Build();

        var weatherService = host.Services.GetRequiredService<WeatherService>();
        await weatherService.InitializeWeatherAsync(
            host.Configuration["WeatherServiceUrl"]);

        await host.RunAsync();
    }
}
```

Blazor Server

After creating a new app, examine the `Startup.ConfigureServices` method:

```
using Microsoft.Extensions.DependencyInjection;

...

public void ConfigureServices(IServiceCollection services)
{
    ...
}
```

The ConfigureServices method is passed an IServiceCollection, which is a list of service descriptor objects (ServiceDescriptor). Services are added in the `ConfigureServices` method by providing service descriptors to the service collection. The following example demonstrates the concept with the `IDataAccess` interface and its concrete implementation `DataAccess`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSingleton<IDataAccess, DataAccess>();
}
```

Service lifetime

Services can be configured with the lifetimes shown in the following table.

LIFETIME	DESCRIPTION

LIFETIME	DESCRIPTION
Scoped	Blazor WebAssembly apps don't currently have a concept of DI scopes. `Scoped`-registered services behave like `Singleton` services. However, the Blazor Server hosting model supports the `Scoped` lifetime. In Blazor Server apps, a scoped service registration is scoped to the *connection*. For this reason, using scoped services is preferred for services that should be scoped to the current user, even if the current intent is to run client-side in the browser.
Singleton	DI creates a *single instance* of the service. All components requiring a `Singleton` service receive an instance of the same service.
Transient	Whenever a component obtains an instance of a `Transient` service from the service container, it receives a *new instance* of the service.

The DI system is based on the DI system in ASP.NET Core. For more information, see Dependency injection in ASP.NET Core.

Request a service in a component

After services are added to the service collection, inject the services into the components using the @inject Razor directive. `@inject` has two parameters:

- Type: The type of the service to inject.
- Property: The name of the property receiving the injected app service. The property doesn't require manual creation. The compiler creates the property.

For more information, see Dependency injection into views in ASP.NET Core.

Use multiple `@inject` statements to inject different services.

The following example shows how to use `@inject`. The service implementing `Services.IDataAccess` is injected into the component's property `DataRepository`. Note how the code is only using the `IDataAccess` abstraction:

```
@page "/customer-list"
@using Services
@inject IDataAccess DataRepository

@if (customers != null)
{
    <ul>
        @foreach (var customer in customers)
        {
            <li>@customer.FirstName @customer.LastName</li>
        }
    </ul>
}

@code {
    private IReadOnlyList<Customer> customers;

    protected override async Task OnInitializedAsync()
    {
        customers = await DataRepository.GetAllCustomersAsync();
    }
}
```

Internally, the generated property (`DataRepository`) uses the `[Inject]` attribute. Typically, this attribute isn't used directly. If a base class is required for components and injected properties are also required for the base class, manually add the `[Inject]` attribute:

```
using Microsoft.AspNetCore.Components;

public class ComponentBase : IComponent
{
    [Inject]
    protected IDataAccess DataRepository { get; set; }

    ...
}
```

In components derived from the base class, the `@inject` directive isn't required. The InjectAttribute of the base class is sufficient:

```
@page "/demo"
@inherits ComponentBase

<h1>Demo Component</h1>
```

Use DI in services

Complex services might require additional services. In the prior example, `DataAccess` might require the HttpClient default service. `@inject` (or the `[Inject]` attribute) isn't available for use in services. *Constructor injection* must be used instead. Required services are added by adding parameters to the service's constructor. When DI creates the service, it recognizes the services it requires in the constructor and provides them accordingly. In the following example, the constructor receives an HttpClient via DI. HttpClient is a default service.

```
public class DataAccess : IDataAccess
{
    public DataAccess(HttpClient client)
    {
        ...
    }
}
```

Prerequisites for constructor injection:

- One constructor must exist whose arguments can all be fulfilled by DI. Additional parameters not covered by DI are allowed if they specify default values.
- The applicable constructor must be `public`.
- One applicable constructor must exist. In case of an ambiguity, DI throws an exception.

Utility base component classes to manage a DI scope

In ASP.NET Core apps, scoped services are typically scoped to the current request. After the request completes, any scoped or transient services are disposed by the DI system. In Blazor Server apps, the request scope lasts for the duration of the client connection, which can result in transient and scoped services living much longer than expected. In Blazor WebAssembly apps, services registered with a scoped lifetime are treated as singletons, so they live longer than scoped services in typical ASP.NET Core apps.

> **NOTE**
>
> To detect disposable transient services in an app, see the Detect transient disposables section.

An approach that limits a service lifetime in Blazor apps is use of the OwningComponentBase type. OwningComponentBase is an abstract type derived from ComponentBase that creates a DI scope corresponding to the lifetime of the component. Using this scope, it's possible to use DI services with a scoped lifetime and have them live as long as the component. When the component is destroyed, services from the component's scoped service provider are disposed as well. This can be useful for services that:

- Should be reused within a component, as the transient lifetime is inappropriate.
- Shouldn't be shared across components, as the singleton lifetime is inappropriate.

Two versions of the OwningComponentBase type are available:

- OwningComponentBase is an abstract, disposable child of the ComponentBase type with a protected ScopedServices property of type IServiceProvider. This provider can be used to resolve services that are scoped to the lifetime of the component.

  DI services injected into the component using `@inject` or the `[Inject]` attribute aren't created in the component's scope. To use the component's scope, services must be resolved using GetRequiredService or GetService. Any services resolved using the ScopedServices provider have their dependencies provided from that same scope.

```
@page "/preferences"
@using Microsoft.Extensions.DependencyInjection
@inherits OwningComponentBase

<h1>User (@UserService.Name)</h1>

<ul>
    @foreach (var setting in SettingService.GetSettings())
    {
        <li>@setting.SettingName: @setting.SettingValue</li>
    }
</ul>

@code {
    private IUserService UserService { get; set; }
    private ISettingService SettingService { get; set; }

    protected override void OnInitialized()
    {
        UserService = ScopedServices.GetRequiredService<IUserService>();
        SettingService = ScopedServices.GetRequiredService<ISettingService>();
    }
}
```

- OwningComponentBase<TService> derives from OwningComponentBase and adds a Service property that returns an instance of `T` from the scoped DI provider. This type is a convenient way to access scoped services without using an instance of IServiceProvider when there's one primary service the app requires from the DI container using the component's scope. The ScopedServices property is available, so the app can get services of other types, if necessary.

```
@page "/users"
@attribute [Authorize]
@inherits OwningComponentBase<AppDbContext>

<h1>Users (@Service.Users.Count())</h1>

<ul>
    @foreach (var user in Service.Users)
    {
        <li>@user.UserName</li>
    }
</ul>
```

Use of an Entity Framework Core (EF Core) DbContext from DI

For more information, see ASP.NET Core Blazor Server with Entity Framework Core (EFCore).

Detect transient disposables

The following examples show how to detect disposable transient services in an app that should use OwningComponentBase. For more information, see the Utility base component classes to manage a DI scope section.

Blazor WebAssembly

`DetectIncorrectUsagesOfTransientDisposables.cs`:

```
using System;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.DependencyInjection.Extensions;
```

```
namespace Microsoft.Extensions.DependencyInjection
{
    using BlazorServerTransientDisposable;
    using Microsoft.AspNetCore.Components.WebAssembly.Hosting;

    public static class WebHostBuilderTransientDisposableExtensions
    {
        public static WebAssemblyHostBuilder DetectIncorrectUsageOfTransients(
            this WebAssemblyHostBuilder builder)
        {
            builder
                .ConfigureContainer(
                    new DetectIncorrectUsageOfTransientDisposablesServiceFactory());

            return builder;
        }

        public static WebAssemblyHost EnableTransientDisposableDetection(
            this WebAssemblyHost webAssemblyHost)
        {
            webAssemblyHost.Services
                .GetRequiredService<ThrowOnTransientDisposable>().ShouldThrow = true;
            return webAssemblyHost;
        }
    }
}

namespace BlazorServerTransientDisposable
{
    public class DetectIncorrectUsageOfTransientDisposablesServiceFactory
        : IServiceProviderFactory<IServiceCollection>
    {
        public IServiceCollection CreateBuilder(IServiceCollection services) =>
            services;

        public IServiceProvider CreateServiceProvider(
            IServiceCollection containerBuilder)
        {
            var collection = new ServiceCollection();
            foreach (var descriptor in containerBuilder)
            {
                if (descriptor.Lifetime == ServiceLifetime.Transient &&
                    descriptor.ImplementationType != null &&
                    typeof(IDisposable).IsAssignableFrom(
                        descriptor.ImplementationType))
                {
                    collection.Add(CreatePatchedDescriptor(descriptor));
                }
                else if (descriptor.Lifetime == ServiceLifetime.Transient &&
                         descriptor.ImplementationFactory != null)
                {
                    collection.Add(CreatePatchedFactoryDescriptor(descriptor));
                }
                else
                {
                    collection.Add(descriptor);
                }
            }

            collection.AddScoped<ThrowOnTransientDisposable>();

            return collection.BuildServiceProvider();
        }

        private ServiceDescriptor CreatePatchedFactoryDescriptor(
            ServiceDescriptor original)
        {
            var newDescriptor = new ServiceDescriptor(
```

```
                original.ServiceType,
                (sp) =>
                {
                    var originalFactory = original.ImplementationFactory;
                    var originalResult = originalFactory(sp);

                    var throwOnTransientDisposable =
                        sp.GetRequiredService<ThrowOnTransientDisposable>();
                    if (throwOnTransientDisposable.ShouldThrow &&
                        originalResult is IDisposable d)
                    {
                        throw new InvalidOperationException("Trying to resolve " +
                            $"transient disposable service {d.GetType().Name} in " +
                            "the wrong scope. Use an 'OwningComponentBase<T>' " +
                            "component base class for the service 'T' you are " +
                            "trying to resolve.");
                    }

                    return originalResult;
                },
                original.Lifetime);

            return newDescriptor;
        }

        private ServiceDescriptor CreatePatchedDescriptor(ServiceDescriptor original)
        {
            var newDescriptor = new ServiceDescriptor(
                original.ServiceType,
                (sp) => {
                    var throwOnTransientDisposable =
                        sp.GetRequiredService<ThrowOnTransientDisposable>();
                    if (throwOnTransientDisposable.ShouldThrow)
                    {
                        throw new InvalidOperationException("Trying to resolve " +
                        "transient disposable service " +
                        $"{original.ImplementationType.Name} in the wrong " +
                        "scope. Use an 'OwningComponentBase<T>' component base " +
                        "class for the service 'T' you are trying to resolve.");
                    }

                    return ActivatorUtilities.CreateInstance(sp,
                        original.ImplementationType);
                },
                ServiceLifetime.Transient);
            return newDescriptor;
        }
    }

    internal class ThrowOnTransientDisposable
    {
        public bool ShouldThrow { get; set; }
    }
}
```

The `TransientDisposable` in the following example is detected (`Program.cs`):

```
public class Program
{
    public static async Task Main(string[] args)
    {
        var builder = WebAssemblyHostBuilder.CreateDefault(args);
        builder.DetectIncorrectUsageOfTransients();
        builder.RootComponents.Add<App>("app");

        builder.Services.AddTransient<TransientDisposable>();
        builder.Services.AddScoped(sp =>
            new HttpClient
            {
                BaseAddress = new Uri(builder.HostEnvironment.BaseAddress)
            });

        var host = builder.Build();
        host.EnableTransientDisposableDetection();
        await host.RunAsync();
    }
}

public class TransientDisposable : IDisposable
{
    public void Dispose() => throw new NotImplementedException();
}
```

Blazor Server

`DetectIncorrectUsagesOfTransientDisposables.cs`:

```
using System;
using Microsoft.AspNetCore.Components.Server.Circuits;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.DependencyInjection.Extensions;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;

namespace Microsoft.Extensions.DependencyInjection
{
    using BlazorServerTransientDisposable;

    public static class WebHostBuilderTransientDisposableExtensions
    {
        public static IHostBuilder DetectIncorrectUsageOfTransients(
            this IHostBuilder builder)
        {
            builder
                .UseServiceProviderFactory(
                    new DetectIncorrectUsageOfTransientDisposablesServiceFactory())
                .ConfigureServices(
                    s => s.TryAddEnumerable(ServiceDescriptor.Scoped<CircuitHandler,
                        ThrowOnTransientDisposableHandler>()));

            return builder;
        }
    }
}

namespace BlazorServerTransientDisposable
{
    internal class ThrowOnTransientDisposableHandler : CircuitHandler
    {
        public ThrowOnTransientDisposableHandler(
            ThrowOnTransientDisposable throwOnTransientDisposable)
        {
            throwOnTransientDisposable.ShouldThrow = true;
```

```
    }
}

public class DetectIncorrectUsageOfTransientDisposablesServiceFactory
    : IServiceProviderFactory<IServiceCollection>
{
    public IServiceCollection CreateBuilder(IServiceCollection services) =>
        services;

    public IServiceProvider CreateServiceProvider(
        IServiceCollection containerBuilder)
    {
        var collection = new ServiceCollection();
        foreach (var descriptor in containerBuilder)
        {
            if (descriptor.Lifetime == ServiceLifetime.Transient &&

                collection.Add(descriptor);
            }
        }

        collection.AddScoped<ThrowOnTransientDisposable>();

        return collection.BuildServiceProvider();
    }

    private ServiceDescriptor CreatePatchedFactoryDescriptor(
        ServiceDescriptor original)
    {
        var newDescriptor = new ServiceDescriptor(
            original.ServiceType,
            (sp) =>
            {
                var originalFactory = original.ImplementationFactory;
                var originalResult = originalFactory(sp);

                var throwOnTransientDisposable =
                    sp.GetRequiredService<ThrowOnTransientDisposable>();
                if (throwOnTransientDisposable.ShouldThrow &&
                    originalResult is IDisposable d)
                {
                    throw new InvalidOperationException("Trying to resolve " +
                        $"transient disposable service {d.GetType().Name} in " +
                        "the wrong scope. Use an 'OwningComponentBase<T>' " +
                        "component base class for the service 'T' you are " +
                        "trying to resolve.");
                }

                return originalResult;
            },
            original.Lifetime);

        return newDescriptor;
    }

    private ServiceDescriptor CreatePatchedDescriptor(
        ServiceDescriptor original)
```

```
        {
            var newDescriptor = new ServiceDescriptor(
                original.ServiceType,
                (sp) => {
                    var throwOnTransientDisposable =
                        sp.GetRequiredService<ThrowOnTransientDisposable>();
                    if (throwOnTransientDisposable.ShouldThrow)
                    {
                        throw new InvalidOperationException("Trying to resolve " +
                            "transient disposable service " +
                            $"{original.ImplementationType.Name} in the wrong " +
                            "scope. Use an 'OwningComponentBase<T>' component " +
                            "base class for the service 'T' you are trying to " +
                            "resolve.");
                    }

                    return ActivatorUtilities.CreateInstance(sp,
                        original.ImplementationType);
                },
                ServiceLifetime.Transient);
            return newDescriptor;
        }
    }

    internal class ThrowOnTransientDisposable
    {
        public bool ShouldThrow { get; set; }
    }
}
```

`Program`:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .DetectIncorrectUsageOfTransients()
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

The `TransientDependency` in the following example is detected (`Startup.cs`):

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();
    services.AddServerSideBlazor();
    services.AddSingleton<WeatherForecastService>();
    services.AddTransient<TransientDependency>();
    services.AddTransient<ITransitiveTransientDisposableDependency,
        TransitiveTransientDisposableDependency>();
}

public class TransitiveTransientDisposableDependency
    : ITransitiveTransientDisposableDependency, IDisposable
{
    public void Dispose() { }
}

public interface ITransitiveTransientDisposableDependency
{
}

public class TransientDependency
{
    private readonly ITransitiveTransientDisposableDependency
        _transitiveTransientDisposableDependency;

    public TransientDependency(ITransitiveTransientDisposableDependency
        transitiveTransientDisposableDependency)
    {
        _transitiveTransientDisposableDependency =
            transitiveTransientDisposableDependency;
    }
}
```

ASP.NET Core Blazor environments

9/22/2020 • 2 minutes to read • Edit Online

> **NOTE**
>
> This topic applies to Blazor WebAssembly. For general guidance on ASP.NET Core app configuration, see Use multiple environments in ASP.NET Core.

When running an app locally, the environment defaults to Development. When the app is published, the environment defaults to Production.

A hosted Blazor WebAssembly app picks up the environment from the server via a middleware that communicates the environment to the browser by adding the `blazor-environment` header. The value of the header is the environment. The hosted Blazor app and the server app share the same environment. For more information, including how to configure the environment, see Use multiple environments in ASP.NET Core.

For a standalone app running locally, the development server adds the `blazor-environment` header to specify the Development environment. To specify the environment for other hosting environments, add the `blazor-environment` header.

In the following example for IIS, add the custom header to the published `web.config` file. The `web.config` file is located in the `bin/Release/{TARGET FRAMEWORK}/publish` folder:

```
<?xml version="1.0" encoding="UTF-8"?>
<configuration>
  <system.webServer>

    ...

    <httpProtocol>
      <customHeaders>
        <add name="blazor-environment" value="Staging" />
      </customHeaders>
    </httpProtocol>
  </system.webServer>
</configuration>
```

> **NOTE**
>
> To use a custom `web.config` file for IIS that isn't overwritten when the app is published to the `publish` folder, see Host and deploy ASP.NET Core Blazor WebAssembly.

Obtain the app's environment in a component by injecting IWebAssemblyHostEnvironment and reading the Environment property:

```
@page "/"
@using Microsoft.AspNetCore.Components.WebAssembly.Hosting
@inject IWebAssemblyHostEnvironment HostEnvironment

<h1>Environment example</h1>

<p>Environment: @HostEnvironment.Environment</p>
```

During startup, the WebAssemblyHostBuilder exposes the IWebAssemblyHostEnvironment through the HostEnvironment property, which enables developers to have environment-specific logic in their code:

```
if (builder.HostEnvironment.Environment == "Custom")
{
    ...
};
```

The following convenience extension methods permit checking the current environment for Development, Production, Staging, and custom environment names:

- `IsDevelopment()`
- `IsProduction()`
- `IsStaging()`
- `IsEnvironment("{ENVIRONMENT NAME}")`

```
if (builder.HostEnvironment.IsStaging())
{
    ...
};

if (builder.HostEnvironment.IsEnvironment("Custom"))
{
    ...
};
```

The IWebAssemblyHostEnvironment.BaseAddress property can be used during startup when the NavigationManager service isn't available.

ASP.NET Core Blazor logging

9/22/2020 • 2 minutes to read • Edit Online

Blazor WebAssembly

Configure logging in Blazor WebAssembly apps with the `WebAssemblyHostBuilder.Logging` property in `Program.Main`:

```
using Microsoft.AspNetCore.Components.WebAssembly.Hosting;

...

var builder = WebAssemblyHostBuilder.CreateDefault(args);

builder.Logging.SetMinimumLevel(LogLevel.Debug);
builder.Logging.AddProvider(new CustomLoggingProvider());
```

The `Logging` property is of type ILoggingBuilder, so all of the extension methods available on ILoggingBuilder are also available on `Logging`.

Logging configuration can be loaded from app settings files. For more information, see ASP.NET Core Blazor configuration.

Blazor Server

For general ASP.NET Core logging guidance, see Logging in .NET Core and ASP.NET Core.

Blazor WebAssembly SignalR .NET client logging

Inject an ILoggerProvider to add a `WebAssemblyConsoleLogger` to the logging providers passed to HubConnectionBuilder. Unlike a traditional ConsoleLogger, `WebAssemblyConsoleLogger` is a wrapper around browser-specific logging APIs (for example, `console.log`). Use of `WebAssemblyConsoleLogger` makes logging possible within Mono inside a browser context.

```
@using Microsoft.Extensions.Logging
@inject ILoggerProvider LoggerProvider

...

var connection = new HubConnectionBuilder()
    .WithUrl(NavigationManager.ToAbsoluteUri("/chathub"))
    .ConfigureLogging(logging => logging.AddProvider(LoggerProvider))
    .Build();
```

Log in Razor components

Loggers respect app startup configuration.

The `using` directive for Microsoft.Extensions.Logging is required to support Intellisense completions for APIs, such as LogWarning and LogError.

The following example demonstrates logging with an ILogger in Razor components:

```
@page "/counter"
@using Microsoft.Extensions.Logging;
@inject ILogger<Counter> logger;

<h1>Counter</h1>

<p>Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    private void IncrementCount()
    {
        logger.LogWarning("Someone has clicked me!");

        currentCount++;
    }
}
```

The following example demonstrates logging with an ILoggerFactory in Razor components:

```
@page "/counter"
@using Microsoft.Extensions.Logging;
@inject ILoggerFactory LoggerFactory

<h1>Counter</h1>

<p>Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    private void IncrementCount()
    {
        var logger = LoggerFactory.CreateLogger<Counter>();
        logger.LogWarning("Someone has clicked me!");

        currentCount++;
    }
}
```

Handle errors in ASP.NET Core Blazor apps

9/22/2020 • 11 minutes to read • Edit Online

By Steve Sanderson

This article describes how Blazor manages unhandled exceptions and how to develop apps that detect and handle errors.

Detailed errors during development

When a Blazor app isn't functioning properly during development, receiving detailed error information from the app assists in troubleshooting and fixing the issue. When an error occurs, Blazor apps display a gold bar at the bottom of the screen:

- During development, the gold bar directs you to the browser console, where you can see the exception.
- In production, the gold bar notifies the user that an error has occurred and recommends refreshing the browser.

The UI for this error handling experience is part of the Blazor project templates.

In a Blazor WebAssembly app, customize the experience in the `wwwroot/index.html` file:

```
<div id="blazor-error-ui">
    An unhandled error has occurred.
    <a href="" class="reload">Reload</a>
    <a class="dismiss">🗙</a>
</div>
```

In a Blazor Server app, customize the experience in the `Pages/_Host.cshtml` file:

```
<div id="blazor-error-ui">
    <environment include="Staging,Production">
        An error has occurred. This application may no longer respond until reloaded.
    </environment>
    <environment include="Development">
        An unhandled exception has occurred. See browser dev tools for details.
    </environment>
    <a href="" class="reload">Reload</a>
    <a class="dismiss">🗙</a>
</div>
```

The `blazor-error-ui` element is hidden by the styles included in the Blazor templates (`wwwroot/css/app.css` or `wwwroot/css/site.css`) and then shown when an error occurs:

```
#blazor-error-ui {
    background: lightyellow;
    bottom: 0;
    box-shadow: 0 -1px 2px rgba(0, 0, 0, 0.2);
    display: none;
    left: 0;
    padding: 0.6rem 1.25rem 0.7rem 1.25rem;
    position: fixed;
    width: 100%;
    z-index: 1000;
}

#blazor-error-ui .dismiss {
    cursor: pointer;
    position: absolute;
    right: 0.75rem;
    top: 0.5rem;
}
```

How a Blazor Server app reacts to unhandled exceptions

Blazor Server is a stateful framework. While users interact with an app, they maintain a connection to the server known as a *circuit*. The circuit holds active component instances, plus many other aspects of state, such as:

- The most recent rendered output of components.
- The current set of event-handling delegates that could be triggered by client-side events.

If a user opens the app in multiple browser tabs, they have multiple independent circuits.

Blazor treats most unhandled exceptions as fatal to the circuit where they occur. If a circuit is terminated due to an unhandled exception, the user can only continue to interact with the app by reloading the page to create a new circuit. Circuits outside of the one that's terminated, which are circuits for other users or other browser tabs, aren't affected. This scenario is similar to a desktop app that crashes. The crashed app must be restarted, but other apps aren't affected.

A circuit is terminated when an unhandled exception occurs for the following reasons:

- An unhandled exception often leaves the circuit in an undefined state.
- The app's normal operation can't be guaranteed after an unhandled exception.
- Security vulnerabilities may appear in the app if the circuit continues.

Manage unhandled exceptions in developer code

For an app to continue after an error, the app must have error handling logic. Later sections of this article describe potential sources of unhandled exceptions.

In production, don't render framework exception messages or stack traces in the UI. Rendering exception messages or stack traces could:

- Disclose sensitive information to end users.
- Help a malicious user discover weaknesses in an app that can compromise the security of the app, server, or network.

Log errors with a persistent provider

If an unhandled exception occurs, the exception is logged to ILogger instances configured in the service container. By default, Blazor apps log to console output with the Console Logging Provider. Consider logging to a more permanent location with a provider that manages log size and log rotation. For more information, see Logging in

.NET Core and ASP.NET Core.

During development, Blazor usually sends the full details of exceptions to the browser's console to aid in debugging. In production, detailed errors in the browser's console are disabled by default, which means that errors aren't sent to clients but the exception's full details are still logged server-side. For more information, see Handle errors in ASP.NET Core.

You must decide which incidents to log and the level of severity of logged incidents. Hostile users might be able to trigger errors deliberately. For example, don't log an incident from an error where an unknown `ProductId` is supplied in the URL of a component that displays product details. Not all errors should be treated as high-severity incidents for logging.

For more information, see ASP.NET Core Blazor logging.

Places where errors may occur

Framework and app code may trigger unhandled exceptions in any of the following locations:

- Component instantiation
- Lifecycle methods
- Rendering logic
- Event handlers
- Component disposal
- JavaScript interop
- Blazor Server rerendering

The preceding unhandled exceptions are described in the following sections of this article.

Component instantiation

When Blazor creates an instance of a component:

- The component's constructor is invoked.
- The constructors of any non-singleton DI services supplied to the component's constructor via the `@inject` directive or the `[Inject]` attribute are invoked.

A Blazor Server circuit fails when any executed constructor or a setter for any `[Inject]` property throws an unhandled exception. The exception is fatal because the framework can't instantiate the component. If constructor logic may throw exceptions, the app should trap the exceptions using a `try-catch` statement with error handling and logging.

Lifecycle methods

During the lifetime of a component, Blazor invokes the following lifecycle methods:

- OnInitialized / OnInitializedAsync
- OnParametersSet / OnParametersSetAsync
- ShouldRender
- OnAfterRender / OnAfterRenderAsync

If any lifecycle method throws an exception, synchronously or asynchronously, the exception is fatal to a Blazor Server circuit. For components to deal with errors in lifecycle methods, add error handling logic.

In the following example where OnParametersSetAsync calls a method to obtain a product:

- An exception thrown in the `ProductRepository.GetProductByIdAsync` method is handled by a `try-catch` statement.
- When the `catch` block is executed:

- `loadFailed` is set to `true`, which is used to display an error message to the user.
- The error is logged.

```
@page "/product-details/{ProductId:int}"
@using Microsoft.Extensions.Logging
@inject IProductRepository ProductRepository
@inject ILogger<ProductDetails> Logger

@if (details != null)
{
    <h1>@details.ProductName</h1>
    <p>@details.Description</p>
}
else if (loadFailed)
{
    <h1>Sorry, we could not load this product due to an error.</h1>
}
else
{
    <h1>Loading...</h1>
}

@code {
    private ProductDetails details;
    private bool loadFailed;

    [Parameter]
    public int ProductId { get; set; }

    protected override async Task OnParametersSetAsync()
    {
        try
        {
            loadFailed = false;
            details = await ProductRepository.GetProductByIdAsync(ProductId);
        }
        catch (Exception ex)
        {
            loadFailed = true;
            Logger.LogWarning(ex, "Failed to load product {ProductId}", ProductId);
        }
    }
}
```

Rendering logic

The declarative markup in a `.razor` component file is compiled into a C# method called BuildRenderTree. When a component renders, BuildRenderTree executes and builds up a data structure describing the elements, text, and child components of the rendered component.

Rendering logic can throw an exception. An example of this scenario occurs when `@someObject.PropertyName` is evaluated but `@someObject` is `null`. An unhandled exception thrown by rendering logic is fatal to a Blazor Server circuit.

To prevent a null reference exception in rendering logic, check for a `null` object before accessing its members. In the following example, `person.Address` properties aren't accessed if `person.Address` is `null`:

```
@if (person.Address != null)
{
    <div>@person.Address.Line1</div>
    <div>@person.Address.Line2</div>
    <div>@person.Address.City</div>
    <div>@person.Address.Country</div>
}
```

The preceding code assumes that `person` isn't `null`. Often, the structure of the code guarantees that an object exists at the time the component is rendered. In those cases, it isn't necessary to check for `null` in rendering logic. In the prior example, `person` might be guaranteed to exist because `person` is created when the component is instantiated.

Event handlers

Client-side code triggers invocations of C# code when event handlers are created using:

- `@onclick`
- `@onchange`
- Other `@on...` attributes
- `@bind`

Event handler code might throw an unhandled exception in these scenarios.

If an event handler throws an unhandled exception (for example, a database query fails), the exception is fatal to a Blazor Server circuit. If the app calls code that could fail for external reasons, trap exceptions using a `try-catch` statement with error handling and logging.

If user code doesn't trap and handle the exception, the framework logs the exception and terminates the circuit.

Component disposal

A component may be removed from the UI, for example, because the user has navigated to another page. When a component that implements System.IDisposable is removed from the UI, the framework calls the component's Dispose method.

If the component's `Dispose` method throws an unhandled exception, the exception is fatal to a Blazor Server circuit. If disposal logic may throw exceptions, the app should trap the exceptions using a `try-catch` statement with error handling and logging.

For more information on component disposal, see ASP.NET Core Blazor lifecycle.

JavaScript interop

IJSRuntime.InvokeAsync allows .NET code to make asynchronous calls to the JavaScript runtime in the user's browser.

The following conditions apply to error handling with InvokeAsync:

- If a call to InvokeAsync fails synchronously, a .NET exception occurs. A call to InvokeAsync may fail, for example, because the supplied arguments can't be serialized. Developer code must catch the exception. If app code in an event handler or component lifecycle method doesn't handle an exception, the resulting exception is fatal to a Blazor Server circuit.
- If a call to InvokeAsync fails asynchronously, the .NET Task fails. A call to InvokeAsync may fail, for example, because the JavaScript-side code throws an exception or returns a `Promise` that completed as `rejected`. Developer code must catch the exception. If using the `await` operator, consider wrapping the method call in a `try-catch` statement with error handling and logging. Otherwise, the failing code results in an unhandled exception that's fatal to a Blazor Server circuit.
- By default, calls to InvokeAsync must complete within a certain period or else the call times out. The default

timeout period is one minute. The timeout protects the code against a loss in network connectivity or JavaScript code that never sends back a completion message. If the call times out, the resulting System.Threading.Tasks fails with an OperationCanceledException. Trap and process the exception with logging.

Similarly, JavaScript code may initiate calls to .NET methods indicated by the `[JSInvokable]` attribute. If these .NET methods throw an unhandled exception:

- The exception isn't treated as fatal to a Blazor Server circuit.
- The JavaScript-side `Promise` is rejected.

You have the option of using error handling code on either the .NET side or the JavaScript side of the method call.

For more information, see the following articles:

- Call JavaScript functions from .NET methods in ASP.NET Core Blazor
- Call .NET methods from JavaScript functions in ASP.NET Core Blazor

Blazor Server prerendering

Blazor components can be prerendered using the Component Tag Helper so that their rendered HTML markup is returned as part of the user's initial HTTP request. This works by:

- Creating a new circuit for all of the prerendered components that are part of the same page.
- Generating the initial HTML.
- Treating the circuit as `disconnected` until the user's browser establishes a SignalR connection back to the same server. When the connection is established, interactivity on the circuit is resumed and the components' HTML markup is updated.

If any component throws an unhandled exception during prerendering, for example, during a lifecycle method or in rendering logic:

- The exception is fatal to the circuit.
- The exception is thrown up the call stack from the ComponentTagHelper Tag Helper. Therefore, the entire HTTP request fails unless the exception is explicitly caught by developer code.

Under normal circumstances when prerendering fails, continuing to build and render the component doesn't make sense because a working component can't be rendered.

To tolerate errors that may occur during prerendering, error handling logic must be placed inside a component that may throw exceptions. Use `try-catch` statements with error handling and logging. Instead of wrapping the ComponentTagHelper Tag Helper in a `try-catch` statement, place error handling logic in the component rendered by the ComponentTagHelper Tag Helper.

Advanced scenarios

Recursive rendering

Components can be nested recursively. This is useful for representing recursive data structures. For example, a `TreeNode` component can render more `TreeNode` components for each of the node's children.

When rendering recursively, avoid coding patterns that result in infinite recursion:

- Don't recursively render a data structure that contains a cycle. For example, don't render a tree node whose children includes itself.
- Don't create a chain of layouts that contain a cycle. For example, don't create a layout whose layout is itself.
- Don't allow an end user to violate recursion invariants (rules) through malicious data entry or JavaScript interop calls.

Infinite loops during rendering:

- Causes the rendering process to continue forever.
- Is equivalent to creating an unterminated loop.

In these scenarios, an affected Blazor Server circuit fails, and the thread usually attempts to:

- Consume as much CPU time as permitted by the operating system, indefinitely.
- Consume an unlimited amount of server memory. Consuming unlimited memory is equivalent to the scenario where an unterminated loop adds entries to a collection on every iteration.

To avoid infinite recursion patterns, ensure that recursive rendering code contains suitable stopping conditions.

Custom render tree logic

Most Blazor components are implemented as `.razor` files and are compiled to produce logic that operates on a RenderTreeBuilder to render their output. A developer may manually implement RenderTreeBuilder logic using procedural C# code. For more information, see ASP.NET Core Blazor advanced scenarios.

> **WARNING**
> Use of manual render tree builder logic is considered an advanced and unsafe scenario, not recommended for general component development.

If RenderTreeBuilder code is written, the developer must guarantee the correctness of the code. For example, the developer must ensure that:

- Calls to OpenElement and CloseElement are correctly balanced.
- Attributes are only added in the correct places.

Incorrect manual render tree builder logic can cause arbitrary undefined behavior, including crashes, server hangs, and security vulnerabilities.

Consider manual render tree builder logic on the same level of complexity and with the same level of *danger* as writing assembly code or MSIL instructions by hand.

ASP.NET Core Blazor hosting model configuration

9/22/2020 • 7 minutes to read • Edit Online

By Daniel Roth, Mackinnon Buck, and Luke Latham

This article covers hosting model configuration.

SignalR cross-origin negotiation for authentication

This section applies to Blazor WebAssembly.

To configure SignalR's underlying client to send credentials, such as cookies or HTTP authentication headers:

- Use SetBrowserRequestCredentials to set Include on cross-origin `fetch` requests:

```
public class IncludeRequestCredentialsMessageHandler : DelegatingHandler
{
    protected override Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {
        request.SetBrowserRequestCredentials(BrowserRequestCredentials.Include);
        return base.SendAsync(request, cancellationToken);
    }
}
```

- Assign the HttpMessageHandler to the HttpMessageHandlerFactory option:

```
var connection = new HubConnectionBuilder()
    .WithUrl(new Uri("http://signalr.example.com"), options =>
    {
        options.HttpMessageHandlerFactory = innerHandler =>
            new IncludeRequestCredentialsMessageHandler { InnerHandler = innerHandler };
    }).Build();
```

For more information, see ASP.NET Core SignalR configuration.

Reflect the connection state in the UI

This section applies to Blazor Server.

When the client detects that the connection has been lost, a default UI is displayed to the user while the client attempts to reconnect. If reconnection fails, the user is provided the option to retry.

To customize the UI, define an element with an `id` of `components-reconnect-modal` in the `<body>` of the `_Host.cshtml` Razor page:

```
<div id="components-reconnect-modal">
    ...
</div>
```

Add the following to the app's stylesheet (`wwwroot/css/app.css` or `wwwroot/css/site.css`):

```
#components-reconnect-modal {
    display: none;
}

#components-reconnect-modal.components-reconnect-show {
    display: block;
}
```

The following table describes the CSS classes applied to the `components-reconnect-modal` element.

CSS CLASS	INDICATES...
`components-reconnect-show`	A lost connection. The client is attempting to reconnect. Show the modal.
`components-reconnect-hide`	An active connection is re-established to the server. Hide the modal.
`components-reconnect-failed`	Reconnection failed, probably due to a network failure. To attempt reconnection, call `window.Blazor.reconnect()`.
`components-reconnect-rejected`	Reconnection rejected. The server was reached but refused the connection, and the user's state on the server is lost. To reload the app, call `location.reload()`. This connection state may result when: • A crash in the server-side circuit occurs. • The client is disconnected long enough for the server to drop the user's state. Instances of the components that the user is interacting with are disposed. • The server is restarted, or the app's worker process is recycled.

Render mode

This section applies to Blazor Server.

Blazor Server apps are set up by default to prerender the UI on the server before the client connection to the server is established. This is set up in the `_Host.cshtml` Razor page:

```
<body>
    <app>
      <component type="typeof(App)" render-mode="ServerPrerendered" />
    </app>

    <script src="_framework/blazor.server.js"></script>
</body>
```

RenderMode configures whether the component:

- Is prerendered into the page.
- Is rendered as static HTML on the page or if it includes the necessary information to bootstrap a Blazor app from the user agent.

RENDER MODE	DESCRIPTION
ServerPrerendered	Renders the component into static HTML and includes a marker for a Blazor Server app. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Server	Renders a marker for a Blazor Server app. Output from the component isn't included. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Static	Renders the component into static HTML.

Rendering server components from a static HTML page isn't supported.

Initialize the Blazor circuit

This section applies to Blazor Server.

Configure the manual start of a Blazor Server app's SignalR circuit in the `Pages/_Host.cshtml` file:

- Add an `autostart="false"` attribute to the `<script>` tag for the `blazor.server.js` script.
- Place a script that calls `Blazor.start` after the `blazor.server.js` script's tag and inside the closing `</body>` tag.

When `autostart` is disabled, any aspect of the app that doesn't depend on the circuit works normally. For example, client-side routing is operational. However, any aspect that depends on the circuit isn't operational until `Blazor.start` is called. App behavior is unpredictable without an established circuit. For example, component methods fail to execute while the circuit is disconnected.

Initialize Blazor when the document is ready

To initialize the Blazor app when the document is ready:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      document.addEventListener("DOMContentLoaded", function() {
        Blazor.start();
      });
    </script>
</body>
```

Chain to the `Promise` that results from a manual start

To perform additional tasks, such as JS interop initialization, use `then` to chain to the `Promise` that results from a manual Blazor app start:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start().then(function () {
        ...
      });
    </script>
</body>
```

Configure the SignalR client

Logging

To configure SignalR client logging, pass in a configuration object (`configureSignalR`) that calls `configureLogging` with the log level on the client builder:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start({
        configureSignalR: function (builder) {
          builder.configureLogging("information");
        }
      });
    </script>
</body>
```

In the preceding example, `information` is equivalent to a log level of LogLevel.Information.

Modify the reconnection handler

The reconnection handler's circuit connection events can be modified for custom behaviors, such as:

- To notify the user if the connection is dropped.
- To perform logging (from the client) when a circuit is connected.

To modify the connection events, register callbacks for the following connection changes:

- Dropped connections use `onConnectionDown` .
- Established/re-established connections use `onConnectionUp` .

Both `onConnectionDown` and `onConnectionUp` must be specified:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start({
        reconnectionHandler: {
          onConnectionDown: (options, error) => console.error(error);
          onConnectionUp: () => console.log("Up, up, and away!");
        }
      });
    </script>
</body>
```

Adjust the reconnection retry count and interval

To adjust the reconnection retry count and interval, set the number of retries (`maxRetries`) and period in milliseconds permitted for each retry attempt (`retryIntervalMilliseconds`):

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start({
        reconnectionOptions: {
          maxRetries: 3,
          retryIntervalMilliseconds: 2000
        }
      });
    </script>
</body>
```

Hide or replace the reconnection display

To hide the reconnection display, set the reconnection handler's `_reconnectionDisplay` to an empty object (`{}` or `new Object()`):

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      window.addEventListener('beforeunload', function () {
        Blazor.defaultReconnectionHandler._reconnectionDisplay = {};
      });

      Blazor.start();
    </script>
</body>
```

To replace the reconnection display, set `_reconnectionDisplay` in the preceding example to the element for display:

```
Blazor.defaultReconnectionHandler._reconnectionDisplay =
  document.getElementById("{ELEMENT ID}");
```

The placeholder `{ELEMENT ID}` is the ID of the HTML element to display.

Customize the delay before the reconnection display appears by setting the `transition-delay` property in the app's CSS (`wwwroot/css/site.css`) for the modal element. The following example sets the transition delay from 500 ms (default) to 1,000 ms (1 second):

```
#components-reconnect-modal {
    transition: visibility 0s linear 1000ms;
}
```

Influence HTML `<head>` tag elements

This section applies to the upcoming ASP.NET Core 5.0 release of Blazor WebAssembly and Blazor Server.

When rendered, the `Title`, `Link`, and `Meta` components add or update data in the HTML `<head>` tag elements:

```
@using Microsoft.AspNetCore.Components.Web.Extensions.Head

<Title Value="{TITLE}" />
<Link href="{URL}" rel="stylesheet" />
<Meta content="{DESCRIPTION}" name="description" />
```

In the preceding example, placeholders for `{TITLE}`, `{URL}`, and `{DESCRIPTION}` are string values, Razor variables, or Razor expressions.

The following characteristics apply:

- Server-side prerendering is supported.
- The `Value` parameter is the only valid parameter for the `Title` component.
- HTML attributes provided to the `Meta` and `Link` components are captured in additional attributes and passed through to the rendered HTML tag.
- For multiple `Title` components, the title of the page reflects the `Value` of the last `Title` component rendered.
- If multiple `Meta` or `Link` components are included with identical attributes, there's exactly one HTML tag rendered per `Meta` or `Link` component. Two `Meta` or `Link` components can't refer to the same rendered HTML tag.
- Changes to the parameters of existing `Meta` or `Link` components are reflected in their rendered HTML tags.
- When the `Link` or `Meta` components are no longer rendered and thus disposed by the framework, their rendered HTML tags are removed.

When one of the framework components is used in a child component, the rendered HTML tag influences any other child component of the parent component as long as the child component containing the framework component is rendered. The distinction between using the one of these framework components in a child component and placing a an HTML tag in `wwwroot/index.html` or `Pages/_Host.cshtml` is that a framework component's rendered HTML tag:

- Can be modified by application state. A hard-coded HTML tag can't be modified by application state.
- Is removed from the HTML `<head>` when the parent component is no longer rendered.

Static files

This section applies to Blazor Server.

To create additional file mappings with a FileExtensionContentTypeProvider or configure other StaticFileOptions, use **one** of the following approaches. In the following examples, the `{EXTENSION}` placeholder is the file extension, and the `{CONTENT TYPE}` placeholder is the content type.

- Configure options through dependency injection (DI) in `Startup.ConfigureServices` (`Startup.cs`) using StaticFileOptions:

```
using Microsoft.AspNetCore.StaticFiles;

...

var provider = new FileExtensionContentTypeProvider();
provider.Mappings["{EXTENSION}"] = "{CONTENT TYPE}";

services.Configure<StaticFileOptions>(options =>
{
    options.ContentTypeProvider = provider;
});
```

  Because this approach configures the same file provider used to serve `blazor.server.js`, make sure that your custom configuration doesn't interfere with serving `blazor.server.js`. For example, don't remove the mapping for JavaScript files by configuring the provider with `provider.Mappings.Remove(".js")`.

- Use two calls to UseStaticFiles in `Startup.Configure` (`Startup.cs`):
  - Configure the custom file provider in the first call with StaticFileOptions.
  - The second middleware serves `blazor.server.js`, which uses the default static files configuration provided by the Blazor framework.

```
using Microsoft.AspNetCore.StaticFiles;

...

var provider = new FileExtensionContentTypeProvider();
provider.Mappings["{EXTENSION}"] = "{CONTENT TYPE}";

app.UseStaticFiles(new StaticFileOptions { ContentTypeProvider = provider });
app.UseStaticFiles();
```

Create and use ASP.NET Core Razor components

9/22/2020 • 21 minutes to read • Edit Online

By Luke Latham, Daniel Roth, and Tobias Bartsch

View or download sample code (how to download)

Blazor apps are built using *components*. A component is a self-contained chunk of user interface (UI), such as a page, dialog, or form. A component includes HTML markup and the processing logic required to inject data or respond to UI events. Components are flexible and lightweight. They can be nested, reused, and shared among projects.

Component classes

Components are implemented in Razor component files (`.razor`) using a combination of C# and HTML markup. A component in Blazor is formally referred to as a *Razor component*.

Razor syntax

Razor components in Blazor apps extensively use Razor syntax. If you aren't familiar with the Razor markup language, we recommend reading razor syntax reference for ASP.NET Core before proceeding.

When accessing the content on Razor syntax, pay special attention to the following sections:

- Directives: `@`-prefixed reserved keywords that typically change the way component markup is parsed or function.
- Directive attributes: `@`-prefixed reserved keywords that typically change the way component elements are parsed or function.

Names

A component's name must start with an uppercase character. For example, `MyCoolComponent.razor` is valid, and `myCoolComponent.razor` is invalid.

Routing

Routing in Blazor is achieved by providing a route template to each accessible component in the app. When a Razor file with an `@page` directive is compiled, the generated class is given a RouteAttribute specifying the route template. At runtime, the router looks for component classes with a RouteAttribute and renders whichever component has a route template that matches the requested URL. For more information, see ASP.NET Core Blazor routing.

```
@page "/ParentComponent"

...
```

Markup

The UI for a component is defined using HTML. Dynamic rendering logic (for example, loops, conditionals, expressions) is added using an embedded C# syntax called *Razor*. When an app is compiled, the HTML markup and C# rendering logic are converted into a component class. The name of the generated class matches the name of the file.

Members of the component class are defined in an `@code` block. In the `@code` block, component state (properties, fields) is specified with methods for event handling or for defining other component logic. More than one `@code`

block is permissible.

Component members can be used as part of the component's rendering logic using C# expressions that start with `@`. For example, a C# field is rendered by prefixing `@` to the field name. The following example evaluates and renders:

- `headingFontStyle` to the CSS property value for `font-style`.
- `headingText` to the content of the `<h1>` element.

```
<h1 style="font-style:@headingFontStyle">@headingText</h1>

@code {
    private string headingFontStyle = "italic";
    private string headingText = "Put on your new Blazor!";
}
```

After the component is initially rendered, the component regenerates its render tree in response to events. Blazor then compares the new render tree against the previous one and applies any modifications to the browser's Document Object Model (DOM).

Components are ordinary C# classes and can be placed anywhere within a project. Components that produce webpages usually reside in the `Pages` folder. Non-page components are frequently placed in the `Shared` folder or a custom folder added to the project.

Namespaces

Typically, a component's namespace is derived from the app's root namespace and the component's location (folder) within the app. If the app's root namespace is `BlazorSample` and the `Counter` component resides in the `Pages` folder:

- The `Counter` component's namespace is `BlazorSample.Pages`.
- The fully qualified type name of the component is `BlazorSample.Pages.Counter`.

For custom folders that hold components, add a `@using` directive to the parent component or to the app's `_Imports.razor` file. The following example makes components in the `Components` folder available:

```
@using BlazorSample.Components
```

Components can also be referenced using their fully qualified names, which doesn't require the `@using` directive:

```
<BlazorSample.Components.MyComponent />
```

The namespace of a component authored with Razor is based on (in priority order):

- `@namespace` designation in Razor file (`.razor`) markup (`@namespace BlazorSample.MyNamespace`).
- The project's `RootNamespace` in the project file (`<RootNamespace>BlazorSample</RootNamespace>`).
- The project name, taken from the project file's file name (`.csproj`), and the path from the project root to the component. For example, the framework resolves `{PROJECT ROOT}/Pages/Index.razor` (`BlazorSample.csproj`) to the namespace `BlazorSample.Pages`. Components follow C# name binding rules. For the `Index` component in this example, the components in scope are all of the components:
  - In the same folder, `Pages`.
  - The components in the project's root that don't explicitly specify a different namespace.

> **NOTE**
>
> The `global::` qualification isn't supported.
>
> Importing components with aliased `using` statements (for example, `@using Foo = Bar`) isn't supported.
>
> Partially qualified names aren't supported. For example, adding `@using BlazorSample` and referencing the `NavMenu` component (`NavMenu.razor`) with `<Shared.NavMenu></Shared.NavMenu>` isn't supported.

Partial class support

Razor components are generated as partial classes. Razor components are authored using either of the following approaches:

- C# code is defined in an `@code` block with HTML markup and Razor code in a single file. Blazor templates define their Razor components using this approach.
- C# code is placed in a code-behind file defined as a partial class.

The following example shows the default `Counter` component with an `@code` block in an app generated from a Blazor template. HTML markup, Razor code, and C# code are in the same file:

`Pages/Counter.razor`:

```
@page "/counter"

<h1>Counter</h1>

<p>Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    void IncrementCount()
    {
        currentCount++;
    }
}
```

The `Counter` component can also be created using a code-behind file with a partial class:

`Pages/Counter.razor`:

```
@page "/counter"

<h1>Counter</h1>

<p>Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>
```

`Counter.razor.cs`:

```
namespace BlazorSample.Pages
{
    public partial class Counter
    {
        private int currentCount = 0;

        void IncrementCount()
        {
            currentCount++;
        }
    }
}
```

Add any required namespaces to the partial class file as needed. Typical namespaces used by Razor components include:

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Authorization;
using Microsoft.AspNetCore.Components.Forms;
using Microsoft.AspNetCore.Components.Routing;
using Microsoft.AspNetCore.Components.Web;
```

IMPORTANT

`@using` directives in the `_Imports.razor` file are only applied to Razor files (`.razor`), not C# files (`.cs`).

Specify a base class

The `@inherits` directive can be used to specify a base class for a component. The following example shows how a component can inherit a base class, `BlazorRocksBase`, to provide the component's properties and methods. The base class should derive from ComponentBase.

`Pages/BlazorRocks.razor`:

```
@page "/BlazorRocks"
@inherits BlazorRocksBase

<h1>@BlazorRocksText</h1>
```

`BlazorRocksBase.cs`:

```
using Microsoft.AspNetCore.Components;

namespace BlazorSample
{
    public class BlazorRocksBase : ComponentBase
    {
        public string BlazorRocksText { get; set; } =
            "Blazor rocks the browser!";
    }
}
```

Use components

Components can include other components by declaring them using HTML element syntax. The markup for using a component looks like an HTML tag where the name of the tag is the component type.

The following markup in `Pages/Index.razor` renders a `HeadingComponent` instance:

```
<HeadingComponent />
```

`Components/HeadingComponent.razor`:

```
@using System.Globalization

<h1 style="font-style:@headingFontStyle">@headingText</h1>

<form>
    <div>
        <label class="form-check-label">
            <input type="checkbox" id="italicsCheck"
               @bind="italicsCheck" />
            Use italics
        </label>
    </div>

    <button type="button" class="btn btn-primary" @onclick="UpdateHeading">
        Update heading
    </button>
</form>

@code {
    private static TextInfo tinfo = CultureInfo.CurrentCulture.TextInfo;
    private string headingText =
        tinfo.ToTitleCase("welcome to blazor!");
    private string headingFontStyle = "normal";
    private bool italicsCheck = false;

    public void UpdateHeading()
    {
        headingFontStyle = italicsCheck ? "italic" : "normal";
    }
}
```

If a component contains an HTML element with an uppercase first letter that doesn't match a component name, a warning is emitted indicating that the element has an unexpected name. Adding an `@using` directive for the component's namespace makes the component available, which resolves the warning.

Parameters

Route parameters

Components can receive route parameters from the route template provided in the `@page` directive. The router uses route parameters to populate the corresponding component parameters.

`Pages/RouteParameter.razor`:

```
@page "/RouteParameter"
@page "/RouteParameter/{text}"

<h1>Blazor is @Text!</h1>

@code {
    [Parameter]
    public string Text { get; set; }

    protected override void OnInitialized()
    {
        Text = Text ?? "fantastic";
    }
}
```

Optional parameters aren't supported, so two `@page` directives are applied in the preceding example. The first permits navigation to the component without a parameter. The second `@page` directive receives the `{text}` route parameter and assigns the value to the `Text` property.

For information on catch-all route parameters (`{*pageRoute}`), which capture paths across multiple folder boundaries, see ASP.NET Core Blazor routing.

Component parameters

Components can have *component parameters*, which are defined using public properties on the component class with the `[Parameter]` attribute. Use attributes to specify arguments for a component in markup.

`Components/ChildComponent.razor` :

```
<div class="panel panel-default">
    <div class="panel-heading">@Title</div>
    <div class="panel-body">@ChildContent</div>

    <button class="btn btn-primary" @onclick="OnClickCallback">
        Trigger a Parent component method
    </button>
</div>

@code {
    [Parameter]
    public string Title { get; set; }

    [Parameter]
    public RenderFragment ChildContent { get; set; }

    [Parameter]
    public EventCallback<MouseEventArgs> OnClickCallback { get; set; }
}
```

In the following example from the sample app, the `ParentComponent` sets the value of the `Title` property of the `ChildComponent` .

`Pages/ParentComponent.razor` :

```
@page "/ParentComponent"

<h1>Parent-child example</h1>

<ChildComponent Title="Panel Title from Parent"
                OnClickCallback="@ShowMessage">
    Content of the child component is supplied
    by the parent component.
</ChildComponent>
```

WARNING

Don't create components that write to their own *component parameters*, use a private field instead. For more information, see the Overwritten parameters section.

Child content

Components can set the content of another component. The assigning component provides the content between the tags that specify the receiving component.

In the following example, the `ChildComponent` has a `ChildContent` property that represents a RenderFragment, which represents a segment of UI to render. The value of `ChildContent` is positioned in the component's markup where the content should be rendered. The value of `ChildContent` is received from the parent component and rendered inside the Bootstrap panel's `panel-body`.

`Components/ChildComponent.razor`:

```
<div class="panel panel-default">
    <div class="panel-heading">@Title</div>
    <div class="panel-body">@ChildContent</div>

    <button class="btn btn-primary" @onclick="OnClickCallback">
        Trigger a Parent component method
    </button>
</div>

@code {
    [Parameter]
    public string Title { get; set; }

    [Parameter]
    public RenderFragment ChildContent { get; set; }

    [Parameter]
    public EventCallback<MouseEventArgs> OnClickCallback { get; set; }
}
```

NOTE

The property receiving the RenderFragment content must be named `ChildContent` by convention.

The `ParentComponent` in the sample app can provide content for rendering the `ChildComponent` by placing the content inside the `<ChildComponent>` tags.

`Pages/ParentComponent.razor`:

```
@page "/ParentComponent"

<h1>Parent-child example</h1>

<ChildComponent Title="Panel Title from Parent"
                OnClickCallback="@ShowMessage">
    Content of the child component is supplied
    by the parent component.
</ChildComponent>
```

Due to the way that Blazor renders child content, rendering components inside a `for` loop requires a local index variable if the incrementing loop variable is used in the child component's content:

```
@for (int c = 0; c < 10; c++)
{
    var current = c;
    <ChildComponent Param1="@c">
        Child Content: Count: @current
    </ChildComponent>
}
```

Alternatively, use a `foreach` loop with Enumerable.Range:

```
@foreach(var c in Enumerable.Range(0,10))
{
    <ChildComponent Param1="@c">
        Child Content: Count: @c
    </ChildComponent>
}
```

Attribute splatting and arbitrary parameters

Components can capture and render additional attributes in addition to the component's declared parameters. Additional attributes can be captured in a dictionary and then *splatted* onto an element when the component is rendered using the `@attributes` Razor directive. This scenario is useful when defining a component that produces a markup element that supports a variety of customizations. For example, it can be tedious to define attributes separately for an `<input>` that supports many parameters.

In the following example, the first `<input>` element (`id="useIndividualParams"`) uses individual component parameters, while the second `<input>` element (`id="useAttributesDict"`) uses attribute splatting:

```
<input id="useIndividualParams"
       maxlength="@maxlength"
       placeholder="@placeholder"
       required="@required"
       size="@size" />

<input id="useAttributesDict"
       @attributes="InputAttributes" />

@code {
    public string maxlength = "10";
    public string placeholder = "Input placeholder text";
    public string required = "required";
    public string size = "50";

    public Dictionary<string, object> InputAttributes { get; set; } =
        new Dictionary<string, object>()
        {
            { "maxlength", "10" },
            { "placeholder", "Input placeholder text" },
            { "required", "required" },
            { "size", "50" }
        };
}
```

The type of the parameter must implement `IEnumerable<KeyValuePair<string, object>>` or `IReadOnlyDictionary<string, object>` with string keys.

The rendered `<input>` elements using both approaches is identical:

```
<input id="useIndividualParams"
       maxlength="10"
       placeholder="Input placeholder text"
       required="required"
       size="50">

<input id="useAttributesDict"
       maxlength="10"
       placeholder="Input placeholder text"
       required="required"
       size="50">
```

To accept arbitrary attributes, define a component parameter using the `[Parameter]` attribute with the CaptureUnmatchedValues property set to `true`:

```
@code {
    [Parameter(CaptureUnmatchedValues = true)]
    public Dictionary<string, object> InputAttributes { get; set; }
}
```

The CaptureUnmatchedValues property on `[Parameter]` allows the parameter to match all attributes that don't match any other parameter. A component can only define a single parameter with CaptureUnmatchedValues. The property type used with CaptureUnmatchedValues must be assignable from `Dictionary<string, object>` with string keys. `IEnumerable<KeyValuePair<string, object>>` or `IReadOnlyDictionary<string, object>` are also options in this scenario.

The position of `@attributes` relative to the position of element attributes is important. When `@attributes` are splatted on the element, the attributes are processed from right to left (last to first). Consider the following example of a component that consumes a `Child` component:

`ParentComponent.razor`:

```
<ChildComponent extra="10" />
```

`ChildComponent.razor`:

```
<div @attributes="AdditionalAttributes" extra="5" />

[Parameter(CaptureUnmatchedValues = true)]
public IDictionary<string, object> AdditionalAttributes { get; set; }
```

The `Child` component's `extra` attribute is set to the right of `@attributes`. The `Parent` component's rendered `<div>` contains `extra="5"` when passed through the additional attribute because the attributes are processed right to left (last to first):

```
<div extra="5" />
```

In the following example, the order of `extra` and `@attributes` is reversed in the `Child` component's `<div>`:

`ParentComponent.razor`:

```
<ChildComponent extra="10" />
```

`ChildComponent.razor`:

```
<div extra="5" @attributes="AdditionalAttributes" />

[Parameter(CaptureUnmatchedValues = true)]
public IDictionary<string, object> AdditionalAttributes { get; set; }
```

The rendered `<div>` in the `Parent` component contains `extra="10"` when passed through the additional attribute:

```
<div extra="10" />
```

Capture references to components

Component references provide a way to reference a component instance so that you can issue commands to that instance, such as `Show` or `Reset`. To capture a component reference:

- Add an `@ref` attribute to the child component.
- Define a field with the same type as the child component.

```
<CustomLoginDialog @ref="loginDialog" ... />

@code {
    private CustomLoginDialog loginDialog;

    private void OnSomething()
    {
        loginDialog.Show();
    }
}
```

When the component is rendered, the `loginDialog` field is populated with the `MyLoginDialog` child component instance. You can then invoke .NET methods on the component instance.

IMPORTANT

The `loginDialog` variable is only populated after the component is rendered and its output includes the `MyLoginDialog` element. Until the component is rendered, there's nothing to reference.

To manipulate components references after the component has finished rendering, use the `OnAfterRenderAsync` or `OnAfterRender` methods.

To use a reference variable with an event handler, use a lambda expression or assign the event handler delegate in the `OnAfterRenderAsync` or `OnAfterRender` methods. This ensures that the reference variable is assigned before the event handler is assigned.

```
<button type="button"
    @onclick="@(() => loginDialog.DoSomething())">Do Something</button>

<MyLoginDialog @ref="loginDialog" ... />

@code {
    private MyLoginDialog loginDialog;
}
```

To reference components in a loop, see Capture references to multiple similar child-components (dotnet/aspnetcore #13358).

While capturing component references use a similar syntax to capturing element references, it isn't a JavaScript interop feature. Component references aren't passed to JavaScript code. Component references are only used in .NET code.

NOTE

Do **not** use component references to mutate the state of child components. Instead, use normal declarative parameters to pass data to child components. Use of normal declarative parameters result in child components that rerender at the correct times automatically.

Synchronization context

Blazor uses a synchronization context (SynchronizationContext) to enforce a single logical thread of execution. A component's lifecycle methods and any event callbacks that are raised by Blazor are executed on the synchronization context.

Blazor Server's synchronization context attempts to emulate a single-threaded environment so that it closely matches the WebAssembly model in the browser, which is single threaded. At any given point in time, work is performed on exactly one thread, giving the impression of a single logical thread. No two operations execute

concurrently.

Avoid thread-blocking calls

Generally, don't call the following methods. The following methods block the thread and thus block the app from resuming work until the underlying Task is complete:

- Result
- Wait
- WaitAny
- WaitAll
- Sleep
- GetResult

Invoke component methods externally to update state

In the event a component must be updated based on an external event, such as a timer or other notifications, use the `InvokeAsync` method, which dispatches to Blazor's synchronization context. For example, consider a *notifier service* that can notify any listening component of the updated state:

```
public class NotifierService
{
    // Can be called from anywhere
    public async Task Update(string key, int value)
    {
        if (Notify != null)
        {
            await Notify.Invoke(key, value);
        }
    }

    public event Func<string, int, Task> Notify;
}
```

Register the `NotifierService`:

- In Blazor WebAssembly, register the service as singleton in `Program.Main`:

  ```
  builder.Services.AddSingleton<NotifierService>();
  ```

- In Blazor Server, register the service as scoped in `Startup.ConfigureServices`:

  ```
  services.AddScoped<NotifierService>();
  ```

Use the `NotifierService` to update a component:

```
@page "/"
@inject NotifierService Notifier
@implements IDisposable

<p>Last update: @lastNotification.key = @lastNotification.value</p>

@code {
    private (string key, int value) lastNotification;

    protected override void OnInitialized()
    {
        Notifier.Notify += OnNotify;
    }

    public async Task OnNotify(string key, int value)
    {
        await InvokeAsync(() =>
        {
            lastNotification = (key, value);
            StateHasChanged();
        });
    }

    public void Dispose()
    {
        Notifier.Notify -= OnNotify;
    }
}
```

In the preceding example, `NotifierService` invokes the component's `OnNotify` method outside of Blazor's synchronization context. `InvokeAsync` is used to switch to the correct context and queue a render.

Use @key to control the preservation of elements and components

When rendering a list of elements or components and the elements or components subsequently change, Blazor's diffing algorithm must decide which of the previous elements or components can be retained and how model objects should map to them. Normally, this process is automatic and can be ignored, but there are cases where you may want to control the process.

Consider the following example:

```
@foreach (var person in People)
{
    <DetailsEditor Details="@person.Details" />
}

@code {
    [Parameter]
    public IEnumerable<Person> People { get; set; }
}
```

The contents of the `People` collection may change with inserted, deleted, or re-ordered entries. When the component rerenders, the `<DetailsEditor>` component may change to receive different `Details` parameter values. This may cause more complex rerendering than expected. In some cases, rerendering can lead to visible behavior differences, such as lost element focus.

The mapping process can be controlled with the `@key` directive attribute. `@key` causes the diffing algorithm to guarantee preservation of elements or components based on the key's value:

```
@foreach (var person in People)
{
    <DetailsEditor @key="person" Details="@person.Details" />
}

@code {
    [Parameter]
    public IEnumerable<Person> People { get; set; }
}
```

When the `People` collection changes, the diffing algorithm retains the association between `<DetailsEditor>` instances and `person` instances:

- If a `Person` is deleted from the `People` list, only the corresponding `<DetailsEditor>` instance is removed from the UI. Other instances are left unchanged.
- If a `Person` is inserted at some position in the list, one new `<DetailsEditor>` instance is inserted at that corresponding position. Other instances are left unchanged.
- If `Person` entries are re-ordered, the corresponding `<DetailsEditor>` instances are preserved and re-ordered in the UI.

In some scenarios, use of `@key` minimizes the complexity of rerendering and avoids potential issues with stateful parts of the DOM changing, such as focus position.

> **IMPORTANT**
> Keys are local to each container element or component. Keys aren't compared globally across the document.

When to use @key

Typically, it makes sense to use `@key` whenever a list is rendered (for example, in a foreach block) and a suitable value exists to define the `@key`.

You can also use `@key` to prevent Blazor from preserving an element or component subtree when an object changes:

```
<div @key="currentPerson">
    ... content that depends on currentPerson ...
</div>
```

If `@currentPerson` changes, the `@key` attribute directive forces Blazor to discard the entire `<div>` and its descendants and rebuild the subtree within the UI with new elements and components. This can be useful if you need to guarantee that no UI state is preserved when `@currentPerson` changes.

When not to use @key

There's a performance cost when diffing with `@key`. The performance cost isn't large, but only specify `@key` if controlling the element or component preservation rules benefit the app.

Even if `@key` isn't used, Blazor preserves child element and component instances as much as possible. The only advantage to using `@key` is control over *how* model instances are mapped to the preserved component instances, instead of the diffing algorithm selecting the mapping.

What values to use for @key

Generally, it makes sense to supply one of the following kinds of value for `@key`:

- Model object instances (for example, a `Person` instance as in the earlier example). This ensures preservation based on object reference equality.

- Unique identifiers (for example, primary key values of type `int`, `string`, or `Guid`).

Ensure that values used for `@key` don't clash. If clashing values are detected within the same parent element, Blazor throws an exception because it can't deterministically map old elements or components to new elements or components. Only use distinct values, such as object instances or primary key values.

Overwritten parameters

New parameter values are supplied, typically overwriting existing ones, when the parent component rerenders.

Consider the following `Expander` component that:

- Renders child content.
- Toggles showing child content with a component parameter.

```
<div @onclick="@Toggle" class="card bg-light mb-3" style="width:30rem">
    <div class="card-body">
        <h2 class="card-title">Toggle (<code>Expanded</code> = @Expanded)</h2>

        @if (Expanded)
        {
            <p class="card-text">@ChildContent</p>
        }
    </div>
</div>

@code {
    [Parameter]
    public bool Expanded { get; set; }

    [Parameter]
    public RenderFragment ChildContent { get; set; }

    private void Toggle()
    {
        Expanded = !Expanded;
    }
}
```

The `Expander` component is added to a parent component that may call StateHasChanged:

```
@page "/expander"

<Expander Expanded="true">
    Expander 1 content
</Expander>

<Expander Expanded="true" />

<button @onclick="StateHasChanged">
    Call StateHasChanged
</button>
```

Initially, the `Expander` components behave independently when their `Expanded` properties are toggled. The child components maintain their states as expected. When StateHasChanged is called in the parent, the `Expanded` parameter of the first child component is reset back to its initial value (`true`). The second `Expander` component's `Expanded` value isn't reset because no child content is rendered in the second component.

To maintain state in the preceding scenario, use a *private field* in the `Expander` component to maintain its toggled state.

The following revised `Expander` component:

- Accepts the `Expanded` component parameter value from the parent.
- Assigns the component parameter value to a *private field* (`expanded`) in the OnInitialized event.
- Uses the private field to maintain its internal toggle state.

```
<div @onclick="@Toggle" class="card bg-light mb-3" style="width:30rem">
    <div class="card-body">
        <h2 class="card-title">Toggle (<code>expanded</code> = @expanded)</h2>

        @if (expanded)
        {
            <p class="card-text">@ChildContent</p>
        }
    </div>
</div>

@code {
    private bool expanded;

    [Parameter]
    public bool Expanded { get; set; }

    [Parameter]
    public RenderFragment ChildContent { get; set; }

    protected override void OnInitialized()
    {
        expanded = Expanded;
    }

    private void Toggle()
    {
        expanded = !expanded;
    }
}
```

Apply an attribute

Attributes can be applied to Razor components with the `@attribute` directive. The following example applies the `[Authorize]` attribute to the component class:

```
@page "/"
@attribute [Authorize]
```

Conditional HTML element attributes

HTML element attributes are conditionally rendered based on the .NET value. If the value is `false` or `null`, the attribute isn't rendered. If the value is `true`, the attribute is rendered minimized.

In the following example, `IsCompleted` determines if `checked` is rendered in the element's markup:

```
<input type="checkbox" checked="@IsCompleted" />

@code {
    [Parameter]
    public bool IsCompleted { get; set; }
}
```

If `IsCompleted` is `true`, the check box is rendered as:

```
<input type="checkbox" checked />
```

If `IsCompleted` is `false`, the check box is rendered as:

```
<input type="checkbox" />
```

For more information, see razor syntax reference for ASP.NET Core.

> **WARNING**
> Some HTML attributes, such as `aria-pressed`, don't function properly when the .NET type is a `bool`. In those cases, use a `string` type instead of a `bool`.

Raw HTML

Strings are normally rendered using DOM text nodes, which means that any markup they may contain is ignored and treated as literal text. To render raw HTML, wrap the HTML content in a `MarkupString` value. The value is parsed as HTML or SVG and inserted into the DOM.

> **WARNING**
> Rendering raw HTML constructed from any untrusted source is a **security risk** and should be avoided!

The following example shows using the `MarkupString` type to add a block of static HTML content to the rendered output of a component:

```
@((MarkupString)myMarkup)

@code {
    private string myMarkup =
        "<p class='markup'>This is a <em>markup string</em>.</p>";
}
```

Razor templates

Render fragments can be defined using Razor template syntax. Razor templates are a way to define a UI snippet and assume the following format:

```
@<{HTML tag}>...</{HTML tag}>
```

The following example illustrates how to specify RenderFragment and RenderFragment<TValue> values and render templates directly in a component. Render fragments can also be passed as arguments to templated components.

```
@timeTemplate

@petTemplate(new Pet { Name = "Rex" })

@code {
    private RenderFragment timeTemplate = @<p>The time is @DateTime.Now.</p>;
    private RenderFragment<Pet> petTemplate = (pet) => @<p>Pet: @pet.Name</p>;

    private class Pet
    {
        public string Name { get; set; }
    }
}
```

Rendered output of the preceding code:

```
<p>The time is 10/04/2018 01:26:52.</p>

<p>Pet: Rex</p>
```

Static assets

Blazor follows the convention of ASP.NET Core apps placing static assets under the project's `web root (wwwroot)` folder.

Use a base-relative path (`/`) to refer to the web root for a static asset. In the following example, `logo.png` is physically located in the `{PROJECT ROOT}/wwwroot/images` folder:

```
<img alt="Company logo" src="/images/logo.png" />
```

Razor components do **not** support tilde-slash notation (`~/`).

For information on setting an app's base path, see Host and deploy ASP.NET Core Blazor.

Tag Helpers aren't supported in components

`Tag Helpers` aren't supported in Razor components (`.razor` files). To provide Tag Helper-like functionality in Blazor, create a component with the same functionality as the Tag Helper and use the component instead.

Scalable Vector Graphics (SVG) images

Since Blazor renders HTML, browser-supported images, including Scalable Vector Graphics (SVG) images (`.svg`), are supported via the `<img>` tag:

```
<img alt="Example image" src="some-image.svg" />
```

Similarly, SVG images are supported in the CSS rules of a stylesheet file (`.css`):

```
.my-element {
    background-image: url("some-image.svg");
}
```

However, inline SVG markup isn't supported in all scenarios. If you place an `<svg>` tag directly into a component file (`.razor`), basic image rendering is supported but many advanced scenarios aren't yet supported. For example,

`<use>` tags aren't currently respected, and `@bind` can't be used with some SVG tags. For more information, see SVG support in Blazor (dotnet/aspnetcore #18271).

ASP.NET Core Blazor templates

9/22/2020 • 3 minutes to read • Edit Online

By Daniel Roth and Luke Latham

The Blazor framework provides templates to develop apps for each of the Blazor hosting models:

- Blazor WebAssembly (`blazorwasm`)
- Blazor Server (`blazorserver`)

For more information on Blazor's hosting models, see ASP.NET Core Blazor hosting models.

Template options are available by passing the `--help` option to the `dotnet new` CLI command:

```
dotnet new blazorwasm --help
dotnet new blazorserver --help
```

Blazor project structure

The following files and folders make up a Blazor app generated from a Blazor project template:

- `Program.cs` : The app's entry point that sets up the:
  - ASP.NET Core host (Blazor Server)
  - WebAssembly host (Blazor WebAssembly): The code in this file is unique to apps created from the Blazor WebAssembly template (`blazorwasm`).
    - The `App` component is the root component of the app. The `App` component is specified as the `app` DOM element (`<app>...</app>`) to the root component collection (`builder.RootComponents.Add<App>("app")`).
    - Services are added and configured (for example, `builder.Services.AddSingleton<IMyDependency, MyDependency>()`).
- `Startup.cs` (Blazor Server): Contains the app's startup logic. The `Startup` class defines two methods:
  - `ConfigureServices` : Configures the app's dependency injection (DI) services. In Blazor Server apps, services are added by calling AddServerSideBlazor, and the `WeatherForecastService` is added to the service container for use by the example `FetchData` component.
  - `Configure` : Configures the app's request handling pipeline:
    - MapBlazorHub is called to set up an endpoint for the real-time connection with the browser. The connection is created with SignalR, which is a framework for adding real-time web functionality to apps.
    - `MapFallbackToPage("/_Host")` is called to set up the root page of the app (`Pages/_Host.cshtml`) and enable navigation.
- `wwwroot/index.html` (Blazor WebAssembly): The root page of the app implemented as an HTML page:
  - When any page of the app is initially requested, this page is rendered and returned in the response.
  - The page specifies where the root `App` component is rendered. The component is rendered at the location of the `app` DOM element (`<app>...</app>`).
  - The `_framework/blazor.webassembly.js` JavaScript file is loaded, which:
    - Downloads the .NET runtime, the app, and the app's dependencies.

    - Initializes the runtime to run the app.
- `App.razor`: The root component of the app that sets up client-side routing using the Router component. The Router component intercepts browser navigation and renders the page that matches the requested address.
- `Pages` folder: Contains the routable components/pages (`.razor`) that make up the Blazor app and the root Razor page of a Blazor Server app. The route for each page is specified using the `@page` directive. The template includes the following:
    - `_Host.cshtml` (Blazor Server): The root page of the app implemented as a Razor Page:
        - When any page of the app is initially requested, this page is rendered and returned in the response.
        - The `_framework/blazor.server.js` JavaScript file is loaded, which sets up the real-time SignalR connection between the browser and the server.
        - The Host page specifies where the root `App` component (`App.razor`) is rendered.
    - `Counter` (`Pages/Counter.razor`): Implements the Counter page.
    - `Error` (`Error.razor`, Blazor Server app only): Rendered when an unhandled exception occurs in the app.
    - `FetchData` (`Pages/FetchData.razor`): Implements the Fetch data page.
    - `Index` (`Pages/Index.razor`): Implements the Home page.
- `Properties/launchSettings.json`: Holds development environment configuration.
- `Shared` folder: Contains other UI components (`.razor`) used by the app:
    - `MainLayout` (`MainLayout.razor`): The app's layout component.
    - `NavMenu` (`NavMenu.razor`): Implements sidebar navigation. Includes the `NavLink` component (NavLink), which renders navigation links to other Razor components. The NavLink component automatically indicates a selected state when its component is loaded, which helps the user understand which component is currently displayed.
- `_Imports.razor`: Includes common Razor directives to include in the app's components (`.razor`), such as `@using` directives for namespaces.
- `Data` folder (Blazor Server): Contains the `WeatherForecast` class and implementation of the `WeatherForecastService` that provide example weather data to the app's `FetchData` component.
- `wwwroot`: The Web Root folder for the app containing the app's public static assets.
- `appsettings.json`: Holds configuration settings for the app. In a Blazor WebAssembly app, the app settings file is located in the `wwwroot` folder. In a Blazor Server app, the app settings file is located at the project root.

Secure ASP.NET Core Blazor WebAssembly

9/22/2020 • 5 minutes to read • Edit Online

By Javier Calvarro Nelson

Blazor WebAssembly apps are secured in the same manner as Single Page Applications (SPAs). There are several approaches for authenticating users to SPAs, but the most common and comprehensive approach is to use an implementation based on the OAuth 2.0 protocol, such as OpenID Connect (OIDC).

Authentication library

Blazor WebAssembly supports authenticating and authorizing apps using OIDC via the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` library. The library provides a set of primitives for seamlessly authenticating against ASP.NET Core backends. The library integrates ASP.NET Core Identity with API authorization support built on top of Identity Server. The library can authenticate against any third-party Identity Provider (IP) that supports OIDC, which are called OpenID Providers (OP).

The authentication support in Blazor WebAssembly is built on top of the `oidc-client.js` library, which is used to handle the underlying authentication protocol details.

Other options for authenticating SPAs exist, such as the use of SameSite cookies. However, the engineering design of Blazor WebAssembly is settled on OAuth and OIDC as the best option for authentication in Blazor WebAssembly apps. Token-based authentication based on JSON Web Tokens (JWTs) was chosen over cookie-based authentication for functional and security reasons:

- Using a token-based protocol offers a smaller attack surface area, as the tokens aren't sent in all requests.
- Server endpoints don't require protection against Cross-Site Request Forgery (CSRF) because the tokens are sent explicitly. This allows you to host Blazor WebAssembly apps alongside MVC or Razor pages apps.
- Tokens have narrower permissions than cookies. For example, tokens can't be used to manage the user account or change a user's password unless such functionality is explicitly implemented.
- Tokens have a short lifetime, one hour by default, which limits the attack window. Tokens can also be revoked at any time.
- Self-contained JWTs offer guarantees to the client and server about the authentication process. For example, a client has the means to detect and validate that the tokens it receives are legitimate and were emitted as part of a given authentication process. If a third party attempts to switch a token in the middle of the authentication process, the client can detect the switched token and avoid using it.
- Tokens with OAuth and OIDC don't rely on the user agent behaving correctly to ensure that the app is secure.
- Token-based protocols, such as OAuth and OIDC, allow for authenticating and authorizing hosted and standalone apps with the same set of security characteristics.

Authentication process with OIDC

The `Microsoft.AspNetCore.Components.WebAssembly.Authentication` library offers several primitives to implement authentication and authorization using OIDC. In broad terms, authentication works as follows:

- When an anonymous user selects the login button or requests a page with the `[Authorize]` attribute applied, the user is redirected to the app's login page (`/authentication/login`).
- In the login page, the authentication library prepares for a redirect to the authorization endpoint. The authorization endpoint is outside of the Blazor WebAssembly app and can be hosted at a separate origin. The endpoint is responsible for determining whether the user is authenticated and for issuing one or more tokens in

response. The authentication library provides a login callback to receive the authentication response.
    - If the user isn't authenticated, the user is redirected to the underlying authentication system, which is usually ASP.NET Core Identity.
    - If the user was already authenticated, the authorization endpoint generates the appropriate tokens and redirects the browser back to the login callback endpoint (`/authentication/login-callback`).
- When the Blazor WebAssembly app loads the login callback endpoint (`/authentication/login-callback`), the authentication response is processed.
    - If the authentication process completes successfully, the user is authenticated and optionally sent back to the original protected URL that the user requested.
    - If the authentication process fails for any reason, the user is sent to the login failed page (`/authentication/login-failed`), and an error is displayed.

`Authentication` component

The `Authentication` component (`Pages/Authentication.razor`) handles remote authentication operations and permits the app to:

- Configure app routes for authentication states.
- Set UI content for authentication states.
- Manage authentication state.

Authentication actions, such as registering or signing in a user, are passed to the Blazor framework's RemoteAuthenticatorViewCore<TAuthenticationState> component, which persists and controls state across authentication operations.

For more information and examples, see ASP.NET Core Blazor WebAssembly additional security scenarios.

Authorization

In Blazor WebAssembly apps, authorization checks can be bypassed because all client-side code can be modified by users. The same is true for all client-side app technologies, including JavaScript SPA frameworks or native apps for any operating system.

Always perform authorization checks on the server within any API endpoints accessed by your client-side app.

Require authorization for the entire app

Apply the `[Authorize]` attribute (API documentation) to each Razor component of the app using one of the following approaches:

- Use the `@attribute` directive in the `_Imports.razor` file:

```
@using Microsoft.AspNetCore.Authorization
@attribute [Authorize]
```

- Add the attribute to each Razor component in the `Pages` folder.

> **NOTE**
>
> Setting an AuthorizationOptions.FallbackPolicy to a policy with RequireAuthenticatedUser is **not** supported.

Refresh tokens

Refresh tokens can't be secured client-side in Blazor WebAssembly apps. Therefore, refresh tokens shouldn't be sent to the app for direct use.

Refresh tokens can be maintained and used by the server-side app in a Hosted Blazor WebAssembly solution to access third-party APIs. For more information, see ASP.NET Core Blazor WebAssembly additional security scenarios.

Establish claims for users

Apps often require claims for users based on a web API call to a server. For example, claims are frequently used to establish authorization in an app. In these scenarios, the app requests an access token to access the service and uses the token to obtain the user data for the claims. For examples, see the following resources:

- Additional scenarios: Customize the user
- ASP.NET Core Blazor WebAssembly with Azure Active Directory groups and roles

Implementation guidance

Articles under this *Overview* provide information on authenticating users in Blazor WebAssembly apps against specific providers.

Standalone Blazor WebAssembly apps:

- General guidance for OIDC providers and the WebAssembly Authentication Library
- Microsoft Accounts
- Azure Active Directory (AAD)
- Azure Active Directory (AAD) B2C

Hosted Blazor WebAssembly apps:

- Azure Active Directory (AAD)
- Azure Active Directory (AAD) B2C
- Identity Server

For further guidance on configuration, see ASP.NET Core Blazor WebAssembly additional security scenarios.

ASP.NET Core Blazor authentication and authorization

9/22/2020 • 10 minutes to read • Edit Online

By Steve Sanderson and Luke Latham

ASP.NET Core supports the configuration and management of security in Blazor apps.

Security scenarios differ between Blazor Server and Blazor WebAssembly apps. Because Blazor Server apps run on the server, authorization checks are able to determine:

- The UI options presented to a user (for example, which menu entries are available to a user).
- Access rules for areas of the app and components.

Blazor WebAssembly apps run on the client. Authorization is *only* used to determine which UI options to show. Since client-side checks can be modified or bypassed by a user, a Blazor WebAssembly app can't enforce authorization access rules.

Razor Pages authorization conventions don't apply to routable Razor components. If a non-routable Razor component is embedded in a page, the page's authorization conventions indirectly affect the Razor component along with the rest of the page's content.

> **NOTE**
> SignInManager<TUser> and UserManager<TUser> aren't supported in Razor components.

Authentication

Blazor uses the existing ASP.NET Core authentication mechanisms to establish the user's identity. The exact mechanism depends on how the Blazor app is hosted, Blazor WebAssembly or Blazor Server.

Blazor WebAssembly authentication

In Blazor WebAssembly apps, authentication checks can be bypassed because all client-side code can be modified by users. The same is true for all client-side app technologies, including JavaScript SPA frameworks or native apps for any operating system.

Add the following:

- A package reference for `Microsoft.AspNetCore.Components.Authorization` to the app's project file.
- The `Microsoft.AspNetCore.Components.Authorization` namespace to the app's `_Imports.razor` file.

To handle authentication, use of a built-in or custom AuthenticationStateProvider service is covered in the following sections.

For more information on creating apps and configuration, see Secure ASP.NET Core Blazor WebAssembly.

Blazor Server authentication

Blazor Server apps operate over a real-time connection that's created using SignalR. Authentication in SignalR-based apps is handled when the connection is established. Authentication can be based on a cookie or some other bearer token.

The built-in AuthenticationStateProvider service for Blazor Server apps obtains authentication state data from

ASP.NET Core's `HttpContext.User`. This is how authentication state integrates with existing ASP.NET Core authentication mechanisms.

For more information on creating apps and configuration, see Secure ASP.NET Core Blazor Server apps.

AuthenticationStateProvider service

AuthenticationStateProvider is the underlying service used by the AuthorizeView component and CascadingAuthenticationState component to get the authentication state.

You don't typically use AuthenticationStateProvider directly. Use the `AuthorizeView` component or `Task<AuthenticationState>` approaches described later in this article. The main drawback to using AuthenticationStateProvider directly is that the component isn't notified automatically if the underlying authentication state data changes.

The AuthenticationStateProvider service can provide the current user's ClaimsPrincipal data, as shown in the following example:

```
@page "/"
@using System.Security.Claims
@using Microsoft.AspNetCore.Components.Authorization
@inject AuthenticationStateProvider AuthenticationStateProvider

<h3>ClaimsPrincipal Data</h3>

<button @onclick="GetClaimsPrincipalData">Get ClaimsPrincipal Data</button>

<p>@_authMessage</p>

@if (_claims.Count() > 0)
{
    <ul>
        @foreach (var claim in _claims)
        {
            <li>@claim.Type: @claim.Value</li>
        }
    </ul>
}

<p>@_surnameMessage</p>

@code {
    private string _authMessage;
    private string _surnameMessage;
    private IEnumerable<Claim> _claims = Enumerable.Empty<Claim>();

    private async Task GetClaimsPrincipalData()
    {
        var authState = await AuthenticationStateProvider.GetAuthenticationStateAsync();
        var user = authState.User;

        if (user.Identity.IsAuthenticated)
        {
            _authMessage = $"{user.Identity.Name} is authenticated.";
            _claims = user.Claims;
            _surnameMessage =
                $"Surname: {user.FindFirst(c => c.Type == ClaimTypes.Surname)?.Value}";
        }
        else
        {
            _authMessage = "The user is NOT authenticated.";
        }
    }
}
```

If `user.Identity.IsAuthenticated` is `true` and because the user is a ClaimsPrincipal, claims can be enumerated and membership in roles evaluated.

For more information on dependency injection (DI) and services, see ASP.NET Core Blazor dependency injection and Dependency injection in ASP.NET Core.

Implement a custom AuthenticationStateProvider

If the app requires a custom provider, implement AuthenticationStateProvider and override `GetAuthenticationStateAsync`:

```
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Components.Authorization;

public class CustomAuthStateProvider : AuthenticationStateProvider
{
    public override Task<AuthenticationState> GetAuthenticationStateAsync()
    {
        var identity = new ClaimsIdentity(new[]
        {
            new Claim(ClaimTypes.Name, "mrfibuli"),
        }, "Fake authentication type");

        var user = new ClaimsPrincipal(identity);

        return Task.FromResult(new AuthenticationState(user));
    }
}
```

In a Blazor WebAssembly app, the `CustomAuthStateProvider` service is registered in `Main` of `Program.cs`:

```
using Microsoft.AspNetCore.Components.Authorization;

...

builder.Services.AddScoped<AuthenticationStateProvider, CustomAuthStateProvider>();
```

In a Blazor Server app, the `CustomAuthStateProvider` service is registered in `Startup.ConfigureServices`:

```
using Microsoft.AspNetCore.Components.Authorization;

...

services.AddScoped<AuthenticationStateProvider, CustomAuthStateProvider>();
```

Using the `CustomAuthStateProvider` in the preceding example, all users are authenticated with the username `mrfibuli`.

Expose the authentication state as a cascading parameter

If authentication state data is required for procedural logic, such as when performing an action triggered by the user, obtain the authentication state data by defining a cascading parameter of type `Task<` AuthenticationState `>`:

```
@page "/"

<button @onclick="LogUsername">Log username</button>

<p>@_authMessage</p>

@code {
    [CascadingParameter]
    private Task<AuthenticationState> authenticationStateTask { get; set; }

    private string _authMessage;

    private async Task LogUsername()
    {
        var authState = await authenticationStateTask;
        var user = authState.User;

        if (user.Identity.IsAuthenticated)
        {
            _authMessage = $"{user.Identity.Name} is authenticated.";
        }
        else
        {
            _authMessage = "The user is NOT authenticated.";
        }
    }
}
```

If `user.Identity.IsAuthenticated` is `true`, claims can be enumerated and membership in roles evaluated.

Set up the `Task<` AuthenticationState `>` cascading parameter using the AuthorizeRouteView and CascadingAuthenticationState components in the `App` component (`App.razor`):

```
<CascadingAuthenticationState>
    <Router AppAssembly="@typeof(Program).Assembly">
        <Found Context="routeData">
            <AuthorizeRouteView RouteData="@routeData"
                DefaultLayout="@typeof(MainLayout)" />
        </Found>
        <NotFound>
            <LayoutView Layout="@typeof(MainLayout)">
                <p>Sorry, there's nothing at this address.</p>
            </LayoutView>
        </NotFound>
    </Router>
</CascadingAuthenticationState>
```

In a Blazor WebAssembly App, add services for options and authorization to `Program.Main`:

```
builder.Services.AddOptions();
builder.Services.AddAuthorizationCore();
```

In a Blazor Server app, services for options and authorization are already present, so no further action is required.

Authorization

After a user is authenticated, *authorization* rules are applied to control what the user can do.

Access is typically granted or denied based on whether:

- A user is authenticated (signed in).

- A user is in a *role*.
- A user has a *claim*.
- A *policy* is satisfied.

Each of these concepts is the same as in an ASP.NET Core MVC or Razor Pages app. For more information on ASP.NET Core security, see the articles under ASP.NET Core Security and Identity.

AuthorizeView component

The AuthorizeView component selectively displays UI depending on whether the user is authorized to see it. This approach is useful when you only need to *display* data for the user and don't need to use the user's identity in procedural logic.

The component exposes a `context` variable of type AuthenticationState, which you can use to access information about the signed-in user:

```
<AuthorizeView>
    <h1>Hello, @context.User.Identity.Name!</h1>
    <p>You can only see this content if you're authenticated.</p>
</AuthorizeView>
```

You can also supply different content for display if the user isn't authenticated:

```
<AuthorizeView>
    <Authorized>
        <h1>Hello, @context.User.Identity.Name!</h1>
        <p>You can only see this content if you're authenticated.</p>
    </Authorized>
    <NotAuthorized>
        <h1>Authentication Failure!</h1>
        <p>You're not signed in.</p>
    </NotAuthorized>
</AuthorizeView>
```

The AuthorizeView component can be used in the `NavMenu` component (`Shared/NavMenu.razor`) to display a list item (`<li>...</li>`) for a `NavLink` component (NavLink), but note that this approach only removes the list item from the rendered output. It doesn't prevent the user from navigating to the component.

The content of `<Authorized>` and `<NotAuthorized>` tags can include arbitrary items, such as other interactive components.

Authorization conditions, such as roles or policies that control UI options or access, are covered in the Authorization section.

If authorization conditions aren't specified, AuthorizeView uses a default policy and treats:

- Authenticated (signed-in) users as authorized.
- Unauthenticated (signed-out) users as unauthorized.

Role-based and policy-based authorization

The AuthorizeView component supports *role-based* or *policy-based* authorization.

For role-based authorization, use the Roles parameter:

```
<AuthorizeView Roles="admin, superuser">
    <p>You can only see this if you're an admin or superuser.</p>
</AuthorizeView>
```

For more information, see Role-based authorization in ASP.NET Core.

For policy-based authorization, use the Policy parameter:

```
<AuthorizeView Policy="content-editor">
    <p>You can only see this if you satisfy the "content-editor" policy.</p>
</AuthorizeView>
```

Claims-based authorization is a special case of policy-based authorization. For example, you can define a policy that requires users to have a certain claim. For more information, see Policy-based authorization in ASP.NET Core.

These APIs can be used in either Blazor Server or Blazor WebAssembly apps.

If neither Roles nor Policy is specified, AuthorizeView uses the default policy.

Content displayed during asynchronous authentication

Blazor allows for authentication state to be determined *asynchronously*. The primary scenario for this approach is in Blazor WebAssembly apps that make a request to an external endpoint for authentication.

While authentication is in progress, AuthorizeView displays no content by default. To display content while authentication occurs, use the `<Authorizing>` tag:

```
<AuthorizeView>
    <Authorized>
        <h1>Hello, @context.User.Identity.Name!</h1>
        <p>You can only see this content if you're authenticated.</p>
    </Authorized>
    <Authorizing>
        <h1>Authentication in progress</h1>
        <p>You can only see this content while authentication is in progress.</p>
    </Authorizing>
</AuthorizeView>
```

This approach isn't normally applicable to Blazor Server apps. Blazor Server apps know the authentication state as soon as the state is established. Authorizing content can be provided in a Blazor Server app's AuthorizeView component, but the content is never displayed.

[Authorize] attribute

The `[Authorize]` attribute can be used in Razor components:

```
@page "/"
@attribute [Authorize]

You can only see this if you're signed in.
```

> **IMPORTANT**
>
> Only use `[Authorize]` on `@page` components reached via the Blazor Router. Authorization is only performed as an aspect of routing and *not* for child components rendered within a page. To authorize the display of specific parts within a page, use AuthorizeView instead.

The `[Authorize]` attribute also supports role-based or policy-based authorization. For role-based authorization, use the Roles parameter:

```
@page "/"
@attribute [Authorize(Roles = "admin, superuser")]

<p>You can only see this if you're in the 'admin' or 'superuser' role.</p>
```

For policy-based authorization, use the Policy parameter:

```
@page "/"
@attribute [Authorize(Policy = "content-editor")]

<p>You can only see this if you satisfy the 'content-editor' policy.</p>
```

If neither Roles nor Policy is specified, `[Authorize]` uses the default policy, which by default is to treat:

- Authenticated (signed-in) users as authorized.
- Unauthenticated (signed-out) users as unauthorized.

Customize unauthorized content with the Router component

The Router component, in conjunction with the AuthorizeRouteView component, allows the app to specify custom content if:

- Content isn't found.
- The user fails an `[Authorize]` condition applied to the component. The `[Authorize]` attribute is covered in the `[Authorize]` attribute section.
- Asynchronous authentication is in progress.

In the default Blazor Server project template, the `App` component (`App.razor`) demonstrates how to set custom content:

```
<CascadingAuthenticationState>
    <Router AppAssembly="@typeof(Program).Assembly">
        <Found Context="routeData">
            <AuthorizeRouteView RouteData="@routeData"
                DefaultLayout="@typeof(MainLayout)">
                <NotAuthorized>
                    <h1>Sorry</h1>
                    <p>You're not authorized to reach this page.</p>
                    <p>You may need to log in as a different user.</p>
                </NotAuthorized>
                <Authorizing>
                    <h1>Authentication in progress</h1>
                    <p>Only visible while authentication is in progress.</p>
                </Authorizing>
            </AuthorizeRouteView>
        </Found>
        <NotFound>
            <LayoutView Layout="@typeof(MainLayout)">
                <h1>Sorry</h1>
                <p>Sorry, there's nothing at this address.</p>
            </LayoutView>
        </NotFound>
    </Router>
</CascadingAuthenticationState>
```

The content of `<NotFound>`, `<NotAuthorized>`, and `<Authorizing>` tags can include arbitrary items, such as other interactive components.

If the `<NotAuthorized>` tag isn't specified, the AuthorizeRouteView uses the following fallback message:

```
Not authorized.
```

Notification about authentication state changes

If the app determines that the underlying authentication state data has changed (for example, because the user signed out or another user has changed their roles), a custom `AuthenticationStateProvider` can optionally invoke the method NotifyAuthenticationStateChanged on the AuthenticationStateProvider base class. This notifies consumers of the authentication state data (for example, AuthorizeView) to rerender using the new data.

Procedural logic

If the app is required to check authorization rules as part of procedural logic, use a cascaded parameter of type `Task<` AuthenticationState `>` to obtain the user's ClaimsPrincipal. `Task<` AuthenticationState `>` can be combined with other services, such as `IAuthorizationService`, to evaluate policies.

```
@using Microsoft.AspNetCore.Authorization
@inject IAuthorizationService AuthorizationService

<button @onclick="@DoSomething">Do something important</button>

@code {
    [CascadingParameter]
    private Task<AuthenticationState> authenticationStateTask { get; set; }

    private async Task DoSomething()
    {
        var user = (await authenticationStateTask).User;

        if (user.Identity.IsAuthenticated)
        {
            // Perform an action only available to authenticated (signed-in) users.
        }

        if (user.IsInRole("admin"))
        {
            // Perform an action only available to users in the 'admin' role.
        }

        if ((await AuthorizationService.AuthorizeAsync(user, "content-editor"))
            .Succeeded)
        {
            // Perform an action only available to users satisfying the
            // 'content-editor' policy.
        }
    }
}
```

NOTE

In a Blazor WebAssembly app component, add the Microsoft.AspNetCore.Authorization and Microsoft.AspNetCore.Components.Authorization namespaces:

```
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.Authorization
```

These namespaces can be provided globally by adding them to the app's `_Imports.razor` file.

Troubleshoot errors

Common errors:

- **Authorization requires a cascading parameter of type `Task\<AuthenticationState>`. Consider using `CascadingAuthenticationState` to supply this.**
- **`null` value is received for `authenticationStateTask`**

It's likely that the project wasn't created using a Blazor Server template with authentication enabled. Wrap a `<CascadingAuthenticationState>` around some part of the UI tree, for example in the `App` component (`App.razor`) as follows:

```
<CascadingAuthenticationState>
    <Router AppAssembly="typeof(Startup).Assembly">
        ...
    </Router>
</CascadingAuthenticationState>
```

The CascadingAuthenticationState supplies the `Task<` AuthenticationState `>` cascading parameter, which in turn it receives from the underlying AuthenticationStateProvider DI service.

ASP.NET Core Blazor forms and validation

9/22/2020 • 22 minutes to read • Edit Online

By Daniel Roth, Rémi Bourgarel, and Luke Latham

Forms and validation are supported in Blazor using data annotations.

The following `ExampleModel` type defines validation logic using data annotations:

```
using System.ComponentModel.DataAnnotations;

public class ExampleModel
{
    [Required]
    [StringLength(10, ErrorMessage = "Name is too long.")]
    public string Name { get; set; }
}
```

A form is defined using the EditForm component. The following form demonstrates typical elements, components, and Razor code:

```
<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <InputText id="name" @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }
}
```

In the preceding example:

- The form validates user input in the `name` field using the validation defined in the `ExampleModel` type. The model is created in the component's `@code` block and held in a private field (`exampleModel`). The field is assigned to the `Model` attribute of the `<EditForm>` element.
- The InputText component's `@bind-Value` binds:
  - The model property (`exampleModel.Name`) to the InputText component's `Value` property. For more information on property binding, see ASP.NET Core Blazor data binding.
  - A change event delegate to the InputText component's `ValueChanged` property.
- The DataAnnotationsValidator validator component attaches validation support using data annotations.
- The ValidationSummary component summarizes validation messages.
- `HandleValidSubmit` is triggered when the form successfully submits (passes validation).

Built-in forms components

A set of built-in components are available to receive and validate user input. Inputs are validated when they're changed and when a form is submitted. Available input components are shown in the following table.

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
`InputFile`	`<input type="file">`
InputNumber<TValue>	`<input type="number">`
`InputRadio`	`<input type="radio">`
`InputRadioGroup`	`<input type="radio">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
InputNumber<TValue>	`<input type="number">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

> **NOTE**
>
> The `InputRadio` and `InputRadioGroup` components are available in ASP.NET Core 5.0 or later. For more information, select a 5.0 or later version of this article.

All of the input components, including EditForm, support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the rendered HTML element.

Input components provide default behavior for validating when a field is changed, including updating the field CSS class to reflect the field state. Some components include useful parsing logic. For example, InputDate<TValue> and InputNumber<TValue> handle unparseable values gracefully by registering unparseable values as validation errors. Types that can accept null values also support nullability of the target field (for example, `int?`).

The following `Starship` type defines validation logic using a larger set of properties and data annotations than the

earlier `ExampleModel`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    [Required]
    [StringLength(16, ErrorMessage = "Identifier too long (16 character limit).")]
    public string Identifier { get; set; }

    public string Description { get; set; }

    [Required]
    public string Classification { get; set; }

    [Range(1, 100000, ErrorMessage = "Accommodation invalid (1-100000).")]
    public int MaximumAccommodation { get; set; }

    [Required]
    [Range(typeof(bool), "true", "true",
        ErrorMessage = "This form disallows unapproved ships.")]
    public bool IsValidatedDesign { get; set; }

    [Required]
    public DateTime ProductionDate { get; set; }
}
```

In the preceding example, `Description` is optional because no data annotations are present.

The following form validates user input using the validation defined in the `Starship` model:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <p>
        <label>
            Identifier:
            <InputText @bind-Value="starship.Identifier" />
        </label>
    </p>
    <p>
        <label>
            Description (optional):
            <InputTextArea @bind-Value="starship.Description" />
        </label>
    </p>
    <p>
        <label>
            Primary Classification:
            <InputSelect @bind-Value="starship.Classification">
                <option value="">Select classification ...</option>
                <option value="Exploration">Exploration</option>
                <option value="Diplomacy">Diplomacy</option>
                <option value="Defense">Defense</option>
            </InputSelect>
        </label>
    </p>
    <p>
```

```
        <label>
            Maximum Accommodation:
            <InputNumber @bind-Value="starship.MaximumAccommodation" />
        </label>
    </p>
    <p>
        <label>
            Engineering Approval:
            <InputCheckbox @bind-Value="starship.IsValidatedDesign" />
        </label>
    </p>
    <p>
        <label>
            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" />
        </label>
    </p>

    <button type="submit">Submit</button>

    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        ...
    }
}
```

The EditForm creates an EditContext as a cascading value that tracks metadata about the edit process, including which fields have been modified and the current validation messages.

Assign **either** an EditContext **or** an EditForm.Model to an EditForm. Assignment of both isn't supported and generates a **runtime error**.

The EditForm provides convenient events for valid and invalid form submission:

- OnValidSubmit
- OnInvalidSubmit

Use OnSubmit to use custom code to trigger validation and check field values.

In the following example:

- The `HandleSubmit` method executes when the `Submit` button is selected.
- The form is validated by calling EditContext.Validate.
- Additional code is executed depending on the validation result. Place business logic in the method assigned to OnSubmit.

```
<EditForm EditContext="@editContext" OnSubmit="@HandleSubmit">

    ...

    <button type="submit">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
    }

    private async Task HandleSubmit()
    {
        var isValid = editContext.Validate();

        if (isValid)
        {
            ...
        }
        else
        {
            ...
        }
    }
}
```

NOTE

Framework API doesn't exist to clear validation messages directly from an EditContext. Therefore, we don't generally recommend adding validation messages to a new ValidationMessageStore in a form. To manage validation messages, use a validator component with your business logic validation code, as described in this article.

Display name support

This section applies to ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.

The following built-in components support display names with the `DisplayName` parameter:

- InputDate<TValue>
- InputNumber<TValue>
- InputSelect<TValue>

In the following `InputDate` component example:

- The display name (`DisplayName`) is set to `birthday`.
- The component is bound to the `BirthDate` property as a `DateTime` type.

```
<InputDate @bind-Value="@BirthDate" DisplayName="birthday" />

@code {
    public DateTime BirthDate { get; set; }
}
```

If the user doesn't provide a date value, the validation error appears as:

```
The birthday must be a date.
```

Validator components

Validator components support form validation by managing a ValidationMessageStore for a form's EditContext.

The Blazor framework provides the DataAnnotationsValidator component to attach validation support to forms based on validation attributes (data annotations). Create custom validator components to process validation messages for different forms on the same page or the same form at different steps of form processing, for example client-side validation followed by server-side validation. The validator component example shown in this section, `CustomValidator`, is used in the following sections of this article:

- Business logic validation
- Server validation

> **NOTE**
> Custom data annotation validation attributes can be used instead of custom validator components in many cases. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, any custom attributes applied to the model must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Create a validator component from ComponentBase:

- The form's EditContext is a cascading parameter of the component.
- When the validator component is initialized, a new ValidationMessageStore is created to maintain a current list of form errors.
- The message store receives errors when developer code in the form's component calls the `DisplayErrors` method. The errors are passed to the `DisplayErrors` method in a `Dictionary<string, List<string>>`. In the dictionary, the key is the name of the form field that has one or more errors. The value is the error list.
- Messages are cleared when any of the following have occurred:
  - Validation is requested on the EditContext when the OnValidationRequested event is raised. All of the errors are cleared.
  - A field changes in the form when the OnFieldChanged event is raised. Only the errors for the field are cleared.
  - The `ClearErrors` method is called by developer code. All of the errors are cleared.

```
using System;
using System.Collections.Generic;
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Forms;

namespace BlazorSample.Client
{
    public class CustomValidator : ComponentBase
    {
        private ValidationMessageStore messageStore;

        [CascadingParameter]
        private EditContext CurrentEditContext { get; set; }

        protected override void OnInitialized()
        {
            if (CurrentEditContext == null)
            {
                throw new InvalidOperationException(
                    $"{nameof(CustomValidator)} requires a cascading " +
                    $"parameter of type {nameof(EditContext)}. " +
                    $"For example, you can use {nameof(CustomValidator)} " +
                    $"inside an {nameof(EditForm)}.");
            }

            messageStore = new ValidationMessageStore(CurrentEditContext);

            CurrentEditContext.OnValidationRequested += (s, e) =>
                messageStore.Clear();
            CurrentEditContext.OnFieldChanged += (s, e) =>
                messageStore.Clear(e.FieldIdentifier);
        }

        public void DisplayErrors(Dictionary<string, List<string>> errors)
        {
            foreach (var err in errors)
            {
                messageStore.Add(CurrentEditContext.Field(err.Key), err.Value);
            }

            CurrentEditContext.NotifyValidationStateChanged();
        }

        public void ClearErrors()
        {
            messageStore.Clear();
            CurrentEditContext.NotifyValidationStateChanged();
        }
    }
}
```

Business logic validation

Business logic validation can be accomplished with a validator component that receives form errors in a dictionary.

In the following example:

- The `CustomValidator` component from the Validator components section of this article is used.
- The validation requires a value for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

When validation messages are set in the component, they're added to the validator's ValidationMessageStore and shown in the EditForm:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    ...

</EditForm>

@code {
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        customValidator.ClearErrors();

        var errors = new Dictionary<string, List<string>>();

        if (starship.Classification == "Defense" &&
                string.IsNullOrEmpty(starship.Description))
        {
            errors.Add(nameof(starship.Description),
                new List<string>() { "For a 'Defense' ship classification, " +
                "'Description' is required." });
        }

        if (errors.Count() > 0)
        {
            customValidator.DisplayErrors(errors);
        }
        else
        {
            // Process the form
        }
    }
}
```

NOTE

As an alternative to using validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Server validation

Server validation can be accomplished with a server validator component:

- Process client-side validation in the form with the DataAnnotationsValidator component.
- When the form passes client-side validation (OnValidSubmit is called), send the EditContext.Model to a backend server API for form processing.
- Process model validation on the server.
- The server API includes both the built-in framework data annotations validation and custom validation logic supplied by the developer. If validation passes on the server, process the form and send back a success status code (*200 - OK*). If validation fails, return a failure status code (*400 - Bad Request*) and the field validation errors.

- Either disable the form on success or display the errors.

The following example is based on:

- A hosted Blazor solution created by the Blazor Hosted project template. The example can be used with any of the secure hosted Blazor solutions described in the Security and Identity documentation.
- The *Starfleet Starship Database* form example in the preceding Built-in forms components section.
- The Blazor framework's DataAnnotationsValidator component.
- The `CustomValidator` component shown in the Validator components section.

In the following example, the server API validates that a value is provided for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

Place the `Starship` model into the solution's `Shared` project so that both the client and server apps can use the model. Since the model requires data annotations, add a package reference for `System.ComponentModel.Annotations` to the `Shared` project's project file:

```
<ItemGroup>
  <PackageReference Include="System.ComponentModel.Annotations" Version="{VERSION}" />
</ItemGroup>
```

To determine the latest non-preview version of the package, see the package **Version History** at NuGet.org.

In the server API project, add a controller to process starship validation requests (`Controllers/StarshipValidation.cs`) and return failed validation messages:

```
using System;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Logging;
using BlazorSample.Shared;

namespace BlazorSample.Server.Controllers
{
    [Authorize]
    [ApiController]
    [Route("[controller]")]
    public class StarshipValidationController : ControllerBase
    {
        private readonly ILogger<StarshipValidationController> logger;

        public StarshipValidationController(
            ILogger<StarshipValidationController> logger)
        {
            this.logger = logger;
        }

        [HttpPost]
        public async Task<IActionResult> Post(Starship starship)
        {
            try
            {
                if (starship.Classification == "Defense" &&
                    string.IsNullOrEmpty(starship.Description))
                {
                    ModelState.AddModelError(nameof(starship.Description),
                        "For a 'Defense' ship " +
                        "classification, 'Description' is required.");
                }
                else
                {
                    // Process the form asynchronously
                    // async ...

                    return Ok(ModelState);
                }
            }
            catch (Exception ex)
            {
                logger.LogError("Validation Error: {MESSAGE}", ex.Message);
            }

            return BadRequest(ModelState);
        }
    }
}
```

When a model binding validation error occurs on the server, an `ApiController` (ApiControllerAttribute) normally returns a default bad request response with a ValidationProblemDetails. The response contains more data than just the validation errors, as shown in the following example when all of the fields of the *Starfleet Starship Database* form aren't submitted and the form fails validation:

```
{
  "title": "One or more validation errors occurred.",
  "status": 400,
  "errors": {
    "Identifier": ["The Identifier field is required."],
    "Classification": ["The Classification field is required."],
    "IsValidatedDesign": ["This form disallows unapproved ships."],
    "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
  }
}
```

If the server API returns the preceding default JSON response, it's possible for the client to parse the response to obtain the children of the `errors` node. However, it's inconvenient to parse the file. Parsing the JSON requires additional code after calling ReadFromJsonAsync in order to produce a `Dictionary<string, List<string>>` of errors for forms validation error processing. Ideally, the server API should only return the validation errors:

```
{
  "Identifier": ["The Identifier field is required."],
  "Classification": ["The Classification field is required."],
  "IsValidatedDesign": ["This form disallows unapproved ships."],
  "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
}
```

To modify the server API's response to make it only return the validation errors, change the delegate that's invoked on actions that are annotated with ApiControllerAttribute in `Startup.ConfigureServices`. For the API endpoint (`/StarshipValidation`), return a BadRequestObjectResult with the ModelStateDictionary. For any other API endpoints, preserve the default behavior by returning the object result with a new ValidationProblemDetails:

```
using Microsoft.AspNetCore.Mvc;

...

services.AddControllersWithViews()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.InvalidModelStateResponseFactory = context =>
        {
            if (context.HttpContext.Request.Path == "/StarshipValidation")
            {
                return new BadRequestObjectResult(context.ModelState);
            }
            else
            {
                return new BadRequestObjectResult(
                    new ValidationProblemDetails(context.ModelState));
            }
        };
    });
```

For more information, see Handle errors in ASP.NET Core web APIs.

In the client project, add the validator component shown in the Validator components section.

In the client project, the *Starfleet Starship Database* form is updated to show server validation errors with help of the `CustomValidator` component. When the server API returns validation messages, they're added to the `CustomValidator` component's ValidationMessageStore. The errors are available in the form's EditContext for display by the form's ValidationSummary:

```
@page "/FormValidation"
```

```
@using System.Net
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@using Microsoft.Extensions.Logging
@using BlazorSample.Shared
@attribute [Authorize]
@inject HttpClient Http
@inject ILogger<FormValidation> Logger

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    <p>
        <label>

                disabled="@disabled" />
        </label>
    </p>
    <p>
        <label>
            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" disabled="@disabled" />
        </label>
    </p>

    <button type="submit" disabled="@disabled">Submit</button>

    <p style="@messageStyles">
        @message
    </p>
```

```
    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private bool disabled;
    private string message;
    private string messageStyles = "visibility:hidden";
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private async Task HandleValidSubmit(EditContext editContext)
    {
        customValidator.ClearErrors();

        try
        {
            var response = await Http.PostAsJsonAsync<Starship>(
                "StarshipValidation", (Starship)editContext.Model);

            var errors = await response.Content
                .ReadFromJsonAsync<Dictionary<string, List<string>>>();

            if (response.StatusCode == HttpStatusCode.BadRequest &&
                errors.Count() > 0)
            {
                customValidator.DisplayErrors(errors);
            }
            else if (!response.IsSuccessStatusCode)
            {
                throw new HttpRequestException(
                    $"Validation failed. Status Code: {response.StatusCode}");
            }
            else
            {
                disabled = true;
                messageStyles = "color:green";
                message = "The form has been processed.";
            }
        }
        catch (AccessTokenNotAvailableException ex)
        {
            ex.Redirect();
        }
        catch (Exception ex)
        {
            Logger.LogError("Form processing error: {MESSAGE}", ex.Message);
            disabled = true;
            messageStyles = "color:red";
            message = "There was an error processing the form.";
        }
    }
}
```

NOTE

As an alternative to validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

NOTE

The server-side validation approach in this section is suitable for any of the Blazor WebAssembly hosted solution examples in this documentation set:

- Azure Active Directory (AAD)
- Azure Active Directory (AAD) B2C
- Identity Server

InputText based on the input event

Use the InputText component to create a custom component that uses the `input` event instead of the `change` event.

In the following example, the `CustomInputText` component inherits the framework's `InputText` component and sets the event binding (CreateBinder) to the `oninput` event.

`Shared/CustomInputText.razor`:

```
@inherits InputText

<input
    @attributes="AdditionalAttributes"
    class="@CssClass"
    value="@CurrentValue"
    @oninput="EventCallback.Factory.CreateBinder<string>(
         this, __value => CurrentValueAsString = __value,
         CurrentValueAsString)" />
```

The `CustomInputText` component can be used anywhere InputText is used:

`Pages/TestForm.razor`:

```
@page "/testform"
@using System.ComponentModel.DataAnnotations;

<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <CustomInputText @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

<p>
    CurrentValue: @exampleModel.Name
</p>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }

    public class ExampleModel
    {
        [Required]
        [StringLength(10, ErrorMessage = "Name is too long.")]
        public string Name { get; set; }
    }
}
```

Radio buttons

Use `InputRadio` components with the `InputRadioGroup` component to create a radio button group. In the following example, properties are added to the `Starship` model described in the Built-in forms components section:

```
[Required]
[Range(typeof(Manufacturer), nameof(Manufacturer.SpaceX),
    nameof(Manufacturer.VirginGalactic), ErrorMessage = "Pick a manufacturer.")]
public Manufacturer Manufacturer { get; set; } = Manufacturer.Unknown;

[Required, EnumDataType(typeof(Color))]
public Color? Color { get; set; } = null;

[Required, EnumDataType(typeof(Engine))]
public Engine? Engine { get; set; } = null;
```

Add the following `enums` to the app. Create a new file to hold the `enums` or add the `enums` to the `Starship.cs` file. Make the `enums` accessible to the `Starship` model and the *Starfleet Starship Database* form:

```
public enum Manufacturer { SpaceX, NASA, ULA, Virgin, Unknown }
public enum Color { ImperialRed, SpacecruiserGreen, StarshipBlue, VoyagerOrange }
public enum Engine { Ion, Plasma, Fusion, Warp }
```

Update the *Starfleet Starship Database* form described in the Built-in forms components section. Add the components to produce:

- A radio button group for the ship manufacturer.
- A nested radio button group for ship color and engine.

```
<p>
    <InputRadioGroup @bind-Value="starship.Manufacturer">
        Manufacturer:
        <br>
        @foreach (var manufacturer in (Manufacturer[])Enum
            .GetValues(typeof(Manufacturer)))
        {
            <InputRadio Value="manufacturer" />
            @manufacturer
            <br>
        }
    </InputRadioGroup>
</p>

<p>
    Pick one color and one engine:
    <InputRadioGroup Name="engine" @bind-Value="starship.Engine">
        <InputRadioGroup Name="color" @bind-Value="starship.Color">
            <InputRadio Name="color" Value="Color.ImperialRed" />Imperial Red<br>
            <InputRadio Name="engine" Value="Engine.Ion" />Ion<br>
            <InputRadio Name="color" Value="Color.SpacecruiserGreen" />
                Spacecruiser Green<br>
            <InputRadio Name="engine" Value="Engine.Plasma" />Plasma<br>
            <InputRadio Name="color" Value="Color.StarshipBlue" />Starship Blue<br>
            <InputRadio Name="engine" Value="Engine.Fusion" />Fusion<br>
            <InputRadio Name="color" Value="Color.VoyagerOrange" />
                Voyager Orange<br>
            <InputRadio Name="engine" Value="Engine.Warp" />Warp<br>
        </InputRadioGroup>
    </InputRadioGroup>
</p>
```

NOTE

If `Name` is omitted, `InputRadio` components are grouped by their most recent ancestor.

When working with radio buttons in a form, data binding is handled differently than other elements because radio buttons are evaluated as a group. The value of each radio button is fixed, but the value of the radio button group is the value of the selected radio button. The following example shows how to:

- Handle data binding for a radio button group.
- Support validation using a custom `InputRadio` component.

```
@using System.Globalization
@typeparam TValue
@inherits InputBase<TValue>

<input @attributes="AdditionalAttributes" type="radio" value="@SelectedValue"
       checked="@(SelectedValue.Equals(Value))" @onchange="OnChange" />

@code {
    [Parameter]
    public TValue SelectedValue { get; set; }

    private void OnChange(ChangeEventArgs args)
    {
        CurrentValueAsString = args.Value.ToString();
    }

    protected override bool TryParseValueFromString(string value,
        out TValue result, out string errorMessage)
    {
        var success = BindConverter.TryConvertTo<TValue>(
            value, CultureInfo.CurrentCulture, out var parsedValue);
        if (success)
        {
            result = parsedValue;
            errorMessage = null;

            return true;
        }
        else
        {
            result = default;
            errorMessage = $"{FieldIdentifier.FieldName} field isn't valid.";

            return false;
        }
    }
}
```

The following EditForm uses the preceding `InputRadio` component to obtain and validate a rating from the user:

```
@page "/RadioButtonExample"
@using System.ComponentModel.DataAnnotations

<h1>Radio Button Group Test</h1>

<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    @for (int i = 1; i <= 5; i++)
    {
        <label>
            <InputRadio name="rate" SelectedValue="i" @bind-Value="model.Rating" />
            @i
        </label>
    }

    <button type="submit">Submit</button>
</EditForm>

<p>You chose: @model.Rating</p>

@code {
    private Model model = new Model();

    private void HandleValidSubmit()
    {
        ...
    }

    public class Model
    {
        [Range(1, 5)]
        public int Rating { get; set; }
    }
}
```

Binding `<select>` element options to C# object `null` values

There's no sensible way to represent a `<select>` element option value as a C# object `null` value, because:

- HTML attributes can't have `null` values. The closest equivalent to `null` in HTML is absence of the HTML `value` attribute from the `<option>` element.
- When selecting an `<option>` with no `value` attribute, the browser treats the value as the *text content* of that `<option>`'s element.

The Blazor framework doesn't attempt to suppress the default behavior because it would involve:

- Creating a chain of special-case workarounds in the framework.
- Breaking changes to current framework behavior.

The most plausible `null` equivalent in HTML is an *empty string* `value`. The Blazor framework handles `null` to empty string conversions for two-way binding to a `<select>`'s value.

The Blazor framework doesn't automatically handle `null` to empty string conversions when attempting two-way binding to a `<select>`'s value. For more information, see Fix binding `<select>` to a null value (dotnet/aspnetcore #23221).

Validation support

The DataAnnotationsValidator component attaches validation support using data annotations to the cascaded

EditContext. Enabling support for validation using data annotations requires this explicit gesture. To use a different validation system than data annotations, replace the DataAnnotationsValidator with a custom implementation. The ASP.NET Core implementation is available for inspection in the reference source: `DataAnnotationsValidator` / `AddDataAnnotationsValidation`. The preceding links to reference source provide code from the repository's `master` branch, which represents the product unit's current development for the next release of ASP.NET Core. To select the branch for a different release, use the GitHub branch selector (for example `release/3.1`).

Blazor performs two types of validation:

- *Field validation* is performed when the user tabs out of a field. During field validation, the DataAnnotationsValidator component associates all reported validation results with the field.
- *Model validation* is performed when the user submits the form. During model validation, the DataAnnotationsValidator component attempts to determine the field based on the member name that the validation result reports. Validation results that aren't associated with an individual member are associated with the model rather than a field.

Validation Summary and Validation Message components

The ValidationSummary component summarizes all validation messages, which is similar to the Validation Summary Tag Helper:

```
<ValidationSummary />
```

Output validation messages for a specific model with the `Model` parameter:

```
<ValidationSummary Model="@starship" />
```

The ValidationMessage<TValue> component displays validation messages for a specific field, which is similar to the Validation Message Tag Helper. Specify the field for validation with the `For` attribute and a lambda expression naming the model property:

```
<ValidationMessage For="@(() => starship.MaximumAccommodation)" />
```

The ValidationMessage<TValue> and ValidationSummary components support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the generated `<div>` or `<ul>` element.

Control the style of validation messages in the app's stylesheet (`wwwroot/css/app.css` or `wwwroot/css/site.css`). The default `validation-message` class sets the text color of validation messages to red:

```
.validation-message {
    color: red;
}
```

Custom validation attributes

To ensure that a validation result is correctly associated with a field when using a custom validation attribute, pass the validation context's MemberName when creating the ValidationResult:

```
using System;
using System.ComponentModel.DataAnnotations;

private class CustomValidator : ValidationAttribute
{
    protected override ValidationResult IsValid(object value,
        ValidationContext validationContext)
    {
        ...

        return new ValidationResult("Validation message to user.",
            new[] { validationContext.MemberName });
    }
}
```

NOTE

ValidationContext.GetService is `null`. Injecting services for validation in the `IsValid` method isn't supported.

Custom validation class attributes

Custom validation class names are useful when integrating with CSS frameworks, such as Bootstrap. To specify custom validation class names, create a class derived from `FieldCssClassProvider` and set the class on the EditContext instance:

```
var editContext = new EditContext(model);
editContext.SetFieldCssClassProvider(new MyFieldClassProvider());

...

private class MyFieldClassProvider : FieldCssClassProvider
{
    public override string GetFieldCssClass(EditContext editContext,
        in FieldIdentifier fieldIdentifier)
    {
        var isValid = !editContext.GetValidationMessages(fieldIdentifier).Any();

        return isValid ? "good field" : "bad field";
    }
}
```

Blazor data annotations validation package

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` is a package that fills validation experience gaps using the DataAnnotationsValidator component. The package is currently *experimental*.

NOTE

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package has a latest version of *release candidate* at Nuget.org. Continue to use the *experimental* release candidate package at this time. The package's assembly might be moved to either the framework or the runtime in a future release. Watch the Announcements GitHub repository, the dotnet/aspnetcore GitHub repository, or this topic section for further updates.

[CompareProperty] attribute

The CompareAttribute doesn't work well with the DataAnnotationsValidator component because it doesn't associate the validation result with a specific member. This can result in inconsistent behavior between field-level validation and when the entire model is validated on a submit. The

`Microsoft.AspNetCore.Components.DataAnnotations.Validation` *experimental* package introduces an additional validation attribute, `ComparePropertyAttribute`, that works around these limitations. In a Blazor app, `[CompareProperty]` is a direct replacement for the `[Compare]` attribute.

Nested models, collection types, and complex types

Blazor provides support for validating form input using data annotations with the built-in DataAnnotationsValidator. However, the DataAnnotationsValidator only validates top-level properties of the model bound to the form that aren't collection- or complex-type properties.

To validate the bound model's entire object graph, including collection- and complex-type properties, use the `ObjectGraphDataAnnotationsValidator` provided by the *experimental* `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package:

```
<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <ObjectGraphDataAnnotationsValidator />
    ...
</EditForm>
```

Annotate model properties with `[ValidateComplexType]`. In the following model classes, the `ShipDescription` class contains additional data annotations to validate when the model is bound to the form:

`Starship.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    ...

    [ValidateComplexType]
    public ShipDescription ShipDescription { get; set; } =
        new ShipDescription();

    ...
}
```

`ShipDescription.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class ShipDescription
{
    [Required]
    [StringLength(40, ErrorMessage = "Description too long (40 char).")]
    public string ShortDescription { get; set; }

    [Required]
    [StringLength(240, ErrorMessage = "Description too long (240 char).")]
    public string LongDescription { get; set; }
}
```

Enable the submit button based on form validation

To enable and disable the submit button based on form validation:

- Use the form's EditContext to assign the model when the component is initialized.
- Validate the form in the context's OnFieldChanged callback to enable and disable the submit button.

- Unhook the event handler in the `Dispose` method. For more information, see ASP.NET Core Blazor lifecycle.

> **NOTE**
> When using an EditContext, don't also assign a Model to the EditForm.

```
@implements IDisposable

<EditForm EditContext="@editContext">
    <DataAnnotationsValidator />
    <ValidationSummary />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private bool formInvalid = true;
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
        editContext.OnFieldChanged += HandleFieldChanged;
    }

    private void HandleFieldChanged(object sender, FieldChangedEventArgs e)
    {
        formInvalid = !editContext.Validate();
        StateHasChanged();
    }

    public void Dispose()
    {
        editContext.OnFieldChanged -= HandleFieldChanged;
    }
}
```

In the preceding example, set `formInvalid` to `false` if:

- The form is preloaded with valid default values.
- You want the submit button enabled when the form loads.

A side effect of the preceding approach is that a ValidationSummary component is populated with invalid fields after the user interacts with any one field. This scenario can be addressed in either of the following ways:

- Don't use a ValidationSummary component on the form.
- Make the ValidationSummary component visible when the submit button is selected (for example, in a `HandleValidSubmit` method).

```
<EditForm EditContext="@editContext" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary style="@displaySummary" />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private string displaySummary = "display:none";

    ...

    private void HandleValidSubmit()
    {
        displaySummary = "display:block";
    }
}
```

Troubleshoot

> InvalidOperationException: EditForm requires a Model parameter, or an EditContext parameter, but not both.

Confirm that the EditForm has a Model **or** EditContext. Don't use both for the same form.

When assigning a Model to the form, confirm that the model type is instantiated, as the following example shows:

```
private ExampleModel exampleModel = new ExampleModel();
```

ASP.NET Core Blazor forms and validation

9/22/2020 • 22 minutes to read • Edit Online

By Daniel Roth, Rémi Bourgarel, and Luke Latham

Forms and validation are supported in Blazor using data annotations.

The following `ExampleModel` type defines validation logic using data annotations:

```
using System.ComponentModel.DataAnnotations;

public class ExampleModel
{
    [Required]
    [StringLength(10, ErrorMessage = "Name is too long.")]
    public string Name { get; set; }
}
```

A form is defined using the EditForm component. The following form demonstrates typical elements, components, and Razor code:

```
<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <InputText id="name" @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }
}
```

In the preceding example:

- The form validates user input in the `name` field using the validation defined in the `ExampleModel` type. The model is created in the component's `@code` block and held in a private field (`exampleModel`). The field is assigned to the `Model` attribute of the `<EditForm>` element.
- The InputText component's `@bind-Value` binds:
  - The model property (`exampleModel.Name`) to the InputText component's `Value` property. For more information on property binding, see ASP.NET Core Blazor data binding.
  - A change event delegate to the InputText component's `ValueChanged` property.
- The DataAnnotationsValidator validator component attaches validation support using data annotations.
- The ValidationSummary component summarizes validation messages.
- `HandleValidSubmit` is triggered when the form successfully submits (passes validation).

Built-in forms components

A set of built-in components are available to receive and validate user input. Inputs are validated when they're changed and when a form is submitted. Available input components are shown in the following table.

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
`InputFile`	`<input type="file">`
InputNumber<TValue>	`<input type="number">`
`InputRadio`	`<input type="radio">`
`InputRadioGroup`	`<input type="radio">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
InputNumber<TValue>	`<input type="number">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

> **NOTE**
>
> The `InputRadio` and `InputRadioGroup` components are available in ASP.NET Core 5.0 or later. For more information, select a 5.0 or later version of this article.

All of the input components, including EditForm, support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the rendered HTML element.

Input components provide default behavior for validating when a field is changed, including updating the field CSS class to reflect the field state. Some components include useful parsing logic. For example, InputDate<TValue> and InputNumber<TValue> handle unparseable values gracefully by registering unparseable values as validation errors. Types that can accept null values also support nullability of the target field (for example, `int?`).

The following `Starship` type defines validation logic using a larger set of properties and data annotations than the

earlier `ExampleModel`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    [Required]
    [StringLength(16, ErrorMessage = "Identifier too long (16 character limit).")]
    public string Identifier { get; set; }

    public string Description { get; set; }

    [Required]
    public string Classification { get; set; }

    [Range(1, 100000, ErrorMessage = "Accommodation invalid (1-100000).")]
    public int MaximumAccommodation { get; set; }

    [Required]
    [Range(typeof(bool), "true", "true",
        ErrorMessage = "This form disallows unapproved ships.")]
    public bool IsValidatedDesign { get; set; }

    [Required]
    public DateTime ProductionDate { get; set; }
}
```

In the preceding example, `Description` is optional because no data annotations are present.

The following form validates user input using the validation defined in the `Starship` model:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <p>
        <label>
            Identifier:
            <InputText @bind-Value="starship.Identifier" />
        </label>
    </p>
    <p>
        <label>
            Description (optional):
            <InputTextArea @bind-Value="starship.Description" />
        </label>
    </p>
    <p>
        <label>
            Primary Classification:
            <InputSelect @bind-Value="starship.Classification">
                <option value="">Select classification ...</option>
                <option value="Exploration">Exploration</option>
                <option value="Diplomacy">Diplomacy</option>
                <option value="Defense">Defense</option>
            </InputSelect>
        </label>
    </p>
    <p>
```

```
        <label>
            Maximum Accommodation:
            <InputNumber @bind-Value="starship.MaximumAccommodation" />
        </label>
    </p>
    <p>
        <label>
            Engineering Approval:
            <InputCheckbox @bind-Value="starship.IsValidatedDesign" />
        </label>
    </p>
    <p>
        <label>
            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" />
        </label>
    </p>

    <button type="submit">Submit</button>

    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        ...
    }
}
```

The EditForm creates an EditContext as a cascading value that tracks metadata about the edit process, including which fields have been modified and the current validation messages.

Assign **either** an EditContext **or** an EditForm.Model to an EditForm. Assignment of both isn't supported and generates a **runtime error**.

The EditForm provides convenient events for valid and invalid form submission:

- OnValidSubmit
- OnInvalidSubmit

Use OnSubmit to use custom code to trigger validation and check field values.

In the following example:

- The `HandleSubmit` method executes when the `Submit` button is selected.
- The form is validated by calling EditContext.Validate.
- Additional code is executed depending on the validation result. Place business logic in the method assigned to OnSubmit.

```
<EditForm EditContext="@editContext" OnSubmit="@HandleSubmit">

    ...

    <button type="submit">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
    }

    private async Task HandleSubmit()
    {
        var isValid = editContext.Validate();

        if (isValid)
        {
            ...
        }
        else
        {
            ...
        }
    }
}
```

NOTE

Framework API doesn't exist to clear validation messages directly from an EditContext. Therefore, we don't generally recommend adding validation messages to a new ValidationMessageStore in a form. To manage validation messages, use a validator component with your business logic validation code, as described in this article.

Display name support

This section applies to ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.

The following built-in components support display names with the `DisplayName` parameter:

- InputDate<TValue>
- InputNumber<TValue>
- InputSelect<TValue>

In the following `InputDate` component example:

- The display name (`DisplayName`) is set to `birthday`.
- The component is bound to the `BirthDate` property as a `DateTime` type.

```
<InputDate @bind-Value="@BirthDate" DisplayName="birthday" />

@code {
    public DateTime BirthDate { get; set; }
}
```

If the user doesn't provide a date value, the validation error appears as:

```
The birthday must be a date.
```

Validator components

Validator components support form validation by managing a ValidationMessageStore for a form's EditContext.

The Blazor framework provides the DataAnnotationsValidator component to attach validation support to forms based on validation attributes (data annotations). Create custom validator components to process validation messages for different forms on the same page or the same form at different steps of form processing, for example client-side validation followed by server-side validation. The validator component example shown in this section, `CustomValidator`, is used in the following sections of this article:

- Business logic validation
- Server validation

> **NOTE**
> Custom data annotation validation attributes can be used instead of custom validator components in many cases. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, any custom attributes applied to the model must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Create a validator component from ComponentBase:

- The form's EditContext is a cascading parameter of the component.
- When the validator component is initialized, a new ValidationMessageStore is created to maintain a current list of form errors.
- The message store receives errors when developer code in the form's component calls the `DisplayErrors` method. The errors are passed to the `DisplayErrors` method in a `Dictionary<string, List<string>>`. In the dictionary, the key is the name of the form field that has one or more errors. The value is the error list.
- Messages are cleared when any of the following have occurred:
  - Validation is requested on the EditContext when the OnValidationRequested event is raised. All of the errors are cleared.
  - A field changes in the form when the OnFieldChanged event is raised. Only the errors for the field are cleared.
  - The `ClearErrors` method is called by developer code. All of the errors are cleared.

```
using System;
using System.Collections.Generic;
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Forms;

namespace BlazorSample.Client
{
    public class CustomValidator : ComponentBase
    {
        private ValidationMessageStore messageStore;

        [CascadingParameter]
        private EditContext CurrentEditContext { get; set; }

        protected override void OnInitialized()
        {
            if (CurrentEditContext == null)
            {
                throw new InvalidOperationException(
                    $"{nameof(CustomValidator)} requires a cascading " +
                    $"parameter of type {nameof(EditContext)}. " +
                    $"For example, you can use {nameof(CustomValidator)} " +
                    $"inside an {nameof(EditForm)}.");
            }

            messageStore = new ValidationMessageStore(CurrentEditContext);

            CurrentEditContext.OnValidationRequested += (s, e) =>
                messageStore.Clear();
            CurrentEditContext.OnFieldChanged += (s, e) =>
                messageStore.Clear(e.FieldIdentifier);
        }

        public void DisplayErrors(Dictionary<string, List<string>> errors)
        {
            foreach (var err in errors)
            {
                messageStore.Add(CurrentEditContext.Field(err.Key), err.Value);
            }

            CurrentEditContext.NotifyValidationStateChanged();
        }

        public void ClearErrors()
        {
            messageStore.Clear();
            CurrentEditContext.NotifyValidationStateChanged();
        }
    }
}
```

Business logic validation

Business logic validation can be accomplished with a validator component that receives form errors in a dictionary.

In the following example:

- The `CustomValidator` component from the Validator components section of this article is used.
- The validation requires a value for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

When validation messages are set in the component, they're added to the validator's ValidationMessageStore and shown in the EditForm:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    ...

</EditForm>

@code {
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        customValidator.ClearErrors();

        var errors = new Dictionary<string, List<string>>();

        if (starship.Classification == "Defense" &&
                string.IsNullOrEmpty(starship.Description))
        {
            errors.Add(nameof(starship.Description),
                new List<string>() { "For a 'Defense' ship classification, " +
                "'Description' is required." });
        }

        if (errors.Count() > 0)
        {
            customValidator.DisplayErrors(errors);
        }
        else
        {
            // Process the form
        }
    }
}
```

NOTE

As an alternative to using validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Server validation

Server validation can be accomplished with a server validator component:

- Process client-side validation in the form with the DataAnnotationsValidator component.
- When the form passes client-side validation (OnValidSubmit is called), send the EditContext.Model to a backend server API for form processing.
- Process model validation on the server.
- The server API includes both the built-in framework data annotations validation and custom validation logic supplied by the developer. If validation passes on the server, process the form and send back a success status code (*200 - OK*). If validation fails, return a failure status code (*400 - Bad Request*) and the field validation errors.

- Either disable the form on success or display the errors.

The following example is based on:

- A hosted Blazor solution created by the Blazor Hosted project template. The example can be used with any of the secure hosted Blazor solutions described in the Security and Identity documentation.
- The *Starfleet Starship Database* form example in the preceding Built-in forms components section.
- The Blazor framework's DataAnnotationsValidator component.
- The `CustomValidator` component shown in the Validator components section.

In the following example, the server API validates that a value is provided for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

Place the `Starship` model into the solution's `Shared` project so that both the client and server apps can use the model. Since the model requires data annotations, add a package reference for `System.ComponentModel.Annotations` to the `Shared` project's project file:

```
<ItemGroup>
  <PackageReference Include="System.ComponentModel.Annotations" Version="{VERSION}" />
</ItemGroup>
```

To determine the latest non-preview version of the package, see the package **Version History** at NuGet.org.

In the server API project, add a controller to process starship validation requests (`Controllers/StarshipValidation.cs`) and return failed validation messages:

```
using System;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Logging;
using BlazorSample.Shared;

namespace BlazorSample.Server.Controllers
{
    [Authorize]
    [ApiController]
    [Route("[controller]")]
    public class StarshipValidationController : ControllerBase
    {
        private readonly ILogger<StarshipValidationController> logger;

        public StarshipValidationController(
            ILogger<StarshipValidationController> logger)
        {
            this.logger = logger;
        }

        [HttpPost]
        public async Task<IActionResult> Post(Starship starship)
        {
            try
            {
                if (starship.Classification == "Defense" &&
                    string.IsNullOrEmpty(starship.Description))
                {
                    ModelState.AddModelError(nameof(starship.Description),
                        "For a 'Defense' ship " +
                        "classification, 'Description' is required.");
                }
                else
                {
                    // Process the form asynchronously
                    // async ...

                    return Ok(ModelState);
                }
            }
            catch (Exception ex)
            {
                logger.LogError("Validation Error: {MESSAGE}", ex.Message);
            }

            return BadRequest(ModelState);
        }
    }
}
```

When a model binding validation error occurs on the server, an `ApiController` (ApiControllerAttribute) normally returns a default bad request response with a ValidationProblemDetails. The response contains more data than just the validation errors, as shown in the following example when all of the fields of the *Starfleet Starship Database* form aren't submitted and the form fails validation:

```
{
  "title": "One or more validation errors occurred.",
  "status": 400,
  "errors": {
    "Identifier": ["The Identifier field is required."],
    "Classification": ["The Classification field is required."],
    "IsValidatedDesign": ["This form disallows unapproved ships."],
    "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
  }
}
```

If the server API returns the preceding default JSON response, it's possible for the client to parse the response to obtain the children of the `errors` node. However, it's inconvenient to parse the file. Parsing the JSON requires additional code after calling ReadFromJsonAsync in order to produce a `Dictionary<string, List<string>>` of errors for forms validation error processing. Ideally, the server API should only return the validation errors:

```
{
  "Identifier": ["The Identifier field is required."],
  "Classification": ["The Classification field is required."],
  "IsValidatedDesign": ["This form disallows unapproved ships."],
  "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
}
```

To modify the server API's response to make it only return the validation errors, change the delegate that's invoked on actions that are annotated with ApiControllerAttribute in `Startup.ConfigureServices`. For the API endpoint (`/StarshipValidation`), return a BadRequestObjectResult with the ModelStateDictionary. For any other API endpoints, preserve the default behavior by returning the object result with a new ValidationProblemDetails:

```
using Microsoft.AspNetCore.Mvc;

...

services.AddControllersWithViews()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.InvalidModelStateResponseFactory = context =>
        {
            if (context.HttpContext.Request.Path == "/StarshipValidation")
            {
                return new BadRequestObjectResult(context.ModelState);
            }
            else
            {
                return new BadRequestObjectResult(
                    new ValidationProblemDetails(context.ModelState));
            }
        };
    });
```

For more information, see Handle errors in ASP.NET Core web APIs.

In the client project, add the validator component shown in the Validator components section.

In the client project, the *Starfleet Starship Database* form is updated to show server validation errors with help of the `CustomValidator` component. When the server API returns validation messages, they're added to the `CustomValidator` component's ValidationMessageStore. The errors are available in the form's EditContext for display by the form's ValidationSummary:

```
@page "/FormValidation"
```

```
@using System.Net
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@using Microsoft.Extensions.Logging
@using BlazorSample.Shared
@attribute [Authorize]
@inject HttpClient Http
@inject ILogger<FormValidation> Logger

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    <p>
        <label>
            Identifier:
            <InputText @bind-Value="starship.Identifier" disabled="@disabled" />
        </label>
    </p>
    <p>
        <label>
            Description (optional):
            <InputTextArea @bind-Value="starship.Description"
                disabled="@disabled" />
        </label>
    </p>
    <p>

                <option value="Exploration">Exploration</option>
                <option value="Diplomacy">Diplomacy</option>
                <option value="Defense">Defense</option>
            </InputSelect>
        </label>
    </p>
    <p>
        <label>
            Maximum Accommodation:
            <InputNumber @bind-Value="starship.MaximumAccommodation"
                disabled="@disabled" />
        </label>
    </p>
    <p>
        <label>
            Engineering Approval:
            <InputCheckbox @bind-Value="starship.IsValidatedDesign"
                disabled="@disabled" />
        </label>
    </p>
    <p>
        <label>
            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" disabled="@disabled" />
        </label>
    </p>

    <button type="submit" disabled="@disabled">Submit</button>

    <p style="@messageStyles">
        @message
    </p>
```

```
    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private bool disabled;
    private string message;
    private string messageStyles = "visibility:hidden";
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private async Task HandleValidSubmit(EditContext editContext)
    {
        customValidator.ClearErrors();

        try
        {
            var response = await Http.PostAsJsonAsync<Starship>(
                "StarshipValidation", (Starship)editContext.Model);

            var errors = await response.Content
                .ReadFromJsonAsync<Dictionary<string, List<string>>>();

            if (response.StatusCode == HttpStatusCode.BadRequest &&
                errors.Count() > 0)
            {
                customValidator.DisplayErrors(errors);
            }
            else if (!response.IsSuccessStatusCode)
            {
                throw new HttpRequestException(
                    $"Validation failed. Status Code: {response.StatusCode}");
            }
            else
            {
                disabled = true;
                messageStyles = "color:green";
                message = "The form has been processed.";
            }
        }
        catch (AccessTokenNotAvailableException ex)
        {
            ex.Redirect();
        }
        catch (Exception ex)
        {
            Logger.LogError("Form processing error: {MESSAGE}", ex.Message);
            disabled = true;
            messageStyles = "color:red";
            message = "There was an error processing the form.";
        }
    }
}
```

NOTE

As an alternative to validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

NOTE

The server-side validation approach in this section is suitable for any of the Blazor WebAssembly hosted solution examples in this documentation set:

- Azure Active Directory (AAD)
- Azure Active Directory (AAD) B2C
- Identity Server

InputText based on the input event

Use the InputText component to create a custom component that uses the `input` event instead of the `change` event.

In the following example, the `CustomInputText` component inherits the framework's `InputText` component and sets the event binding (CreateBinder) to the `oninput` event.

`Shared/CustomInputText.razor`:

```
@inherits InputText

<input
    @attributes="AdditionalAttributes"
    class="@CssClass"
    value="@CurrentValue"
    @oninput="EventCallback.Factory.CreateBinder<string>(
         this, __value => CurrentValueAsString = __value,
         CurrentValueAsString)" />
```

The `CustomInputText` component can be used anywhere InputText is used:

`Pages/TestForm.razor`:

```
@page "/testform"
@using System.ComponentModel.DataAnnotations;

<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <CustomInputText @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

<p>
    CurrentValue: @exampleModel.Name
</p>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }

    public class ExampleModel
    {
        [Required]
        [StringLength(10, ErrorMessage = "Name is too long.")]
        public string Name { get; set; }
    }
}
```

Radio buttons

Use `InputRadio` components with the `InputRadioGroup` component to create a radio button group. In the following example, properties are added to the `Starship` model described in the Built-in forms components section:

```
[Required]
[Range(typeof(Manufacturer), nameof(Manufacturer.SpaceX),
    nameof(Manufacturer.VirginGalactic), ErrorMessage = "Pick a manufacturer.")]
public Manufacturer Manufacturer { get; set; } = Manufacturer.Unknown;

[Required, EnumDataType(typeof(Color))]
public Color? Color { get; set; } = null;

[Required, EnumDataType(typeof(Engine))]
public Engine? Engine { get; set; } = null;
```

Add the following `enums` to the app. Create a new file to hold the `enums` or add the `enums` to the `Starship.cs` file. Make the `enums` accessible to the `Starship` model and the *Starfleet Starship Database* form:

```
public enum Manufacturer { SpaceX, NASA, ULA, Virgin, Unknown }
public enum Color { ImperialRed, SpacecruiserGreen, StarshipBlue, VoyagerOrange }
public enum Engine { Ion, Plasma, Fusion, Warp }
```

Update the *Starfleet Starship Database* form described in the Built-in forms components section. Add the components to produce:

- A radio button group for the ship manufacturer.
- A nested radio button group for ship color and engine.

```
<p>
    <InputRadioGroup @bind-Value="starship.Manufacturer">
        Manufacturer:
        <br>
        @foreach (var manufacturer in (Manufacturer[])Enum
            .GetValues(typeof(Manufacturer)))
        {
            <InputRadio Value="manufacturer" />
            @manufacturer
            <br>
        }
    </InputRadioGroup>
</p>

<p>
    Pick one color and one engine:
    <InputRadioGroup Name="engine" @bind-Value="starship.Engine">
        <InputRadioGroup Name="color" @bind-Value="starship.Color">
            <InputRadio Name="color" Value="Color.ImperialRed" />Imperial Red<br>
            <InputRadio Name="engine" Value="Engine.Ion" />Ion<br>
            <InputRadio Name="color" Value="Color.SpacecruiserGreen" />
                Spacecruiser Green<br>
            <InputRadio Name="engine" Value="Engine.Plasma" />Plasma<br>
            <InputRadio Name="color" Value="Color.StarshipBlue" />Starship Blue<br>
            <InputRadio Name="engine" Value="Engine.Fusion" />Fusion<br>
            <InputRadio Name="color" Value="Color.VoyagerOrange" />
                Voyager Orange<br>
            <InputRadio Name="engine" Value="Engine.Warp" />Warp<br>
        </InputRadioGroup>
    </InputRadioGroup>
</p>
```

NOTE

If `Name` is omitted, `InputRadio` components are grouped by their most recent ancestor.

When working with radio buttons in a form, data binding is handled differently than other elements because radio buttons are evaluated as a group. The value of each radio button is fixed, but the value of the radio button group is the value of the selected radio button. The following example shows how to:

- Handle data binding for a radio button group.
- Support validation using a custom `InputRadio` component.

```
@using System.Globalization
@typeparam TValue
@inherits InputBase<TValue>

<input @attributes="AdditionalAttributes" type="radio" value="@SelectedValue"
       checked="@(SelectedValue.Equals(Value))" @onchange="OnChange" />

@code {
    [Parameter]
    public TValue SelectedValue { get; set; }

    private void OnChange(ChangeEventArgs args)
    {
        CurrentValueAsString = args.Value.ToString();
    }

    protected override bool TryParseValueFromString(string value,
        out TValue result, out string errorMessage)
    {
        var success = BindConverter.TryConvertTo<TValue>(
            value, CultureInfo.CurrentCulture, out var parsedValue);
        if (success)
        {
            result = parsedValue;
            errorMessage = null;

            return true;
        }
        else
        {
            result = default;
            errorMessage = $"{FieldIdentifier.FieldName} field isn't valid.";

            return false;
        }
    }
}
```

The following EditForm uses the preceding `InputRadio` component to obtain and validate a rating from the user:

```
@page "/RadioButtonExample"
@using System.ComponentModel.DataAnnotations

<h1>Radio Button Group Test</h1>

<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    @for (int i = 1; i <= 5; i++)
    {
        <label>
            <InputRadio name="rate" SelectedValue="i" @bind-Value="model.Rating" />
            @i
        </label>
    }

    <button type="submit">Submit</button>
</EditForm>

<p>You chose: @model.Rating</p>

@code {
    private Model model = new Model();

    private void HandleValidSubmit()
    {
        ...
    }

    public class Model
    {
        [Range(1, 5)]
        public int Rating { get; set; }
    }
}
```

Binding `<select>` element options to C# object `null` values

There's no sensible way to represent a `<select>` element option value as a C# object `null` value, because:

- HTML attributes can't have `null` values. The closest equivalent to `null` in HTML is absence of the HTML `value` attribute from the `<option>` element.
- When selecting an `<option>` with no `value` attribute, the browser treats the value as the *text content* of that `<option>`'s element.

The Blazor framework doesn't attempt to suppress the default behavior because it would involve:

- Creating a chain of special-case workarounds in the framework.
- Breaking changes to current framework behavior.

The most plausible `null` equivalent in HTML is an *empty string* `value`. The Blazor framework handles `null` to empty string conversions for two-way binding to a `<select>`'s value.

The Blazor framework doesn't automatically handle `null` to empty string conversions when attempting two-way binding to a `<select>`'s value. For more information, see Fix binding `<select>` to a null value (dotnet/aspnetcore #23221).

Validation support

The DataAnnotationsValidator component attaches validation support using data annotations to the cascaded

EditContext. Enabling support for validation using data annotations requires this explicit gesture. To use a different validation system than data annotations, replace the DataAnnotationsValidator with a custom implementation. The ASP.NET Core implementation is available for inspection in the reference source: `DataAnnotationsValidator` / `AddDataAnnotationsValidation`. The preceding links to reference source provide code from the repository's `master` branch, which represents the product unit's current development for the next release of ASP.NET Core. To select the branch for a different release, use the GitHub branch selector (for example `release/3.1`).

Blazor performs two types of validation:

- *Field validation* is performed when the user tabs out of a field. During field validation, the DataAnnotationsValidator component associates all reported validation results with the field.
- *Model validation* is performed when the user submits the form. During model validation, the DataAnnotationsValidator component attempts to determine the field based on the member name that the validation result reports. Validation results that aren't associated with an individual member are associated with the model rather than a field.

Validation Summary and Validation Message components

The ValidationSummary component summarizes all validation messages, which is similar to the Validation Summary Tag Helper:

```
<ValidationSummary />
```

Output validation messages for a specific model with the `Model` parameter:

```
<ValidationSummary Model="@starship" />
```

The ValidationMessage<TValue> component displays validation messages for a specific field, which is similar to the Validation Message Tag Helper. Specify the field for validation with the `For` attribute and a lambda expression naming the model property:

```
<ValidationMessage For="@(() => starship.MaximumAccommodation)" />
```

The ValidationMessage<TValue> and ValidationSummary components support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the generated `<div>` or `<ul>` element.

Control the style of validation messages in the app's stylesheet (`wwwroot/css/app.css` or `wwwroot/css/site.css`). The default `validation-message` class sets the text color of validation messages to red:

```
.validation-message {
    color: red;
}
```

Custom validation attributes

To ensure that a validation result is correctly associated with a field when using a custom validation attribute, pass the validation context's MemberName when creating the ValidationResult:

```
using System;
using System.ComponentModel.DataAnnotations;

private class CustomValidator : ValidationAttribute
{
    protected override ValidationResult IsValid(object value,
        ValidationContext validationContext)
    {
        ...

        return new ValidationResult("Validation message to user.",
            new[] { validationContext.MemberName });
    }
}
```

NOTE

ValidationContext.GetService is `null`. Injecting services for validation in the `IsValid` method isn't supported.

Custom validation class attributes

Custom validation class names are useful when integrating with CSS frameworks, such as Bootstrap. To specify custom validation class names, create a class derived from `FieldCssClassProvider` and set the class on the EditContext instance:

```
var editContext = new EditContext(model);
editContext.SetFieldCssClassProvider(new MyFieldClassProvider());

...

private class MyFieldClassProvider : FieldCssClassProvider
{
    public override string GetFieldCssClass(EditContext editContext,
        in FieldIdentifier fieldIdentifier)
    {
        var isValid = !editContext.GetValidationMessages(fieldIdentifier).Any();

        return isValid ? "good field" : "bad field";
    }
}
```

Blazor data annotations validation package

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` is a package that fills validation experience gaps using the DataAnnotationsValidator component. The package is currently *experimental*.

NOTE

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package has a latest version of *release candidate* at Nuget.org. Continue to use the *experimental* release candidate package at this time. The package's assembly might be moved to either the framework or the runtime in a future release. Watch the Announcements GitHub repository, the dotnet/aspnetcore GitHub repository, or this topic section for further updates.

[CompareProperty] attribute

The CompareAttribute doesn't work well with the DataAnnotationsValidator component because it doesn't associate the validation result with a specific member. This can result in inconsistent behavior between field-level validation and when the entire model is validated on a submit. The

`Microsoft.AspNetCore.Components.DataAnnotations.Validation` *experimental* package introduces an additional validation attribute, `ComparePropertyAttribute`, that works around these limitations. In a Blazor app, `[CompareProperty]` is a direct replacement for the `[Compare]` attribute.

Nested models, collection types, and complex types

Blazor provides support for validating form input using data annotations with the built-in DataAnnotationsValidator. However, the DataAnnotationsValidator only validates top-level properties of the model bound to the form that aren't collection- or complex-type properties.

To validate the bound model's entire object graph, including collection- and complex-type properties, use the `ObjectGraphDataAnnotationsValidator` provided by the *experimental* `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package:

```
<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <ObjectGraphDataAnnotationsValidator />
    ...
</EditForm>
```

Annotate model properties with `[ValidateComplexType]`. In the following model classes, the `ShipDescription` class contains additional data annotations to validate when the model is bound to the form:

`Starship.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    ...

    [ValidateComplexType]
    public ShipDescription ShipDescription { get; set; } =
        new ShipDescription();

    ...
}
```

`ShipDescription.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class ShipDescription
{
    [Required]
    [StringLength(40, ErrorMessage = "Description too long (40 char).")]
    public string ShortDescription { get; set; }

    [Required]
    [StringLength(240, ErrorMessage = "Description too long (240 char).")]
    public string LongDescription { get; set; }
}
```

Enable the submit button based on form validation

To enable and disable the submit button based on form validation:

- Use the form's EditContext to assign the model when the component is initialized.
- Validate the form in the context's OnFieldChanged callback to enable and disable the submit button.

- Unhook the event handler in the `Dispose` method. For more information, see ASP.NET Core Blazor lifecycle.

> **NOTE**
> When using an EditContext, don't also assign a Model to the EditForm.

```
@implements IDisposable

<EditForm EditContext="@editContext">
    <DataAnnotationsValidator />
    <ValidationSummary />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private bool formInvalid = true;
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
        editContext.OnFieldChanged += HandleFieldChanged;
    }

    private void HandleFieldChanged(object sender, FieldChangedEventArgs e)
    {
        formInvalid = !editContext.Validate();
        StateHasChanged();
    }

    public void Dispose()
    {
        editContext.OnFieldChanged -= HandleFieldChanged;
    }
}
```

In the preceding example, set `formInvalid` to `false` if:

- The form is preloaded with valid default values.
- You want the submit button enabled when the form loads.

A side effect of the preceding approach is that a ValidationSummary component is populated with invalid fields after the user interacts with any one field. This scenario can be addressed in either of the following ways:

- Don't use a ValidationSummary component on the form.
- Make the ValidationSummary component visible when the submit button is selected (for example, in a `HandleValidSubmit` method).

```
<EditForm EditContext="@editContext" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary style="@displaySummary" />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private string displaySummary = "display:none";

    ...

    private void HandleValidSubmit()
    {
        displaySummary = "display:block";
    }
}
```

Troubleshoot

> InvalidOperationException: EditForm requires a Model parameter, or an EditContext parameter, but not both.

Confirm that the EditForm has a Model **or** EditContext. Don't use both for the same form.

When assigning a Model to the form, confirm that the model type is instantiated, as the following example shows:

```
private ExampleModel exampleModel = new ExampleModel();
```

- ASP.NET Core Blazor file uploads

ASP.NET Core Blazor file uploads

9/22/2020 • 2 minutes to read • Edit Online

By Daniel Roth

Use the `InputFile` component to read browser file data into .NET code, including for file uploads. The `InputFile` component renders as an HTML input of type `file`.

By default, the user selects single files. Add the `multiple` attribute to permit the user to upload multiple files at once. When one or more files is selected by the user, the `InputFile` component fires an `OnChange` event and passes in an `InputFileChangeEventArgs` that provides access to the selected file list and details about each file.

A component that receives an image file can call the `RequestImageFileAsync` convenience method on the file to resize the image data within the browser's JavaScript runtime before the image is streamed into the app.

The following example demonstrates multiple image file upload in a component:

```
<h3>Upload PNG images</h3>

<p>
    <InputFile OnChange="@OnInputFileChange" multiple />
</p>

@if (imageDataUrls.Count > 0)
{
    <h3>Images</h3>

    <div class="card" style="width:30rem;">
        <div class="card-body">
            @foreach (var imageDataUrl in imageDataUrls)
            {
                <img class="rounded m-1" src="@imageDataUrl" />
            }
        </div>
    </div>
}

@code {
    IList<string> imageDataUrls = new List<string>();

    private async Task OnInputFileChange(InputFileChangeEventArgs e)
    {
        var imageFiles = e.GetMultipleFiles();
        var format = "image/png";

        foreach (var imageFile in imageFiles)
        {
            var resizedImageFile = await imageFile.RequestImageFileAsync(format,
                100, 100);
            var buffer = new byte[resizedImageFile.Size];
            await resizedImageFile.OpenReadStream().ReadAsync(buffer);
            var imageDataUrl =
                $"data:{format};base64,{Convert.ToBase64String(buffer)}";
            imageDataUrls.Add(imageDataUrl);
        }
    }
}
```

To read data from a user-selected file, call `OpenReadStream` on the file and read from the returned stream. In a Blazor

WebAssembly app, the data is streamed directly into the .NET code within the browser. In a Blazor Server app, the file data is streamed into .NET code on the server as the file is read from the stream.

ASP.NET Core Blazor forms and validation

9/22/2020 • 22 minutes to read • Edit Online

By Daniel Roth, Rémi Bourgarel, and Luke Latham

Forms and validation are supported in Blazor using data annotations.

The following `ExampleModel` type defines validation logic using data annotations:

```
using System.ComponentModel.DataAnnotations;

public class ExampleModel
{
    [Required]
    [StringLength(10, ErrorMessage = "Name is too long.")]
    public string Name { get; set; }
}
```

A form is defined using the EditForm component. The following form demonstrates typical elements, components, and Razor code:

```
<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <InputText id="name" @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }
}
```

In the preceding example:

- The form validates user input in the `name` field using the validation defined in the `ExampleModel` type. The model is created in the component's `@code` block and held in a private field (`exampleModel`). The field is assigned to the `Model` attribute of the `<EditForm>` element.
- The InputText component's `@bind-Value` binds:
  - The model property (`exampleModel.Name`) to the InputText component's `Value` property. For more information on property binding, see ASP.NET Core Blazor data binding.
  - A change event delegate to the InputText component's `ValueChanged` property.
- The DataAnnotationsValidator validator component attaches validation support using data annotations.
- The ValidationSummary component summarizes validation messages.
- `HandleValidSubmit` is triggered when the form successfully submits (passes validation).

Built-in forms components

A set of built-in components are available to receive and validate user input. Inputs are validated when they're changed and when a form is submitted. Available input components are shown in the following table.

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
`InputFile`	`<input type="file">`
InputNumber<TValue>	`<input type="number">`
`InputRadio`	`<input type="radio">`
`InputRadioGroup`	`<input type="radio">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
InputNumber<TValue>	`<input type="number">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

> **NOTE**
>
> The `InputRadio` and `InputRadioGroup` components are available in ASP.NET Core 5.0 or later. For more information, select a 5.0 or later version of this article.

All of the input components, including EditForm, support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the rendered HTML element.

Input components provide default behavior for validating when a field is changed, including updating the field CSS class to reflect the field state. Some components include useful parsing logic. For example, InputDate<TValue> and InputNumber<TValue> handle unparseable values gracefully by registering unparseable values as validation errors. Types that can accept null values also support nullability of the target field (for example, `int?`).

The following `Starship` type defines validation logic using a larger set of properties and data annotations than the

earlier `ExampleModel`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    [Required]
    [StringLength(16, ErrorMessage = "Identifier too long (16 character limit).")]
    public string Identifier { get; set; }

    public string Description { get; set; }

    [Required]
    public string Classification { get; set; }

    [Range(1, 100000, ErrorMessage = "Accommodation invalid (1-100000).")]
    public int MaximumAccommodation { get; set; }

    [Required]
    [Range(typeof(bool), "true", "true",
        ErrorMessage = "This form disallows unapproved ships.")]
    public bool IsValidatedDesign { get; set; }

    [Required]
    public DateTime ProductionDate { get; set; }
}
```

In the preceding example, `Description` is optional because no data annotations are present.

The following form validates user input using the validation defined in the `Starship` model:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <p>
        <label>
            Identifier:
            <InputText @bind-Value="starship.Identifier" />
        </label>
    </p>
    <p>
        <label>
            Description (optional):
            <InputTextArea @bind-Value="starship.Description" />
        </label>
    </p>
    <p>
        <label>
            Primary Classification:
            <InputSelect @bind-Value="starship.Classification">
                <option value="">Select classification ...</option>
                <option value="Exploration">Exploration</option>
                <option value="Diplomacy">Diplomacy</option>
                <option value="Defense">Defense</option>
            </InputSelect>
        </label>
    </p>
    <p>
```

```
        <label>
            Maximum Accommodation:
            <InputNumber @bind-Value="starship.MaximumAccommodation" />
        </label>
    </p>
    <p>
        <label>
            Engineering Approval:
            <InputCheckbox @bind-Value="starship.IsValidatedDesign" />
        </label>
    </p>
    <p>
        <label>
            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" />
        </label>
    </p>

    <button type="submit">Submit</button>

    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        ...
    }
}
```

The EditForm creates an EditContext as a cascading value that tracks metadata about the edit process, including which fields have been modified and the current validation messages.

Assign **either** an EditContext **or** an EditForm.Model to an EditForm. Assignment of both isn't supported and generates a **runtime error**.

The EditForm provides convenient events for valid and invalid form submission:

- OnValidSubmit
- OnInvalidSubmit

Use OnSubmit to use custom code to trigger validation and check field values.

In the following example:

- The `HandleSubmit` method executes when the `Submit` button is selected.
- The form is validated by calling EditContext.Validate.
- Additional code is executed depending on the validation result. Place business logic in the method assigned to OnSubmit.

```
<EditForm EditContext="@editContext" OnSubmit="@HandleSubmit">

    ...

    <button type="submit">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
    }

    private async Task HandleSubmit()
    {
        var isValid = editContext.Validate();

        if (isValid)
        {
            ...
        }
        else
        {
            ...
        }
    }
}
```

NOTE

Framework API doesn't exist to clear validation messages directly from an EditContext. Therefore, we don't generally recommend adding validation messages to a new ValidationMessageStore in a form. To manage validation messages, use a validator component with your business logic validation code, as described in this article.

Display name support

This section applies to ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.

The following built-in components support display names with the `DisplayName` parameter:

- InputDate<TValue>
- InputNumber<TValue>
- InputSelect<TValue>

In the following `InputDate` component example:

- The display name (`DisplayName`) is set to `birthday`.
- The component is bound to the `BirthDate` property as a `DateTime` type.

```
<InputDate @bind-Value="@BirthDate" DisplayName="birthday" />

@code {
    public DateTime BirthDate { get; set; }
}
```

If the user doesn't provide a date value, the validation error appears as:

```
The birthday must be a date.
```

Validator components

Validator components support form validation by managing a ValidationMessageStore for a form's EditContext.

The Blazor framework provides the DataAnnotationsValidator component to attach validation support to forms based on validation attributes (data annotations). Create custom validator components to process validation messages for different forms on the same page or the same form at different steps of form processing, for example client-side validation followed by server-side validation. The validator component example shown in this section, `CustomValidator`, is used in the following sections of this article:

- Business logic validation
- Server validation

> **NOTE**
> Custom data annotation validation attributes can be used instead of custom validator components in many cases. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, any custom attributes applied to the model must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Create a validator component from ComponentBase:

- The form's EditContext is a cascading parameter of the component.
- When the validator component is initialized, a new ValidationMessageStore is created to maintain a current list of form errors.
- The message store receives errors when developer code in the form's component calls the `DisplayErrors` method. The errors are passed to the `DisplayErrors` method in a `Dictionary<string, List<string>>`. In the dictionary, the key is the name of the form field that has one or more errors. The value is the error list.
- Messages are cleared when any of the following have occurred:
  - Validation is requested on the EditContext when the OnValidationRequested event is raised. All of the errors are cleared.
  - A field changes in the form when the OnFieldChanged event is raised. Only the errors for the field are cleared.
  - The `ClearErrors` method is called by developer code. All of the errors are cleared.

```
using System;
using System.Collections.Generic;
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Forms;

namespace BlazorSample.Client
{
    public class CustomValidator : ComponentBase
    {
        private ValidationMessageStore messageStore;

        [CascadingParameter]
        private EditContext CurrentEditContext { get; set; }

        protected override void OnInitialized()
        {
            if (CurrentEditContext == null)
            {
                throw new InvalidOperationException(
                    $"{nameof(CustomValidator)} requires a cascading " +
                    $"parameter of type {nameof(EditContext)}. " +
                    $"For example, you can use {nameof(CustomValidator)} " +
                    $"inside an {nameof(EditForm)}.");
            }

            messageStore = new ValidationMessageStore(CurrentEditContext);

            CurrentEditContext.OnValidationRequested += (s, e) =>
                messageStore.Clear();
            CurrentEditContext.OnFieldChanged += (s, e) =>
                messageStore.Clear(e.FieldIdentifier);
        }

        public void DisplayErrors(Dictionary<string, List<string>> errors)
        {
            foreach (var err in errors)
            {
                messageStore.Add(CurrentEditContext.Field(err.Key), err.Value);
            }

            CurrentEditContext.NotifyValidationStateChanged();
        }

        public void ClearErrors()
        {
            messageStore.Clear();
            CurrentEditContext.NotifyValidationStateChanged();
        }
    }
}
```

Business logic validation

Business logic validation can be accomplished with a validator component that receives form errors in a dictionary.

In the following example:

- The `CustomValidator` component from the Validator components section of this article is used.
- The validation requires a value for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

When validation messages are set in the component, they're added to the validator's ValidationMessageStore and shown in the EditForm:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    ...

</EditForm>

@code {
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        customValidator.ClearErrors();

        var errors = new Dictionary<string, List<string>>();

        if (starship.Classification == "Defense" &&
                string.IsNullOrEmpty(starship.Description))
        {
            errors.Add(nameof(starship.Description),
                new List<string>() { "For a 'Defense' ship classification, " +
                "'Description' is required." });
        }

        if (errors.Count() > 0)
        {
            customValidator.DisplayErrors(errors);
        }
        else
        {
            // Process the form
        }
    }
}
```

NOTE

As an alternative to using validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Server validation

Server validation can be accomplished with a server validator component:

- Process client-side validation in the form with the DataAnnotationsValidator component.
- When the form passes client-side validation (OnValidSubmit is called), send the EditContext.Model to a backend server API for form processing.
- Process model validation on the server.
- The server API includes both the built-in framework data annotations validation and custom validation logic supplied by the developer. If validation passes on the server, process the form and send back a success status code (*200 - OK*). If validation fails, return a failure status code (*400 - Bad Request*) and the field validation errors.

- Either disable the form on success or display the errors.

The following example is based on:

- A hosted Blazor solution created by the Blazor Hosted project template. The example can be used with any of the secure hosted Blazor solutions described in the Security and Identity documentation.
- The *Starfleet Starship Database* form example in the preceding Built-in forms components section.
- The Blazor framework's DataAnnotationsValidator component.
- The `CustomValidator` component shown in the Validator components section.

In the following example, the server API validates that a value is provided for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

Place the `Starship` model into the solution's `Shared` project so that both the client and server apps can use the model. Since the model requires data annotations, add a package reference for `System.ComponentModel.Annotations` to the `Shared` project's project file:

```
<ItemGroup>
  <PackageReference Include="System.ComponentModel.Annotations" Version="{VERSION}" />
</ItemGroup>
```

To determine the latest non-preview version of the package, see the package **Version History** at NuGet.org.

In the server API project, add a controller to process starship validation requests (`Controllers/StarshipValidation.cs`) and return failed validation messages:

```
using System;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Logging;
using BlazorSample.Shared;

namespace BlazorSample.Server.Controllers
{
    [Authorize]
    [ApiController]
    [Route("[controller]")]
    public class StarshipValidationController : ControllerBase
    {
        private readonly ILogger<StarshipValidationController> logger;

        public StarshipValidationController(
            ILogger<StarshipValidationController> logger)
        {
            this.logger = logger;
        }

        [HttpPost]
        public async Task<IActionResult> Post(Starship starship)
        {
            try
            {
                if (starship.Classification == "Defense" &&
                    string.IsNullOrEmpty(starship.Description))
                {
                    ModelState.AddModelError(nameof(starship.Description),
                        "For a 'Defense' ship " +
                        "classification, 'Description' is required.");
                }
                else
                {
                    // Process the form asynchronously
                    // async ...

                    return Ok(ModelState);
                }
            }
            catch (Exception ex)
            {
                logger.LogError("Validation Error: {MESSAGE}", ex.Message);
            }

            return BadRequest(ModelState);
        }
    }
}
```

When a model binding validation error occurs on the server, an `ApiController` (ApiControllerAttribute) normally returns a default bad request response with a ValidationProblemDetails. The response contains more data than just the validation errors, as shown in the following example when all of the fields of the *Starfleet Starship Database* form aren't submitted and the form fails validation:

```
{
  "title": "One or more validation errors occurred.",
  "status": 400,
  "errors": {
    "Identifier": ["The Identifier field is required."],
    "Classification": ["The Classification field is required."],
    "IsValidatedDesign": ["This form disallows unapproved ships."],
    "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
  }
}
```

If the server API returns the preceding default JSON response, it's possible for the client to parse the response to obtain the children of the `errors` node. However, it's inconvenient to parse the file. Parsing the JSON requires additional code after calling ReadFromJsonAsync in order to produce a `Dictionary<string, List<string>>` of errors for forms validation error processing. Ideally, the server API should only return the validation errors:

```
{
  "Identifier": ["The Identifier field is required."],
  "Classification": ["The Classification field is required."],
  "IsValidatedDesign": ["This form disallows unapproved ships."],
  "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
}
```

To modify the server API's response to make it only return the validation errors, change the delegate that's invoked on actions that are annotated with ApiControllerAttribute in `Startup.ConfigureServices`. For the API endpoint (`/StarshipValidation`), return a BadRequestObjectResult with the ModelStateDictionary. For any other API endpoints, preserve the default behavior by returning the object result with a new ValidationProblemDetails:

```
using Microsoft.AspNetCore.Mvc;

...

services.AddControllersWithViews()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.InvalidModelStateResponseFactory = context =>
        {
            if (context.HttpContext.Request.Path == "/StarshipValidation")
            {
                return new BadRequestObjectResult(context.ModelState);
            }
            else
            {
                return new BadRequestObjectResult(
                    new ValidationProblemDetails(context.ModelState));
            }
        };
    });
```

For more information, see Handle errors in ASP.NET Core web APIs.

In the client project, add the validator component shown in the Validator components section.

In the client project, the *Starfleet Starship Database* form is updated to show server validation errors with help of the `CustomValidator` component. When the server API returns validation messages, they're added to the `CustomValidator` component's ValidationMessageStore. The errors are available in the form's EditContext for display by the form's ValidationSummary:

```
@page "/FormValidation"
```

```
@using System.Net
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@using Microsoft.Extensions.Logging
@using BlazorSample.Shared
@attribute [Authorize]
@inject HttpClient Http
@inject ILogger<FormValidation> Logger

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    <p>
        <label>
            Identifier:
            <InputText @bind-Value="starship.Identifier" disabled="@disabled" />
        </label>
    </p>
    <p>
        <label>

            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" disabled="@disabled" />
        </label>
    </p>

    <button type="submit" disabled="@disabled">Submit</button>

    <p style="@messageStyles">
        @message
    </p>
```

```
    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private bool disabled;
    private string message;
    private string messageStyles = "visibility:hidden";
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private async Task HandleValidSubmit(EditContext editContext)
    {
        customValidator.ClearErrors();

        try
        {
            var response = await Http.PostAsJsonAsync<Starship>(
                "StarshipValidation", (Starship)editContext.Model);

            var errors = await response.Content
                .ReadFromJsonAsync<Dictionary<string, List<string>>>();

            if (response.StatusCode == HttpStatusCode.BadRequest &&
                errors.Count() > 0)
            {
                customValidator.DisplayErrors(errors);
            }
            else if (!response.IsSuccessStatusCode)
            {
                throw new HttpRequestException(
                    $"Validation failed. Status Code: {response.StatusCode}");
            }
            else
            {
                disabled = true;
                messageStyles = "color:green";
                message = "The form has been processed.";
            }
        }
        catch (AccessTokenNotAvailableException ex)
        {
            ex.Redirect();
        }
        catch (Exception ex)
        {
            Logger.LogError("Form processing error: {MESSAGE}", ex.Message);
            disabled = true;
            messageStyles = "color:red";
            message = "There was an error processing the form.";
        }
    }
}
```

NOTE

As an alternative to validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

NOTE

The server-side validation approach in this section is suitable for any of the Blazor WebAssembly hosted solution examples in this documentation set:

- Azure Active Directory (AAD)
- Azure Active Directory (AAD) B2C
- Identity Server

InputText based on the input event

Use the InputText component to create a custom component that uses the `input` event instead of the `change` event.

In the following example, the `CustomInputText` component inherits the framework's `InputText` component and sets the event binding (CreateBinder) to the `oninput` event.

`Shared/CustomInputText.razor`:

```
@inherits InputText

<input
    @attributes="AdditionalAttributes"
    class="@CssClass"
    value="@CurrentValue"
    @oninput="EventCallback.Factory.CreateBinder<string>(
         this, __value => CurrentValueAsString = __value,
         CurrentValueAsString)" />
```

The `CustomInputText` component can be used anywhere InputText is used:

`Pages/TestForm.razor`:

```
@page "/testform"
@using System.ComponentModel.DataAnnotations;

<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <CustomInputText @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

<p>
    CurrentValue: @exampleModel.Name
</p>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }

    public class ExampleModel
    {
        [Required]
        [StringLength(10, ErrorMessage = "Name is too long.")]
        public string Name { get; set; }
    }
}
```

Radio buttons

Use `InputRadio` components with the `InputRadioGroup` component to create a radio button group. In the following example, properties are added to the `Starship` model described in the Built-in forms components section:

```
[Required]
[Range(typeof(Manufacturer), nameof(Manufacturer.SpaceX),
    nameof(Manufacturer.VirginGalactic), ErrorMessage = "Pick a manufacturer.")]
public Manufacturer Manufacturer { get; set; } = Manufacturer.Unknown;

[Required, EnumDataType(typeof(Color))]
public Color? Color { get; set; } = null;

[Required, EnumDataType(typeof(Engine))]
public Engine? Engine { get; set; } = null;
```

Add the following `enums` to the app. Create a new file to hold the `enums` or add the `enums` to the `Starship.cs` file. Make the `enums` accessible to the `Starship` model and the *Starfleet Starship Database* form:

```
public enum Manufacturer { SpaceX, NASA, ULA, Virgin, Unknown }
public enum Color { ImperialRed, SpacecruiserGreen, StarshipBlue, VoyagerOrange }
public enum Engine { Ion, Plasma, Fusion, Warp }
```

Update the *Starfleet Starship Database* form described in the Built-in forms components section. Add the components to produce:

- A radio button group for the ship manufacturer.
- A nested radio button group for ship color and engine.

```
<p>
    <InputRadioGroup @bind-Value="starship.Manufacturer">
        Manufacturer:
        <br>
        @foreach (var manufacturer in (Manufacturer[])Enum
            .GetValues(typeof(Manufacturer)))
        {
            <InputRadio Value="manufacturer" />
            @manufacturer
            <br>
        }
    </InputRadioGroup>
</p>

<p>
    Pick one color and one engine:
    <InputRadioGroup Name="engine" @bind-Value="starship.Engine">
        <InputRadioGroup Name="color" @bind-Value="starship.Color">
            <InputRadio Name="color" Value="Color.ImperialRed" />Imperial Red<br>
            <InputRadio Name="engine" Value="Engine.Ion" />Ion<br>
            <InputRadio Name="color" Value="Color.SpacecruiserGreen" />
                Spacecruiser Green<br>
            <InputRadio Name="engine" Value="Engine.Plasma" />Plasma<br>
            <InputRadio Name="color" Value="Color.StarshipBlue" />Starship Blue<br>
            <InputRadio Name="engine" Value="Engine.Fusion" />Fusion<br>
            <InputRadio Name="color" Value="Color.VoyagerOrange" />
                Voyager Orange<br>
            <InputRadio Name="engine" Value="Engine.Warp" />Warp<br>
        </InputRadioGroup>
    </InputRadioGroup>
</p>
```

NOTE

If `Name` is omitted, `InputRadio` components are grouped by their most recent ancestor.

When working with radio buttons in a form, data binding is handled differently than other elements because radio buttons are evaluated as a group. The value of each radio button is fixed, but the value of the radio button group is the value of the selected radio button. The following example shows how to:

- Handle data binding for a radio button group.
- Support validation using a custom `InputRadio` component.

```
@using System.Globalization
@typeparam TValue
@inherits InputBase<TValue>

<input @attributes="AdditionalAttributes" type="radio" value="@SelectedValue"
       checked="@(SelectedValue.Equals(Value))" @onchange="OnChange" />

@code {
    [Parameter]
    public TValue SelectedValue { get; set; }

    private void OnChange(ChangeEventArgs args)
    {
        CurrentValueAsString = args.Value.ToString();
    }

    protected override bool TryParseValueFromString(string value,
        out TValue result, out string errorMessage)
    {
        var success = BindConverter.TryConvertTo<TValue>(
            value, CultureInfo.CurrentCulture, out var parsedValue);
        if (success)
        {
            result = parsedValue;
            errorMessage = null;

            return true;
        }
        else
        {
            result = default;
            errorMessage = $"{FieldIdentifier.FieldName} field isn't valid.";

            return false;
        }
    }
}
```

The following EditForm uses the preceding `InputRadio` component to obtain and validate a rating from the user:

```
@page "/RadioButtonExample"
@using System.ComponentModel.DataAnnotations

<h1>Radio Button Group Test</h1>

<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    @for (int i = 1; i <= 5; i++)
    {
        <label>
            <InputRadio name="rate" SelectedValue="i" @bind-Value="model.Rating" />
            @i
        </label>
    }

    <button type="submit">Submit</button>
</EditForm>

<p>You chose: @model.Rating</p>

@code {
    private Model model = new Model();

    private void HandleValidSubmit()
    {
        ...
    }

    public class Model
    {
        [Range(1, 5)]
        public int Rating { get; set; }
    }
}
```

Binding `<select>` element options to C# object `null` values

There's no sensible way to represent a `<select>` element option value as a C# object `null` value, because:

- HTML attributes can't have `null` values. The closest equivalent to `null` in HTML is absence of the HTML `value` attribute from the `<option>` element.
- When selecting an `<option>` with no `value` attribute, the browser treats the value as the *text content* of that `<option>`'s element.

The Blazor framework doesn't attempt to suppress the default behavior because it would involve:

- Creating a chain of special-case workarounds in the framework.
- Breaking changes to current framework behavior.

The most plausible `null` equivalent in HTML is an *empty string* `value`. The Blazor framework handles `null` to empty string conversions for two-way binding to a `<select>`'s value.

The Blazor framework doesn't automatically handle `null` to empty string conversions when attempting two-way binding to a `<select>`'s value. For more information, see Fix binding `<select>` to a null value (dotnet/aspnetcore #23221).

Validation support

The DataAnnotationsValidator component attaches validation support using data annotations to the cascaded

EditContext. Enabling support for validation using data annotations requires this explicit gesture. To use a different validation system than data annotations, replace the DataAnnotationsValidator with a custom implementation. The ASP.NET Core implementation is available for inspection in the reference source: `DataAnnotationsValidator` / `AddDataAnnotationsValidation`. The preceding links to reference source provide code from the repository's `master` branch, which represents the product unit's current development for the next release of ASP.NET Core. To select the branch for a different release, use the GitHub branch selector (for example `release/3.1`).

Blazor performs two types of validation:

- *Field validation* is performed when the user tabs out of a field. During field validation, the DataAnnotationsValidator component associates all reported validation results with the field.
- *Model validation* is performed when the user submits the form. During model validation, the DataAnnotationsValidator component attempts to determine the field based on the member name that the validation result reports. Validation results that aren't associated with an individual member are associated with the model rather than a field.

Validation Summary and Validation Message components

The ValidationSummary component summarizes all validation messages, which is similar to the Validation Summary Tag Helper:

```
<ValidationSummary />
```

Output validation messages for a specific model with the `Model` parameter:

```
<ValidationSummary Model="@starship" />
```

The ValidationMessage<TValue> component displays validation messages for a specific field, which is similar to the Validation Message Tag Helper. Specify the field for validation with the `For` attribute and a lambda expression naming the model property:

```
<ValidationMessage For="@(() => starship.MaximumAccommodation)" />
```

The ValidationMessage<TValue> and ValidationSummary components support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the generated `<div>` or `<ul>` element.

Control the style of validation messages in the app's stylesheet (`wwwroot/css/app.css` or `wwwroot/css/site.css`). The default `validation-message` class sets the text color of validation messages to red:

```
.validation-message {
    color: red;
}
```

Custom validation attributes

To ensure that a validation result is correctly associated with a field when using a custom validation attribute, pass the validation context's MemberName when creating the ValidationResult:

```
using System;
using System.ComponentModel.DataAnnotations;

private class CustomValidator : ValidationAttribute
{
    protected override ValidationResult IsValid(object value,
        ValidationContext validationContext)
    {
        ...

        return new ValidationResult("Validation message to user.",
            new[] { validationContext.MemberName });
    }
}
```

NOTE

ValidationContext.GetService is `null`. Injecting services for validation in the `IsValid` method isn't supported.

Custom validation class attributes

Custom validation class names are useful when integrating with CSS frameworks, such as Bootstrap. To specify custom validation class names, create a class derived from `FieldCssClassProvider` and set the class on the EditContext instance:

```
var editContext = new EditContext(model);
editContext.SetFieldCssClassProvider(new MyFieldClassProvider());

...

private class MyFieldClassProvider : FieldCssClassProvider
{
    public override string GetFieldCssClass(EditContext editContext,
        in FieldIdentifier fieldIdentifier)
    {
        var isValid = !editContext.GetValidationMessages(fieldIdentifier).Any();

        return isValid ? "good field" : "bad field";
    }
}
```

Blazor data annotations validation package

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` is a package that fills validation experience gaps using the DataAnnotationsValidator component. The package is currently *experimental*.

NOTE

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package has a latest version of *release candidate* at Nuget.org. Continue to use the *experimental* release candidate package at this time. The package's assembly might be moved to either the framework or the runtime in a future release. Watch the Announcements GitHub repository, the dotnet/aspnetcore GitHub repository, or this topic section for further updates.

[CompareProperty] attribute

The CompareAttribute doesn't work well with the DataAnnotationsValidator component because it doesn't associate the validation result with a specific member. This can result in inconsistent behavior between field-level validation and when the entire model is validated on a submit. The

`Microsoft.AspNetCore.Components.DataAnnotations.Validation` *experimental* package introduces an additional validation attribute, `ComparePropertyAttribute`, that works around these limitations. In a Blazor app, `[CompareProperty]` is a direct replacement for the `[Compare]` attribute.

Nested models, collection types, and complex types

Blazor provides support for validating form input using data annotations with the built-in DataAnnotationsValidator. However, the DataAnnotationsValidator only validates top-level properties of the model bound to the form that aren't collection- or complex-type properties.

To validate the bound model's entire object graph, including collection- and complex-type properties, use the `ObjectGraphDataAnnotationsValidator` provided by the *experimental* `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package:

```
<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <ObjectGraphDataAnnotationsValidator />
    ...
</EditForm>
```

Annotate model properties with `[ValidateComplexType]`. In the following model classes, the `ShipDescription` class contains additional data annotations to validate when the model is bound to the form:

`Starship.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    ...

    [ValidateComplexType]
    public ShipDescription ShipDescription { get; set; } =
        new ShipDescription();

    ...
}
```

`ShipDescription.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class ShipDescription
{
    [Required]
    [StringLength(40, ErrorMessage = "Description too long (40 char).")]
    public string ShortDescription { get; set; }

    [Required]
    [StringLength(240, ErrorMessage = "Description too long (240 char).")]
    public string LongDescription { get; set; }
}
```

Enable the submit button based on form validation

To enable and disable the submit button based on form validation:

- Use the form's EditContext to assign the model when the component is initialized.
- Validate the form in the context's OnFieldChanged callback to enable and disable the submit button.

- Unhook the event handler in the `Dispose` method. For more information, see ASP.NET Core Blazor lifecycle.

> **NOTE**
> When using an EditContext, don't also assign a Model to the EditForm.

```
@implements IDisposable

<EditForm EditContext="@editContext">
    <DataAnnotationsValidator />
    <ValidationSummary />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private bool formInvalid = true;
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
        editContext.OnFieldChanged += HandleFieldChanged;
    }

    private void HandleFieldChanged(object sender, FieldChangedEventArgs e)
    {
        formInvalid = !editContext.Validate();
        StateHasChanged();
    }

    public void Dispose()
    {
        editContext.OnFieldChanged -= HandleFieldChanged;
    }
}
```

In the preceding example, set `formInvalid` to `false` if:

- The form is preloaded with valid default values.
- You want the submit button enabled when the form loads.

A side effect of the preceding approach is that a ValidationSummary component is populated with invalid fields after the user interacts with any one field. This scenario can be addressed in either of the following ways:

- Don't use a ValidationSummary component on the form.
- Make the ValidationSummary component visible when the submit button is selected (for example, in a `HandleValidSubmit` method).

```
<EditForm EditContext="@editContext" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary style="@displaySummary" />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private string displaySummary = "display:none";

    ...

    private void HandleValidSubmit()
    {
        displaySummary = "display:block";
    }
}
```

Troubleshoot

> InvalidOperationException: EditForm requires a Model parameter, or an EditContext parameter, but not both.

Confirm that the EditForm has a Model **or** EditContext. Don't use both for the same form.

When assigning a Model to the form, confirm that the model type is instantiated, as the following example shows:

```
private ExampleModel exampleModel = new ExampleModel();
```

ASP.NET Core Blazor forms and validation

9/22/2020 • 22 minutes to read • Edit Online

By Daniel Roth, Rémi Bourgarel, and Luke Latham

Forms and validation are supported in Blazor using data annotations.

The following `ExampleModel` type defines validation logic using data annotations:

```
using System.ComponentModel.DataAnnotations;

public class ExampleModel
{
    [Required]
    [StringLength(10, ErrorMessage = "Name is too long.")]
    public string Name { get; set; }
}
```

A form is defined using the EditForm component. The following form demonstrates typical elements, components, and Razor code:

```
<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <InputText id="name" @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }
}
```

In the preceding example:

- The form validates user input in the `name` field using the validation defined in the `ExampleModel` type. The model is created in the component's `@code` block and held in a private field (`exampleModel`). The field is assigned to the `Model` attribute of the `<EditForm>` element.
- The InputText component's `@bind-Value` binds:
  - The model property (`exampleModel.Name`) to the InputText component's `Value` property. For more information on property binding, see ASP.NET Core Blazor data binding.
  - A change event delegate to the InputText component's `ValueChanged` property.
- The DataAnnotationsValidator validator component attaches validation support using data annotations.
- The ValidationSummary component summarizes validation messages.
- `HandleValidSubmit` is triggered when the form successfully submits (passes validation).

Built-in forms components

A set of built-in components are available to receive and validate user input. Inputs are validated when they're changed and when a form is submitted. Available input components are shown in the following table.

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
`InputFile`	`<input type="file">`
InputNumber<TValue>	`<input type="number">`
`InputRadio`	`<input type="radio">`
`InputRadioGroup`	`<input type="radio">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
InputNumber<TValue>	`<input type="number">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

> **NOTE**
>
> The `InputRadio` and `InputRadioGroup` components are available in ASP.NET Core 5.0 or later. For more information, select a 5.0 or later version of this article.

All of the input components, including EditForm, support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the rendered HTML element.

Input components provide default behavior for validating when a field is changed, including updating the field CSS class to reflect the field state. Some components include useful parsing logic. For example, InputDate<TValue> and InputNumber<TValue> handle unparseable values gracefully by registering unparseable values as validation errors. Types that can accept null values also support nullability of the target field (for example, `int?`).

The following `Starship` type defines validation logic using a larger set of properties and data annotations than the

earlier `ExampleModel`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    [Required]
    [StringLength(16, ErrorMessage = "Identifier too long (16 character limit).")]
    public string Identifier { get; set; }

    public string Description { get; set; }

    [Required]
    public string Classification { get; set; }

    [Range(1, 100000, ErrorMessage = "Accommodation invalid (1-100000).")]
    public int MaximumAccommodation { get; set; }

    [Required]
    [Range(typeof(bool), "true", "true",
        ErrorMessage = "This form disallows unapproved ships.")]
    public bool IsValidatedDesign { get; set; }

    [Required]
    public DateTime ProductionDate { get; set; }
}
```

In the preceding example, `Description` is optional because no data annotations are present.

The following form validates user input using the validation defined in the `Starship` model:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <p>
        <label>
            Identifier:
            <InputText @bind-Value="starship.Identifier" />
        </label>
    </p>
    <p>
        <label>
            Description (optional):
            <InputTextArea @bind-Value="starship.Description" />
        </label>
    </p>
    <p>
        <label>
            Primary Classification:
            <InputSelect @bind-Value="starship.Classification">
                <option value="">Select classification ...</option>
                <option value="Exploration">Exploration</option>
                <option value="Diplomacy">Diplomacy</option>
                <option value="Defense">Defense</option>
            </InputSelect>
        </label>
    </p>
    <p>
```

```
        <label>
            Maximum Accommodation:
            <InputNumber @bind-Value="starship.MaximumAccommodation" />
        </label>
    </p>
    <p>
        <label>
            Engineering Approval:
            <InputCheckbox @bind-Value="starship.IsValidatedDesign" />
        </label>
    </p>
    <p>
        <label>
            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" />
        </label>
    </p>

    <button type="submit">Submit</button>

    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        ...
    }
}
```

The EditForm creates an EditContext as a cascading value that tracks metadata about the edit process, including which fields have been modified and the current validation messages.

Assign **either** an EditContext **or** an EditForm.Model to an EditForm. Assignment of both isn't supported and generates a **runtime error**.

The EditForm provides convenient events for valid and invalid form submission:

- OnValidSubmit
- OnInvalidSubmit

Use OnSubmit to use custom code to trigger validation and check field values.

In the following example:

- The `HandleSubmit` method executes when the `Submit` button is selected.
- The form is validated by calling EditContext.Validate.
- Additional code is executed depending on the validation result. Place business logic in the method assigned to OnSubmit.

```
<EditForm EditContext="@editContext" OnSubmit="@HandleSubmit">

    ...

    <button type="submit">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
    }

    private async Task HandleSubmit()
    {
        var isValid = editContext.Validate();

        if (isValid)
        {
            ...
        }
        else
        {
            ...
        }
    }
}
```

NOTE

Framework API doesn't exist to clear validation messages directly from an EditContext. Therefore, we don't generally recommend adding validation messages to a new ValidationMessageStore in a form. To manage validation messages, use a validator component with your business logic validation code, as described in this article.

Display name support

This section applies to ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.

The following built-in components support display names with the `DisplayName` parameter:

- InputDate<TValue>
- InputNumber<TValue>
- InputSelect<TValue>

In the following `InputDate` component example:

- The display name (`DisplayName`) is set to `birthday`.
- The component is bound to the `BirthDate` property as a `DateTime` type.

```
<InputDate @bind-Value="@BirthDate" DisplayName="birthday" />

@code {
    public DateTime BirthDate { get; set; }
}
```

If the user doesn't provide a date value, the validation error appears as:

```
The birthday must be a date.
```

Validator components

Validator components support form validation by managing a ValidationMessageStore for a form's EditContext.

The Blazor framework provides the DataAnnotationsValidator component to attach validation support to forms based on validation attributes (data annotations). Create custom validator components to process validation messages for different forms on the same page or the same form at different steps of form processing, for example client-side validation followed by server-side validation. The validator component example shown in this section, `CustomValidator`, is used in the following sections of this article:

- Business logic validation
- Server validation

> **NOTE**
> Custom data annotation validation attributes can be used instead of custom validator components in many cases. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, any custom attributes applied to the model must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Create a validator component from ComponentBase:

- The form's EditContext is a cascading parameter of the component.
- When the validator component is initialized, a new ValidationMessageStore is created to maintain a current list of form errors.
- The message store receives errors when developer code in the form's component calls the `DisplayErrors` method. The errors are passed to the `DisplayErrors` method in a `Dictionary<string, List<string>>`. In the dictionary, the key is the name of the form field that has one or more errors. The value is the error list.
- Messages are cleared when any of the following have occurred:
  - Validation is requested on the EditContext when the OnValidationRequested event is raised. All of the errors are cleared.
  - A field changes in the form when the OnFieldChanged event is raised. Only the errors for the field are cleared.
  - The `ClearErrors` method is called by developer code. All of the errors are cleared.

```
using System;
using System.Collections.Generic;
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Forms;

namespace BlazorSample.Client
{
    public class CustomValidator : ComponentBase
    {
        private ValidationMessageStore messageStore;

        [CascadingParameter]
        private EditContext CurrentEditContext { get; set; }

        protected override void OnInitialized()
        {
            if (CurrentEditContext == null)
            {
                throw new InvalidOperationException(
                    $"{nameof(CustomValidator)} requires a cascading " +
                    $"parameter of type {nameof(EditContext)}. " +
                    $"For example, you can use {nameof(CustomValidator)} " +
                    $"inside an {nameof(EditForm)}.");
            }

            messageStore = new ValidationMessageStore(CurrentEditContext);

            CurrentEditContext.OnValidationRequested += (s, e) =>
                messageStore.Clear();
            CurrentEditContext.OnFieldChanged += (s, e) =>
                messageStore.Clear(e.FieldIdentifier);
        }

        public void DisplayErrors(Dictionary<string, List<string>> errors)
        {
            foreach (var err in errors)
            {
                messageStore.Add(CurrentEditContext.Field(err.Key), err.Value);
            }

            CurrentEditContext.NotifyValidationStateChanged();
        }

        public void ClearErrors()
        {
            messageStore.Clear();
            CurrentEditContext.NotifyValidationStateChanged();
        }
    }
}
```

Business logic validation

Business logic validation can be accomplished with a validator component that receives form errors in a dictionary.

In the following example:

- The `CustomValidator` component from the Validator components section of this article is used.
- The validation requires a value for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

When validation messages are set in the component, they're added to the validator's ValidationMessageStore and shown in the EditForm:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    ...

</EditForm>

@code {
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        customValidator.ClearErrors();

        var errors = new Dictionary<string, List<string>>();

        if (starship.Classification == "Defense" &&
                string.IsNullOrEmpty(starship.Description))
        {
            errors.Add(nameof(starship.Description),
                new List<string>() { "For a 'Defense' ship classification, " +
                "'Description' is required." });
        }

        if (errors.Count() > 0)
        {
            customValidator.DisplayErrors(errors);
        }
        else
        {
            // Process the form
        }
    }
}
```

NOTE

As an alternative to using validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Server validation

Server validation can be accomplished with a server validator component:

- Process client-side validation in the form with the DataAnnotationsValidator component.
- When the form passes client-side validation (OnValidSubmit is called), send the EditContext.Model to a backend server API for form processing.
- Process model validation on the server.
- The server API includes both the built-in framework data annotations validation and custom validation logic supplied by the developer. If validation passes on the server, process the form and send back a success status code (*200 - OK*). If validation fails, return a failure status code (*400 - Bad Request*) and the field validation errors.

- Either disable the form on success or display the errors.

The following example is based on:

- A hosted Blazor solution created by the Blazor Hosted project template. The example can be used with any of the secure hosted Blazor solutions described in the Security and Identity documentation.
- The *Starfleet Starship Database* form example in the preceding Built-in forms components section.
- The Blazor framework's DataAnnotationsValidator component.
- The `CustomValidator` component shown in the Validator components section.

In the following example, the server API validates that a value is provided for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

Place the `Starship` model into the solution's `Shared` project so that both the client and server apps can use the model. Since the model requires data annotations, add a package reference for `System.ComponentModel.Annotations` to the `Shared` project's project file:

```
<ItemGroup>
  <PackageReference Include="System.ComponentModel.Annotations" Version="{VERSION}" />
</ItemGroup>
```

To determine the latest non-preview version of the package, see the package **Version History** at NuGet.org.

In the server API project, add a controller to process starship validation requests (`Controllers/StarshipValidation.cs`) and return failed validation messages:

```
using System;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Logging;
using BlazorSample.Shared;

namespace BlazorSample.Server.Controllers
{
    [Authorize]
    [ApiController]
    [Route("[controller]")]
    public class StarshipValidationController : ControllerBase
    {
        private readonly ILogger<StarshipValidationController> logger;

        public StarshipValidationController(
            ILogger<StarshipValidationController> logger)
        {
            this.logger = logger;
        }

        [HttpPost]
        public async Task<IActionResult> Post(Starship starship)
        {
            try
            {
                if (starship.Classification == "Defense" &&
                    string.IsNullOrEmpty(starship.Description))
                {
                    ModelState.AddModelError(nameof(starship.Description),
                        "For a 'Defense' ship " +
                        "classification, 'Description' is required.");
                }
                else
                {
                    // Process the form asynchronously
                    // async ...

                    return Ok(ModelState);
                }
            }
            catch (Exception ex)
            {
                logger.LogError("Validation Error: {MESSAGE}", ex.Message);
            }

            return BadRequest(ModelState);
        }
    }
}
```

When a model binding validation error occurs on the server, an `ApiController` (ApiControllerAttribute) normally returns a default bad request response with a ValidationProblemDetails. The response contains more data than just the validation errors, as shown in the following example when all of the fields of the *Starfleet Starship Database* form aren't submitted and the form fails validation:

```
{
  "title": "One or more validation errors occurred.",
  "status": 400,
  "errors": {
    "Identifier": ["The Identifier field is required."],
    "Classification": ["The Classification field is required."],
    "IsValidatedDesign": ["This form disallows unapproved ships."],
    "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
  }
}
```

If the server API returns the preceding default JSON response, it's possible for the client to parse the response to obtain the children of the `errors` node. However, it's inconvenient to parse the file. Parsing the JSON requires additional code after calling ReadFromJsonAsync in order to produce a `Dictionary<string, List<string>>` of errors for forms validation error processing. Ideally, the server API should only return the validation errors:

```
{
  "Identifier": ["The Identifier field is required."],
  "Classification": ["The Classification field is required."],
  "IsValidatedDesign": ["This form disallows unapproved ships."],
  "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
}
```

To modify the server API's response to make it only return the validation errors, change the delegate that's invoked on actions that are annotated with ApiControllerAttribute in `Startup.ConfigureServices`. For the API endpoint (`/StarshipValidation`), return a BadRequestObjectResult with the ModelStateDictionary. For any other API endpoints, preserve the default behavior by returning the object result with a new ValidationProblemDetails:

```
using Microsoft.AspNetCore.Mvc;

...

services.AddControllersWithViews()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.InvalidModelStateResponseFactory = context =>
        {
            if (context.HttpContext.Request.Path == "/StarshipValidation")
            {
                return new BadRequestObjectResult(context.ModelState);
            }
            else
            {
                return new BadRequestObjectResult(
                    new ValidationProblemDetails(context.ModelState));
            }
        };
    });
```

For more information, see Handle errors in ASP.NET Core web APIs.

In the client project, add the validator component shown in the Validator components section.

In the client project, the *Starfleet Starship Database* form is updated to show server validation errors with help of the `CustomValidator` component. When the server API returns validation messages, they're added to the `CustomValidator` component's ValidationMessageStore. The errors are available in the form's EditContext for display by the form's ValidationSummary:

```
@page "/FormValidation"
```

```
@using System.Net
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@using Microsoft.Extensions.Logging
@using BlazorSample.Shared
@attribute [Authorize]
@inject HttpClient Http
@inject ILogger<FormValidation> Logger

<h1>Starfleet Starship Database</h1>

        try
        {
            var response = await Http.PostAsJsonAsync<Starship>(
                "StarshipValidation", (Starship)editContext.Model);

            var errors = await response.Content
                .ReadFromJsonAsync<Dictionary<string, List<string>>>();

            if (response.StatusCode == HttpStatusCode.BadRequest &&
                errors.Count() > 0)
            {
                customValidator.DisplayErrors(errors);
            }
            else if (!response.IsSuccessStatusCode)
            {
                throw new HttpRequestException(
                    $"Validation failed. Status Code: {response.StatusCode}");
            }
            else
            {
                disabled = true;
                messageStyles = "color:green";
                message = "The form has been processed.";
            }
        }
        catch (AccessTokenNotAvailableException ex)
        {
            ex.Redirect();
        }
        catch (Exception ex)
        {
            Logger.LogError("Form processing error: {MESSAGE}", ex.Message);
            disabled = true;
            messageStyles = "color:red";
            message = "There was an error processing the form.";
        }
    }
}
```

NOTE

As an alternative to validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

NOTE

The server-side validation approach in this section is suitable for any of the Blazor WebAssembly hosted solution examples in this documentation set:

- Azure Active Directory (AAD)
- Azure Active Directory (AAD) B2C
- Identity Server

InputText based on the input event

Use the InputText component to create a custom component that uses the `input` event instead of the `change` event.

In the following example, the `CustomInputText` component inherits the framework's `InputText` component and sets the event binding (CreateBinder) to the `oninput` event.

`Shared/CustomInputText.razor`:

```
@inherits InputText

<input
    @attributes="AdditionalAttributes"
    class="@CssClass"
    value="@CurrentValue"
    @oninput="EventCallback.Factory.CreateBinder<string>(
         this, __value => CurrentValueAsString = __value,
         CurrentValueAsString)" />
```

The `CustomInputText` component can be used anywhere InputText is used:

`Pages/TestForm.razor`:

```
@page "/testform"
@using System.ComponentModel.DataAnnotations;

<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <CustomInputText @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

<p>
    CurrentValue: @exampleModel.Name
</p>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }

    public class ExampleModel
    {
        [Required]
        [StringLength(10, ErrorMessage = "Name is too long.")]
        public string Name { get; set; }
    }
}
```

Radio buttons

Use `InputRadio` components with the `InputRadioGroup` component to create a radio button group. In the following example, properties are added to the `Starship` model described in the Built-in forms components section:

```
[Required]
[Range(typeof(Manufacturer), nameof(Manufacturer.SpaceX),
    nameof(Manufacturer.VirginGalactic), ErrorMessage = "Pick a manufacturer.")]
public Manufacturer Manufacturer { get; set; } = Manufacturer.Unknown;

[Required, EnumDataType(typeof(Color))]
public Color? Color { get; set; } = null;

[Required, EnumDataType(typeof(Engine))]
public Engine? Engine { get; set; } = null;
```

Add the following `enums` to the app. Create a new file to hold the `enums` or add the `enums` to the `Starship.cs` file. Make the `enums` accessible to the `Starship` model and the *Starfleet Starship Database* form:

```
public enum Manufacturer { SpaceX, NASA, ULA, Virgin, Unknown }
public enum Color { ImperialRed, SpacecruiserGreen, StarshipBlue, VoyagerOrange }
public enum Engine { Ion, Plasma, Fusion, Warp }
```

Update the *Starfleet Starship Database* form described in the Built-in forms components section. Add the components to produce:

- A radio button group for the ship manufacturer.
- A nested radio button group for ship color and engine.

```
<p>
    <InputRadioGroup @bind-Value="starship.Manufacturer">
        Manufacturer:
        <br>
        @foreach (var manufacturer in (Manufacturer[])Enum
            .GetValues(typeof(Manufacturer)))
        {
            <InputRadio Value="manufacturer" />
            @manufacturer
            <br>
        }
    </InputRadioGroup>
</p>

<p>
    Pick one color and one engine:
    <InputRadioGroup Name="engine" @bind-Value="starship.Engine">
        <InputRadioGroup Name="color" @bind-Value="starship.Color">
            <InputRadio Name="color" Value="Color.ImperialRed" />Imperial Red<br>
            <InputRadio Name="engine" Value="Engine.Ion" />Ion<br>
            <InputRadio Name="color" Value="Color.SpacecruiserGreen" />
                Spacecruiser Green<br>
            <InputRadio Name="engine" Value="Engine.Plasma" />Plasma<br>
            <InputRadio Name="color" Value="Color.StarshipBlue" />Starship Blue<br>
            <InputRadio Name="engine" Value="Engine.Fusion" />Fusion<br>
            <InputRadio Name="color" Value="Color.VoyagerOrange" />
                Voyager Orange<br>
            <InputRadio Name="engine" Value="Engine.Warp" />Warp<br>
        </InputRadioGroup>
    </InputRadioGroup>
</p>
```

NOTE

If `Name` is omitted, `InputRadio` components are grouped by their most recent ancestor.

When working with radio buttons in a form, data binding is handled differently than other elements because radio buttons are evaluated as a group. The value of each radio button is fixed, but the value of the radio button group is the value of the selected radio button. The following example shows how to:

- Handle data binding for a radio button group.
- Support validation using a custom `InputRadio` component.

```
@using System.Globalization
@typeparam TValue
@inherits InputBase<TValue>

<input @attributes="AdditionalAttributes" type="radio" value="@SelectedValue"
       checked="@(SelectedValue.Equals(Value))" @onchange="OnChange" />

@code {
    [Parameter]
    public TValue SelectedValue { get; set; }

    private void OnChange(ChangeEventArgs args)
    {
        CurrentValueAsString = args.Value.ToString();
    }

    protected override bool TryParseValueFromString(string value,
        out TValue result, out string errorMessage)
    {
        var success = BindConverter.TryConvertTo<TValue>(
            value, CultureInfo.CurrentCulture, out var parsedValue);
        if (success)
        {
            result = parsedValue;
            errorMessage = null;

            return true;
        }
        else
        {
            result = default;
            errorMessage = $"{FieldIdentifier.FieldName} field isn't valid.";

            return false;
        }
    }
}
```

The following EditForm uses the preceding `InputRadio` component to obtain and validate a rating from the user:

```
@page "/RadioButtonExample"
@using System.ComponentModel.DataAnnotations

<h1>Radio Button Group Test</h1>

<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    @for (int i = 1; i <= 5; i++)
    {
        <label>
            <InputRadio name="rate" SelectedValue="i" @bind-Value="model.Rating" />
            @i
        </label>
    }

    <button type="submit">Submit</button>
</EditForm>

<p>You chose: @model.Rating</p>

@code {
    private Model model = new Model();

    private void HandleValidSubmit()
    {
        ...
    }

    public class Model
    {
        [Range(1, 5)]
        public int Rating { get; set; }
    }
}
```

Binding `<select>` element options to C# object `null` values

There's no sensible way to represent a `<select>` element option value as a C# object `null` value, because:

- HTML attributes can't have `null` values. The closest equivalent to `null` in HTML is absence of the HTML `value` attribute from the `<option>` element.
- When selecting an `<option>` with no `value` attribute, the browser treats the value as the *text content* of that `<option>`'s element.

The Blazor framework doesn't attempt to suppress the default behavior because it would involve:

- Creating a chain of special-case workarounds in the framework.
- Breaking changes to current framework behavior.

The most plausible `null` equivalent in HTML is an *empty string* `value`. The Blazor framework handles `null` to empty string conversions for two-way binding to a `<select>`'s value.

The Blazor framework doesn't automatically handle `null` to empty string conversions when attempting two-way binding to a `<select>`'s value. For more information, see Fix binding `<select>` to a null value (dotnet/aspnetcore #23221).

Validation support

The DataAnnotationsValidator component attaches validation support using data annotations to the cascaded

EditContext. Enabling support for validation using data annotations requires this explicit gesture. To use a different validation system than data annotations, replace the DataAnnotationsValidator with a custom implementation. The ASP.NET Core implementation is available for inspection in the reference source: `DataAnnotationsValidator` / `AddDataAnnotationsValidation`. The preceding links to reference source provide code from the repository's `master` branch, which represents the product unit's current development for the next release of ASP.NET Core. To select the branch for a different release, use the GitHub branch selector (for example `release/3.1`).

Blazor performs two types of validation:

- *Field validation* is performed when the user tabs out of a field. During field validation, the DataAnnotationsValidator component associates all reported validation results with the field.
- *Model validation* is performed when the user submits the form. During model validation, the DataAnnotationsValidator component attempts to determine the field based on the member name that the validation result reports. Validation results that aren't associated with an individual member are associated with the model rather than a field.

Validation Summary and Validation Message components

The ValidationSummary component summarizes all validation messages, which is similar to the Validation Summary Tag Helper:

```
<ValidationSummary />
```

Output validation messages for a specific model with the `Model` parameter:

```
<ValidationSummary Model="@starship" />
```

The ValidationMessage<TValue> component displays validation messages for a specific field, which is similar to the Validation Message Tag Helper. Specify the field for validation with the `For` attribute and a lambda expression naming the model property:

```
<ValidationMessage For="@(() => starship.MaximumAccommodation)" />
```

The ValidationMessage<TValue> and ValidationSummary components support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the generated `<div>` or `<ul>` element.

Control the style of validation messages in the app's stylesheet (`wwwroot/css/app.css` or `wwwroot/css/site.css`). The default `validation-message` class sets the text color of validation messages to red:

```
.validation-message {
    color: red;
}
```

Custom validation attributes

To ensure that a validation result is correctly associated with a field when using a custom validation attribute, pass the validation context's MemberName when creating the ValidationResult:

```
using System;
using System.ComponentModel.DataAnnotations;

private class CustomValidator : ValidationAttribute
{
    protected override ValidationResult IsValid(object value,
        ValidationContext validationContext)
    {
        ...

        return new ValidationResult("Validation message to user.",
            new[] { validationContext.MemberName });
    }
}
```

NOTE

ValidationContext.GetService is `null`. Injecting services for validation in the `IsValid` method isn't supported.

Custom validation class attributes

Custom validation class names are useful when integrating with CSS frameworks, such as Bootstrap. To specify custom validation class names, create a class derived from `FieldCssClassProvider` and set the class on the EditContext instance:

```
var editContext = new EditContext(model);
editContext.SetFieldCssClassProvider(new MyFieldClassProvider());

...

private class MyFieldClassProvider : FieldCssClassProvider
{
    public override string GetFieldCssClass(EditContext editContext,
        in FieldIdentifier fieldIdentifier)
    {
        var isValid = !editContext.GetValidationMessages(fieldIdentifier).Any();

        return isValid ? "good field" : "bad field";
    }
}
```

Blazor data annotations validation package

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` is a package that fills validation experience gaps using the DataAnnotationsValidator component. The package is currently *experimental*.

NOTE

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package has a latest version of *release candidate* at Nuget.org. Continue to use the *experimental* release candidate package at this time. The package's assembly might be moved to either the framework or the runtime in a future release. Watch the Announcements GitHub repository, the dotnet/aspnetcore GitHub repository, or this topic section for further updates.

[CompareProperty] attribute

The CompareAttribute doesn't work well with the DataAnnotationsValidator component because it doesn't associate the validation result with a specific member. This can result in inconsistent behavior between field-level validation and when the entire model is validated on a submit. The

`Microsoft.AspNetCore.Components.DataAnnotations.Validation` *experimental* package introduces an additional validation attribute, `ComparePropertyAttribute`, that works around these limitations. In a Blazor app, `[CompareProperty]` is a direct replacement for the `[Compare]` attribute.

Nested models, collection types, and complex types

Blazor provides support for validating form input using data annotations with the built-in DataAnnotationsValidator. However, the DataAnnotationsValidator only validates top-level properties of the model bound to the form that aren't collection- or complex-type properties.

To validate the bound model's entire object graph, including collection- and complex-type properties, use the `ObjectGraphDataAnnotationsValidator` provided by the *experimental* `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package:

```
<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <ObjectGraphDataAnnotationsValidator />
    ...
</EditForm>
```

Annotate model properties with `[ValidateComplexType]`. In the following model classes, the `ShipDescription` class contains additional data annotations to validate when the model is bound to the form:

`Starship.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    ...

    [ValidateComplexType]
    public ShipDescription ShipDescription { get; set; } =
        new ShipDescription();

    ...
}
```

`ShipDescription.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class ShipDescription
{
    [Required]
    [StringLength(40, ErrorMessage = "Description too long (40 char).")]
    public string ShortDescription { get; set; }

    [Required]
    [StringLength(240, ErrorMessage = "Description too long (240 char).")]
    public string LongDescription { get; set; }
}
```

Enable the submit button based on form validation

To enable and disable the submit button based on form validation:

- Use the form's EditContext to assign the model when the component is initialized.
- Validate the form in the context's OnFieldChanged callback to enable and disable the submit button.

- Unhook the event handler in the `Dispose` method. For more information, see ASP.NET Core Blazor lifecycle.

> **NOTE**
> When using an EditContext, don't also assign a Model to the EditForm.

```
@implements IDisposable

<EditForm EditContext="@editContext">
    <DataAnnotationsValidator />
    <ValidationSummary />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private bool formInvalid = true;
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
        editContext.OnFieldChanged += HandleFieldChanged;
    }

    private void HandleFieldChanged(object sender, FieldChangedEventArgs e)
    {
        formInvalid = !editContext.Validate();
        StateHasChanged();
    }

    public void Dispose()
    {
        editContext.OnFieldChanged -= HandleFieldChanged;
    }
}
```

In the preceding example, set `formInvalid` to `false` if:

- The form is preloaded with valid default values.
- You want the submit button enabled when the form loads.

A side effect of the preceding approach is that a ValidationSummary component is populated with invalid fields after the user interacts with any one field. This scenario can be addressed in either of the following ways:

- Don't use a ValidationSummary component on the form.
- Make the ValidationSummary component visible when the submit button is selected (for example, in a `HandleValidSubmit` method).

```
<EditForm EditContext="@editContext" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary style="@displaySummary" />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private string displaySummary = "display:none";

    ...

    private void HandleValidSubmit()
    {
        displaySummary = "display:block";
    }
}
```

Troubleshoot

> InvalidOperationException: EditForm requires a Model parameter, or an EditContext parameter, but not both.

Confirm that the EditForm has a Model **or** EditContext. Don't use both for the same form.

When assigning a Model to the form, confirm that the model type is instantiated, as the following example shows:

```
private ExampleModel exampleModel = new ExampleModel();
```

ASP.NET Core Blazor forms and validation

9/22/2020 • 22 minutes to read • Edit Online

By Daniel Roth, Rémi Bourgarel, and Luke Latham

Forms and validation are supported in Blazor using data annotations.

The following `ExampleModel` type defines validation logic using data annotations:

```
using System.ComponentModel.DataAnnotations;

public class ExampleModel
{
    [Required]
    [StringLength(10, ErrorMessage = "Name is too long.")]
    public string Name { get; set; }
}
```

A form is defined using the EditForm component. The following form demonstrates typical elements, components, and Razor code:

```
<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <InputText id="name" @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }
}
```

In the preceding example:

- The form validates user input in the `name` field using the validation defined in the `ExampleModel` type. The model is created in the component's `@code` block and held in a private field (`exampleModel`). The field is assigned to the `Model` attribute of the `<EditForm>` element.
- The InputText component's `@bind-Value` binds:
  - The model property (`exampleModel.Name`) to the InputText component's `Value` property. For more information on property binding, see ASP.NET Core Blazor data binding.
  - A change event delegate to the InputText component's `ValueChanged` property.
- The DataAnnotationsValidator validator component attaches validation support using data annotations.
- The ValidationSummary component summarizes validation messages.
- `HandleValidSubmit` is triggered when the form successfully submits (passes validation).

Built-in forms components

A set of built-in components are available to receive and validate user input. Inputs are validated when they're changed and when a form is submitted. Available input components are shown in the following table.

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
`InputFile`	`<input type="file">`
InputNumber<TValue>	`<input type="number">`
`InputRadio`	`<input type="radio">`
`InputRadioGroup`	`<input type="radio">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
InputNumber<TValue>	`<input type="number">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

> **NOTE**
>
> The `InputRadio` and `InputRadioGroup` components are available in ASP.NET Core 5.0 or later. For more information, select a 5.0 or later version of this article.

All of the input components, including EditForm, support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the rendered HTML element.

Input components provide default behavior for validating when a field is changed, including updating the field CSS class to reflect the field state. Some components include useful parsing logic. For example, InputDate<TValue> and InputNumber<TValue> handle unparseable values gracefully by registering unparseable values as validation errors. Types that can accept null values also support nullability of the target field (for example, `int?`).

The following `Starship` type defines validation logic using a larger set of properties and data annotations than the

earlier `ExampleModel`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    [Required]
    [StringLength(16, ErrorMessage = "Identifier too long (16 character limit).")]
    public string Identifier { get; set; }

    public string Description { get; set; }

    [Required]
    public string Classification { get; set; }

    [Range(1, 100000, ErrorMessage = "Accommodation invalid (1-100000).")]
    public int MaximumAccommodation { get; set; }

    [Required]
    [Range(typeof(bool), "true", "true",
        ErrorMessage = "This form disallows unapproved ships.")]
    public bool IsValidatedDesign { get; set; }

    [Required]
    public DateTime ProductionDate { get; set; }
}
```

In the preceding example, `Description` is optional because no data annotations are present.

The following form validates user input using the validation defined in the `Starship` model:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <p>
        <label>
            Identifier:
            <InputText @bind-Value="starship.Identifier" />
        </label>
    </p>
    <p>
        <label>
            Description (optional):
            <InputTextArea @bind-Value="starship.Description" />
        </label>
    </p>
    <p>
        <label>
            Primary Classification:
            <InputSelect @bind-Value="starship.Classification">
                <option value="">Select classification ...</option>
                <option value="Exploration">Exploration</option>
                <option value="Diplomacy">Diplomacy</option>
                <option value="Defense">Defense</option>
            </InputSelect>
        </label>
    </p>
    <p>
```

```
        <label>
            Maximum Accommodation:
            <InputNumber @bind-Value="starship.MaximumAccommodation" />
        </label>
    </p>
    <p>
        <label>
            Engineering Approval:
            <InputCheckbox @bind-Value="starship.IsValidatedDesign" />
        </label>
    </p>
    <p>
        <label>
            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" />
        </label>
    </p>

    <button type="submit">Submit</button>

    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        ...
    }
}
```

The EditForm creates an EditContext as a cascading value that tracks metadata about the edit process, including which fields have been modified and the current validation messages.

Assign **either** an EditContext **or** an EditForm.Model to an EditForm. Assignment of both isn't supported and generates a **runtime error**.

The EditForm provides convenient events for valid and invalid form submission:

- OnValidSubmit
- OnInvalidSubmit

Use OnSubmit to use custom code to trigger validation and check field values.

In the following example:

- The `HandleSubmit` method executes when the `Submit` button is selected.
- The form is validated by calling EditContext.Validate.
- Additional code is executed depending on the validation result. Place business logic in the method assigned to OnSubmit.

```
<EditForm EditContext="@editContext" OnSubmit="@HandleSubmit">

    ...

    <button type="submit">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
    }

    private async Task HandleSubmit()
    {
        var isValid = editContext.Validate();

        if (isValid)
        {
            ...
        }
        else
        {
            ...
        }
    }
}
```

NOTE

Framework API doesn't exist to clear validation messages directly from an EditContext. Therefore, we don't generally recommend adding validation messages to a new ValidationMessageStore in a form. To manage validation messages, use a validator component with your business logic validation code, as described in this article.

Display name support

This section applies to ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.

The following built-in components support display names with the `DisplayName` parameter:

- InputDate<TValue>
- InputNumber<TValue>
- InputSelect<TValue>

In the following `InputDate` component example:

- The display name (`DisplayName`) is set to `birthday`.
- The component is bound to the `BirthDate` property as a `DateTime` type.

```
<InputDate @bind-Value="@BirthDate" DisplayName="birthday" />

@code {
    public DateTime BirthDate { get; set; }
}
```

If the user doesn't provide a date value, the validation error appears as:

```
The birthday must be a date.
```

Validator components

Validator components support form validation by managing a ValidationMessageStore for a form's EditContext.

The Blazor framework provides the DataAnnotationsValidator component to attach validation support to forms based on validation attributes (data annotations). Create custom validator components to process validation messages for different forms on the same page or the same form at different steps of form processing, for example client-side validation followed by server-side validation. The validator component example shown in this section, `CustomValidator`, is used in the following sections of this article:

- Business logic validation
- Server validation

> **NOTE**
> Custom data annotation validation attributes can be used instead of custom validator components in many cases. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, any custom attributes applied to the model must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Create a validator component from ComponentBase:

- The form's EditContext is a cascading parameter of the component.
- When the validator component is initialized, a new ValidationMessageStore is created to maintain a current list of form errors.
- The message store receives errors when developer code in the form's component calls the `DisplayErrors` method. The errors are passed to the `DisplayErrors` method in a `Dictionary<string, List<string>>`. In the dictionary, the key is the name of the form field that has one or more errors. The value is the error list.
- Messages are cleared when any of the following have occurred:
  - Validation is requested on the EditContext when the OnValidationRequested event is raised. All of the errors are cleared.
  - A field changes in the form when the OnFieldChanged event is raised. Only the errors for the field are cleared.
  - The `ClearErrors` method is called by developer code. All of the errors are cleared.

```
using System;
using System.Collections.Generic;
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Forms;

namespace BlazorSample.Client
{
    public class CustomValidator : ComponentBase
    {
        private ValidationMessageStore messageStore;

        [CascadingParameter]
        private EditContext CurrentEditContext { get; set; }

        protected override void OnInitialized()
        {
            if (CurrentEditContext == null)
            {
                throw new InvalidOperationException(
                    $"{nameof(CustomValidator)} requires a cascading " +
                    $"parameter of type {nameof(EditContext)}. " +
                    $"For example, you can use {nameof(CustomValidator)} " +
                    $"inside an {nameof(EditForm)}.");
            }

            messageStore = new ValidationMessageStore(CurrentEditContext);

            CurrentEditContext.OnValidationRequested += (s, e) =>
                messageStore.Clear();
            CurrentEditContext.OnFieldChanged += (s, e) =>
                messageStore.Clear(e.FieldIdentifier);
        }

        public void DisplayErrors(Dictionary<string, List<string>> errors)
        {
            foreach (var err in errors)
            {
                messageStore.Add(CurrentEditContext.Field(err.Key), err.Value);
            }

            CurrentEditContext.NotifyValidationStateChanged();
        }

        public void ClearErrors()
        {
            messageStore.Clear();
            CurrentEditContext.NotifyValidationStateChanged();
        }
    }
}
```

Business logic validation

Business logic validation can be accomplished with a validator component that receives form errors in a dictionary.

In the following example:

- The `CustomValidator` component from the Validator components section of this article is used.
- The validation requires a value for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

When validation messages are set in the component, they're added to the validator's ValidationMessageStore and shown in the EditForm:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    ...

</EditForm>

@code {
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        customValidator.ClearErrors();

        var errors = new Dictionary<string, List<string>>();

        if (starship.Classification == "Defense" &&
                string.IsNullOrEmpty(starship.Description))
        {
            errors.Add(nameof(starship.Description),
                new List<string>() { "For a 'Defense' ship classification, " +
                "'Description' is required." });
        }

        if (errors.Count() > 0)
        {
            customValidator.DisplayErrors(errors);
        }
        else
        {
            // Process the form
        }
    }
}
```

NOTE

As an alternative to using validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Server validation

Server validation can be accomplished with a server validator component:

- Process client-side validation in the form with the DataAnnotationsValidator component.
- When the form passes client-side validation (OnValidSubmit is called), send the EditContext.Model to a backend server API for form processing.
- Process model validation on the server.
- The server API includes both the built-in framework data annotations validation and custom validation logic supplied by the developer. If validation passes on the server, process the form and send back a success status code (*200 - OK*). If validation fails, return a failure status code (*400 - Bad Request*) and the field validation errors.

- Either disable the form on success or display the errors.

The following example is based on:

- A hosted Blazor solution created by the Blazor Hosted project template. The example can be used with any of the secure hosted Blazor solutions described in the Security and Identity documentation.
- The *Starfleet Starship Database* form example in the preceding Built-in forms components section.
- The Blazor framework's DataAnnotationsValidator component.
- The `CustomValidator` component shown in the Validator components section.

In the following example, the server API validates that a value is provided for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

Place the `Starship` model into the solution's `Shared` project so that both the client and server apps can use the model. Since the model requires data annotations, add a package reference for `System.ComponentModel.Annotations` to the `Shared` project's project file:

```
<ItemGroup>
  <PackageReference Include="System.ComponentModel.Annotations" Version="{VERSION}" />
</ItemGroup>
```

To determine the latest non-preview version of the package, see the package **Version History** at NuGet.org.

In the server API project, add a controller to process starship validation requests (`Controllers/StarshipValidation.cs`) and return failed validation messages:

```
using System;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Logging;
using BlazorSample.Shared;

namespace BlazorSample.Server.Controllers
{
    [Authorize]
    [ApiController]
    [Route("[controller]")]
    public class StarshipValidationController : ControllerBase
    {
        private readonly ILogger<StarshipValidationController> logger;

        public StarshipValidationController(
            ILogger<StarshipValidationController> logger)
        {
            this.logger = logger;
        }

        [HttpPost]
        public async Task<IActionResult> Post(Starship starship)
        {
            try
            {
                if (starship.Classification == "Defense" &&
                    string.IsNullOrEmpty(starship.Description))
                {
                    ModelState.AddModelError(nameof(starship.Description),
                        "For a 'Defense' ship " +
                        "classification, 'Description' is required.");
                }
                else
                {
                    // Process the form asynchronously
                    // async ...

                    return Ok(ModelState);
                }
            }
            catch (Exception ex)
            {
                logger.LogError("Validation Error: {MESSAGE}", ex.Message);
            }

            return BadRequest(ModelState);
        }
    }
}
```

When a model binding validation error occurs on the server, an `ApiController` (ApiControllerAttribute) normally returns a default bad request response with a ValidationProblemDetails. The response contains more data than just the validation errors, as shown in the following example when all of the fields of the *Starfleet Starship Database* form aren't submitted and the form fails validation:

```
{
  "title": "One or more validation errors occurred.",
  "status": 400,
  "errors": {
    "Identifier": ["The Identifier field is required."],
    "Classification": ["The Classification field is required."],
    "IsValidatedDesign": ["This form disallows unapproved ships."],
    "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
  }
}
```

If the server API returns the preceding default JSON response, it's possible for the client to parse the response to obtain the children of the `errors` node. However, it's inconvenient to parse the file. Parsing the JSON requires additional code after calling ReadFromJsonAsync in order to produce a `Dictionary<string, List<string>>` of errors for forms validation error processing. Ideally, the server API should only return the validation errors:

```
{
  "Identifier": ["The Identifier field is required."],
  "Classification": ["The Classification field is required."],
  "IsValidatedDesign": ["This form disallows unapproved ships."],
  "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
}
```

To modify the server API's response to make it only return the validation errors, change the delegate that's invoked on actions that are annotated with ApiControllerAttribute in `Startup.ConfigureServices`. For the API endpoint (`/StarshipValidation`), return a BadRequestObjectResult with the ModelStateDictionary. For any other API endpoints, preserve the default behavior by returning the object result with a new ValidationProblemDetails:

```
using Microsoft.AspNetCore.Mvc;

...

services.AddControllersWithViews()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.InvalidModelStateResponseFactory = context =>
        {
            if (context.HttpContext.Request.Path == "/StarshipValidation")
            {
                return new BadRequestObjectResult(context.ModelState);
            }
            else
            {
                return new BadRequestObjectResult(
                    new ValidationProblemDetails(context.ModelState));
            }
        };
    });
```

For more information, see Handle errors in ASP.NET Core web APIs.

In the client project, add the validator component shown in the Validator components section.

In the client project, the *Starfleet Starship Database* form is updated to show server validation errors with help of the `CustomValidator` component. When the server API returns validation messages, they're added to the `CustomValidator` component's ValidationMessageStore. The errors are available in the form's EditContext for display by the form's ValidationSummary:

```
@page "/FormValidation"
```

```
@using System.Net
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@using Microsoft.Extensions.Logging
@using BlazorSample.Shared
@attribute [Authorize]
@inject HttpClient Http
@inject ILogger<FormValidation> Logger

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    <p>
        <label>
            Identifier:
            <InputText @bind-Value="starship.Identifier" disabled="@disabled" />
        </label>
    </p>
    <p>
        <label>
            Description (optional):
            <InputTextArea @bind-Value="starship.Description"
                disabled="@disabled" />
        </label>
    </p>
    <p>

            Primary Classification:
            <InputSelect @bind-Value="starship.Classification" disabled="@disabled">
                <option value="">Select classification ...</option>
                <option value="Exploration">Exploration</option>
                <option value="Diplomacy">Diplomacy</option>
                <option value="Defense">Defense</option>
            </InputSelect>
        </label>
    </p>
    <p>
        <label>
            Maximum Accommodation:
            <InputNumber @bind-Value="starship.MaximumAccommodation"
                disabled="@disabled" />
        </label>
    </p>
    <p>
        <label>
            Engineering Approval:
            <InputCheckbox @bind-Value="starship.IsValidatedDesign"
                disabled="@disabled" />
        </label>
    </p>
    <p>
        <label>
            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" disabled="@disabled" />
        </label>
    </p>

    <button type="submit" disabled="@disabled">Submit</button>

    <p style="@messageStyles">
        @message
    </p>
```

```
    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private bool disabled;
    private string message;
    private string messageStyles = "visibility:hidden";
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private async Task HandleValidSubmit(EditContext editContext)
    {
        customValidator.ClearErrors();

        try
        {
            var response = await Http.PostAsJsonAsync<Starship>(
                "StarshipValidation", (Starship)editContext.Model);

            var errors = await response.Content
                .ReadFromJsonAsync<Dictionary<string, List<string>>>();

            if (response.StatusCode == HttpStatusCode.BadRequest &&
                errors.Count() > 0)
            {
                customValidator.DisplayErrors(errors);
            }
            else if (!response.IsSuccessStatusCode)
            {
                throw new HttpRequestException(
                    $"Validation failed. Status Code: {response.StatusCode}");
            }
            else
            {
                disabled = true;
                messageStyles = "color:green";
                message = "The form has been processed.";
            }
        }
        catch (AccessTokenNotAvailableException ex)
        {
            ex.Redirect();
        }
        catch (Exception ex)
        {
            Logger.LogError("Form processing error: {MESSAGE}", ex.Message);
            disabled = true;
            messageStyles = "color:red";
            message = "There was an error processing the form.";
        }
    }
}
```

NOTE

As an alternative to validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

NOTE

The server-side validation approach in this section is suitable for any of the Blazor WebAssembly hosted solution examples in this documentation set:

- Azure Active Directory (AAD)
- Azure Active Directory (AAD) B2C
- Identity Server

InputText based on the input event

Use the InputText component to create a custom component that uses the `input` event instead of the `change` event.

In the following example, the `CustomInputText` component inherits the framework's `InputText` component and sets the event binding (CreateBinder) to the `oninput` event.

`Shared/CustomInputText.razor`:

```
@inherits InputText

<input
    @attributes="AdditionalAttributes"
    class="@CssClass"
    value="@CurrentValue"
    @oninput="EventCallback.Factory.CreateBinder<string>(
         this, __value => CurrentValueAsString = __value,
         CurrentValueAsString)" />
```

The `CustomInputText` component can be used anywhere InputText is used:

`Pages/TestForm.razor`:

```
@page "/testform"
@using System.ComponentModel.DataAnnotations;

<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <CustomInputText @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

<p>
    CurrentValue: @exampleModel.Name
</p>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }

    public class ExampleModel
    {
        [Required]
        [StringLength(10, ErrorMessage = "Name is too long.")]
        public string Name { get; set; }
    }
}
```

Radio buttons

Use `InputRadio` components with the `InputRadioGroup` component to create a radio button group. In the following example, properties are added to the `Starship` model described in the Built-in forms components section:

```
[Required]
[Range(typeof(Manufacturer), nameof(Manufacturer.SpaceX),
    nameof(Manufacturer.VirginGalactic), ErrorMessage = "Pick a manufacturer.")]
public Manufacturer Manufacturer { get; set; } = Manufacturer.Unknown;

[Required, EnumDataType(typeof(Color))]
public Color? Color { get; set; } = null;

[Required, EnumDataType(typeof(Engine))]
public Engine? Engine { get; set; } = null;
```

Add the following `enums` to the app. Create a new file to hold the `enums` or add the `enums` to the `Starship.cs` file. Make the `enums` accessible to the `Starship` model and the *Starfleet Starship Database* form:

```
public enum Manufacturer { SpaceX, NASA, ULA, Virgin, Unknown }
public enum Color { ImperialRed, SpacecruiserGreen, StarshipBlue, VoyagerOrange }
public enum Engine { Ion, Plasma, Fusion, Warp }
```

Update the *Starfleet Starship Database* form described in the Built-in forms components section. Add the components to produce:

- A radio button group for the ship manufacturer.
- A nested radio button group for ship color and engine.

```
<p>
    <InputRadioGroup @bind-Value="starship.Manufacturer">
        Manufacturer:
        <br>
        @foreach (var manufacturer in (Manufacturer[])Enum
            .GetValues(typeof(Manufacturer)))
        {
            <InputRadio Value="manufacturer" />
            @manufacturer
            <br>
        }
    </InputRadioGroup>
</p>

<p>
    Pick one color and one engine:
    <InputRadioGroup Name="engine" @bind-Value="starship.Engine">
        <InputRadioGroup Name="color" @bind-Value="starship.Color">
            <InputRadio Name="color" Value="Color.ImperialRed" />Imperial Red<br>
            <InputRadio Name="engine" Value="Engine.Ion" />Ion<br>
            <InputRadio Name="color" Value="Color.SpacecruiserGreen" />
                Spacecruiser Green<br>
            <InputRadio Name="engine" Value="Engine.Plasma" />Plasma<br>
            <InputRadio Name="color" Value="Color.StarshipBlue" />Starship Blue<br>
            <InputRadio Name="engine" Value="Engine.Fusion" />Fusion<br>
            <InputRadio Name="color" Value="Color.VoyagerOrange" />
                Voyager Orange<br>
            <InputRadio Name="engine" Value="Engine.Warp" />Warp<br>
        </InputRadioGroup>
    </InputRadioGroup>
</p>
```

NOTE

If `Name` is omitted, `InputRadio` components are grouped by their most recent ancestor.

When working with radio buttons in a form, data binding is handled differently than other elements because radio buttons are evaluated as a group. The value of each radio button is fixed, but the value of the radio button group is the value of the selected radio button. The following example shows how to:

- Handle data binding for a radio button group.
- Support validation using a custom `InputRadio` component.

```
@using System.Globalization
@typeparam TValue
@inherits InputBase<TValue>

<input @attributes="AdditionalAttributes" type="radio" value="@SelectedValue"
       checked="@(SelectedValue.Equals(Value))" @onchange="OnChange" />

@code {
    [Parameter]
    public TValue SelectedValue { get; set; }

    private void OnChange(ChangeEventArgs args)
    {
        CurrentValueAsString = args.Value.ToString();
    }

    protected override bool TryParseValueFromString(string value,
        out TValue result, out string errorMessage)
    {
        var success = BindConverter.TryConvertTo<TValue>(
            value, CultureInfo.CurrentCulture, out var parsedValue);
        if (success)
        {
            result = parsedValue;
            errorMessage = null;

            return true;
        }
        else
        {
            result = default;
            errorMessage = $"{FieldIdentifier.FieldName} field isn't valid.";

            return false;
        }
    }
}
```

The following EditForm uses the preceding `InputRadio` component to obtain and validate a rating from the user:

```
@page "/RadioButtonExample"
@using System.ComponentModel.DataAnnotations

<h1>Radio Button Group Test</h1>

<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    @for (int i = 1; i <= 5; i++)
    {
        <label>
            <InputRadio name="rate" SelectedValue="i" @bind-Value="model.Rating" />
            @i
        </label>
    }

    <button type="submit">Submit</button>
</EditForm>

<p>You chose: @model.Rating</p>

@code {
    private Model model = new Model();

    private void HandleValidSubmit()
    {
        ...
    }

    public class Model
    {
        [Range(1, 5)]
        public int Rating { get; set; }
    }
}
```

Binding `<select>` element options to C# object `null` values

There's no sensible way to represent a `<select>` element option value as a C# object `null` value, because:

- HTML attributes can't have `null` values. The closest equivalent to `null` in HTML is absence of the HTML `value` attribute from the `<option>` element.
- When selecting an `<option>` with no `value` attribute, the browser treats the value as the *text content* of that `<option>`'s element.

The Blazor framework doesn't attempt to suppress the default behavior because it would involve:

- Creating a chain of special-case workarounds in the framework.
- Breaking changes to current framework behavior.

The most plausible `null` equivalent in HTML is an *empty string* `value`. The Blazor framework handles `null` to empty string conversions for two-way binding to a `<select>`'s value.

The Blazor framework doesn't automatically handle `null` to empty string conversions when attempting two-way binding to a `<select>`'s value. For more information, see Fix binding `<select>` to a null value (dotnet/aspnetcore #23221).

Validation support

The DataAnnotationsValidator component attaches validation support using data annotations to the cascaded

EditContext. Enabling support for validation using data annotations requires this explicit gesture. To use a different validation system than data annotations, replace the DataAnnotationsValidator with a custom implementation. The ASP.NET Core implementation is available for inspection in the reference source: `DataAnnotationsValidator` / `AddDataAnnotationsValidation`. The preceding links to reference source provide code from the repository's `master` branch, which represents the product unit's current development for the next release of ASP.NET Core. To select the branch for a different release, use the GitHub branch selector (for example `release/3.1`).

Blazor performs two types of validation:

- *Field validation* is performed when the user tabs out of a field. During field validation, the DataAnnotationsValidator component associates all reported validation results with the field.
- *Model validation* is performed when the user submits the form. During model validation, the DataAnnotationsValidator component attempts to determine the field based on the member name that the validation result reports. Validation results that aren't associated with an individual member are associated with the model rather than a field.

Validation Summary and Validation Message components

The ValidationSummary component summarizes all validation messages, which is similar to the Validation Summary Tag Helper:

```
<ValidationSummary />
```

Output validation messages for a specific model with the `Model` parameter:

```
<ValidationSummary Model="@starship" />
```

The ValidationMessage<TValue> component displays validation messages for a specific field, which is similar to the Validation Message Tag Helper. Specify the field for validation with the `For` attribute and a lambda expression naming the model property:

```
<ValidationMessage For="@(() => starship.MaximumAccommodation)" />
```

The ValidationMessage<TValue> and ValidationSummary components support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the generated `<div>` or `<ul>` element.

Control the style of validation messages in the app's stylesheet (`wwwroot/css/app.css` or `wwwroot/css/site.css`). The default `validation-message` class sets the text color of validation messages to red:

```
.validation-message {
    color: red;
}
```

Custom validation attributes

To ensure that a validation result is correctly associated with a field when using a custom validation attribute, pass the validation context's MemberName when creating the ValidationResult:

```
using System;
using System.ComponentModel.DataAnnotations;

private class CustomValidator : ValidationAttribute
{
    protected override ValidationResult IsValid(object value,
        ValidationContext validationContext)
    {
        ...

        return new ValidationResult("Validation message to user.",
            new[] { validationContext.MemberName });
    }
}
```

NOTE

ValidationContext.GetService is `null`. Injecting services for validation in the `IsValid` method isn't supported.

Custom validation class attributes

Custom validation class names are useful when integrating with CSS frameworks, such as Bootstrap. To specify custom validation class names, create a class derived from `FieldCssClassProvider` and set the class on the EditContext instance:

```
var editContext = new EditContext(model);
editContext.SetFieldCssClassProvider(new MyFieldClassProvider());

...

private class MyFieldClassProvider : FieldCssClassProvider
{
    public override string GetFieldCssClass(EditContext editContext,
        in FieldIdentifier fieldIdentifier)
    {
        var isValid = !editContext.GetValidationMessages(fieldIdentifier).Any();

        return isValid ? "good field" : "bad field";
    }
}
```

Blazor data annotations validation package

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` is a package that fills validation experience gaps using the DataAnnotationsValidator component. The package is currently *experimental*.

NOTE

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package has a latest version of *release candidate* at Nuget.org. Continue to use the *experimental* release candidate package at this time. The package's assembly might be moved to either the framework or the runtime in a future release. Watch the Announcements GitHub repository, the dotnet/aspnetcore GitHub repository, or this topic section for further updates.

[CompareProperty] attribute

The CompareAttribute doesn't work well with the DataAnnotationsValidator component because it doesn't associate the validation result with a specific member. This can result in inconsistent behavior between field-level validation and when the entire model is validated on a submit. The

`Microsoft.AspNetCore.Components.DataAnnotations.Validation` *experimental* package introduces an additional validation attribute, `ComparePropertyAttribute`, that works around these limitations. In a Blazor app, `[CompareProperty]` is a direct replacement for the `[Compare]` attribute.

Nested models, collection types, and complex types

Blazor provides support for validating form input using data annotations with the built-in DataAnnotationsValidator. However, the DataAnnotationsValidator only validates top-level properties of the model bound to the form that aren't collection- or complex-type properties.

To validate the bound model's entire object graph, including collection- and complex-type properties, use the `ObjectGraphDataAnnotationsValidator` provided by the *experimental* `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package:

```
<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <ObjectGraphDataAnnotationsValidator />
    ...
</EditForm>
```

Annotate model properties with `[ValidateComplexType]`. In the following model classes, the `ShipDescription` class contains additional data annotations to validate when the model is bound to the form:

`Starship.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    ...

    [ValidateComplexType]
    public ShipDescription ShipDescription { get; set; } =
        new ShipDescription();

    ...
}
```

`ShipDescription.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class ShipDescription
{
    [Required]
    [StringLength(40, ErrorMessage = "Description too long (40 char).")]
    public string ShortDescription { get; set; }

    [Required]
    [StringLength(240, ErrorMessage = "Description too long (240 char).")]
    public string LongDescription { get; set; }
}
```

Enable the submit button based on form validation

To enable and disable the submit button based on form validation:

- Use the form's EditContext to assign the model when the component is initialized.
- Validate the form in the context's OnFieldChanged callback to enable and disable the submit button.

- Unhook the event handler in the `Dispose` method. For more information, see ASP.NET Core Blazor lifecycle.

> **NOTE**
> When using an EditContext, don't also assign a Model to the EditForm.

```
@implements IDisposable

<EditForm EditContext="@editContext">
    <DataAnnotationsValidator />
    <ValidationSummary />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private bool formInvalid = true;
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
        editContext.OnFieldChanged += HandleFieldChanged;
    }

    private void HandleFieldChanged(object sender, FieldChangedEventArgs e)
    {
        formInvalid = !editContext.Validate();
        StateHasChanged();
    }

    public void Dispose()
    {
        editContext.OnFieldChanged -= HandleFieldChanged;
    }
}
```

In the preceding example, set `formInvalid` to `false` if:

- The form is preloaded with valid default values.
- You want the submit button enabled when the form loads.

A side effect of the preceding approach is that a ValidationSummary component is populated with invalid fields after the user interacts with any one field. This scenario can be addressed in either of the following ways:

- Don't use a ValidationSummary component on the form.
- Make the ValidationSummary component visible when the submit button is selected (for example, in a `HandleValidSubmit` method).

```
<EditForm EditContext="@editContext" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary style="@displaySummary" />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private string displaySummary = "display:none";

    ...

    private void HandleValidSubmit()
    {
        displaySummary = "display:block";
    }
}
```

Troubleshoot

> InvalidOperationException: EditForm requires a Model parameter, or an EditContext parameter, but not both.

Confirm that the EditForm has a Model **or** EditContext. Don't use both for the same form.

When assigning a Model to the form, confirm that the model type is instantiated, as the following example shows:

```
private ExampleModel exampleModel = new ExampleModel();
```

ASP.NET Core Blazor forms and validation

9/22/2020 • 22 minutes to read • Edit Online

By Daniel Roth, Rémi Bourgarel, and Luke Latham

Forms and validation are supported in Blazor using data annotations.

The following `ExampleModel` type defines validation logic using data annotations:

```
using System.ComponentModel.DataAnnotations;

public class ExampleModel
{
    [Required]
    [StringLength(10, ErrorMessage = "Name is too long.")]
    public string Name { get; set; }
}
```

A form is defined using the EditForm component. The following form demonstrates typical elements, components, and Razor code:

```
<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <InputText id="name" @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }
}
```

In the preceding example:

- The form validates user input in the `name` field using the validation defined in the `ExampleModel` type. The model is created in the component's `@code` block and held in a private field (`exampleModel`). The field is assigned to the `Model` attribute of the `<EditForm>` element.
- The InputText component's `@bind-Value` binds:
  - The model property (`exampleModel.Name`) to the InputText component's `Value` property. For more information on property binding, see ASP.NET Core Blazor data binding.
  - A change event delegate to the InputText component's `ValueChanged` property.
- The DataAnnotationsValidator validator component attaches validation support using data annotations.
- The ValidationSummary component summarizes validation messages.
- `HandleValidSubmit` is triggered when the form successfully submits (passes validation).

Built-in forms components

A set of built-in components are available to receive and validate user input. Inputs are validated when they're changed and when a form is submitted. Available input components are shown in the following table.

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
`InputFile`	`<input type="file">`
InputNumber<TValue>	`<input type="number">`
`InputRadio`	`<input type="radio">`
`InputRadioGroup`	`<input type="radio">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
InputNumber<TValue>	`<input type="number">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

> **NOTE**
>
> The `InputRadio` and `InputRadioGroup` components are available in ASP.NET Core 5.0 or later. For more information, select a 5.0 or later version of this article.

All of the input components, including EditForm, support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the rendered HTML element.

Input components provide default behavior for validating when a field is changed, including updating the field CSS class to reflect the field state. Some components include useful parsing logic. For example, InputDate<TValue> and InputNumber<TValue> handle unparseable values gracefully by registering unparseable values as validation errors. Types that can accept null values also support nullability of the target field (for example, `int?`).

The following `Starship` type defines validation logic using a larger set of properties and data annotations than the

earlier `ExampleModel`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    [Required]
    [StringLength(16, ErrorMessage = "Identifier too long (16 character limit).")]
    public string Identifier { get; set; }

    public string Description { get; set; }

    [Required]
    public string Classification { get; set; }

    [Range(1, 100000, ErrorMessage = "Accommodation invalid (1-100000).")]
    public int MaximumAccommodation { get; set; }

    [Required]
    [Range(typeof(bool), "true", "true",
        ErrorMessage = "This form disallows unapproved ships.")]
    public bool IsValidatedDesign { get; set; }

    [Required]
    public DateTime ProductionDate { get; set; }
}
```

In the preceding example, `Description` is optional because no data annotations are present.

The following form validates user input using the validation defined in the `Starship` model:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <p>
        <label>
            Identifier:
            <InputText @bind-Value="starship.Identifier" />
        </label>
    </p>
    <p>
        <label>
            Description (optional):
            <InputTextArea @bind-Value="starship.Description" />
        </label>
    </p>
    <p>
        <label>
            Primary Classification:
            <InputSelect @bind-Value="starship.Classification">
                <option value="">Select classification ...</option>
                <option value="Exploration">Exploration</option>
                <option value="Diplomacy">Diplomacy</option>
                <option value="Defense">Defense</option>
            </InputSelect>
        </label>
    </p>
    <p>
```

```
        <label>
            Maximum Accommodation:
            <InputNumber @bind-Value="starship.MaximumAccommodation" />
        </label>
    </p>
    <p>
        <label>
            Engineering Approval:
            <InputCheckbox @bind-Value="starship.IsValidatedDesign" />
        </label>
    </p>
    <p>
        <label>
            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" />
        </label>
    </p>

    <button type="submit">Submit</button>

    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        ...
    }
}
```

The EditForm creates an EditContext as a cascading value that tracks metadata about the edit process, including which fields have been modified and the current validation messages.

Assign **either** an EditContext **or** an EditForm.Model to an EditForm. Assignment of both isn't supported and generates a **runtime error**.

The EditForm provides convenient events for valid and invalid form submission:

- OnValidSubmit
- OnInvalidSubmit

Use OnSubmit to use custom code to trigger validation and check field values.

In the following example:

- The `HandleSubmit` method executes when the `Submit` button is selected.
- The form is validated by calling EditContext.Validate.
- Additional code is executed depending on the validation result. Place business logic in the method assigned to OnSubmit.

```
<EditForm EditContext="@editContext" OnSubmit="@HandleSubmit">

    ...

    <button type="submit">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
    }

    private async Task HandleSubmit()
    {
        var isValid = editContext.Validate();

        if (isValid)
        {
            ...
        }
        else
        {
            ...
        }
    }
}
```

NOTE

Framework API doesn't exist to clear validation messages directly from an EditContext. Therefore, we don't generally recommend adding validation messages to a new ValidationMessageStore in a form. To manage validation messages, use a validator component with your business logic validation code, as described in this article.

Display name support

This section applies to ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.

The following built-in components support display names with the `DisplayName` parameter:

- InputDate<TValue>
- InputNumber<TValue>
- InputSelect<TValue>

In the following `InputDate` component example:

- The display name (`DisplayName`) is set to `birthday`.
- The component is bound to the `BirthDate` property as a `DateTime` type.

```
<InputDate @bind-Value="@BirthDate" DisplayName="birthday" />

@code {
    public DateTime BirthDate { get; set; }
}
```

If the user doesn't provide a date value, the validation error appears as:

```
The birthday must be a date.
```

Validator components

Validator components support form validation by managing a ValidationMessageStore for a form's EditContext.

The Blazor framework provides the DataAnnotationsValidator component to attach validation support to forms based on validation attributes (data annotations). Create custom validator components to process validation messages for different forms on the same page or the same form at different steps of form processing, for example client-side validation followed by server-side validation. The validator component example shown in this section, `CustomValidator`, is used in the following sections of this article:

- Business logic validation
- Server validation

> **NOTE**
> Custom data annotation validation attributes can be used instead of custom validator components in many cases. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, any custom attributes applied to the model must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Create a validator component from ComponentBase:

- The form's EditContext is a cascading parameter of the component.
- When the validator component is initialized, a new ValidationMessageStore is created to maintain a current list of form errors.
- The message store receives errors when developer code in the form's component calls the `DisplayErrors` method. The errors are passed to the `DisplayErrors` method in a `Dictionary<string, List<string>>`. In the dictionary, the key is the name of the form field that has one or more errors. The value is the error list.
- Messages are cleared when any of the following have occurred:
  - Validation is requested on the EditContext when the OnValidationRequested event is raised. All of the errors are cleared.
  - A field changes in the form when the OnFieldChanged event is raised. Only the errors for the field are cleared.
  - The `ClearErrors` method is called by developer code. All of the errors are cleared.

```
using System;
using System.Collections.Generic;
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Forms;

namespace BlazorSample.Client
{
    public class CustomValidator : ComponentBase
    {
        private ValidationMessageStore messageStore;

        [CascadingParameter]
        private EditContext CurrentEditContext { get; set; }

        protected override void OnInitialized()
        {
            if (CurrentEditContext == null)
            {
                throw new InvalidOperationException(
                    $"{nameof(CustomValidator)} requires a cascading " +
                    $"parameter of type {nameof(EditContext)}. " +
                    $"For example, you can use {nameof(CustomValidator)} " +
                    $"inside an {nameof(EditForm)}.");
            }

            messageStore = new ValidationMessageStore(CurrentEditContext);

            CurrentEditContext.OnValidationRequested += (s, e) =>
                messageStore.Clear();
            CurrentEditContext.OnFieldChanged += (s, e) =>
                messageStore.Clear(e.FieldIdentifier);
        }

        public void DisplayErrors(Dictionary<string, List<string>> errors)
        {
            foreach (var err in errors)
            {
                messageStore.Add(CurrentEditContext.Field(err.Key), err.Value);
            }

            CurrentEditContext.NotifyValidationStateChanged();
        }

        public void ClearErrors()
        {
            messageStore.Clear();
            CurrentEditContext.NotifyValidationStateChanged();
        }
    }
}
```

Business logic validation

Business logic validation can be accomplished with a validator component that receives form errors in a dictionary.

In the following example:

- The `CustomValidator` component from the Validator components section of this article is used.
- The validation requires a value for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

When validation messages are set in the component, they're added to the validator's ValidationMessageStore and shown in the EditForm:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    ...

</EditForm>

@code {
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        customValidator.ClearErrors();

        var errors = new Dictionary<string, List<string>>();

        if (starship.Classification == "Defense" &&
                string.IsNullOrEmpty(starship.Description))
        {
            errors.Add(nameof(starship.Description),
                new List<string>() { "For a 'Defense' ship classification, " +
                "'Description' is required." });
        }

        if (errors.Count() > 0)
        {
            customValidator.DisplayErrors(errors);
        }
        else
        {
            // Process the form
        }
    }
}
```

NOTE

As an alternative to using validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Server validation

Server validation can be accomplished with a server validator component:

- Process client-side validation in the form with the DataAnnotationsValidator component.
- When the form passes client-side validation (OnValidSubmit is called), send the EditContext.Model to a backend server API for form processing.
- Process model validation on the server.
- The server API includes both the built-in framework data annotations validation and custom validation logic supplied by the developer. If validation passes on the server, process the form and send back a success status code (*200 - OK*). If validation fails, return a failure status code (*400 - Bad Request*) and the field validation errors.

- Either disable the form on success or display the errors.

The following example is based on:

- A hosted Blazor solution created by the Blazor Hosted project template. The example can be used with any of the secure hosted Blazor solutions described in the Security and Identity documentation.
- The *Starfleet Starship Database* form example in the preceding Built-in forms components section.
- The Blazor framework's DataAnnotationsValidator component.
- The `CustomValidator` component shown in the Validator components section.

In the following example, the server API validates that a value is provided for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

Place the `Starship` model into the solution's `Shared` project so that both the client and server apps can use the model. Since the model requires data annotations, add a package reference for `System.ComponentModel.Annotations` to the `Shared` project's project file:

```
<ItemGroup>
  <PackageReference Include="System.ComponentModel.Annotations" Version="{VERSION}" />
</ItemGroup>
```

To determine the latest non-preview version of the package, see the package **Version History** at NuGet.org.

In the server API project, add a controller to process starship validation requests (`Controllers/StarshipValidation.cs`) and return failed validation messages:

```
using System;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Logging;
using BlazorSample.Shared;

namespace BlazorSample.Server.Controllers
{
    [Authorize]
    [ApiController]
    [Route("[controller]")]
    public class StarshipValidationController : ControllerBase
    {
        private readonly ILogger<StarshipValidationController> logger;

        public StarshipValidationController(
            ILogger<StarshipValidationController> logger)
        {
            this.logger = logger;
        }

        [HttpPost]
        public async Task<IActionResult> Post(Starship starship)
        {
            try
            {
                if (starship.Classification == "Defense" &&
                    string.IsNullOrEmpty(starship.Description))
                {
                    ModelState.AddModelError(nameof(starship.Description),
                        "For a 'Defense' ship " +
                        "classification, 'Description' is required.");
                }
                else
                {
                    // Process the form asynchronously
                    // async ...

                    return Ok(ModelState);
                }
            }
            catch (Exception ex)
            {
                logger.LogError("Validation Error: {MESSAGE}", ex.Message);
            }

            return BadRequest(ModelState);
        }
    }
}
```

When a model binding validation error occurs on the server, an `ApiController` (ApiControllerAttribute) normally returns a default bad request response with a ValidationProblemDetails. The response contains more data than just the validation errors, as shown in the following example when all of the fields of the *Starfleet Starship Database* form aren't submitted and the form fails validation:

```
{
  "title": "One or more validation errors occurred.",
  "status": 400,
  "errors": {
    "Identifier": ["The Identifier field is required."],
    "Classification": ["The Classification field is required."],
    "IsValidatedDesign": ["This form disallows unapproved ships."],
    "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
  }
}
```

If the server API returns the preceding default JSON response, it's possible for the client to parse the response to obtain the children of the `errors` node. However, it's inconvenient to parse the file. Parsing the JSON requires additional code after calling ReadFromJsonAsync in order to produce a `Dictionary<string, List<string>>` of errors for forms validation error processing. Ideally, the server API should only return the validation errors:

```
{
  "Identifier": ["The Identifier field is required."],
  "Classification": ["The Classification field is required."],
  "IsValidatedDesign": ["This form disallows unapproved ships."],
  "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
}
```

To modify the server API's response to make it only return the validation errors, change the delegate that's invoked on actions that are annotated with ApiControllerAttribute in `Startup.ConfigureServices`. For the API endpoint (`/StarshipValidation`), return a BadRequestObjectResult with the ModelStateDictionary. For any other API endpoints, preserve the default behavior by returning the object result with a new ValidationProblemDetails:

```
using Microsoft.AspNetCore.Mvc;

...

services.AddControllersWithViews()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.InvalidModelStateResponseFactory = context =>
        {
            if (context.HttpContext.Request.Path == "/StarshipValidation")
            {
                return new BadRequestObjectResult(context.ModelState);
            }
            else
            {
                return new BadRequestObjectResult(
                    new ValidationProblemDetails(context.ModelState));
            }
        };
    });
```

For more information, see Handle errors in ASP.NET Core web APIs.

In the client project, add the validator component shown in the Validator components section.

In the client project, the *Starfleet Starship Database* form is updated to show server validation errors with help of the `CustomValidator` component. When the server API returns validation messages, they're added to the `CustomValidator` component's ValidationMessageStore. The errors are available in the form's EditContext for display by the form's ValidationSummary:

```
@page "/FormValidation"
```

```

    </p>
</EditForm>

@code {
    private bool disabled;
    private string message;
    private string messageStyles = "visibility:hidden";
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private async Task HandleValidSubmit(EditContext editContext)
    {
        customValidator.ClearErrors();

        try
        {
            var response = await Http.PostAsJsonAsync<Starship>(
                "StarshipValidation", (Starship)editContext.Model);

            var errors = await response.Content
                .ReadFromJsonAsync<Dictionary<string, List<string>>>();

            if (response.StatusCode == HttpStatusCode.BadRequest &&
                errors.Count() > 0)
            {
                customValidator.DisplayErrors(errors);
            }
            else if (!response.IsSuccessStatusCode)
            {
                throw new HttpRequestException(
                    $"Validation failed. Status Code: {response.StatusCode}");
            }
            else
            {
                disabled = true;
                messageStyles = "color:green";
                message = "The form has been processed.";
            }
        }
        catch (AccessTokenNotAvailableException ex)
        {
            ex.Redirect();
        }
        catch (Exception ex)
        {
            Logger.LogError("Form processing error: {MESSAGE}", ex.Message);
            disabled = true;
            messageStyles = "color:red";
            message = "There was an error processing the form.";
        }
    }
}
```

NOTE

As an alternative to validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

NOTE

The server-side validation approach in this section is suitable for any of the Blazor WebAssembly hosted solution examples in this documentation set:

- Azure Active Directory (AAD)
- Azure Active Directory (AAD) B2C
- Identity Server

InputText based on the input event

Use the InputText component to create a custom component that uses the `input` event instead of the `change` event.

In the following example, the `CustomInputText` component inherits the framework's `InputText` component and sets the event binding (CreateBinder) to the `oninput` event.

`Shared/CustomInputText.razor`:

```
@inherits InputText

<input
    @attributes="AdditionalAttributes"
    class="@CssClass"
    value="@CurrentValue"
    @oninput="EventCallback.Factory.CreateBinder<string>(
         this, __value => CurrentValueAsString = __value,
         CurrentValueAsString)" />
```

The `CustomInputText` component can be used anywhere InputText is used:

`Pages/TestForm.razor`:

```
@page "/testform"
@using System.ComponentModel.DataAnnotations;

<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <CustomInputText @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

<p>
    CurrentValue: @exampleModel.Name
</p>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }

    public class ExampleModel
    {
        [Required]
        [StringLength(10, ErrorMessage = "Name is too long.")]
        public string Name { get; set; }
    }
}
```

Radio buttons

Use `InputRadio` components with the `InputRadioGroup` component to create a radio button group. In the following example, properties are added to the `Starship` model described in the Built-in forms components section:

```
[Required]
[Range(typeof(Manufacturer), nameof(Manufacturer.SpaceX),
    nameof(Manufacturer.VirginGalactic), ErrorMessage = "Pick a manufacturer.")]
public Manufacturer Manufacturer { get; set; } = Manufacturer.Unknown;

[Required, EnumDataType(typeof(Color))]
public Color? Color { get; set; } = null;

[Required, EnumDataType(typeof(Engine))]
public Engine? Engine { get; set; } = null;
```

Add the following `enums` to the app. Create a new file to hold the `enums` or add the `enums` to the `Starship.cs` file. Make the `enums` accessible to the `Starship` model and the *Starfleet Starship Database* form:

```
public enum Manufacturer { SpaceX, NASA, ULA, Virgin, Unknown }
public enum Color { ImperialRed, SpacecruiserGreen, StarshipBlue, VoyagerOrange }
public enum Engine { Ion, Plasma, Fusion, Warp }
```

Update the *Starfleet Starship Database* form described in the Built-in forms components section. Add the components to produce:

- A radio button group for the ship manufacturer.
- A nested radio button group for ship color and engine.

```
<p>
    <InputRadioGroup @bind-Value="starship.Manufacturer">
        Manufacturer:
        <br>
        @foreach (var manufacturer in (Manufacturer[])Enum
            .GetValues(typeof(Manufacturer)))
        {
            <InputRadio Value="manufacturer" />
            @manufacturer
            <br>
        }
    </InputRadioGroup>
</p>

<p>
    Pick one color and one engine:
    <InputRadioGroup Name="engine" @bind-Value="starship.Engine">
        <InputRadioGroup Name="color" @bind-Value="starship.Color">
            <InputRadio Name="color" Value="Color.ImperialRed" />Imperial Red<br>
            <InputRadio Name="engine" Value="Engine.Ion" />Ion<br>
            <InputRadio Name="color" Value="Color.SpacecruiserGreen" />
                Spacecruiser Green<br>
            <InputRadio Name="engine" Value="Engine.Plasma" />Plasma<br>
            <InputRadio Name="color" Value="Color.StarshipBlue" />Starship Blue<br>
            <InputRadio Name="engine" Value="Engine.Fusion" />Fusion<br>
            <InputRadio Name="color" Value="Color.VoyagerOrange" />
                Voyager Orange<br>
            <InputRadio Name="engine" Value="Engine.Warp" />Warp<br>
        </InputRadioGroup>
    </InputRadioGroup>
</p>
```

NOTE

If `Name` is omitted, `InputRadio` components are grouped by their most recent ancestor.

When working with radio buttons in a form, data binding is handled differently than other elements because radio buttons are evaluated as a group. The value of each radio button is fixed, but the value of the radio button group is the value of the selected radio button. The following example shows how to:

- Handle data binding for a radio button group.
- Support validation using a custom `InputRadio` component.

```
@using System.Globalization
@typeparam TValue
@inherits InputBase<TValue>

<input @attributes="AdditionalAttributes" type="radio" value="@SelectedValue"
       checked="@(SelectedValue.Equals(Value))" @onchange="OnChange" />

@code {
    [Parameter]
    public TValue SelectedValue { get; set; }

    private void OnChange(ChangeEventArgs args)
    {
        CurrentValueAsString = args.Value.ToString();
    }

    protected override bool TryParseValueFromString(string value,
        out TValue result, out string errorMessage)
    {
        var success = BindConverter.TryConvertTo<TValue>(
            value, CultureInfo.CurrentCulture, out var parsedValue);
        if (success)
        {
            result = parsedValue;
            errorMessage = null;

            return true;
        }
        else
        {
            result = default;
            errorMessage = $"{FieldIdentifier.FieldName} field isn't valid.";

            return false;
        }
    }
}
```

The following EditForm uses the preceding `InputRadio` component to obtain and validate a rating from the user:

```
@page "/RadioButtonExample"
@using System.ComponentModel.DataAnnotations

<h1>Radio Button Group Test</h1>

<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    @for (int i = 1; i <= 5; i++)
    {
        <label>
            <InputRadio name="rate" SelectedValue="i" @bind-Value="model.Rating" />
            @i
        </label>
    }

    <button type="submit">Submit</button>
</EditForm>

<p>You chose: @model.Rating</p>

@code {
    private Model model = new Model();

    private void HandleValidSubmit()
    {
        ...
    }

    public class Model
    {
        [Range(1, 5)]
        public int Rating { get; set; }
    }
}
```

Binding `<select>` element options to C# object `null` values

There's no sensible way to represent a `<select>` element option value as a C# object `null` value, because:

- HTML attributes can't have `null` values. The closest equivalent to `null` in HTML is absence of the HTML `value` attribute from the `<option>` element.
- When selecting an `<option>` with no `value` attribute, the browser treats the value as the *text content* of that `<option>`'s element.

The Blazor framework doesn't attempt to suppress the default behavior because it would involve:

- Creating a chain of special-case workarounds in the framework.
- Breaking changes to current framework behavior.

The most plausible `null` equivalent in HTML is an *empty string* `value`. The Blazor framework handles `null` to empty string conversions for two-way binding to a `<select>`'s value.

The Blazor framework doesn't automatically handle `null` to empty string conversions when attempting two-way binding to a `<select>`'s value. For more information, see Fix binding `<select>` to a null value (dotnet/aspnetcore #23221).

Validation support

The DataAnnotationsValidator component attaches validation support using data annotations to the cascaded

EditContext. Enabling support for validation using data annotations requires this explicit gesture. To use a different validation system than data annotations, replace the DataAnnotationsValidator with a custom implementation. The ASP.NET Core implementation is available for inspection in the reference source: `DataAnnotationsValidator` / `AddDataAnnotationsValidation`. The preceding links to reference source provide code from the repository's `master` branch, which represents the product unit's current development for the next release of ASP.NET Core. To select the branch for a different release, use the GitHub branch selector (for example `release/3.1`).

Blazor performs two types of validation:

- *Field validation* is performed when the user tabs out of a field. During field validation, the DataAnnotationsValidator component associates all reported validation results with the field.
- *Model validation* is performed when the user submits the form. During model validation, the DataAnnotationsValidator component attempts to determine the field based on the member name that the validation result reports. Validation results that aren't associated with an individual member are associated with the model rather than a field.

Validation Summary and Validation Message components

The ValidationSummary component summarizes all validation messages, which is similar to the Validation Summary Tag Helper:

```
<ValidationSummary />
```

Output validation messages for a specific model with the `Model` parameter:

```
<ValidationSummary Model="@starship" />
```

The ValidationMessage<TValue> component displays validation messages for a specific field, which is similar to the Validation Message Tag Helper. Specify the field for validation with the `For` attribute and a lambda expression naming the model property:

```
<ValidationMessage For="@(() => starship.MaximumAccommodation)" />
```

The ValidationMessage<TValue> and ValidationSummary components support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the generated `<div>` or `<ul>` element.

Control the style of validation messages in the app's stylesheet (`wwwroot/css/app.css` or `wwwroot/css/site.css`). The default `validation-message` class sets the text color of validation messages to red:

```
.validation-message {
    color: red;
}
```

Custom validation attributes

To ensure that a validation result is correctly associated with a field when using a custom validation attribute, pass the validation context's MemberName when creating the ValidationResult:

```
using System;
using System.ComponentModel.DataAnnotations;

private class CustomValidator : ValidationAttribute
{
    protected override ValidationResult IsValid(object value,
        ValidationContext validationContext)
    {
        ...

        return new ValidationResult("Validation message to user.",
            new[] { validationContext.MemberName });
    }
}
```

NOTE

ValidationContext.GetService is `null`. Injecting services for validation in the `IsValid` method isn't supported.

Custom validation class attributes

Custom validation class names are useful when integrating with CSS frameworks, such as Bootstrap. To specify custom validation class names, create a class derived from `FieldCssClassProvider` and set the class on the EditContext instance:

```
var editContext = new EditContext(model);
editContext.SetFieldCssClassProvider(new MyFieldClassProvider());

...

private class MyFieldClassProvider : FieldCssClassProvider
{
    public override string GetFieldCssClass(EditContext editContext,
        in FieldIdentifier fieldIdentifier)
    {
        var isValid = !editContext.GetValidationMessages(fieldIdentifier).Any();

        return isValid ? "good field" : "bad field";
    }
}
```

Blazor data annotations validation package

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` is a package that fills validation experience gaps using the DataAnnotationsValidator component. The package is currently *experimental*.

NOTE

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package has a latest version of *release candidate* at Nuget.org. Continue to use the *experimental* release candidate package at this time. The package's assembly might be moved to either the framework or the runtime in a future release. Watch the Announcements GitHub repository, the dotnet/aspnetcore GitHub repository, or this topic section for further updates.

[CompareProperty] attribute

The CompareAttribute doesn't work well with the DataAnnotationsValidator component because it doesn't associate the validation result with a specific member. This can result in inconsistent behavior between field-level validation and when the entire model is validated on a submit. The

`Microsoft.AspNetCore.Components.DataAnnotations.Validation` *experimental* package introduces an additional validation attribute, `ComparePropertyAttribute`, that works around these limitations. In a Blazor app, `[CompareProperty]` is a direct replacement for the `[Compare]` attribute.

Nested models, collection types, and complex types

Blazor provides support for validating form input using data annotations with the built-in DataAnnotationsValidator. However, the DataAnnotationsValidator only validates top-level properties of the model bound to the form that aren't collection- or complex-type properties.

To validate the bound model's entire object graph, including collection- and complex-type properties, use the `ObjectGraphDataAnnotationsValidator` provided by the *experimental* `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package:

```
<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <ObjectGraphDataAnnotationsValidator />
    ...
</EditForm>
```

Annotate model properties with `[ValidateComplexType]`. In the following model classes, the `ShipDescription` class contains additional data annotations to validate when the model is bound to the form:

`Starship.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    ...

    [ValidateComplexType]
    public ShipDescription ShipDescription { get; set; } =
        new ShipDescription();

    ...
}
```

`ShipDescription.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class ShipDescription
{
    [Required]
    [StringLength(40, ErrorMessage = "Description too long (40 char).")]
    public string ShortDescription { get; set; }

    [Required]
    [StringLength(240, ErrorMessage = "Description too long (240 char).")]
    public string LongDescription { get; set; }
}
```

Enable the submit button based on form validation

To enable and disable the submit button based on form validation:

- Use the form's EditContext to assign the model when the component is initialized.
- Validate the form in the context's OnFieldChanged callback to enable and disable the submit button.

- Unhook the event handler in the `Dispose` method. For more information, see ASP.NET Core Blazor lifecycle.

> **NOTE**
> When using an EditContext, don't also assign a Model to the EditForm.

```
@implements IDisposable

<EditForm EditContext="@editContext">
    <DataAnnotationsValidator />
    <ValidationSummary />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private bool formInvalid = true;
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
        editContext.OnFieldChanged += HandleFieldChanged;
    }

    private void HandleFieldChanged(object sender, FieldChangedEventArgs e)
    {
        formInvalid = !editContext.Validate();
        StateHasChanged();
    }

    public void Dispose()
    {
        editContext.OnFieldChanged -= HandleFieldChanged;
    }
}
```

In the preceding example, set `formInvalid` to `false` if:

- The form is preloaded with valid default values.
- You want the submit button enabled when the form loads.

A side effect of the preceding approach is that a ValidationSummary component is populated with invalid fields after the user interacts with any one field. This scenario can be addressed in either of the following ways:

- Don't use a ValidationSummary component on the form.
- Make the ValidationSummary component visible when the submit button is selected (for example, in a `HandleValidSubmit` method).

```
<EditForm EditContext="@editContext" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary style="@displaySummary" />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private string displaySummary = "display:none";

    ...

    private void HandleValidSubmit()
    {
        displaySummary = "display:block";
    }
}
```

Troubleshoot

> InvalidOperationException: EditForm requires a Model parameter, or an EditContext parameter, but not both.

Confirm that the EditForm has a Model **or** EditContext. Don't use both for the same form.

When assigning a Model to the form, confirm that the model type is instantiated, as the following example shows:

```
private ExampleModel exampleModel = new ExampleModel();
```

ASP.NET Core Blazor forms and validation

9/22/2020 • 22 minutes to read • Edit Online

By Daniel Roth, Rémi Bourgarel, and Luke Latham

Forms and validation are supported in Blazor using data annotations.

The following `ExampleModel` type defines validation logic using data annotations:

```
using System.ComponentModel.DataAnnotations;

public class ExampleModel
{
    [Required]
    [StringLength(10, ErrorMessage = "Name is too long.")]
    public string Name { get; set; }
}
```

A form is defined using the EditForm component. The following form demonstrates typical elements, components, and Razor code:

```
<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <InputText id="name" @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }
}
```

In the preceding example:

- The form validates user input in the `name` field using the validation defined in the `ExampleModel` type. The model is created in the component's `@code` block and held in a private field (`exampleModel`). The field is assigned to the `Model` attribute of the `<EditForm>` element.
- The InputText component's `@bind-Value` binds:
  - The model property (`exampleModel.Name`) to the InputText component's `Value` property. For more information on property binding, see ASP.NET Core Blazor data binding.
  - A change event delegate to the InputText component's `ValueChanged` property.
- The DataAnnotationsValidator validator component attaches validation support using data annotations.
- The ValidationSummary component summarizes validation messages.
- `HandleValidSubmit` is triggered when the form successfully submits (passes validation).

Built-in forms components

A set of built-in components are available to receive and validate user input. Inputs are validated when they're changed and when a form is submitted. Available input components are shown in the following table.

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
`InputFile`	`<input type="file">`
InputNumber<TValue>	`<input type="number">`
`InputRadio`	`<input type="radio">`
`InputRadioGroup`	`<input type="radio">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
InputNumber<TValue>	`<input type="number">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

> **NOTE**
>
> The `InputRadio` and `InputRadioGroup` components are available in ASP.NET Core 5.0 or later. For more information, select a 5.0 or later version of this article.

All of the input components, including EditForm, support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the rendered HTML element.

Input components provide default behavior for validating when a field is changed, including updating the field CSS class to reflect the field state. Some components include useful parsing logic. For example, InputDate<TValue> and InputNumber<TValue> handle unparseable values gracefully by registering unparseable values as validation errors. Types that can accept null values also support nullability of the target field (for example, `int?`).

The following `Starship` type defines validation logic using a larger set of properties and data annotations than the

earlier `ExampleModel`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    [Required]
    [StringLength(16, ErrorMessage = "Identifier too long (16 character limit).")]
    public string Identifier { get; set; }

    public string Description { get; set; }

    [Required]
    public string Classification { get; set; }

    [Range(1, 100000, ErrorMessage = "Accommodation invalid (1-100000).")]
    public int MaximumAccommodation { get; set; }

    [Required]
    [Range(typeof(bool), "true", "true",
        ErrorMessage = "This form disallows unapproved ships.")]
    public bool IsValidatedDesign { get; set; }

    [Required]
    public DateTime ProductionDate { get; set; }
}
```

In the preceding example, `Description` is optional because no data annotations are present.

The following form validates user input using the validation defined in the `Starship` model:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <p>
        <label>
            Identifier:
            <InputText @bind-Value="starship.Identifier" />
        </label>
    </p>
    <p>
        <label>
            Description (optional):
            <InputTextArea @bind-Value="starship.Description" />
        </label>
    </p>
    <p>
        <label>
            Primary Classification:
            <InputSelect @bind-Value="starship.Classification">
                <option value="">Select classification ...</option>
                <option value="Exploration">Exploration</option>
                <option value="Diplomacy">Diplomacy</option>
                <option value="Defense">Defense</option>
            </InputSelect>
        </label>
    </p>
    <p>
```

```
        <label>
            Maximum Accommodation:
            <InputNumber @bind-Value="starship.MaximumAccommodation" />
        </label>
    </p>
    <p>
        <label>
            Engineering Approval:
            <InputCheckbox @bind-Value="starship.IsValidatedDesign" />
        </label>
    </p>
    <p>
        <label>
            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" />
        </label>
    </p>

    <button type="submit">Submit</button>

    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        ...
    }
}
```

The EditForm creates an EditContext as a cascading value that tracks metadata about the edit process, including which fields have been modified and the current validation messages.

Assign **either** an EditContext **or** an EditForm.Model to an EditForm. Assignment of both isn't supported and generates a **runtime error**.

The EditForm provides convenient events for valid and invalid form submission:

- OnValidSubmit
- OnInvalidSubmit

Use OnSubmit to use custom code to trigger validation and check field values.

In the following example:

- The `HandleSubmit` method executes when the `Submit` button is selected.
- The form is validated by calling EditContext.Validate.
- Additional code is executed depending on the validation result. Place business logic in the method assigned to OnSubmit.

```
<EditForm EditContext="@editContext" OnSubmit="@HandleSubmit">

    ...

    <button type="submit">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
    }

    private async Task HandleSubmit()
    {
        var isValid = editContext.Validate();

        if (isValid)
        {
            ...
        }
        else
        {
            ...
        }
    }
}
```

NOTE

Framework API doesn't exist to clear validation messages directly from an EditContext. Therefore, we don't generally recommend adding validation messages to a new ValidationMessageStore in a form. To manage validation messages, use a validator component with your business logic validation code, as described in this article.

Display name support

This section applies to ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.

The following built-in components support display names with the `DisplayName` parameter:

- InputDate<TValue>
- InputNumber<TValue>
- InputSelect<TValue>

In the following `InputDate` component example:

- The display name (`DisplayName`) is set to `birthday`.
- The component is bound to the `BirthDate` property as a `DateTime` type.

```
<InputDate @bind-Value="@BirthDate" DisplayName="birthday" />

@code {
    public DateTime BirthDate { get; set; }
}
```

If the user doesn't provide a date value, the validation error appears as:

```
The birthday must be a date.
```

Validator components

Validator components support form validation by managing a ValidationMessageStore for a form's EditContext.

The Blazor framework provides the DataAnnotationsValidator component to attach validation support to forms based on validation attributes (data annotations). Create custom validator components to process validation messages for different forms on the same page or the same form at different steps of form processing, for example client-side validation followed by server-side validation. The validator component example shown in this section, `CustomValidator`, is used in the following sections of this article:

- Business logic validation
- Server validation

> **NOTE**
> Custom data annotation validation attributes can be used instead of custom validator components in many cases. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, any custom attributes applied to the model must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Create a validator component from ComponentBase:

- The form's EditContext is a cascading parameter of the component.
- When the validator component is initialized, a new ValidationMessageStore is created to maintain a current list of form errors.
- The message store receives errors when developer code in the form's component calls the `DisplayErrors` method. The errors are passed to the `DisplayErrors` method in a `Dictionary<string, List<string>>`. In the dictionary, the key is the name of the form field that has one or more errors. The value is the error list.
- Messages are cleared when any of the following have occurred:
  - Validation is requested on the EditContext when the OnValidationRequested event is raised. All of the errors are cleared.
  - A field changes in the form when the OnFieldChanged event is raised. Only the errors for the field are cleared.
  - The `ClearErrors` method is called by developer code. All of the errors are cleared.

```
using System;
using System.Collections.Generic;
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Forms;

namespace BlazorSample.Client
{
    public class CustomValidator : ComponentBase
    {
        private ValidationMessageStore messageStore;

        [CascadingParameter]
        private EditContext CurrentEditContext { get; set; }

        protected override void OnInitialized()
        {
            if (CurrentEditContext == null)
            {
                throw new InvalidOperationException(
                    $"{nameof(CustomValidator)} requires a cascading " +
                    $"parameter of type {nameof(EditContext)}. " +
                    $"For example, you can use {nameof(CustomValidator)} " +
                    $"inside an {nameof(EditForm)}.");
            }

            messageStore = new ValidationMessageStore(CurrentEditContext);

            CurrentEditContext.OnValidationRequested += (s, e) =>
                messageStore.Clear();
            CurrentEditContext.OnFieldChanged += (s, e) =>
                messageStore.Clear(e.FieldIdentifier);
        }

        public void DisplayErrors(Dictionary<string, List<string>> errors)
        {
            foreach (var err in errors)
            {
                messageStore.Add(CurrentEditContext.Field(err.Key), err.Value);
            }

            CurrentEditContext.NotifyValidationStateChanged();
        }

        public void ClearErrors()
        {
            messageStore.Clear();
            CurrentEditContext.NotifyValidationStateChanged();
        }
    }
}
```

Business logic validation

Business logic validation can be accomplished with a validator component that receives form errors in a dictionary.

In the following example:

- The `CustomValidator` component from the Validator components section of this article is used.
- The validation requires a value for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

When validation messages are set in the component, they're added to the validator's ValidationMessageStore and shown in the EditForm:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    ...

</EditForm>

@code {
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        customValidator.ClearErrors();

        var errors = new Dictionary<string, List<string>>();

        if (starship.Classification == "Defense" &&
                string.IsNullOrEmpty(starship.Description))
        {
            errors.Add(nameof(starship.Description),
                new List<string>() { "For a 'Defense' ship classification, " +
                "'Description' is required." });
        }

        if (errors.Count() > 0)
        {
            customValidator.DisplayErrors(errors);
        }
        else
        {
            // Process the form
        }
    }
}
```

NOTE

As an alternative to using validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Server validation

Server validation can be accomplished with a server validator component:

- Process client-side validation in the form with the DataAnnotationsValidator component.
- When the form passes client-side validation (OnValidSubmit is called), send the EditContext.Model to a backend server API for form processing.
- Process model validation on the server.
- The server API includes both the built-in framework data annotations validation and custom validation logic supplied by the developer. If validation passes on the server, process the form and send back a success status code (*200 - OK*). If validation fails, return a failure status code (*400 - Bad Request*) and the field validation errors.

- Either disable the form on success or display the errors.

The following example is based on:

- A hosted Blazor solution created by the Blazor Hosted project template. The example can be used with any of the secure hosted Blazor solutions described in the Security and Identity documentation.
- The *Starfleet Starship Database* form example in the preceding Built-in forms components section.
- The Blazor framework's DataAnnotationsValidator component.
- The `CustomValidator` component shown in the Validator components section.

In the following example, the server API validates that a value is provided for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

Place the `Starship` model into the solution's `Shared` project so that both the client and server apps can use the model. Since the model requires data annotations, add a package reference for `System.ComponentModel.Annotations` to the `Shared` project's project file:

```
<ItemGroup>
  <PackageReference Include="System.ComponentModel.Annotations" Version="{VERSION}" />
</ItemGroup>
```

To determine the latest non-preview version of the package, see the package **Version History** at NuGet.org.

In the server API project, add a controller to process starship validation requests (`Controllers/StarshipValidation.cs`) and return failed validation messages:

```
using System;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Logging;
using BlazorSample.Shared;

namespace BlazorSample.Server.Controllers
{
    [Authorize]
    [ApiController]
    [Route("[controller]")]
    public class StarshipValidationController : ControllerBase
    {
        private readonly ILogger<StarshipValidationController> logger;

        public StarshipValidationController(
            ILogger<StarshipValidationController> logger)
        {
            this.logger = logger;
        }

        [HttpPost]
        public async Task<IActionResult> Post(Starship starship)
        {
            try
            {
                if (starship.Classification == "Defense" &&
                    string.IsNullOrEmpty(starship.Description))
                {
                    ModelState.AddModelError(nameof(starship.Description),
                        "For a 'Defense' ship " +
                        "classification, 'Description' is required.");
                }
                else
                {
                    // Process the form asynchronously
                    // async ...

                    return Ok(ModelState);
                }
            }
            catch (Exception ex)
            {
                logger.LogError("Validation Error: {MESSAGE}", ex.Message);
            }

            return BadRequest(ModelState);
        }
    }
}
```

When a model binding validation error occurs on the server, an `ApiController` (ApiControllerAttribute) normally returns a default bad request response with a ValidationProblemDetails. The response contains more data than just the validation errors, as shown in the following example when all of the fields of the *Starfleet Starship Database* form aren't submitted and the form fails validation:

```
{
  "title": "One or more validation errors occurred.",
  "status": 400,
  "errors": {
    "Identifier": ["The Identifier field is required."],
    "Classification": ["The Classification field is required."],
    "IsValidatedDesign": ["This form disallows unapproved ships."],
    "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
  }
}
```

If the server API returns the preceding default JSON response, it's possible for the client to parse the response to obtain the children of the `errors` node. However, it's inconvenient to parse the file. Parsing the JSON requires additional code after calling ReadFromJsonAsync in order to produce a `Dictionary<string, List<string>>` of errors for forms validation error processing. Ideally, the server API should only return the validation errors:

```
{
  "Identifier": ["The Identifier field is required."],
  "Classification": ["The Classification field is required."],
  "IsValidatedDesign": ["This form disallows unapproved ships."],
  "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
}
```

To modify the server API's response to make it only return the validation errors, change the delegate that's invoked on actions that are annotated with ApiControllerAttribute in `Startup.ConfigureServices`. For the API endpoint (`/StarshipValidation`), return a BadRequestObjectResult with the ModelStateDictionary. For any other API endpoints, preserve the default behavior by returning the object result with a new ValidationProblemDetails:

```
using Microsoft.AspNetCore.Mvc;

...

services.AddControllersWithViews()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.InvalidModelStateResponseFactory = context =>
        {
            if (context.HttpContext.Request.Path == "/StarshipValidation")
            {
                return new BadRequestObjectResult(context.ModelState);
            }
            else
            {
                return new BadRequestObjectResult(
                    new ValidationProblemDetails(context.ModelState));
            }
        };
    });
```

For more information, see Handle errors in ASP.NET Core web APIs.

In the client project, add the validator component shown in the Validator components section.

In the client project, the *Starfleet Starship Database* form is updated to show server validation errors with help of the `CustomValidator` component. When the server API returns validation messages, they're added to the `CustomValidator` component's ValidationMessageStore. The errors are available in the form's EditContext for display by the form's ValidationSummary:

```
@page "/FormValidation"
```

```
@using System.Net
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@using Microsoft.Extensions.Logging
@using BlazorSample.Shared
@attribute [Authorize]
@inject HttpClient Http
@inject ILogger<FormValidation> Logger

<h1>Starfleet Starship Database</h1>

            else if (!response.IsSuccessStatusCode)
            {
                throw new HttpRequestException(
                    $"Validation failed. Status Code: {response.StatusCode}");
            }
            else
            {
                disabled = true;
                messageStyles = "color:green";
                message = "The form has been processed.";
            }
        }
        catch (AccessTokenNotAvailableException ex)
        {
            ex.Redirect();
        }
        catch (Exception ex)
        {
            Logger.LogError("Form processing error: {MESSAGE}", ex.Message);
            disabled = true;
            messageStyles = "color:red";
            message = "There was an error processing the form.";
        }
    }
}
```

NOTE

As an alternative to validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

NOTE

The server-side validation approach in this section is suitable for any of the Blazor WebAssembly hosted solution examples in this documentation set:

- Azure Active Directory (AAD)
- Azure Active Directory (AAD) B2C
- Identity Server

InputText based on the input event

Use the InputText component to create a custom component that uses the `input` event instead of the `change` event.

In the following example, the `CustomInputText` component inherits the framework's `InputText` component and sets the event binding (CreateBinder) to the `oninput` event.

`Shared/CustomInputText.razor`:

```
@inherits InputText

<input
    @attributes="AdditionalAttributes"
    class="@CssClass"
    value="@CurrentValue"
    @oninput="EventCallback.Factory.CreateBinder<string>(
         this, __value => CurrentValueAsString = __value,
         CurrentValueAsString)" />
```

The `CustomInputText` component can be used anywhere InputText is used:

`Pages/TestForm.razor`:

```
@page "/testform"
@using System.ComponentModel.DataAnnotations;

<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <CustomInputText @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

<p>
    CurrentValue: @exampleModel.Name
</p>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }

    public class ExampleModel
    {
        [Required]
        [StringLength(10, ErrorMessage = "Name is too long.")]
        public string Name { get; set; }
    }
}
```

Radio buttons

Use `InputRadio` components with the `InputRadioGroup` component to create a radio button group. In the following example, properties are added to the `Starship` model described in the Built-in forms components section:

```
[Required]
[Range(typeof(Manufacturer), nameof(Manufacturer.SpaceX),
    nameof(Manufacturer.VirginGalactic), ErrorMessage = "Pick a manufacturer.")]
public Manufacturer Manufacturer { get; set; } = Manufacturer.Unknown;

[Required, EnumDataType(typeof(Color))]
public Color? Color { get; set; } = null;

[Required, EnumDataType(typeof(Engine))]
public Engine? Engine { get; set; } = null;
```

Add the following `enums` to the app. Create a new file to hold the `enums` or add the `enums` to the `Starship.cs` file. Make the `enums` accessible to the `Starship` model and the *Starfleet Starship Database* form:

```
public enum Manufacturer { SpaceX, NASA, ULA, Virgin, Unknown }
public enum Color { ImperialRed, SpacecruiserGreen, StarshipBlue, VoyagerOrange }
public enum Engine { Ion, Plasma, Fusion, Warp }
```

Update the *Starfleet Starship Database* form described in the Built-in forms components section. Add the components to produce:

- A radio button group for the ship manufacturer.
- A nested radio button group for ship color and engine.

```
<p>
    <InputRadioGroup @bind-Value="starship.Manufacturer">
        Manufacturer:
        <br>
        @foreach (var manufacturer in (Manufacturer[])Enum
            .GetValues(typeof(Manufacturer)))
        {
            <InputRadio Value="manufacturer" />
            @manufacturer
            <br>
        }
    </InputRadioGroup>
</p>

<p>
    Pick one color and one engine:
    <InputRadioGroup Name="engine" @bind-Value="starship.Engine">
        <InputRadioGroup Name="color" @bind-Value="starship.Color">
            <InputRadio Name="color" Value="Color.ImperialRed" />Imperial Red<br>
            <InputRadio Name="engine" Value="Engine.Ion" />Ion<br>
            <InputRadio Name="color" Value="Color.SpacecruiserGreen" />
                Spacecruiser Green<br>
            <InputRadio Name="engine" Value="Engine.Plasma" />Plasma<br>
            <InputRadio Name="color" Value="Color.StarshipBlue" />Starship Blue<br>
            <InputRadio Name="engine" Value="Engine.Fusion" />Fusion<br>
            <InputRadio Name="color" Value="Color.VoyagerOrange" />
                Voyager Orange<br>
            <InputRadio Name="engine" Value="Engine.Warp" />Warp<br>
        </InputRadioGroup>
    </InputRadioGroup>
</p>
```

NOTE

If `Name` is omitted, `InputRadio` components are grouped by their most recent ancestor.

When working with radio buttons in a form, data binding is handled differently than other elements because radio buttons are evaluated as a group. The value of each radio button is fixed, but the value of the radio button group is the value of the selected radio button. The following example shows how to:

- Handle data binding for a radio button group.
- Support validation using a custom `InputRadio` component.

```
@using System.Globalization
@typeparam TValue
@inherits InputBase<TValue>

<input @attributes="AdditionalAttributes" type="radio" value="@SelectedValue"
       checked="@(SelectedValue.Equals(Value))" @onchange="OnChange" />

@code {
    [Parameter]
    public TValue SelectedValue { get; set; }

    private void OnChange(ChangeEventArgs args)
    {
        CurrentValueAsString = args.Value.ToString();
    }

    protected override bool TryParseValueFromString(string value,
        out TValue result, out string errorMessage)
    {
        var success = BindConverter.TryConvertTo<TValue>(
            value, CultureInfo.CurrentCulture, out var parsedValue);
        if (success)
        {
            result = parsedValue;
            errorMessage = null;

            return true;
        }
        else
        {
            result = default;
            errorMessage = $"{FieldIdentifier.FieldName} field isn't valid.";

            return false;
        }
    }
}
```

The following EditForm uses the preceding `InputRadio` component to obtain and validate a rating from the user:

```
@page "/RadioButtonExample"
@using System.ComponentModel.DataAnnotations

<h1>Radio Button Group Test</h1>

<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    @for (int i = 1; i <= 5; i++)
    {
        <label>
            <InputRadio name="rate" SelectedValue="i" @bind-Value="model.Rating" />
            @i
        </label>
    }

    <button type="submit">Submit</button>
</EditForm>

<p>You chose: @model.Rating</p>

@code {
    private Model model = new Model();

    private void HandleValidSubmit()
    {
        ...
    }

    public class Model
    {
        [Range(1, 5)]
        public int Rating { get; set; }
    }
}
```

Binding `<select>` element options to C# object `null` values

There's no sensible way to represent a `<select>` element option value as a C# object `null` value, because:

- HTML attributes can't have `null` values. The closest equivalent to `null` in HTML is absence of the HTML `value` attribute from the `<option>` element.
- When selecting an `<option>` with no `value` attribute, the browser treats the value as the *text content* of that `<option>`'s element.

The Blazor framework doesn't attempt to suppress the default behavior because it would involve:

- Creating a chain of special-case workarounds in the framework.
- Breaking changes to current framework behavior.

The most plausible `null` equivalent in HTML is an *empty string* `value`. The Blazor framework handles `null` to empty string conversions for two-way binding to a `<select>`'s value.

The Blazor framework doesn't automatically handle `null` to empty string conversions when attempting two-way binding to a `<select>`'s value. For more information, see Fix binding `<select>` to a null value (dotnet/aspnetcore #23221).

Validation support

The DataAnnotationsValidator component attaches validation support using data annotations to the cascaded

EditContext. Enabling support for validation using data annotations requires this explicit gesture. To use a different validation system than data annotations, replace the DataAnnotationsValidator with a custom implementation. The ASP.NET Core implementation is available for inspection in the reference source: `DataAnnotationsValidator` / `AddDataAnnotationsValidation`. The preceding links to reference source provide code from the repository's `master` branch, which represents the product unit's current development for the next release of ASP.NET Core. To select the branch for a different release, use the GitHub branch selector (for example `release/3.1`).

Blazor performs two types of validation:

- *Field validation* is performed when the user tabs out of a field. During field validation, the DataAnnotationsValidator component associates all reported validation results with the field.
- *Model validation* is performed when the user submits the form. During model validation, the DataAnnotationsValidator component attempts to determine the field based on the member name that the validation result reports. Validation results that aren't associated with an individual member are associated with the model rather than a field.

Validation Summary and Validation Message components

The ValidationSummary component summarizes all validation messages, which is similar to the Validation Summary Tag Helper:

```
<ValidationSummary />
```

Output validation messages for a specific model with the `Model` parameter:

```
<ValidationSummary Model="@starship" />
```

The ValidationMessage<TValue> component displays validation messages for a specific field, which is similar to the Validation Message Tag Helper. Specify the field for validation with the `For` attribute and a lambda expression naming the model property:

```
<ValidationMessage For="@(() => starship.MaximumAccommodation)" />
```

The ValidationMessage<TValue> and ValidationSummary components support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the generated `<div>` or `<ul>` element.

Control the style of validation messages in the app's stylesheet (`wwwroot/css/app.css` or `wwwroot/css/site.css`). The default `validation-message` class sets the text color of validation messages to red:

```
.validation-message {
    color: red;
}
```

Custom validation attributes

To ensure that a validation result is correctly associated with a field when using a custom validation attribute, pass the validation context's MemberName when creating the ValidationResult:

```
using System;
using System.ComponentModel.DataAnnotations;

private class CustomValidator : ValidationAttribute
{
    protected override ValidationResult IsValid(object value,
        ValidationContext validationContext)
    {
        ...

        return new ValidationResult("Validation message to user.",
            new[] { validationContext.MemberName });
    }
}
```

NOTE

ValidationContext.GetService is `null`. Injecting services for validation in the `IsValid` method isn't supported.

Custom validation class attributes

Custom validation class names are useful when integrating with CSS frameworks, such as Bootstrap. To specify custom validation class names, create a class derived from `FieldCssClassProvider` and set the class on the EditContext instance:

```
var editContext = new EditContext(model);
editContext.SetFieldCssClassProvider(new MyFieldClassProvider());

...

private class MyFieldClassProvider : FieldCssClassProvider
{
    public override string GetFieldCssClass(EditContext editContext,
        in FieldIdentifier fieldIdentifier)
    {
        var isValid = !editContext.GetValidationMessages(fieldIdentifier).Any();

        return isValid ? "good field" : "bad field";
    }
}
```

Blazor data annotations validation package

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` is a package that fills validation experience gaps using the DataAnnotationsValidator component. The package is currently *experimental*.

NOTE

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package has a latest version of *release candidate* at Nuget.org. Continue to use the *experimental* release candidate package at this time. The package's assembly might be moved to either the framework or the runtime in a future release. Watch the Announcements GitHub repository, the dotnet/aspnetcore GitHub repository, or this topic section for further updates.

[CompareProperty] attribute

The CompareAttribute doesn't work well with the DataAnnotationsValidator component because it doesn't associate the validation result with a specific member. This can result in inconsistent behavior between field-level validation and when the entire model is validated on a submit. The

`Microsoft.AspNetCore.Components.DataAnnotations.Validation` *experimental* package introduces an additional validation attribute, `ComparePropertyAttribute`, that works around these limitations. In a Blazor app, `[CompareProperty]` is a direct replacement for the `[Compare]` attribute.

Nested models, collection types, and complex types

Blazor provides support for validating form input using data annotations with the built-in DataAnnotationsValidator. However, the DataAnnotationsValidator only validates top-level properties of the model bound to the form that aren't collection- or complex-type properties.

To validate the bound model's entire object graph, including collection- and complex-type properties, use the `ObjectGraphDataAnnotationsValidator` provided by the *experimental* `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package:

```
<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <ObjectGraphDataAnnotationsValidator />
    ...
</EditForm>
```

Annotate model properties with `[ValidateComplexType]`. In the following model classes, the `ShipDescription` class contains additional data annotations to validate when the model is bound to the form:

`Starship.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    ...

    [ValidateComplexType]
    public ShipDescription ShipDescription { get; set; } =
        new ShipDescription();

    ...
}
```

`ShipDescription.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class ShipDescription
{
    [Required]
    [StringLength(40, ErrorMessage = "Description too long (40 char).")]
    public string ShortDescription { get; set; }

    [Required]
    [StringLength(240, ErrorMessage = "Description too long (240 char).")]
    public string LongDescription { get; set; }
}
```

Enable the submit button based on form validation

To enable and disable the submit button based on form validation:

- Use the form's EditContext to assign the model when the component is initialized.
- Validate the form in the context's OnFieldChanged callback to enable and disable the submit button.

- Unhook the event handler in the `Dispose` method. For more information, see ASP.NET Core Blazor lifecycle.

> **NOTE**
> When using an EditContext, don't also assign a Model to the EditForm.

```
@implements IDisposable

<EditForm EditContext="@editContext">
    <DataAnnotationsValidator />
    <ValidationSummary />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private bool formInvalid = true;
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
        editContext.OnFieldChanged += HandleFieldChanged;
    }

    private void HandleFieldChanged(object sender, FieldChangedEventArgs e)
    {
        formInvalid = !editContext.Validate();
        StateHasChanged();
    }

    public void Dispose()
    {
        editContext.OnFieldChanged -= HandleFieldChanged;
    }
}
```

In the preceding example, set `formInvalid` to `false` if:

- The form is preloaded with valid default values.
- You want the submit button enabled when the form loads.

A side effect of the preceding approach is that a ValidationSummary component is populated with invalid fields after the user interacts with any one field. This scenario can be addressed in either of the following ways:

- Don't use a ValidationSummary component on the form.
- Make the ValidationSummary component visible when the submit button is selected (for example, in a `HandleValidSubmit` method).

```
<EditForm EditContext="@editContext" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary style="@displaySummary" />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private string displaySummary = "display:none";

    ...

    private void HandleValidSubmit()
    {
        displaySummary = "display:block";
    }
}
```

Troubleshoot

> InvalidOperationException: EditForm requires a Model parameter, or an EditContext parameter, but not both.

Confirm that the EditForm has a Model **or** EditContext. Don't use both for the same form.

When assigning a Model to the form, confirm that the model type is instantiated, as the following example shows:

```
private ExampleModel exampleModel = new ExampleModel();
```

ASP.NET Core Blazor forms and validation

9/22/2020 • 22 minutes to read • Edit Online

By Daniel Roth, Rémi Bourgarel, and Luke Latham

Forms and validation are supported in Blazor using data annotations.

The following `ExampleModel` type defines validation logic using data annotations:

```
using System.ComponentModel.DataAnnotations;

public class ExampleModel
{
    [Required]
    [StringLength(10, ErrorMessage = "Name is too long.")]
    public string Name { get; set; }
}
```

A form is defined using the EditForm component. The following form demonstrates typical elements, components, and Razor code:

```
<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <InputText id="name" @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }
}
```

In the preceding example:

- The form validates user input in the `name` field using the validation defined in the `ExampleModel` type. The model is created in the component's `@code` block and held in a private field (`exampleModel`). The field is assigned to the `Model` attribute of the `<EditForm>` element.
- The InputText component's `@bind-Value` binds:
  - The model property (`exampleModel.Name`) to the InputText component's `Value` property. For more information on property binding, see ASP.NET Core Blazor data binding.
  - A change event delegate to the InputText component's `ValueChanged` property.
- The DataAnnotationsValidator validator component attaches validation support using data annotations.
- The ValidationSummary component summarizes validation messages.
- `HandleValidSubmit` is triggered when the form successfully submits (passes validation).

Built-in forms components

A set of built-in components are available to receive and validate user input. Inputs are validated when they're changed and when a form is submitted. Available input components are shown in the following table.

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
`InputFile`	`<input type="file">`
InputNumber<TValue>	`<input type="number">`
`InputRadio`	`<input type="radio">`
`InputRadioGroup`	`<input type="radio">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
InputNumber<TValue>	`<input type="number">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

> **NOTE**
>
> The `InputRadio` and `InputRadioGroup` components are available in ASP.NET Core 5.0 or later. For more information, select a 5.0 or later version of this article.

All of the input components, including EditForm, support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the rendered HTML element.

Input components provide default behavior for validating when a field is changed, including updating the field CSS class to reflect the field state. Some components include useful parsing logic. For example, InputDate<TValue> and InputNumber<TValue> handle unparseable values gracefully by registering unparseable values as validation errors. Types that can accept null values also support nullability of the target field (for example, `int?`).

The following `Starship` type defines validation logic using a larger set of properties and data annotations than the

earlier `ExampleModel`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    [Required]
    [StringLength(16, ErrorMessage = "Identifier too long (16 character limit).")]
    public string Identifier { get; set; }

    public string Description { get; set; }

    [Required]
    public string Classification { get; set; }

    [Range(1, 100000, ErrorMessage = "Accommodation invalid (1-100000).")]
    public int MaximumAccommodation { get; set; }

    [Required]
    [Range(typeof(bool), "true", "true",
        ErrorMessage = "This form disallows unapproved ships.")]
    public bool IsValidatedDesign { get; set; }

    [Required]
    public DateTime ProductionDate { get; set; }
}
```

In the preceding example, `Description` is optional because no data annotations are present.

The following form validates user input using the validation defined in the `Starship` model:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <p>
        <label>
            Identifier:
            <InputText @bind-Value="starship.Identifier" />
        </label>
    </p>
    <p>
        <label>
            Description (optional):
            <InputTextArea @bind-Value="starship.Description" />
        </label>
    </p>
    <p>
        <label>
            Primary Classification:
            <InputSelect @bind-Value="starship.Classification">
                <option value="">Select classification ...</option>
                <option value="Exploration">Exploration</option>
                <option value="Diplomacy">Diplomacy</option>
                <option value="Defense">Defense</option>
            </InputSelect>
        </label>
    </p>
    <p>
```

```
        <label>
            Maximum Accommodation:
            <InputNumber @bind-Value="starship.MaximumAccommodation" />
        </label>
    </p>
    <p>
        <label>
            Engineering Approval:
            <InputCheckbox @bind-Value="starship.IsValidatedDesign" />
        </label>
    </p>
    <p>
        <label>
            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" />
        </label>
    </p>

    <button type="submit">Submit</button>

    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        ...
    }
}
```

The EditForm creates an EditContext as a cascading value that tracks metadata about the edit process, including which fields have been modified and the current validation messages.

Assign **either** an EditContext **or** an EditForm.Model to an EditForm. Assignment of both isn't supported and generates a **runtime error**.

The EditForm provides convenient events for valid and invalid form submission:

- OnValidSubmit
- OnInvalidSubmit

Use OnSubmit to use custom code to trigger validation and check field values.

In the following example:

- The `HandleSubmit` method executes when the `Submit` button is selected.
- The form is validated by calling EditContext.Validate.
- Additional code is executed depending on the validation result. Place business logic in the method assigned to OnSubmit.

```
<EditForm EditContext="@editContext" OnSubmit="@HandleSubmit">

    ...

    <button type="submit">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
    }

    private async Task HandleSubmit()
    {
        var isValid = editContext.Validate();

        if (isValid)
        {
            ...
        }
        else
        {
            ...
        }
    }
}
```

NOTE

Framework API doesn't exist to clear validation messages directly from an EditContext. Therefore, we don't generally recommend adding validation messages to a new ValidationMessageStore in a form. To manage validation messages, use a validator component with your business logic validation code, as described in this article.

Display name support

This section applies to ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.

The following built-in components support display names with the `DisplayName` parameter:

- InputDate<TValue>
- InputNumber<TValue>
- InputSelect<TValue>

In the following `InputDate` component example:

- The display name (`DisplayName`) is set to `birthday`.
- The component is bound to the `BirthDate` property as a `DateTime` type.

```
<InputDate @bind-Value="@BirthDate" DisplayName="birthday" />

@code {
    public DateTime BirthDate { get; set; }
}
```

If the user doesn't provide a date value, the validation error appears as:

```
The birthday must be a date.
```

Validator components

Validator components support form validation by managing a ValidationMessageStore for a form's EditContext.

The Blazor framework provides the DataAnnotationsValidator component to attach validation support to forms based on validation attributes (data annotations). Create custom validator components to process validation messages for different forms on the same page or the same form at different steps of form processing, for example client-side validation followed by server-side validation. The validator component example shown in this section, `CustomValidator`, is used in the following sections of this article:

- Business logic validation
- Server validation

> **NOTE**
> Custom data annotation validation attributes can be used instead of custom validator components in many cases. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, any custom attributes applied to the model must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Create a validator component from ComponentBase:

- The form's EditContext is a cascading parameter of the component.
- When the validator component is initialized, a new ValidationMessageStore is created to maintain a current list of form errors.
- The message store receives errors when developer code in the form's component calls the `DisplayErrors` method. The errors are passed to the `DisplayErrors` method in a `Dictionary<string, List<string>>`. In the dictionary, the key is the name of the form field that has one or more errors. The value is the error list.
- Messages are cleared when any of the following have occurred:
  - Validation is requested on the EditContext when the OnValidationRequested event is raised. All of the errors are cleared.
  - A field changes in the form when the OnFieldChanged event is raised. Only the errors for the field are cleared.
  - The `ClearErrors` method is called by developer code. All of the errors are cleared.

```
using System;
using System.Collections.Generic;
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Forms;

namespace BlazorSample.Client
{
    public class CustomValidator : ComponentBase
    {
        private ValidationMessageStore messageStore;

        [CascadingParameter]
        private EditContext CurrentEditContext { get; set; }

        protected override void OnInitialized()
        {
            if (CurrentEditContext == null)
            {
                throw new InvalidOperationException(
                    $"{nameof(CustomValidator)} requires a cascading " +
                    $"parameter of type {nameof(EditContext)}. " +
                    $"For example, you can use {nameof(CustomValidator)} " +
                    $"inside an {nameof(EditForm)}.");
            }

            messageStore = new ValidationMessageStore(CurrentEditContext);

            CurrentEditContext.OnValidationRequested += (s, e) =>
                messageStore.Clear();
            CurrentEditContext.OnFieldChanged += (s, e) =>
                messageStore.Clear(e.FieldIdentifier);
        }

        public void DisplayErrors(Dictionary<string, List<string>> errors)
        {
            foreach (var err in errors)
            {
                messageStore.Add(CurrentEditContext.Field(err.Key), err.Value);
            }

            CurrentEditContext.NotifyValidationStateChanged();
        }

        public void ClearErrors()
        {
            messageStore.Clear();
            CurrentEditContext.NotifyValidationStateChanged();
        }
    }
}
```

Business logic validation

Business logic validation can be accomplished with a validator component that receives form errors in a dictionary.

In the following example:

- The `CustomValidator` component from the Validator components section of this article is used.
- The validation requires a value for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

When validation messages are set in the component, they're added to the validator's ValidationMessageStore and shown in the EditForm:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    ...

</EditForm>

@code {
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        customValidator.ClearErrors();

        var errors = new Dictionary<string, List<string>>();

        if (starship.Classification == "Defense" &&
                string.IsNullOrEmpty(starship.Description))
        {
            errors.Add(nameof(starship.Description),
                new List<string>() { "For a 'Defense' ship classification, " +
                "'Description' is required." });
        }

        if (errors.Count() > 0)
        {
            customValidator.DisplayErrors(errors);
        }
        else
        {
            // Process the form
        }
    }
}
```

NOTE

As an alternative to using validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Server validation

Server validation can be accomplished with a server validator component:

- Process client-side validation in the form with the DataAnnotationsValidator component.
- When the form passes client-side validation (OnValidSubmit is called), send the EditContext.Model to a backend server API for form processing.
- Process model validation on the server.
- The server API includes both the built-in framework data annotations validation and custom validation logic supplied by the developer. If validation passes on the server, process the form and send back a success status code (*200 - OK*). If validation fails, return a failure status code (*400 - Bad Request*) and the field validation errors.

- Either disable the form on success or display the errors.

The following example is based on:

- A hosted Blazor solution created by the Blazor Hosted project template. The example can be used with any of the secure hosted Blazor solutions described in the Security and Identity documentation.
- The *Starfleet Starship Database* form example in the preceding Built-in forms components section.
- The Blazor framework's DataAnnotationsValidator component.
- The `CustomValidator` component shown in the Validator components section.

In the following example, the server API validates that a value is provided for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

Place the `Starship` model into the solution's `Shared` project so that both the client and server apps can use the model. Since the model requires data annotations, add a package reference for `System.ComponentModel.Annotations` to the `Shared` project's project file:

```
<ItemGroup>
  <PackageReference Include="System.ComponentModel.Annotations" Version="{VERSION}" />
</ItemGroup>
```

To determine the latest non-preview version of the package, see the package **Version History** at NuGet.org.

In the server API project, add a controller to process starship validation requests (`Controllers/StarshipValidation.cs`) and return failed validation messages:

```
using System;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Logging;
using BlazorSample.Shared;

namespace BlazorSample.Server.Controllers
{
    [Authorize]
    [ApiController]
    [Route("[controller]")]
    public class StarshipValidationController : ControllerBase
    {
        private readonly ILogger<StarshipValidationController> logger;

        public StarshipValidationController(
            ILogger<StarshipValidationController> logger)
        {
            this.logger = logger;
        }

        [HttpPost]
        public async Task<IActionResult> Post(Starship starship)
        {
            try
            {
                if (starship.Classification == "Defense" &&
                    string.IsNullOrEmpty(starship.Description))
                {
                    ModelState.AddModelError(nameof(starship.Description),
                        "For a 'Defense' ship " +
                        "classification, 'Description' is required.");
                }
                else
                {
                    // Process the form asynchronously
                    // async ...

                    return Ok(ModelState);
                }
            }
            catch (Exception ex)
            {
                logger.LogError("Validation Error: {MESSAGE}", ex.Message);
            }

            return BadRequest(ModelState);
        }
    }
}
```

When a model binding validation error occurs on the server, an `ApiController` (ApiControllerAttribute) normally returns a default bad request response with a ValidationProblemDetails. The response contains more data than just the validation errors, as shown in the following example when all of the fields of the *Starfleet Starship Database* form aren't submitted and the form fails validation:

```
{
  "title": "One or more validation errors occurred.",
  "status": 400,
  "errors": {
    "Identifier": ["The Identifier field is required."],
    "Classification": ["The Classification field is required."],
    "IsValidatedDesign": ["This form disallows unapproved ships."],
    "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
  }
}
```

If the server API returns the preceding default JSON response, it's possible for the client to parse the response to obtain the children of the `errors` node. However, it's inconvenient to parse the file. Parsing the JSON requires additional code after calling ReadFromJsonAsync in order to produce a `Dictionary<string, List<string>>` of errors for forms validation error processing. Ideally, the server API should only return the validation errors:

```
{
  "Identifier": ["The Identifier field is required."],
  "Classification": ["The Classification field is required."],
  "IsValidatedDesign": ["This form disallows unapproved ships."],
  "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
}
```

To modify the server API's response to make it only return the validation errors, change the delegate that's invoked on actions that are annotated with ApiControllerAttribute in `Startup.ConfigureServices`. For the API endpoint (`/StarshipValidation`), return a BadRequestObjectResult with the ModelStateDictionary. For any other API endpoints, preserve the default behavior by returning the object result with a new ValidationProblemDetails:

```
using Microsoft.AspNetCore.Mvc;

...

services.AddControllersWithViews()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.InvalidModelStateResponseFactory = context =>
        {
            if (context.HttpContext.Request.Path == "/StarshipValidation")
            {
                return new BadRequestObjectResult(context.ModelState);
            }
            else
            {
                return new BadRequestObjectResult(
                    new ValidationProblemDetails(context.ModelState));
            }
        };
    });
```

For more information, see Handle errors in ASP.NET Core web APIs.

In the client project, add the validator component shown in the Validator components section.

In the client project, the *Starfleet Starship Database* form is updated to show server validation errors with help of the `CustomValidator` component. When the server API returns validation messages, they're added to the `CustomValidator` component's ValidationMessageStore. The errors are available in the form's EditContext for display by the form's ValidationSummary:

```
@page "/FormValidation"
```

```
@using System.Net
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@using Microsoft.Extensions.Logging
@using BlazorSample.Shared
@attribute [Authorize]
@inject HttpClient Http
@inject ILogger<FormValidation> Logger

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    <p>
        <label>
            Identifier:
            <InputText @bind-Value="starship.Identifier" disabled="@disabled" />
        </label>
    </p>
    <p>
        <label>
            Description (optional):

                disabled="@disabled" />
        </label>
    </p>
    <p>
        <label>
            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" disabled="@disabled" />
        </label>
    </p>

    <button type="submit" disabled="@disabled">Submit</button>

    <p style="@messageStyles">
        @message
    </p>
```

```
    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private bool disabled;
    private string message;
    private string messageStyles = "visibility:hidden";
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private async Task HandleValidSubmit(EditContext editContext)
    {
        customValidator.ClearErrors();

        try
        {
            var response = await Http.PostAsJsonAsync<Starship>(
                "StarshipValidation", (Starship)editContext.Model);

            var errors = await response.Content
                .ReadFromJsonAsync<Dictionary<string, List<string>>>();

            if (response.StatusCode == HttpStatusCode.BadRequest &&
                errors.Count() > 0)
            {
                customValidator.DisplayErrors(errors);
            }
            else if (!response.IsSuccessStatusCode)
            {
                throw new HttpRequestException(
                    $"Validation failed. Status Code: {response.StatusCode}");
            }
            else
            {
                disabled = true;
                messageStyles = "color:green";
                message = "The form has been processed.";
            }
        }
        catch (AccessTokenNotAvailableException ex)
        {
            ex.Redirect();
        }
        catch (Exception ex)
        {
            Logger.LogError("Form processing error: {MESSAGE}", ex.Message);
            disabled = true;
            messageStyles = "color:red";
            message = "There was an error processing the form.";
        }
    }
}
```

NOTE

As an alternative to validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

NOTE

The server-side validation approach in this section is suitable for any of the Blazor WebAssembly hosted solution examples in this documentation set:

- Azure Active Directory (AAD)
- Azure Active Directory (AAD) B2C
- Identity Server

InputText based on the input event

Use the InputText component to create a custom component that uses the `input` event instead of the `change` event.

In the following example, the `CustomInputText` component inherits the framework's `InputText` component and sets the event binding (CreateBinder) to the `oninput` event.

`Shared/CustomInputText.razor`:

```
@inherits InputText

<input
    @attributes="AdditionalAttributes"
    class="@CssClass"
    value="@CurrentValue"
    @oninput="EventCallback.Factory.CreateBinder<string>(
         this, __value => CurrentValueAsString = __value,
         CurrentValueAsString)" />
```

The `CustomInputText` component can be used anywhere InputText is used:

`Pages/TestForm.razor`:

```
@page "/testform"
@using System.ComponentModel.DataAnnotations;

<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <CustomInputText @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

<p>
    CurrentValue: @exampleModel.Name
</p>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }

    public class ExampleModel
    {
        [Required]
        [StringLength(10, ErrorMessage = "Name is too long.")]
        public string Name { get; set; }
    }
}
```

Radio buttons

Use `InputRadio` components with the `InputRadioGroup` component to create a radio button group. In the following example, properties are added to the `Starship` model described in the Built-in forms components section:

```
[Required]
[Range(typeof(Manufacturer), nameof(Manufacturer.SpaceX),
    nameof(Manufacturer.VirginGalactic), ErrorMessage = "Pick a manufacturer.")]
public Manufacturer Manufacturer { get; set; } = Manufacturer.Unknown;

[Required, EnumDataType(typeof(Color))]
public Color? Color { get; set; } = null;

[Required, EnumDataType(typeof(Engine))]
public Engine? Engine { get; set; } = null;
```

Add the following `enums` to the app. Create a new file to hold the `enums` or add the `enums` to the `Starship.cs` file. Make the `enums` accessible to the `Starship` model and the *Starfleet Starship Database* form:

```
public enum Manufacturer { SpaceX, NASA, ULA, Virgin, Unknown }
public enum Color { ImperialRed, SpacecruiserGreen, StarshipBlue, VoyagerOrange }
public enum Engine { Ion, Plasma, Fusion, Warp }
```

Update the *Starfleet Starship Database* form described in the Built-in forms components section. Add the components to produce:

- A radio button group for the ship manufacturer.
- A nested radio button group for ship color and engine.

```
<p>
    <InputRadioGroup @bind-Value="starship.Manufacturer">
        Manufacturer:
        <br>
        @foreach (var manufacturer in (Manufacturer[])Enum
            .GetValues(typeof(Manufacturer)))
        {
            <InputRadio Value="manufacturer" />
            @manufacturer
            <br>
        }
    </InputRadioGroup>
</p>

<p>
    Pick one color and one engine:
    <InputRadioGroup Name="engine" @bind-Value="starship.Engine">
        <InputRadioGroup Name="color" @bind-Value="starship.Color">
            <InputRadio Name="color" Value="Color.ImperialRed" />Imperial Red<br>
            <InputRadio Name="engine" Value="Engine.Ion" />Ion<br>
            <InputRadio Name="color" Value="Color.SpacecruiserGreen" />
                Spacecruiser Green<br>
            <InputRadio Name="engine" Value="Engine.Plasma" />Plasma<br>
            <InputRadio Name="color" Value="Color.StarshipBlue" />Starship Blue<br>
            <InputRadio Name="engine" Value="Engine.Fusion" />Fusion<br>
            <InputRadio Name="color" Value="Color.VoyagerOrange" />
                Voyager Orange<br>
            <InputRadio Name="engine" Value="Engine.Warp" />Warp<br>
        </InputRadioGroup>
    </InputRadioGroup>
</p>
```

NOTE

If `Name` is omitted, `InputRadio` components are grouped by their most recent ancestor.

When working with radio buttons in a form, data binding is handled differently than other elements because radio buttons are evaluated as a group. The value of each radio button is fixed, but the value of the radio button group is the value of the selected radio button. The following example shows how to:

- Handle data binding for a radio button group.
- Support validation using a custom `InputRadio` component.

```
@using System.Globalization
@typeparam TValue
@inherits InputBase<TValue>

<input @attributes="AdditionalAttributes" type="radio" value="@SelectedValue"
       checked="@(SelectedValue.Equals(Value))" @onchange="OnChange" />

@code {
    [Parameter]
    public TValue SelectedValue { get; set; }

    private void OnChange(ChangeEventArgs args)
    {
        CurrentValueAsString = args.Value.ToString();
    }

    protected override bool TryParseValueFromString(string value,
        out TValue result, out string errorMessage)
    {
        var success = BindConverter.TryConvertTo<TValue>(
            value, CultureInfo.CurrentCulture, out var parsedValue);
        if (success)
        {
            result = parsedValue;
            errorMessage = null;

            return true;
        }
        else
        {
            result = default;
            errorMessage = $"{FieldIdentifier.FieldName} field isn't valid.";

            return false;
        }
    }
}
```

The following EditForm uses the preceding `InputRadio` component to obtain and validate a rating from the user:

```
@page "/RadioButtonExample"
@using System.ComponentModel.DataAnnotations

<h1>Radio Button Group Test</h1>

<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    @for (int i = 1; i <= 5; i++)
    {
        <label>
            <InputRadio name="rate" SelectedValue="i" @bind-Value="model.Rating" />
            @i
        </label>
    }

    <button type="submit">Submit</button>
</EditForm>

<p>You chose: @model.Rating</p>

@code {
    private Model model = new Model();

    private void HandleValidSubmit()
    {
        ...
    }

    public class Model
    {
        [Range(1, 5)]
        public int Rating { get; set; }
    }
}
```

Binding `<select>` element options to C# object `null` values

There's no sensible way to represent a `<select>` element option value as a C# object `null` value, because:

- HTML attributes can't have `null` values. The closest equivalent to `null` in HTML is absence of the HTML `value` attribute from the `<option>` element.
- When selecting an `<option>` with no `value` attribute, the browser treats the value as the *text content* of that `<option>`'s element.

The Blazor framework doesn't attempt to suppress the default behavior because it would involve:

- Creating a chain of special-case workarounds in the framework.
- Breaking changes to current framework behavior.

The most plausible `null` equivalent in HTML is an *empty string* `value`. The Blazor framework handles `null` to empty string conversions for two-way binding to a `<select>`'s value.

The Blazor framework doesn't automatically handle `null` to empty string conversions when attempting two-way binding to a `<select>`'s value. For more information, see Fix binding `<select>` to a null value (dotnet/aspnetcore #23221).

Validation support

The DataAnnotationsValidator component attaches validation support using data annotations to the cascaded

EditContext. Enabling support for validation using data annotations requires this explicit gesture. To use a different validation system than data annotations, replace the DataAnnotationsValidator with a custom implementation. The ASP.NET Core implementation is available for inspection in the reference source: `DataAnnotationsValidator` / `AddDataAnnotationsValidation`. The preceding links to reference source provide code from the repository's `master` branch, which represents the product unit's current development for the next release of ASP.NET Core. To select the branch for a different release, use the GitHub branch selector (for example `release/3.1`).

Blazor performs two types of validation:

- *Field validation* is performed when the user tabs out of a field. During field validation, the DataAnnotationsValidator component associates all reported validation results with the field.
- *Model validation* is performed when the user submits the form. During model validation, the DataAnnotationsValidator component attempts to determine the field based on the member name that the validation result reports. Validation results that aren't associated with an individual member are associated with the model rather than a field.

Validation Summary and Validation Message components

The ValidationSummary component summarizes all validation messages, which is similar to the Validation Summary Tag Helper:

```
<ValidationSummary />
```

Output validation messages for a specific model with the `Model` parameter:

```
<ValidationSummary Model="@starship" />
```

The ValidationMessage<TValue> component displays validation messages for a specific field, which is similar to the Validation Message Tag Helper. Specify the field for validation with the `For` attribute and a lambda expression naming the model property:

```
<ValidationMessage For="@(() => starship.MaximumAccommodation)" />
```

The ValidationMessage<TValue> and ValidationSummary components support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the generated `<div>` or `<ul>` element.

Control the style of validation messages in the app's stylesheet (`wwwroot/css/app.css` or `wwwroot/css/site.css`). The default `validation-message` class sets the text color of validation messages to red:

```
.validation-message {
    color: red;
}
```

Custom validation attributes

To ensure that a validation result is correctly associated with a field when using a custom validation attribute, pass the validation context's MemberName when creating the ValidationResult:

```
using System;
using System.ComponentModel.DataAnnotations;

private class CustomValidator : ValidationAttribute
{
    protected override ValidationResult IsValid(object value,
        ValidationContext validationContext)
    {
        ...

        return new ValidationResult("Validation message to user.",
            new[] { validationContext.MemberName });
    }
}
```

NOTE

ValidationContext.GetService is `null`. Injecting services for validation in the `IsValid` method isn't supported.

Custom validation class attributes

Custom validation class names are useful when integrating with CSS frameworks, such as Bootstrap. To specify custom validation class names, create a class derived from `FieldCssClassProvider` and set the class on the EditContext instance:

```
var editContext = new EditContext(model);
editContext.SetFieldCssClassProvider(new MyFieldClassProvider());

...

private class MyFieldClassProvider : FieldCssClassProvider
{
    public override string GetFieldCssClass(EditContext editContext,
        in FieldIdentifier fieldIdentifier)
    {
        var isValid = !editContext.GetValidationMessages(fieldIdentifier).Any();

        return isValid ? "good field" : "bad field";
    }
}
```

Blazor data annotations validation package

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` is a package that fills validation experience gaps using the DataAnnotationsValidator component. The package is currently *experimental*.

NOTE

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package has a latest version of *release candidate* at Nuget.org. Continue to use the *experimental* release candidate package at this time. The package's assembly might be moved to either the framework or the runtime in a future release. Watch the Announcements GitHub repository, the dotnet/aspnetcore GitHub repository, or this topic section for further updates.

[CompareProperty] attribute

The CompareAttribute doesn't work well with the DataAnnotationsValidator component because it doesn't associate the validation result with a specific member. This can result in inconsistent behavior between field-level validation and when the entire model is validated on a submit. The

`Microsoft.AspNetCore.Components.DataAnnotations.Validation` *experimental* package introduces an additional validation attribute, `ComparePropertyAttribute`, that works around these limitations. In a Blazor app, `[CompareProperty]` is a direct replacement for the `[Compare]` attribute.

Nested models, collection types, and complex types

Blazor provides support for validating form input using data annotations with the built-in DataAnnotationsValidator. However, the DataAnnotationsValidator only validates top-level properties of the model bound to the form that aren't collection- or complex-type properties.

To validate the bound model's entire object graph, including collection- and complex-type properties, use the `ObjectGraphDataAnnotationsValidator` provided by the *experimental* `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package:

```
<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <ObjectGraphDataAnnotationsValidator />
    ...
</EditForm>
```

Annotate model properties with `[ValidateComplexType]`. In the following model classes, the `ShipDescription` class contains additional data annotations to validate when the model is bound to the form:

`Starship.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    ...

    [ValidateComplexType]
    public ShipDescription ShipDescription { get; set; } =
        new ShipDescription();

    ...
}
```

`ShipDescription.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class ShipDescription
{
    [Required]
    [StringLength(40, ErrorMessage = "Description too long (40 char).")]
    public string ShortDescription { get; set; }

    [Required]
    [StringLength(240, ErrorMessage = "Description too long (240 char).")]
    public string LongDescription { get; set; }
}
```

Enable the submit button based on form validation

To enable and disable the submit button based on form validation:

- Use the form's EditContext to assign the model when the component is initialized.
- Validate the form in the context's OnFieldChanged callback to enable and disable the submit button.

- Unhook the event handler in the `Dispose` method. For more information, see ASP.NET Core Blazor lifecycle.

> **NOTE**
> When using an EditContext, don't also assign a Model to the EditForm.

```
@implements IDisposable

<EditForm EditContext="@editContext">
    <DataAnnotationsValidator />
    <ValidationSummary />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private bool formInvalid = true;
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
        editContext.OnFieldChanged += HandleFieldChanged;
    }

    private void HandleFieldChanged(object sender, FieldChangedEventArgs e)
    {
        formInvalid = !editContext.Validate();
        StateHasChanged();
    }

    public void Dispose()
    {
        editContext.OnFieldChanged -= HandleFieldChanged;
    }
}
```

In the preceding example, set `formInvalid` to `false` if:

- The form is preloaded with valid default values.
- You want the submit button enabled when the form loads.

A side effect of the preceding approach is that a ValidationSummary component is populated with invalid fields after the user interacts with any one field. This scenario can be addressed in either of the following ways:

- Don't use a ValidationSummary component on the form.
- Make the ValidationSummary component visible when the submit button is selected (for example, in a `HandleValidSubmit` method).

```
<EditForm EditContext="@editContext" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary style="@displaySummary" />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private string displaySummary = "display:none";

    ...

    private void HandleValidSubmit()
    {
        displaySummary = "display:block";
    }
}
```

Troubleshoot

> InvalidOperationException: EditForm requires a Model parameter, or an EditContext parameter, but not both.

Confirm that the EditForm has a Model **or** EditContext. Don't use both for the same form.

When assigning a Model to the form, confirm that the model type is instantiated, as the following example shows:

```
private ExampleModel exampleModel = new ExampleModel();
```

ASP.NET Core Blazor hosting model configuration

9/22/2020 • 7 minutes to read • Edit Online

By Daniel Roth, Mackinnon Buck, and Luke Latham

This article covers hosting model configuration.

SignalR cross-origin negotiation for authentication

This section applies to Blazor WebAssembly.

To configure SignalR's underlying client to send credentials, such as cookies or HTTP authentication headers:

- Use SetBrowserRequestCredentials to set Include on cross-origin `fetch` requests:

```
public class IncludeRequestCredentialsMessageHandler : DelegatingHandler
{
    protected override Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {
        request.SetBrowserRequestCredentials(BrowserRequestCredentials.Include);
        return base.SendAsync(request, cancellationToken);
    }
}
```

- Assign the HttpMessageHandler to the HttpMessageHandlerFactory option:

```
var connection = new HubConnectionBuilder()
    .WithUrl(new Uri("http://signalr.example.com"), options =>
    {
        options.HttpMessageHandlerFactory = innerHandler =>
            new IncludeRequestCredentialsMessageHandler { InnerHandler = innerHandler };
    }).Build();
```

For more information, see ASP.NET Core SignalR configuration.

Reflect the connection state in the UI

This section applies to Blazor Server.

When the client detects that the connection has been lost, a default UI is displayed to the user while the client attempts to reconnect. If reconnection fails, the user is provided the option to retry.

To customize the UI, define an element with an `id` of `components-reconnect-modal` in the `<body>` of the `_Host.cshtml` Razor page:

```
<div id="components-reconnect-modal">
    ...
</div>
```

Add the following to the app's stylesheet (`wwwroot/css/app.css` or `wwwroot/css/site.css`):

```
#components-reconnect-modal {
    display: none;
}

#components-reconnect-modal.components-reconnect-show {
    display: block;
}
```

The following table describes the CSS classes applied to the `components-reconnect-modal` element.

CSS CLASS	INDICATES...
`components-reconnect-show`	A lost connection. The client is attempting to reconnect. Show the modal.
`components-reconnect-hide`	An active connection is re-established to the server. Hide the modal.
`components-reconnect-failed`	Reconnection failed, probably due to a network failure. To attempt reconnection, call `window.Blazor.reconnect()`.
`components-reconnect-rejected`	Reconnection rejected. The server was reached but refused the connection, and the user's state on the server is lost. To reload the app, call `location.reload()`. This connection state may result when: • A crash in the server-side circuit occurs. • The client is disconnected long enough for the server to drop the user's state. Instances of the components that the user is interacting with are disposed. • The server is restarted, or the app's worker process is recycled.

Render mode

This section applies to Blazor Server.

Blazor Server apps are set up by default to prerender the UI on the server before the client connection to the server is established. This is set up in the `_Host.cshtml` Razor page:

```
<body>
    <app>
      <component type="typeof(App)" render-mode="ServerPrerendered" />
    </app>

    <script src="_framework/blazor.server.js"></script>
</body>
```

RenderMode configures whether the component:

- Is prerendered into the page.
- Is rendered as static HTML on the page or if it includes the necessary information to bootstrap a Blazor app from the user agent.

RENDER MODE	DESCRIPTION
ServerPrerendered	Renders the component into static HTML and includes a marker for a Blazor Server app. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Server	Renders a marker for a Blazor Server app. Output from the component isn't included. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Static	Renders the component into static HTML.

Rendering server components from a static HTML page isn't supported.

Initialize the Blazor circuit

This section applies to Blazor Server.

Configure the manual start of a Blazor Server app's SignalR circuit in the `Pages/_Host.cshtml` file:

- Add an `autostart="false"` attribute to the `<script>` tag for the `blazor.server.js` script.
- Place a script that calls `Blazor.start` after the `blazor.server.js` script's tag and inside the closing `</body>` tag.

When `autostart` is disabled, any aspect of the app that doesn't depend on the circuit works normally. For example, client-side routing is operational. However, any aspect that depends on the circuit isn't operational until `Blazor.start` is called. App behavior is unpredictable without an established circuit. For example, component methods fail to execute while the circuit is disconnected.

Initialize Blazor when the document is ready

To initialize the Blazor app when the document is ready:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      document.addEventListener("DOMContentLoaded", function() {
        Blazor.start();
      });
    </script>
</body>
```

Chain to the `Promise` that results from a manual start

To perform additional tasks, such as JS interop initialization, use `then` to chain to the `Promise` that results from a manual Blazor app start:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start().then(function () {
        ...
      });
    </script>
</body>
```

Configure the SignalR client

Logging

To configure SignalR client logging, pass in a configuration object (`configureSignalR`) that calls `configureLogging` with the log level on the client builder:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start({
        configureSignalR: function (builder) {
          builder.configureLogging("information");
        }
      });
    </script>
</body>
```

In the preceding example, `information` is equivalent to a log level of LogLevel.Information.

Modify the reconnection handler

The reconnection handler's circuit connection events can be modified for custom behaviors, such as:

- To notify the user if the connection is dropped.
- To perform logging (from the client) when a circuit is connected.

To modify the connection events, register callbacks for the following connection changes:

- Dropped connections use `onConnectionDown` .
- Established/re-established connections use `onConnectionUp` .

Both `onConnectionDown` and `onConnectionUp` must be specified:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start({
        reconnectionHandler: {
          onConnectionDown: (options, error) => console.error(error);
          onConnectionUp: () => console.log("Up, up, and away!");
        }
      });
    </script>
</body>
```

Adjust the reconnection retry count and interval

To adjust the reconnection retry count and interval, set the number of retries (`maxRetries`) and period in milliseconds permitted for each retry attempt (`retryIntervalMilliseconds`):

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start({
        reconnectionOptions: {
          maxRetries: 3,
          retryIntervalMilliseconds: 2000
        }
      });
    </script>
</body>
```

Hide or replace the reconnection display

To hide the reconnection display, set the reconnection handler's `_reconnectionDisplay` to an empty object (`{}` or `new Object()`):

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      window.addEventListener('beforeunload', function () {
        Blazor.defaultReconnectionHandler._reconnectionDisplay = {};
      });

      Blazor.start();
    </script>
</body>
```

To replace the reconnection display, set `_reconnectionDisplay` in the preceding example to the element for display:

```
Blazor.defaultReconnectionHandler._reconnectionDisplay =
  document.getElementById("{ELEMENT ID}");
```

The placeholder `{ELEMENT ID}` is the ID of the HTML element to display.

Customize the delay before the reconnection display appears by setting the `transition-delay` property in the app's CSS (`wwwroot/css/site.css`) for the modal element. The following example sets the transition delay from 500 ms (default) to 1,000 ms (1 second):

```
#components-reconnect-modal {
    transition: visibility 0s linear 1000ms;
}
```

Influence HTML `<head>` tag elements

This section applies to the upcoming ASP.NET Core 5.0 release of Blazor WebAssembly and Blazor Server.

When rendered, the `Title`, `Link`, and `Meta` components add or update data in the HTML `<head>` tag elements:

```
@using Microsoft.AspNetCore.Components.Web.Extensions.Head

<Title Value="{TITLE}" />
<Link href="{URL}" rel="stylesheet" />
<Meta content="{DESCRIPTION}" name="description" />
```

In the preceding example, placeholders for `{TITLE}`, `{URL}`, and `{DESCRIPTION}` are string values, Razor variables, or Razor expressions.

The following characteristics apply:

- Server-side prerendering is supported.
- The `Value` parameter is the only valid parameter for the `Title` component.
- HTML attributes provided to the `Meta` and `Link` components are captured in additional attributes and passed through to the rendered HTML tag.
- For multiple `Title` components, the title of the page reflects the `Value` of the last `Title` component rendered.
- If multiple `Meta` or `Link` components are included with identical attributes, there's exactly one HTML tag rendered per `Meta` or `Link` component. Two `Meta` or `Link` components can't refer to the same rendered HTML tag.
- Changes to the parameters of existing `Meta` or `Link` components are reflected in their rendered HTML tags.
- When the `Link` or `Meta` components are no longer rendered and thus disposed by the framework, their rendered HTML tags are removed.

When one of the framework components is used in a child component, the rendered HTML tag influences any other child component of the parent component as long as the child component containing the framework component is rendered. The distinction between using the one of these framework components in a child component and placing a an HTML tag in `wwwroot/index.html` or `Pages/_Host.cshtml` is that a framework component's rendered HTML tag:

- Can be modified by application state. A hard-coded HTML tag can't be modified by application state.
- Is removed from the HTML `<head>` when the parent component is no longer rendered.

Static files

This section applies to Blazor Server.

To create additional file mappings with a FileExtensionContentTypeProvider or configure other StaticFileOptions, use **one** of the following approaches. In the following examples, the `{EXTENSION}` placeholder is the file extension, and the `{CONTENT TYPE}` placeholder is the content type.

- Configure options through dependency injection (DI) in `Startup.ConfigureServices` (`Startup.cs`) using StaticFileOptions:

```
using Microsoft.AspNetCore.StaticFiles;

...

var provider = new FileExtensionContentTypeProvider();
provider.Mappings["{EXTENSION}"] = "{CONTENT TYPE}";

services.Configure<StaticFileOptions>(options =>
{
    options.ContentTypeProvider = provider;
});
```

  Because this approach configures the same file provider used to serve `blazor.server.js`, make sure that your custom configuration doesn't interfere with serving `blazor.server.js`. For example, don't remove the mapping for JavaScript files by configuring the provider with `provider.Mappings.Remove(".js")`.

- Use two calls to UseStaticFiles in `Startup.Configure` (`Startup.cs`):
  - Configure the custom file provider in the first call with StaticFileOptions.
  - The second middleware serves `blazor.server.js`, which uses the default static files configuration provided by the Blazor framework.

```
using Microsoft.AspNetCore.StaticFiles;

...

var provider = new FileExtensionContentTypeProvider();
provider.Mappings["{EXTENSION}"] = "{CONTENT TYPE}";

app.UseStaticFiles(new StaticFileOptions { ContentTypeProvider = provider });
app.UseStaticFiles();
```

ASP.NET Core Blazor layouts

9/22/2020 • 4 minutes to read • Edit Online

By Rainer Stropek and Luke Latham

Some app elements, such as menus, copyright messages, and company logos, are usually part of app's overall layout and used by every component in the app. Copying the code of these elements into all of the components of an app isn't an efficient approach. Every time one of the elements requires an update, every component must be updated. Such duplication is difficult to maintain and can lead to inconsistent content over time. *Layouts* solve this problem.

Technically, a layout is just another component. A layout is defined in a Razor template or in C# code and can use data binding, dependency injection, and other component scenarios.

To turn a *component* into a *layout*, the component:

- Inherits from LayoutComponentBase, which defines a Body property for the rendered content inside the layout.
- Uses the Razor syntax `@Body` to specify the location in the layout markup where the content is rendered.

The following code sample shows the Razor template of a layout component, `MainLayout.razor`. The layout inherits LayoutComponentBase and sets the `@Body` between the navigation bar and the footer:

```
@inherits LayoutComponentBase

<header>
    <h1>Doctor Who&trade; Episode Database</h1>
</header>

<nav>
    <a href="masterlist">Master Episode List</a>
    <a href="search">Search</a>
    <a href="new">Add Episode</a>
</nav>

@Body

<footer>
    @TrademarkMessage
</footer>

@code {
    public string TrademarkMessage { get; set; } =
        "Doctor Who is a registered trademark of the BBC. " +
        "https://www.doctorwho.tv/";
}
```

`MainLayout` component

In an app based on one of the Blazor project templates, the `MainLayout` component (`MainLayout.razor`) is in the app's `Shared` folder:

```
@inherits LayoutComponentBase

<div class="sidebar">
    <NavMenu />
</div>

<div class="main">
    <div class="content px-4">
        @Body
    </div>
</div>
```

Default layout

Specify the default app layout in the Router component in the app's `App.razor` file. The following Router component, which is provided by the default Blazor templates, sets the default layout to the `MainLayout` component:

```
<Router AppAssembly="@typeof(Startup).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="@routeData" DefaultLayout="@typeof(MainLayout)" />
    </Found>
    <NotFound>
        <p>Sorry, there's nothing at this address.</p>
    </NotFound>
</Router>
```

To supply a default layout for NotFound content, specify a LayoutView for NotFound content:

```
<Router AppAssembly="@typeof(Startup).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="@routeData" DefaultLayout="@typeof(MainLayout)" />
    </Found>
    <NotFound>
        <LayoutView Layout="@typeof(MainLayout)">
            <h1>Page not found</h1>
            <p>Sorry, there's nothing at this address.</p>
        </LayoutView>
    </NotFound>
</Router>
```

For more information on the Router component, see ASP.NET Core Blazor routing.

Specifying the layout as a default layout in the router is a useful practice because it can be overridden on a per-component or per-folder basis. Prefer using the router to set the app's default layout because it's the most general technique.

Specify a layout in a component

Use the Razor directive `@layout` to apply a layout to a component. The compiler converts `@layout` into a LayoutAttribute, which is applied to the component class.

The content of the following `MasterList` component is inserted into the `MasterLayout` at the position of `@Body`:

```
@layout MasterLayout
@page "/masterlist"

<h1>Master Episode List</h1>
```

Specifying the layout directly in a component overrides a *default layout* set in the router or an `@layout` directive imported from `_Imports.razor`.

Centralized layout selection

Every folder of an app can optionally contain a template file named `_Imports.razor`. The compiler includes the directives specified in the imports file in all of the Razor templates in the same folder and recursively in all of its subfolders. Therefore, an `_Imports.razor` file containing `@layout MyCoolLayout` ensures that all of the components in a folder use `MyCoolLayout`. There's no need to repeatedly add `@layout MyCoolLayout` to all of the `.razor` files within the folder and subfolders. `@using` directives are also applied to components in the same way.

The following `_Imports.razor` file imports:

- `MyCoolLayout`.
- All Razor components in the same folder and any subfolders.
- The `BlazorApp1.Data` namespace.

```
@layout MyCoolLayout
@using Microsoft.AspNetCore.Components
@using BlazorApp1.Data
```

The `_Imports.razor` file is similar to the _ViewImports.cshtml file for Razor views and pages but applied specifically to Razor component files.

Specifying a layout in `_Imports.razor` overrides a layout specified as the router's *default layout*.

WARNING

Do **not** add a Razor `@layout` directive to the root `_Imports.razor` file, which results in an infinite loop of layouts in the app. To control the default app layout, specify the layout in the `Router` component. For more information, see the Default layout section.

Nested layouts

Apps can consist of nested layouts. A component can reference a layout which in turn references another layout. For example, nesting layouts are used to create a multi-level menu structure.

The following example shows how to use nested layouts. The `EpisodesComponent.razor` file is the component to display. The component references the `MasterListLayout`:

```
@layout MasterListLayout
@page "/masterlist/episodes"

<h1>Episodes</h1>
```

The `MasterListLayout.razor` file provides the `MasterListLayout`. The layout references another layout, `MasterLayout`, where it's rendered. `EpisodesComponent` is rendered where `@Body` appears:

```
@layout MasterLayout
@inherits LayoutComponentBase

<nav>
    <!-- Menu structure of master list -->
    ...
</nav>

@Body
```

Finally, `MasterLayout` in `MasterLayout.razor` contains the top-level layout elements, such as the header, main menu, and footer. `MasterListLayout` with the `EpisodesComponent` is rendered where `@Body` appears:

```
@inherits LayoutComponentBase

<header>...</header>
<nav>...</nav>

@Body

<footer>
    @TrademarkMessage
</footer>

@code {
    public string TrademarkMessage { get; set; } =
        "Doctor Who is a registered trademark of the BBC. " +
        "https://www.doctorwho.tv/";
}
```

Share a Razor Pages layout with integrated components

When routable components are integrated into a Razor Pages app, the app's shared layout can be used with the components. For more information, see Integrate ASP.NET Core Razor components into Razor Pages and MVC apps.

ASP.NET Core Blazor hosting model configuration

9/22/2020 • 7 minutes to read • Edit Online

By Daniel Roth, Mackinnon Buck, and Luke Latham

This article covers hosting model configuration.

SignalR cross-origin negotiation for authentication

This section applies to Blazor WebAssembly.

To configure SignalR's underlying client to send credentials, such as cookies or HTTP authentication headers:

- Use SetBrowserRequestCredentials to set Include on cross-origin `fetch` requests:

```
public class IncludeRequestCredentialsMessageHandler : DelegatingHandler
{
    protected override Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {
        request.SetBrowserRequestCredentials(BrowserRequestCredentials.Include);
        return base.SendAsync(request, cancellationToken);
    }
}
```

- Assign the HttpMessageHandler to the HttpMessageHandlerFactory option:

```
var connection = new HubConnectionBuilder()
    .WithUrl(new Uri("http://signalr.example.com"), options =>
    {
        options.HttpMessageHandlerFactory = innerHandler =>
            new IncludeRequestCredentialsMessageHandler { InnerHandler = innerHandler };
    }).Build();
```

For more information, see ASP.NET Core SignalR configuration.

Reflect the connection state in the UI

This section applies to Blazor Server.

When the client detects that the connection has been lost, a default UI is displayed to the user while the client attempts to reconnect. If reconnection fails, the user is provided the option to retry.

To customize the UI, define an element with an `id` of `components-reconnect-modal` in the `<body>` of the `_Host.cshtml` Razor page:

```
<div id="components-reconnect-modal">
    ...
</div>
```

Add the following to the app's stylesheet (`wwwroot/css/app.css` or `wwwroot/css/site.css`):

```
#components-reconnect-modal {
    display: none;
}

#components-reconnect-modal.components-reconnect-show {
    display: block;
}
```

The following table describes the CSS classes applied to the `components-reconnect-modal` element.

CSS CLASS	INDICATES...
`components-reconnect-show`	A lost connection. The client is attempting to reconnect. Show the modal.
`components-reconnect-hide`	An active connection is re-established to the server. Hide the modal.
`components-reconnect-failed`	Reconnection failed, probably due to a network failure. To attempt reconnection, call `window.Blazor.reconnect()`.
`components-reconnect-rejected`	Reconnection rejected. The server was reached but refused the connection, and the user's state on the server is lost. To reload the app, call `location.reload()`. This connection state may result when: • A crash in the server-side circuit occurs. • The client is disconnected long enough for the server to drop the user's state. Instances of the components that the user is interacting with are disposed. • The server is restarted, or the app's worker process is recycled.

Render mode

This section applies to Blazor Server.

Blazor Server apps are set up by default to prerender the UI on the server before the client connection to the server is established. This is set up in the `_Host.cshtml` Razor page:

```
<body>
    <app>
      <component type="typeof(App)" render-mode="ServerPrerendered" />
    </app>

    <script src="_framework/blazor.server.js"></script>
</body>
```

RenderMode configures whether the component:

- Is prerendered into the page.
- Is rendered as static HTML on the page or if it includes the necessary information to bootstrap a Blazor app from the user agent.

RENDER MODE	DESCRIPTION
ServerPrerendered	Renders the component into static HTML and includes a marker for a Blazor Server app. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Server	Renders a marker for a Blazor Server app. Output from the component isn't included. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Static	Renders the component into static HTML.

Rendering server components from a static HTML page isn't supported.

Initialize the Blazor circuit

This section applies to Blazor Server.

Configure the manual start of a Blazor Server app's SignalR circuit in the `Pages/_Host.cshtml` file:

- Add an `autostart="false"` attribute to the `<script>` tag for the `blazor.server.js` script.
- Place a script that calls `Blazor.start` after the `blazor.server.js` script's tag and inside the closing `</body>` tag.

When `autostart` is disabled, any aspect of the app that doesn't depend on the circuit works normally. For example, client-side routing is operational. However, any aspect that depends on the circuit isn't operational until `Blazor.start` is called. App behavior is unpredictable without an established circuit. For example, component methods fail to execute while the circuit is disconnected.

Initialize Blazor when the document is ready

To initialize the Blazor app when the document is ready:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      document.addEventListener("DOMContentLoaded", function() {
        Blazor.start();
      });
    </script>
</body>
```

Chain to the `Promise` that results from a manual start

To perform additional tasks, such as JS interop initialization, use `then` to chain to the `Promise` that results from a manual Blazor app start:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start().then(function () {
        ...
      });
    </script>
</body>
```

Configure the SignalR client

Logging

To configure SignalR client logging, pass in a configuration object (`configureSignalR`) that calls `configureLogging` with the log level on the client builder:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start({
        configureSignalR: function (builder) {
          builder.configureLogging("information");
        }
      });
    </script>
</body>
```

In the preceding example, `information` is equivalent to a log level of LogLevel.Information.

Modify the reconnection handler

The reconnection handler's circuit connection events can be modified for custom behaviors, such as:

- To notify the user if the connection is dropped.
- To perform logging (from the client) when a circuit is connected.

To modify the connection events, register callbacks for the following connection changes:

- Dropped connections use `onConnectionDown` .
- Established/re-established connections use `onConnectionUp` .

Both `onConnectionDown` and `onConnectionUp` must be specified:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start({
        reconnectionHandler: {
          onConnectionDown: (options, error) => console.error(error);
          onConnectionUp: () => console.log("Up, up, and away!");
        }
      });
    </script>
</body>
```

Adjust the reconnection retry count and interval

To adjust the reconnection retry count and interval, set the number of retries (`maxRetries`) and period in milliseconds permitted for each retry attempt (`retryIntervalMilliseconds`):

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start({
        reconnectionOptions: {
          maxRetries: 3,
          retryIntervalMilliseconds: 2000
        }
      });
    </script>
</body>
```

Hide or replace the reconnection display

To hide the reconnection display, set the reconnection handler's `_reconnectionDisplay` to an empty object (`{}` or `new Object()`):

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      window.addEventListener('beforeunload', function () {
        Blazor.defaultReconnectionHandler._reconnectionDisplay = {};
      });

      Blazor.start();
    </script>
</body>
```

To replace the reconnection display, set `_reconnectionDisplay` in the preceding example to the element for display:

```
Blazor.defaultReconnectionHandler._reconnectionDisplay =
  document.getElementById("{ELEMENT ID}");
```

The placeholder `{ELEMENT ID}` is the ID of the HTML element to display.

Customize the delay before the reconnection display appears by setting the `transition-delay` property in the app's CSS (`wwwroot/css/site.css`) for the modal element. The following example sets the transition delay from 500 ms (default) to 1,000 ms (1 second):

```
#components-reconnect-modal {
    transition: visibility 0s linear 1000ms;
}
```

Influence HTML `<head>` tag elements

This section applies to the upcoming ASP.NET Core 5.0 release of Blazor WebAssembly and Blazor Server.

When rendered, the `Title`, `Link`, and `Meta` components add or update data in the HTML `<head>` tag elements:

```
@using Microsoft.AspNetCore.Components.Web.Extensions.Head

<Title Value="{TITLE}" />
<Link href="{URL}" rel="stylesheet" />
<Meta content="{DESCRIPTION}" name="description" />
```

In the preceding example, placeholders for `{TITLE}`, `{URL}`, and `{DESCRIPTION}` are string values, Razor variables, or Razor expressions.

The following characteristics apply:

- Server-side prerendering is supported.
- The `Value` parameter is the only valid parameter for the `Title` component.
- HTML attributes provided to the `Meta` and `Link` components are captured in additional attributes and passed through to the rendered HTML tag.
- For multiple `Title` components, the title of the page reflects the `Value` of the last `Title` component rendered.
- If multiple `Meta` or `Link` components are included with identical attributes, there's exactly one HTML tag rendered per `Meta` or `Link` component. Two `Meta` or `Link` components can't refer to the same rendered HTML tag.
- Changes to the parameters of existing `Meta` or `Link` components are reflected in their rendered HTML tags.
- When the `Link` or `Meta` components are no longer rendered and thus disposed by the framework, their rendered HTML tags are removed.

When one of the framework components is used in a child component, the rendered HTML tag influences any other child component of the parent component as long as the child component containing the framework component is rendered. The distinction between using the one of these framework components in a child component and placing a an HTML tag in `wwwroot/index.html` or `Pages/_Host.cshtml` is that a framework component's rendered HTML tag:

- Can be modified by application state. A hard-coded HTML tag can't be modified by application state.
- Is removed from the HTML `<head>` when the parent component is no longer rendered.

Static files

This section applies to Blazor Server.

To create additional file mappings with a FileExtensionContentTypeProvider or configure other StaticFileOptions, use **one** of the following approaches. In the following examples, the `{EXTENSION}` placeholder is the file extension, and the `{CONTENT TYPE}` placeholder is the content type.

- Configure options through dependency injection (DI) in `Startup.ConfigureServices` (`Startup.cs`) using StaticFileOptions:

```
using Microsoft.AspNetCore.StaticFiles;

...

var provider = new FileExtensionContentTypeProvider();
provider.Mappings["{EXTENSION}"] = "{CONTENT TYPE}";

services.Configure<StaticFileOptions>(options =>
{
    options.ContentTypeProvider = provider;
});
```

  Because this approach configures the same file provider used to serve `blazor.server.js`, make sure that your custom configuration doesn't interfere with serving `blazor.server.js`. For example, don't remove the mapping for JavaScript files by configuring the provider with `provider.Mappings.Remove(".js")`.

- Use two calls to UseStaticFiles in `Startup.Configure` (`Startup.cs`):
  - Configure the custom file provider in the first call with StaticFileOptions.
  - The second middleware serves `blazor.server.js`, which uses the default static files configuration provided by the Blazor framework.

```
using Microsoft.AspNetCore.StaticFiles;

...

var provider = new FileExtensionContentTypeProvider();
provider.Mappings["{EXTENSION}"] = "{CONTENT TYPE}";

app.UseStaticFiles(new StaticFileOptions { ContentTypeProvider = provider });
app.UseStaticFiles();
```

ASP.NET Core Blazor routing

9/22/2020 • 9 minutes to read • Edit Online

By Luke Latham

Learn how to route requests and how to use the NavLink component to create navigation links in Blazor apps.

ASP.NET Core endpoint routing integration

Blazor Server is integrated into ASP.NET Core Endpoint Routing. An ASP.NET Core app is configured to accept incoming connections for interactive components with MapBlazorHub in `Startup.Configure`:

```
app.UseRouting();

app.UseEndpoints(endpoints =>
{
    endpoints.MapBlazorHub();
    endpoints.MapFallbackToPage("/_Host");
});
```

The most typical configuration is to route all requests to a Razor page, which acts as the host for the server-side part of the Blazor Server app. By convention, the *host* page is usually named `_Host.cshtml`. The route specified in the host file is called a *fallback route* because it operates with a low priority in route matching. The fallback route is considered when other routes don't match. This allows the app to use others controllers and pages without interfering with the Blazor Server app.

For information on configuring MapFallbackToPage for non-root URL server hosting, see Host and deploy ASP.NET Core Blazor.

Route templates

The Router component enables routing to each component with a specified route. The Router component appears in the `App.razor` file:

```
<Router AppAssembly="@typeof(Startup).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="@routeData" DefaultLayout="@typeof(MainLayout)" />
    </Found>
    <NotFound>
        <p>Sorry, there's nothing at this address.</p>
    </NotFound>
</Router>
```

When a `.razor` file with an `@page` directive is compiled, the generated class is provided a RouteAttribute specifying the route template.

At runtime, the RouteView component:

- Receives the RouteData from the Router along with any desired parameters.
- Renders the specified component with its layout (or an optional default layout) using the specified parameters.

You can optionally specify a DefaultLayout parameter with a layout class to use for components that don't specify a layout. The default Blazor templates specify the `MainLayout` component. `MainLayout.razor` is in the template

project's `Shared` folder. For more information on layouts, see ASP.NET Core Blazor layouts.

Multiple route templates can be applied to a component. The following component responds to requests for `/BlazorRoute` and `/DifferentBlazorRoute`:

```
@page "/BlazorRoute"
@page "/DifferentBlazorRoute"

<h1>Blazor routing</h1>
```

IMPORTANT

For URLs to resolve correctly, the app must include a `<base>` tag in its `wwwroot/index.html` file (Blazor WebAssembly) or `Pages/_Host.cshtml` file (Blazor Server) with the app base path specified in the `href` attribute (`<base href="/">`). For more information, see Host and deploy ASP.NET Core Blazor.

Provide custom content when content isn't found

The Router component allows the app to specify custom content if content isn't found for the requested route.

In the `App.razor` file, set custom content in the NotFound template parameter of the Router component:

```
<Router AppAssembly="typeof(Startup).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="@routeData" DefaultLayout="@typeof(MainLayout)" />
    </Found>
    <NotFound>
        <h1>Sorry</h1>
        <p>Sorry, there's nothing at this address.</p> b
    </NotFound>
</Router>
```

The content of `<NotFound>` tags can include arbitrary items, such as other interactive components. To apply a default layout to NotFound content, see ASP.NET Core Blazor layouts.

Route to components from multiple assemblies

Use the AdditionalAssemblies parameter to specify additional assemblies for the Router component to consider when searching for routable components. Specified assemblies are considered in addition to the `AppAssembly`-specified assembly. In the following example, `Component1` is a routable component defined in a referenced class library. The following AdditionalAssemblies example results in routing support for `Component1`:

```
<Router
    AppAssembly="@typeof(Program).Assembly"
    AdditionalAssemblies="new[] { typeof(Component1).Assembly }">
    ...
</Router>
```

Route parameters

The router uses route parameters to populate the corresponding component parameters with the same name (case insensitive):

```
@page "/RouteParameter"
@page "/RouteParameter/{text}"

<h1>Blazor is @Text!</h1>

@code {
    [Parameter]
    public string Text { get; set; }

    protected override void OnInitialized()
    {
        Text = Text ?? "fantastic";
    }
}
```

Optional parameters aren't supported. Two `@page` directives are applied in the previous example. The first permits navigation to the component without a parameter. The second `@page` directive takes the `{text}` route parameter and assigns the value to the `Text` property.

Route constraints

A route constraint enforces type matching on a route segment to a component.

In the following example, the route to the `Users` component only matches if:

- An `Id` route segment is present on the request URL.
- The `Id` segment is an integer (`int`).

```
@page "/Users/{Id:int}"

<h1>The user Id is @Id!</h1>

@code {
    [Parameter]
    public int Id { get; set; }
}
```

The route constraints shown in the following table are available. For the route constraints that match with the invariant culture, see the warning below the table for more information.

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	INVARIANT CULTURE MATCHING
`bool`	`{active:bool}`	`true`, `FALSE`	No
`datetime`	`{dob:datetime}`	`2016-12-31`, `2016-12-31 7:32pm`	Yes
`decimal`	`{price:decimal}`	`49.99`, `-1,000.01`	Yes
`double`	`{weight:double}`	`1.234`, `-1,001.01e8`	Yes
`float`	`{weight:float}`	`1.234`, `-1,001.01e8`	Yes

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	INVARIANT CULTURE MATCHING
`guid`	`{id:guid}`	`CD2C1638-1638-72D5-1638-DEADBEEF1638`, `{CD2C1638-1638-72D5-1638-DEADBEEF1638}`	No
`int`	`{id:int}`	`123456789`, `-123456789`	Yes
`long`	`{ticks:long}`	`123456789`, `-123456789`	Yes

WARNING

Route constraints that verify the URL and are converted to a CLR type (such as `int` or DateTime) always use the invariant culture. These constraints assume that the URL is non-localizable.

Routing with URLs that contain dots

For hosted Blazor WebAssembly and Blazor Server apps, the server-side default route template assumes that if the last segment of a request URL contains a dot (`.`) that a file is requested (for example, `https://localhost.com:5001/example/some.thing`). Without additional configuration, an app returns a *404 - Not Found* response if this was meant to route to a component. To use a route with one or more parameters that contains a dot, the app must configure the route with a custom template.

Consider the following `Example` component that can receive a route parameter from the last segment of the URL:

```
@page "/example"
@page "/example/{param}"

<p>
    Param: @Param
</p>

@code {
    [Parameter]
    public string Param { get; set; }
}
```

To permit the *Server* app of a hosted Blazor WebAssembly solution to route the request with a dot in the `param` parameter, add a fallback file route template with the optional parameter in `Startup.Configure` (`Startup.cs`):

```
endpoints.MapFallbackToFile("/example/{param?}", "index.html");
```

To configure a Blazor Server app to route the request with a dot in the `param` parameter, add a fallback page route template with the optional parameter in `Startup.Configure` (`Startup.cs`):

```
endpoints.MapFallbackToPage("/example/{param?}", "/_Host");
```

For more information, see Routing in ASP.NET Core.

Catch-all route parameters

This section applies to ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.

Catch-all route parameters, which capture paths across multiple folder boundaries, are supported in components. The catch-all route parameter must be:

- Named to match the route segment name. Naming isn't case sensitive.
- A `string` type. The framework doesn't provide automatic casting.
- At the end of the URL.

```
@page "/page/{*pageRoute}"

@code {
    [Parameter]
    public string PageRoute { get; set; }
}
```

For the URL `/page/this/is/a/test` with a route template of `/page/{*pageRoute}`, the value of `PageRoute` is set to `this/is/a/test`.

Slashes and segments of the captured path are decoded. For a route template of `/page/{*pageRoute}`, the URL `/page/this/is/a%2Ftest%2A` yields `this/is/a/test*`.

Catch-all route parameters are supported in ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.*

NavLink component

Use a NavLink component in place of HTML hyperlink elements (`<a>`) when creating navigation links. A NavLink component behaves like an `<a>` element, except it toggles an `active` CSS class based on whether its `href` matches the current URL. The `active` class helps a user understand which page is the active page among the navigation links displayed. Optionally, assign a CSS class name to NavLink.ActiveClass to apply a custom CSS class to the rendered link when the current route matches the `href`.

The following `NavMenu` component creates a `Bootstrap` navigation bar that demonstrates how to use NavLink components:

```
<div class="@NavMenuCssClass" @onclick="@ToggleNavMenu">
    <ul class="nav flex-column">
        <li class="nav-item px-3">
            <NavLink class="nav-link" href="" Match="NavLinkMatch.All">
                <span class="oi oi-home" aria-hidden="true"></span> Home
            </NavLink>
        </li>
        <li class="nav-item px-3">
            <NavLink class="nav-link" href="MyComponent" Match="NavLinkMatch.Prefix">
                <span class="oi oi-plus" aria-hidden="true"></span> My Component
            </NavLink>
        </li>
    </ul>
</div>
```

There are two NavLinkMatch options that you can assign to the `Match` attribute of the `<NavLink>` element:

- NavLinkMatch.All: The NavLink is active when it matches the entire current URL.
- NavLinkMatch.Prefix (*default*): The NavLink is active when it matches any prefix of the current URL.

In the preceding example, the Home NavLink `href=""` matches the home URL and only receives the `active` CSS class at the app's default base path URL (for example, `https://localhost:5001/`). The second NavLink receives the `active` class when the user visits any URL with a `MyComponent` prefix (for example,

`https://localhost:5001/MyComponent` and `https://localhost:5001/MyComponent/AnotherSegment`).

Additional NavLink component attributes are passed through to the rendered anchor tag. In the following example, the NavLink component includes the `target` attribute:

```
<NavLink href="my-page" target="_blank">My page</NavLink>
```

The following HTML markup is rendered:

```
<a href="my-page" target="_blank">My page</a>
```

WARNING

Due to the way that Blazor renders child content, rendering `NavLink` components inside a `for` loop requires a local index variable if the incrementing loop variable is used in the `NavLink` (child) component's content:

```
@for (int c = 0; c < 10; c++)
{
    var current = c;
    <li ...>
        <NavLink ... href="@c">
            <span ...></span> @current
        </NavLink>
    </li>
}
```

Using an index variable in this scenario is a requirement for **any** child component that uses a loop variable in its child content, not just the `NavLink` component.

Alternatively, use a `foreach` loop with Enumerable.Range:

```
@foreach(var c in Enumerable.Range(0,10))
{
    <li ...>
        <NavLink ... href="@c">
            <span ...></span> @c
        </NavLink>
    </li>
}
```

URI and navigation state helpers

Use NavigationManager to work with URIs and navigation in C# code. NavigationManager provides the event and methods shown in the following table.

MEMBER	DESCRIPTION
Uri	Gets the current absolute URI.
BaseUri	Gets the base URI (with a trailing slash) that can be prepended to relative URI paths to produce an absolute URI. Typically, BaseUri corresponds to the `href` attribute on the document's `<base>` element in `wwwroot/index.html` (Blazor WebAssembly) or `Pages/_Host.cshtml` (Blazor Server).

MEMBER	DESCRIPTION
NavigateTo	Navigates to the specified URI. If `forceLoad` is `true`: • Client-side routing is bypassed. • The browser is forced to load the new page from the server, whether or not the URI is normally handled by the client-side router.
LocationChanged	An event that fires when the navigation location has changed.
ToAbsoluteUri	Converts a relative URI into an absolute URI.
ToBaseRelativePath	Given a base URI (for example, a URI previously returned by BaseUri), converts an absolute URI into a URI relative to the base URI prefix.

The following component navigates to the app's `Counter` component when the button is selected:

```
@page "/navigate"
@inject NavigationManager NavigationManager

<h1>Navigate in Code Example</h1>

<button class="btn btn-primary" @onclick="NavigateToCounterComponent">
    Navigate to the Counter component
</button>

@code {
    private void NavigateToCounterComponent()
    {
        NavigationManager.NavigateTo("counter");
    }
}
```

The following component handles a location changed event by subscribing to NavigationManager.LocationChanged. The `HandleLocationChanged` method is unhooked when `Dispose` is called by the framework. Unhooking the method permits garbage collection of the component.

```
@implements IDisposable
@inject NavigationManager NavigationManager

...

protected override void OnInitialized()
{
    NavigationManager.LocationChanged += HandleLocationChanged;
}

private void HandleLocationChanged(object sender, LocationChangedEventArgs e)
{
    ...
}

public void Dispose()
{
    NavigationManager.LocationChanged -= HandleLocationChanged;
}
```

LocationChangedEventArgs provides the following information about the event:

- Location: The URL of the new location.
- IsNavigationIntercepted: If `true`, Blazor intercepted the navigation from the browser. If `false`, NavigationManager.NavigateTo caused the navigation to occur.

For more information on component disposal, see ASP.NET Core Blazor lifecycle.

Query string and parse parameters

The query string of a request can be obtained from the NavigationManager's Uri property:

```
@inject NavigationManager Navigation

...

var query = new Uri(Navigation.Uri).Query;
```

To parse a query string's parameters:

- Add a package reference for Microsoft.AspNetCore.WebUtilities.
- Obtain the value after parsing the query string with QueryHelpers.ParseQuery.

```
@page "/"
@using Microsoft.AspNetCore.WebUtilities
@inject NavigationManager NavigationManager

<h1>Query string parse example</h1>

<p>Value: @queryValue</p>

@code {
    private string queryValue = "Not set";

    protected override void OnInitialized()
    {
        var query = new Uri(NavigationManager.Uri).Query;

        if (QueryHelpers.ParseQuery(query).TryGetValue("{KEY}", out var value))
        {
            queryValue = value;
        }
    }
}
```

The placeholder `{KEY}` in the preceding example is the query string parameter key. For example, the URL key-value pair `?ship=Tardis` uses a key of `ship`.

ASP.NET Core Blazor routing

9/22/2020 • 9 minutes to read • Edit Online

By Luke Latham

Learn how to route requests and how to use the NavLink component to create navigation links in Blazor apps.

ASP.NET Core endpoint routing integration

Blazor Server is integrated into ASP.NET Core Endpoint Routing. An ASP.NET Core app is configured to accept incoming connections for interactive components with MapBlazorHub in `Startup.Configure`:

```
app.UseRouting();

app.UseEndpoints(endpoints =>
{
    endpoints.MapBlazorHub();
    endpoints.MapFallbackToPage("/_Host");
});
```

The most typical configuration is to route all requests to a Razor page, which acts as the host for the server-side part of the Blazor Server app. By convention, the *host* page is usually named `_Host.cshtml`. The route specified in the host file is called a *fallback route* because it operates with a low priority in route matching. The fallback route is considered when other routes don't match. This allows the app to use others controllers and pages without interfering with the Blazor Server app.

For information on configuring MapFallbackToPage for non-root URL server hosting, see Host and deploy ASP.NET Core Blazor.

Route templates

The Router component enables routing to each component with a specified route. The Router component appears in the `App.razor` file:

```
<Router AppAssembly="@typeof(Startup).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="@routeData" DefaultLayout="@typeof(MainLayout)" />
    </Found>
    <NotFound>
        <p>Sorry, there's nothing at this address.</p>
    </NotFound>
</Router>
```

When a `.razor` file with an `@page` directive is compiled, the generated class is provided a RouteAttribute specifying the route template.

At runtime, the RouteView component:

- Receives the RouteData from the Router along with any desired parameters.
- Renders the specified component with its layout (or an optional default layout) using the specified parameters.

You can optionally specify a DefaultLayout parameter with a layout class to use for components that don't specify a layout. The default Blazor templates specify the `MainLayout` component. `MainLayout.razor` is in the template

project's `Shared` folder. For more information on layouts, see ASP.NET Core Blazor layouts.

Multiple route templates can be applied to a component. The following component responds to requests for `/BlazorRoute` and `/DifferentBlazorRoute`:

```
@page "/BlazorRoute"
@page "/DifferentBlazorRoute"

<h1>Blazor routing</h1>
```

IMPORTANT

For URLs to resolve correctly, the app must include a `<base>` tag in its `wwwroot/index.html` file (Blazor WebAssembly) or `Pages/_Host.cshtml` file (Blazor Server) with the app base path specified in the `href` attribute (`<base href="/">`). For more information, see Host and deploy ASP.NET Core Blazor.

Provide custom content when content isn't found

The Router component allows the app to specify custom content if content isn't found for the requested route.

In the `App.razor` file, set custom content in the NotFound template parameter of the Router component:

```
<Router AppAssembly="typeof(Startup).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="@routeData" DefaultLayout="@typeof(MainLayout)" />
    </Found>
    <NotFound>
        <h1>Sorry</h1>
        <p>Sorry, there's nothing at this address.</p> b
    </NotFound>
</Router>
```

The content of `<NotFound>` tags can include arbitrary items, such as other interactive components. To apply a default layout to NotFound content, see ASP.NET Core Blazor layouts.

Route to components from multiple assemblies

Use the AdditionalAssemblies parameter to specify additional assemblies for the Router component to consider when searching for routable components. Specified assemblies are considered in addition to the `AppAssembly`-specified assembly. In the following example, `Component1` is a routable component defined in a referenced class library. The following AdditionalAssemblies example results in routing support for `Component1`:

```
<Router
    AppAssembly="@typeof(Program).Assembly"
    AdditionalAssemblies="new[] { typeof(Component1).Assembly }">
    ...
</Router>
```

Route parameters

The router uses route parameters to populate the corresponding component parameters with the same name (case insensitive):

```
@page "/RouteParameter"
@page "/RouteParameter/{text}"

<h1>Blazor is @Text!</h1>

@code {
    [Parameter]
    public string Text { get; set; }

    protected override void OnInitialized()
    {
        Text = Text ?? "fantastic";
    }
}
```

Optional parameters aren't supported. Two `@page` directives are applied in the previous example. The first permits navigation to the component without a parameter. The second `@page` directive takes the `{text}` route parameter and assigns the value to the `Text` property.

Route constraints

A route constraint enforces type matching on a route segment to a component.

In the following example, the route to the `Users` component only matches if:

- An `Id` route segment is present on the request URL.
- The `Id` segment is an integer (`int`).

```
@page "/Users/{Id:int}"

<h1>The user Id is @Id!</h1>

@code {
    [Parameter]
    public int Id { get; set; }
}
```

The route constraints shown in the following table are available. For the route constraints that match with the invariant culture, see the warning below the table for more information.

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	INVARIANT CULTURE MATCHING
`bool`	`{active:bool}`	`true`, `FALSE`	No
`datetime`	`{dob:datetime}`	`2016-12-31`, `2016-12-31 7:32pm`	Yes
`decimal`	`{price:decimal}`	`49.99`, `-1,000.01`	Yes
`double`	`{weight:double}`	`1.234`, `-1,001.01e8`	Yes
`float`	`{weight:float}`	`1.234`, `-1,001.01e8`	Yes

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	INVARIANT CULTURE MATCHING
`guid`	`{id:guid}`	`CD2C1638-1638-72D5-1638-DEADBEEF1638`, `{CD2C1638-1638-72D5-1638-DEADBEEF1638}`	No
`int`	`{id:int}`	`123456789`, `-123456789`	Yes
`long`	`{ticks:long}`	`123456789`, `-123456789`	Yes

WARNING

Route constraints that verify the URL and are converted to a CLR type (such as `int` or DateTime) always use the invariant culture. These constraints assume that the URL is non-localizable.

Routing with URLs that contain dots

For hosted Blazor WebAssembly and Blazor Server apps, the server-side default route template assumes that if the last segment of a request URL contains a dot (`.`) that a file is requested (for example, `https://localhost.com:5001/example/some.thing`). Without additional configuration, an app returns a *404 - Not Found* response if this was meant to route to a component. To use a route with one or more parameters that contains a dot, the app must configure the route with a custom template.

Consider the following `Example` component that can receive a route parameter from the last segment of the URL:

```
@page "/example"
@page "/example/{param}"

<p>
    Param: @Param
</p>

@code {
    [Parameter]
    public string Param { get; set; }
}
```

To permit the *Server* app of a hosted Blazor WebAssembly solution to route the request with a dot in the `param` parameter, add a fallback file route template with the optional parameter in `Startup.Configure` (`Startup.cs`):

```
endpoints.MapFallbackToFile("/example/{param?}", "index.html");
```

To configure a Blazor Server app to route the request with a dot in the `param` parameter, add a fallback page route template with the optional parameter in `Startup.Configure` (`Startup.cs`):

```
endpoints.MapFallbackToPage("/example/{param?}", "/_Host");
```

For more information, see Routing in ASP.NET Core.

Catch-all route parameters

This section applies to ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.

Catch-all route parameters, which capture paths across multiple folder boundaries, are supported in components. The catch-all route parameter must be:

- Named to match the route segment name. Naming isn't case sensitive.
- A `string` type. The framework doesn't provide automatic casting.
- At the end of the URL.

```
@page "/page/{*pageRoute}"

@code {
    [Parameter]
    public string PageRoute { get; set; }
}
```

For the URL `/page/this/is/a/test` with a route template of `/page/{*pageRoute}`, the value of `PageRoute` is set to `this/is/a/test`.

Slashes and segments of the captured path are decoded. For a route template of `/page/{*pageRoute}`, the URL `/page/this/is/a%2Ftest%2A` yields `this/is/a/test*`.

Catch-all route parameters are supported in ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.*

NavLink component

Use a NavLink component in place of HTML hyperlink elements (`<a>`) when creating navigation links. A NavLink component behaves like an `<a>` element, except it toggles an `active` CSS class based on whether its `href` matches the current URL. The `active` class helps a user understand which page is the active page among the navigation links displayed. Optionally, assign a CSS class name to NavLink.ActiveClass to apply a custom CSS class to the rendered link when the current route matches the `href`.

The following `NavMenu` component creates a `Bootstrap` navigation bar that demonstrates how to use NavLink components:

```
<div class="@NavMenuCssClass" @onclick="@ToggleNavMenu">
    <ul class="nav flex-column">
        <li class="nav-item px-3">
            <NavLink class="nav-link" href="" Match="NavLinkMatch.All">
                <span class="oi oi-home" aria-hidden="true"></span> Home
            </NavLink>
        </li>
        <li class="nav-item px-3">
            <NavLink class="nav-link" href="MyComponent" Match="NavLinkMatch.Prefix">
                <span class="oi oi-plus" aria-hidden="true"></span> My Component
            </NavLink>
        </li>
    </ul>
</div>
```

There are two NavLinkMatch options that you can assign to the `Match` attribute of the `<NavLink>` element:

- NavLinkMatch.All: The NavLink is active when it matches the entire current URL.
- NavLinkMatch.Prefix (*default*): The NavLink is active when it matches any prefix of the current URL.

In the preceding example, the Home NavLink `href=""` matches the home URL and only receives the `active` CSS class at the app's default base path URL (for example, `https://localhost:5001/`). The second NavLink receives the `active` class when the user visits any URL with a `MyComponent` prefix (for example,

`https://localhost:5001/MyComponent` and `https://localhost:5001/MyComponent/AnotherSegment`).

Additional NavLink component attributes are passed through to the rendered anchor tag. In the following example, the NavLink component includes the `target` attribute:

```
<NavLink href="my-page" target="_blank">My page</NavLink>
```

The following HTML markup is rendered:

```
<a href="my-page" target="_blank">My page</a>
```

WARNING

Due to the way that Blazor renders child content, rendering `NavLink` components inside a `for` loop requires a local index variable if the incrementing loop variable is used in the `NavLink` (child) component's content:

```
@for (int c = 0; c < 10; c++)
{
    var current = c;
    <li ...>
        <NavLink ... href="@c">
            <span ...></span> @current
        </NavLink>
    </li>
}
```

Using an index variable in this scenario is a requirement for **any** child component that uses a loop variable in its child content, not just the `NavLink` component.

Alternatively, use a `foreach` loop with Enumerable.Range:

```
@foreach(var c in Enumerable.Range(0,10))
{
    <li ...>
        <NavLink ... href="@c">
            <span ...></span> @c
        </NavLink>
    </li>
}
```

URI and navigation state helpers

Use NavigationManager to work with URIs and navigation in C# code. NavigationManager provides the event and methods shown in the following table.

MEMBER	DESCRIPTION
Uri	Gets the current absolute URI.
BaseUri	Gets the base URI (with a trailing slash) that can be prepended to relative URI paths to produce an absolute URI. Typically, BaseUri corresponds to the `href` attribute on the document's `<base>` element in `wwwroot/index.html` (Blazor WebAssembly) or `Pages/_Host.cshtml` (Blazor Server).

MEMBER	DESCRIPTION
NavigateTo	Navigates to the specified URI. If `forceLoad` is `true`: • Client-side routing is bypassed. • The browser is forced to load the new page from the server, whether or not the URI is normally handled by the client-side router.
LocationChanged	An event that fires when the navigation location has changed.
ToAbsoluteUri	Converts a relative URI into an absolute URI.
ToBaseRelativePath	Given a base URI (for example, a URI previously returned by BaseUri), converts an absolute URI into a URI relative to the base URI prefix.

The following component navigates to the app's `Counter` component when the button is selected:

```
@page "/navigate"
@inject NavigationManager NavigationManager

<h1>Navigate in Code Example</h1>

<button class="btn btn-primary" @onclick="NavigateToCounterComponent">
    Navigate to the Counter component
</button>

@code {
    private void NavigateToCounterComponent()
    {
        NavigationManager.NavigateTo("counter");
    }
}
```

The following component handles a location changed event by subscribing to NavigationManager.LocationChanged. The `HandleLocationChanged` method is unhooked when `Dispose` is called by the framework. Unhooking the method permits garbage collection of the component.

```
@implements IDisposable
@inject NavigationManager NavigationManager

...

protected override void OnInitialized()
{
    NavigationManager.LocationChanged += HandleLocationChanged;
}

private void HandleLocationChanged(object sender, LocationChangedEventArgs e)
{
    ...
}

public void Dispose()
{
    NavigationManager.LocationChanged -= HandleLocationChanged;
}
```

LocationChangedEventArgs provides the following information about the event:

- Location: The URL of the new location.
- IsNavigationIntercepted: If `true`, Blazor intercepted the navigation from the browser. If `false`, NavigationManager.NavigateTo caused the navigation to occur.

For more information on component disposal, see ASP.NET Core Blazor lifecycle.

Query string and parse parameters

The query string of a request can be obtained from the NavigationManager's Uri property:

```
@inject NavigationManager Navigation

...

var query = new Uri(Navigation.Uri).Query;
```

To parse a query string's parameters:

- Add a package reference for Microsoft.AspNetCore.WebUtilities.
- Obtain the value after parsing the query string with QueryHelpers.ParseQuery.

```
@page "/"
@using Microsoft.AspNetCore.WebUtilities
@inject NavigationManager NavigationManager

<h1>Query string parse example</h1>

<p>Value: @queryValue</p>

@code {
    private string queryValue = "Not set";

    protected override void OnInitialized()
    {
        var query = new Uri(NavigationManager.Uri).Query;

        if (QueryHelpers.ParseQuery(query).TryGetValue("{KEY}", out var value))
        {
            queryValue = value;
        }
    }
}
```

The placeholder `{KEY}` in the preceding example is the query string parameter key. For example, the URL key-value pair `?ship=Tardis` uses a key of `ship`.

ASP.NET Core Blazor routing

9/22/2020 • 9 minutes to read • Edit Online

By Luke Latham

Learn how to route requests and how to use the NavLink component to create navigation links in Blazor apps.

ASP.NET Core endpoint routing integration

Blazor Server is integrated into ASP.NET Core Endpoint Routing. An ASP.NET Core app is configured to accept incoming connections for interactive components with MapBlazorHub in `Startup.Configure`:

```
app.UseRouting();

app.UseEndpoints(endpoints =>
{
    endpoints.MapBlazorHub();
    endpoints.MapFallbackToPage("/_Host");
});
```

The most typical configuration is to route all requests to a Razor page, which acts as the host for the server-side part of the Blazor Server app. By convention, the *host* page is usually named `_Host.cshtml`. The route specified in the host file is called a *fallback route* because it operates with a low priority in route matching. The fallback route is considered when other routes don't match. This allows the app to use others controllers and pages without interfering with the Blazor Server app.

For information on configuring MapFallbackToPage for non-root URL server hosting, see Host and deploy ASP.NET Core Blazor.

Route templates

The Router component enables routing to each component with a specified route. The Router component appears in the `App.razor` file:

```
<Router AppAssembly="@typeof(Startup).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="@routeData" DefaultLayout="@typeof(MainLayout)" />
    </Found>
    <NotFound>
        <p>Sorry, there's nothing at this address.</p>
    </NotFound>
</Router>
```

When a `.razor` file with an `@page` directive is compiled, the generated class is provided a RouteAttribute specifying the route template.

At runtime, the RouteView component:

- Receives the RouteData from the Router along with any desired parameters.
- Renders the specified component with its layout (or an optional default layout) using the specified parameters.

You can optionally specify a DefaultLayout parameter with a layout class to use for components that don't specify a layout. The default Blazor templates specify the `MainLayout` component. `MainLayout.razor` is in the template

project's `Shared` folder. For more information on layouts, see ASP.NET Core Blazor layouts.

Multiple route templates can be applied to a component. The following component responds to requests for `/BlazorRoute` and `/DifferentBlazorRoute`:

```
@page "/BlazorRoute"
@page "/DifferentBlazorRoute"

<h1>Blazor routing</h1>
```

IMPORTANT

For URLs to resolve correctly, the app must include a `<base>` tag in its `wwwroot/index.html` file (Blazor WebAssembly) or `Pages/_Host.cshtml` file (Blazor Server) with the app base path specified in the `href` attribute (`<base href="/">`). For more information, see Host and deploy ASP.NET Core Blazor.

Provide custom content when content isn't found

The Router component allows the app to specify custom content if content isn't found for the requested route.

In the `App.razor` file, set custom content in the NotFound template parameter of the Router component:

```
<Router AppAssembly="typeof(Startup).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="@routeData" DefaultLayout="@typeof(MainLayout)" />
    </Found>
    <NotFound>
        <h1>Sorry</h1>
        <p>Sorry, there's nothing at this address.</p> b
    </NotFound>
</Router>
```

The content of `<NotFound>` tags can include arbitrary items, such as other interactive components. To apply a default layout to NotFound content, see ASP.NET Core Blazor layouts.

Route to components from multiple assemblies

Use the AdditionalAssemblies parameter to specify additional assemblies for the Router component to consider when searching for routable components. Specified assemblies are considered in addition to the `AppAssembly`-specified assembly. In the following example, `Component1` is a routable component defined in a referenced class library. The following AdditionalAssemblies example results in routing support for `Component1`:

```
<Router
    AppAssembly="@typeof(Program).Assembly"
    AdditionalAssemblies="new[] { typeof(Component1).Assembly }">
    ...
</Router>
```

Route parameters

The router uses route parameters to populate the corresponding component parameters with the same name (case insensitive):

```
@page "/RouteParameter"
@page "/RouteParameter/{text}"

<h1>Blazor is @Text!</h1>

@code {
    [Parameter]
    public string Text { get; set; }

    protected override void OnInitialized()
    {
        Text = Text ?? "fantastic";
    }
}
```

Optional parameters aren't supported. Two `@page` directives are applied in the previous example. The first permits navigation to the component without a parameter. The second `@page` directive takes the `{text}` route parameter and assigns the value to the `Text` property.

Route constraints

A route constraint enforces type matching on a route segment to a component.

In the following example, the route to the `Users` component only matches if:

- An `Id` route segment is present on the request URL.
- The `Id` segment is an integer (`int`).

```
@page "/Users/{Id:int}"

<h1>The user Id is @Id!</h1>

@code {
    [Parameter]
    public int Id { get; set; }
}
```

The route constraints shown in the following table are available. For the route constraints that match with the invariant culture, see the warning below the table for more information.

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	INVARIANT CULTURE MATCHING
`bool`	`{active:bool}`	`true`, `FALSE`	No
`datetime`	`{dob:datetime}`	`2016-12-31`, `2016-12-31 7:32pm`	Yes
`decimal`	`{price:decimal}`	`49.99`, `-1,000.01`	Yes
`double`	`{weight:double}`	`1.234`, `-1,001.01e8`	Yes
`float`	`{weight:float}`	`1.234`, `-1,001.01e8`	Yes

CONSTRAINT	EXAMPLE	EXAMPLE MATCHES	INVARIANT CULTURE MATCHING
`guid`	`{id:guid}`	`CD2C1638-1638-72D5-1638-DEADBEEF1638`, `{CD2C1638-1638-72D5-1638-DEADBEEF1638}`	No
`int`	`{id:int}`	`123456789`, `-123456789`	Yes
`long`	`{ticks:long}`	`123456789`, `-123456789`	Yes

> **WARNING**
> Route constraints that verify the URL and are converted to a CLR type (such as `int` or DateTime) always use the invariant culture. These constraints assume that the URL is non-localizable.

Routing with URLs that contain dots

For hosted Blazor WebAssembly and Blazor Server apps, the server-side default route template assumes that if the last segment of a request URL contains a dot (`.`) that a file is requested (for example, `https://localhost.com:5001/example/some.thing`). Without additional configuration, an app returns a *404 - Not Found* response if this was meant to route to a component. To use a route with one or more parameters that contains a dot, the app must configure the route with a custom template.

Consider the following `Example` component that can receive a route parameter from the last segment of the URL:

```
@page "/example"
@page "/example/{param}"

<p>
    Param: @Param
</p>

@code {
    [Parameter]
    public string Param { get; set; }
}
```

To permit the *Server* app of a hosted Blazor WebAssembly solution to route the request with a dot in the `param` parameter, add a fallback file route template with the optional parameter in `Startup.Configure` (`Startup.cs`):

```
endpoints.MapFallbackToFile("/example/{param?}", "index.html");
```

To configure a Blazor Server app to route the request with a dot in the `param` parameter, add a fallback page route template with the optional parameter in `Startup.Configure` (`Startup.cs`):

```
endpoints.MapFallbackToPage("/example/{param?}", "/_Host");
```

For more information, see Routing in ASP.NET Core.

Catch-all route parameters

This section applies to ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.

Catch-all route parameters, which capture paths across multiple folder boundaries, are supported in components. The catch-all route parameter must be:

- Named to match the route segment name. Naming isn't case sensitive.
- A `string` type. The framework doesn't provide automatic casting.
- At the end of the URL.

```
@page "/page/{*pageRoute}"

@code {
    [Parameter]
    public string PageRoute { get; set; }
}
```

For the URL `/page/this/is/a/test` with a route template of `/page/{*pageRoute}`, the value of `PageRoute` is set to `this/is/a/test`.

Slashes and segments of the captured path are decoded. For a route template of `/page/{*pageRoute}`, the URL `/page/this/is/a%2Ftest%2A` yields `this/is/a/test*`.

Catch-all route parameters are supported in ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.*

NavLink component

Use a NavLink component in place of HTML hyperlink elements (`<a>`) when creating navigation links. A NavLink component behaves like an `<a>` element, except it toggles an `active` CSS class based on whether its `href` matches the current URL. The `active` class helps a user understand which page is the active page among the navigation links displayed. Optionally, assign a CSS class name to NavLink.ActiveClass to apply a custom CSS class to the rendered link when the current route matches the `href`.

The following `NavMenu` component creates a `Bootstrap` navigation bar that demonstrates how to use NavLink components:

```
<div class="@NavMenuCssClass" @onclick="@ToggleNavMenu">
    <ul class="nav flex-column">
        <li class="nav-item px-3">
            <NavLink class="nav-link" href="" Match="NavLinkMatch.All">
                <span class="oi oi-home" aria-hidden="true"></span> Home
            </NavLink>
        </li>
        <li class="nav-item px-3">
            <NavLink class="nav-link" href="MyComponent" Match="NavLinkMatch.Prefix">
                <span class="oi oi-plus" aria-hidden="true"></span> My Component
            </NavLink>
        </li>
    </ul>
</div>
```

There are two NavLinkMatch options that you can assign to the `Match` attribute of the `<NavLink>` element:

- NavLinkMatch.All: The NavLink is active when it matches the entire current URL.
- NavLinkMatch.Prefix (*default*): The NavLink is active when it matches any prefix of the current URL.

In the preceding example, the Home NavLink `href=""` matches the home URL and only receives the `active` CSS class at the app's default base path URL (for example, `https://localhost:5001/`). The second NavLink receives the `active` class when the user visits any URL with a `MyComponent` prefix (for example,

`https://localhost:5001/MyComponent` and `https://localhost:5001/MyComponent/AnotherSegment`).

Additional NavLink component attributes are passed through to the rendered anchor tag. In the following example, the NavLink component includes the `target` attribute:

```
<NavLink href="my-page" target="_blank">My page</NavLink>
```

The following HTML markup is rendered:

```
<a href="my-page" target="_blank">My page</a>
```

WARNING

Due to the way that Blazor renders child content, rendering `NavLink` components inside a `for` loop requires a local index variable if the incrementing loop variable is used in the `NavLink` (child) component's content:

```
@for (int c = 0; c < 10; c++)
{
    var current = c;
    <li ...>
        <NavLink ... href="@c">
            <span ...></span> @current
        </NavLink>
    </li>
}
```

Using an index variable in this scenario is a requirement for **any** child component that uses a loop variable in its child content, not just the `NavLink` component.

Alternatively, use a `foreach` loop with Enumerable.Range:

```
@foreach(var c in Enumerable.Range(0,10))
{
    <li ...>
        <NavLink ... href="@c">
            <span ...></span> @c
        </NavLink>
    </li>
}
```

URI and navigation state helpers

Use NavigationManager to work with URIs and navigation in C# code. NavigationManager provides the event and methods shown in the following table.

MEMBER	DESCRIPTION
Uri	Gets the current absolute URI.
BaseUri	Gets the base URI (with a trailing slash) that can be prepended to relative URI paths to produce an absolute URI. Typically, BaseUri corresponds to the `href` attribute on the document's `<base>` element in `wwwroot/index.html` (Blazor WebAssembly) or `Pages/_Host.cshtml` (Blazor Server).

MEMBER	DESCRIPTION
NavigateTo	Navigates to the specified URI. If `forceLoad` is `true`: • Client-side routing is bypassed. • The browser is forced to load the new page from the server, whether or not the URI is normally handled by the client-side router.
LocationChanged	An event that fires when the navigation location has changed.
ToAbsoluteUri	Converts a relative URI into an absolute URI.
ToBaseRelativePath	Given a base URI (for example, a URI previously returned by BaseUri), converts an absolute URI into a URI relative to the base URI prefix.

The following component navigates to the app's `Counter` component when the button is selected:

```
@page "/navigate"
@inject NavigationManager NavigationManager

<h1>Navigate in Code Example</h1>

<button class="btn btn-primary" @onclick="NavigateToCounterComponent">
    Navigate to the Counter component
</button>

@code {
    private void NavigateToCounterComponent()
    {
        NavigationManager.NavigateTo("counter");
    }
}
```

The following component handles a location changed event by subscribing to NavigationManager.LocationChanged. The `HandleLocationChanged` method is unhooked when `Dispose` is called by the framework. Unhooking the method permits garbage collection of the component.

```
@implements IDisposable
@inject NavigationManager NavigationManager

...

protected override void OnInitialized()
{
    NavigationManager.LocationChanged += HandleLocationChanged;
}

private void HandleLocationChanged(object sender, LocationChangedEventArgs e)
{
    ...
}

public void Dispose()
{
    NavigationManager.LocationChanged -= HandleLocationChanged;
}
```

LocationChangedEventArgs provides the following information about the event:

- Location: The URL of the new location.
- IsNavigationIntercepted: If `true`, Blazor intercepted the navigation from the browser. If `false`, NavigationManager.NavigateTo caused the navigation to occur.

For more information on component disposal, see ASP.NET Core Blazor lifecycle.

Query string and parse parameters

The query string of a request can be obtained from the NavigationManager's Uri property:

```
@inject NavigationManager Navigation

...

var query = new Uri(Navigation.Uri).Query;
```

To parse a query string's parameters:

- Add a package reference for Microsoft.AspNetCore.WebUtilities.
- Obtain the value after parsing the query string with QueryHelpers.ParseQuery.

```
@page "/"
@using Microsoft.AspNetCore.WebUtilities
@inject NavigationManager NavigationManager

<h1>Query string parse example</h1>

<p>Value: @queryValue</p>

@code {
    private string queryValue = "Not set";

    protected override void OnInitialized()
    {
        var query = new Uri(NavigationManager.Uri).Query;

        if (QueryHelpers.ParseQuery(query).TryGetValue("{KEY}", out var value))
        {
            queryValue = value;
        }
    }
}
```

The placeholder `{KEY}` in the preceding example is the query string parameter key. For example, the URL key-value pair `?ship=Tardis` uses a key of `ship`.

ASP.NET Core Blazor hosting model configuration

9/22/2020 • 7 minutes to read • Edit Online

By Daniel Roth, Mackinnon Buck, and Luke Latham

This article covers hosting model configuration.

SignalR cross-origin negotiation for authentication

This section applies to Blazor WebAssembly.

To configure SignalR's underlying client to send credentials, such as cookies or HTTP authentication headers:

- Use SetBrowserRequestCredentials to set Include on cross-origin `fetch` requests:

```
public class IncludeRequestCredentialsMessageHandler : DelegatingHandler
{
    protected override Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {
        request.SetBrowserRequestCredentials(BrowserRequestCredentials.Include);
        return base.SendAsync(request, cancellationToken);
    }
}
```

- Assign the HttpMessageHandler to the HttpMessageHandlerFactory option:

```
var connection = new HubConnectionBuilder()
    .WithUrl(new Uri("http://signalr.example.com"), options =>
    {
        options.HttpMessageHandlerFactory = innerHandler =>
            new IncludeRequestCredentialsMessageHandler { InnerHandler = innerHandler };
    }).Build();
```

For more information, see ASP.NET Core SignalR configuration.

Reflect the connection state in the UI

This section applies to Blazor Server.

When the client detects that the connection has been lost, a default UI is displayed to the user while the client attempts to reconnect. If reconnection fails, the user is provided the option to retry.

To customize the UI, define an element with an `id` of `components-reconnect-modal` in the `<body>` of the `_Host.cshtml` Razor page:

```
<div id="components-reconnect-modal">
    ...
</div>
```

Add the following to the app's stylesheet (`wwwroot/css/app.css` or `wwwroot/css/site.css`):

```
#components-reconnect-modal {
    display: none;
}

#components-reconnect-modal.components-reconnect-show {
    display: block;
}
```

The following table describes the CSS classes applied to the `components-reconnect-modal` element.

CSS CLASS	INDICATES...
`components-reconnect-show`	A lost connection. The client is attempting to reconnect. Show the modal.
`components-reconnect-hide`	An active connection is re-established to the server. Hide the modal.
`components-reconnect-failed`	Reconnection failed, probably due to a network failure. To attempt reconnection, call `window.Blazor.reconnect()`.
`components-reconnect-rejected`	Reconnection rejected. The server was reached but refused the connection, and the user's state on the server is lost. To reload the app, call `location.reload()`. This connection state may result when: • A crash in the server-side circuit occurs. • The client is disconnected long enough for the server to drop the user's state. Instances of the components that the user is interacting with are disposed. • The server is restarted, or the app's worker process is recycled.

Render mode

This section applies to Blazor Server.

Blazor Server apps are set up by default to prerender the UI on the server before the client connection to the server is established. This is set up in the `_Host.cshtml` Razor page:

```
<body>
    <app>
      <component type="typeof(App)" render-mode="ServerPrerendered" />
    </app>

    <script src="_framework/blazor.server.js"></script>
</body>
```

RenderMode configures whether the component:

- Is prerendered into the page.
- Is rendered as static HTML on the page or if it includes the necessary information to bootstrap a Blazor app from the user agent.

RENDER MODE	DESCRIPTION
ServerPrerendered	Renders the component into static HTML and includes a marker for a Blazor Server app. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Server	Renders a marker for a Blazor Server app. Output from the component isn't included. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Static	Renders the component into static HTML.

Rendering server components from a static HTML page isn't supported.

Initialize the Blazor circuit

This section applies to Blazor Server.

Configure the manual start of a Blazor Server app's SignalR circuit in the `Pages/_Host.cshtml` file:

- Add an `autostart="false"` attribute to the `<script>` tag for the `blazor.server.js` script.
- Place a script that calls `Blazor.start` after the `blazor.server.js` script's tag and inside the closing `</body>` tag.

When `autostart` is disabled, any aspect of the app that doesn't depend on the circuit works normally. For example, client-side routing is operational. However, any aspect that depends on the circuit isn't operational until `Blazor.start` is called. App behavior is unpredictable without an established circuit. For example, component methods fail to execute while the circuit is disconnected.

Initialize Blazor when the document is ready

To initialize the Blazor app when the document is ready:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      document.addEventListener("DOMContentLoaded", function() {
        Blazor.start();
      });
    </script>
</body>
```

Chain to the `Promise` that results from a manual start

To perform additional tasks, such as JS interop initialization, use `then` to chain to the `Promise` that results from a manual Blazor app start:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start().then(function () {
        ...
      });
    </script>
</body>
```

Configure the SignalR client

Logging

To configure SignalR client logging, pass in a configuration object (`configureSignalR`) that calls `configureLogging` with the log level on the client builder:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start({
        configureSignalR: function (builder) {
          builder.configureLogging("information");
        }
      });
    </script>
</body>
```

In the preceding example, `information` is equivalent to a log level of LogLevel.Information.

Modify the reconnection handler

The reconnection handler's circuit connection events can be modified for custom behaviors, such as:

- To notify the user if the connection is dropped.
- To perform logging (from the client) when a circuit is connected.

To modify the connection events, register callbacks for the following connection changes:

- Dropped connections use `onConnectionDown` .
- Established/re-established connections use `onConnectionUp` .

Both `onConnectionDown` and `onConnectionUp` must be specified:

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start({
        reconnectionHandler: {
          onConnectionDown: (options, error) => console.error(error);
          onConnectionUp: () => console.log("Up, up, and away!");
        }
      });
    </script>
</body>
```

Adjust the reconnection retry count and interval

To adjust the reconnection retry count and interval, set the number of retries (`maxRetries`) and period in milliseconds permitted for each retry attempt (`retryIntervalMilliseconds`):

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      Blazor.start({
        reconnectionOptions: {
          maxRetries: 3,
          retryIntervalMilliseconds: 2000
        }
      });
    </script>
</body>
```

Hide or replace the reconnection display

To hide the reconnection display, set the reconnection handler's `_reconnectionDisplay` to an empty object (`{}` or `new Object()`):

```
<body>

    ...

    <script autostart="false" src="_framework/blazor.server.js"></script>
    <script>
      window.addEventListener('beforeunload', function () {
        Blazor.defaultReconnectionHandler._reconnectionDisplay = {};
      });

      Blazor.start();
    </script>
</body>
```

To replace the reconnection display, set `_reconnectionDisplay` in the preceding example to the element for display:

```
Blazor.defaultReconnectionHandler._reconnectionDisplay =
  document.getElementById("{ELEMENT ID}");
```

The placeholder `{ELEMENT ID}` is the ID of the HTML element to display.

Customize the delay before the reconnection display appears by setting the `transition-delay` property in the app's CSS (`wwwroot/css/site.css`) for the modal element. The following example sets the transition delay from 500 ms (default) to 1,000 ms (1 second):

```
#components-reconnect-modal {
    transition: visibility 0s linear 1000ms;
}
```

Influence HTML `<head>` tag elements

This section applies to the upcoming ASP.NET Core 5.0 release of Blazor WebAssembly and Blazor Server.

When rendered, the `Title` , `Link` , and `Meta` components add or update data in the HTML `<head>` tag elements:

```
@using Microsoft.AspNetCore.Components.Web.Extensions.Head

<Title Value="{TITLE}" />
<Link href="{URL}" rel="stylesheet" />
<Meta content="{DESCRIPTION}" name="description" />
```

In the preceding example, placeholders for `{TITLE}` , `{URL}` , and `{DESCRIPTION}` are string values, Razor variables, or Razor expressions.

The following characteristics apply:

- Server-side prerendering is supported.
- The `Value` parameter is the only valid parameter for the `Title` component.
- HTML attributes provided to the `Meta` and `Link` components are captured in additional attributes and passed through to the rendered HTML tag.
- For multiple `Title` components, the title of the page reflects the `Value` of the last `Title` component rendered.
- If multiple `Meta` or `Link` components are included with identical attributes, there's exactly one HTML tag rendered per `Meta` or `Link` component. Two `Meta` or `Link` components can't refer to the same rendered HTML tag.
- Changes to the parameters of existing `Meta` or `Link` components are reflected in their rendered HTML tags.
- When the `Link` or `Meta` components are no longer rendered and thus disposed by the framework, their rendered HTML tags are removed.

When one of the framework components is used in a child component, the rendered HTML tag influences any other child component of the parent component as long as the child component containing the framework component is rendered. The distinction between using the one of these framework components in a child component and placing a an HTML tag in `wwwroot/index.html` or `Pages/_Host.cshtml` is that a framework component's rendered HTML tag:

- Can be modified by application state. A hard-coded HTML tag can't be modified by application state.
- Is removed from the HTML `<head>` when the parent component is no longer rendered.

Static files

This section applies to Blazor Server.

To create additional file mappings with a FileExtensionContentTypeProvider or configure other StaticFileOptions, use **one** of the following approaches. In the following examples, the `{EXTENSION}` placeholder is the file extension,

and the `{CONTENT TYPE}` placeholder is the content type.

- Configure options through dependency injection (DI) in `Startup.ConfigureServices` (`Startup.cs`) using StaticFileOptions:

  ```
  using Microsoft.AspNetCore.StaticFiles;

  ...

  var provider = new FileExtensionContentTypeProvider();
  provider.Mappings["{EXTENSION}"] = "{CONTENT TYPE}";

  services.Configure<StaticFileOptions>(options =>
  {
      options.ContentTypeProvider = provider;
  });
  ```

  Because this approach configures the same file provider used to serve `blazor.server.js`, make sure that your custom configuration doesn't interfere with serving `blazor.server.js`. For example, don't remove the mapping for JavaScript files by configuring the provider with `provider.Mappings.Remove(".js")`.

- Use two calls to UseStaticFiles in `Startup.Configure` (`Startup.cs`):

  - Configure the custom file provider in the first call with StaticFileOptions.
  - The second middleware serves `blazor.server.js`, which uses the default static files configuration provided by the Blazor framework.

  ```
  using Microsoft.AspNetCore.StaticFiles;

  ...

  var provider = new FileExtensionContentTypeProvider();
  provider.Mappings["{EXTENSION}"] = "{CONTENT TYPE}";

  app.UseStaticFiles(new StaticFileOptions { ContentTypeProvider = provider });
  app.UseStaticFiles();
  ```

ASP.NET Core Blazor component virtualization

9/22/2020 • 3 minutes to read • Edit Online

By Daniel Roth

Improve the perceived performance of component rendering using the Blazor framework's built-in virtualization support. Virtualization is a technique for limiting UI rendering to just the parts that are currently visible. For example, virtualization is helpful when the app must render a long list or a table with many rows and only a subset of items is required to be visible at any given time. Blazor provides the `Virtualize` component that can be used to add virtualization to an app's components.

Without virtualization, a typical list or table-based component might use a C# `foreach` loop to render each item in the list or each row in the table:

```
<table>
    @foreach (var employee in employees)
    {
        <tr>
            <td>@employee.FirstName</td>
            <td>@employee.LastName</td>
            <td>@employee.JobTitle</td>
        </tr>
    }
</table>
```

If the list contains thousands of items, then rendering the list may take a long time. The user may experience a noticeable UI lag.

Instead of rendering each item in the list all at one time, replace the `foreach` loop with the `Virtualize` component and specify a fixed item source with `Items`. Only the items that are currently visible are rendered:

```
<table>
    <Virtualize Context="employee" Items="@employees">
        <tr>
            <td>@employee.FirstName</td>
            <td>@employee.LastName</td>
            <td>@employee.JobTitle</td>
        </tr>
    </Virtualize>
</table>
```

If not specifying a context to the component with `Context`, use the `context` value (`@context.{PROPERTY}`) in the item content template:

```
<table>
    <Virtualize Items="@employees">
        <tr>
            <td>@context.FirstName</td>
            <td>@context.LastName</td>
            <td>@context.JobTitle</td>
        </tr>
    </Virtualize>
</table>
```

The `Virtualize` component calculates how many items to render based on the height of the container and the size of the rendered items.

Item provider delegate

If you don't want to load all of the items into memory, you can specify an items provider delegate method to the component's `ItemsProvider` parameter that asynchronously retrieves the requested items on demand:

```
<table>
    <Virtualize Context="employee" ItemsProvider="@LoadEmployees">
         <tr>
            <td>@employee.FirstName</td>
            <td>@employee.LastName</td>
            <td>@employee.JobTitle</td>
        </tr>
    </Virtualize>
</table>
```

The items provider receives an `ItemsProviderRequest`, which specifies the required number of items starting at a specific start index. The items provider then retrieves the requested items from a database or other service and returns them as an `ItemsProviderResult<TItem>` along with a count of the total items. The items provider can choose to retrieve the items with each request or cache them so that they're readily available. Don't attempt to use an items provider and assign a collection to `Items` for the same `Virtualize` component.

The following example loads employees from an `EmployeeService`:

```
private async ValueTask<ItemsProviderResult<Employee>> LoadEmployees(
    ItemsProviderRequest request)
{
    var numEmployees = Math.Min(request.Count, totalEmployees - request.StartIndex);
    var employees = await EmployeesService.GetEmployeesAsync(request.StartIndex,
        numEmployees, request.CancellationToken);

    return new ItemsProviderResult<Employee>(employees, totalEmployees);
}
```

Placeholder

Because requesting items from a remote data source might take some time, you have the option to render a placeholder (`<Placeholder>...</Placeholder>`) until the item data is available:

```
<table>
    <Virtualize Context="employee" ItemsProvider="@LoadEmployees">
        <ItemContent>
            <tr>
                <td>@employee.FirstName</td>
                <td>@employee.LastName</td>
                <td>@employee.JobTitle</td>
            </tr>
        </ItemContent>
        <Placeholder>
            <tr>
                <td>Loading...</td>
            </tr>
        </Placeholder>
    </Virtualize>
</table>
```

Item size

The size of each item in pixels can be set with `ItemSize` (default: 50px):

```
<table>
    <Virtualize Context="employee" Items="@employees" ItemSize="25">
        ...
    </Virtualize>
</table>
```

Overscan count

`OverscanCount` determines how many additional items are rendered before and after the visible region. This setting helps to reduce the frequency of rendering during scrolling. However, higher values result in more elements rendered in the page (default: 3):

```
<table>
    <Virtualize Context="employee" Items="@employees" OverscanCount="4">
        ...
    </Virtualize>
</table>
```

For example, a grid or list that renders hundreds of rows containing components is processor intensive to render. Consider virtualizing a grid or list layout so that only a subset of the components is rendered at any given time. For an example of component subset rendering, see the following components in the `Virtualization` sample app (aspnet/samples GitHub repository):

- `Virtualize` component (`Shared/Virtualize.razor`): A component written in C# that implements ComponentBase to render a set of weather data rows based on user scrolling.
- `FetchData` component (`Pages/FetchData.razor`): Uses the `Virtualize` component to display 25 rows of weather data at a time.

State changes

When making changes to items rendered by the `Virtualize` component, call StateHasChanged to force re-evaluation and rerendering of the component.

ASP.NET Core Blazor cascading values and parameters

9/22/2020 • 4 minutes to read • Edit Online

By Luke Latham and Daniel Roth

View or download sample code (how to download)

In some scenarios, it's inconvenient to flow data from an ancestor component to a descendent component using component parameters, especially when there are several component layers. Cascading values and parameters solve this problem by providing a convenient way for an ancestor component to provide a value to all of its descendent components. Cascading values and parameters also provide an approach for components to coordinate.

Theme example

In the following example from the sample app, the `ThemeInfo` class specifies the theme information to flow down the component hierarchy so that all of the buttons within a given part of the app share the same style.

`UIThemeClasses/ThemeInfo.cs`:

```
public class ThemeInfo
{
    public string ButtonClass { get; set; }
}
```

An ancestor component can provide a cascading value using the Cascading Value component. The CascadingValue<TValue> component wraps a subtree of the component hierarchy and supplies a single value to all components within that subtree.

For example, the sample app specifies theme information (`ThemeInfo`) in one of the app's layouts as a cascading parameter for all components that make up the layout body of the `@Body` property. `ButtonClass` is assigned a value of `btn-success` in the layout component. Any descendent component can consume this property through the `ThemeInfo` cascading object.

`CascadingValuesParametersLayout` component:

```
@inherits LayoutComponentBase
@using BlazorSample.UIThemeClasses

<div class="container-fluid">
    <div class="row">
        <div class="col-sm-3">
            <NavMenu />
        </div>
        <div class="col-sm-9">
            <CascadingValue Value="theme">
                <div class="content px-4">
                    @Body
                </div>
            </CascadingValue>
        </div>
    </div>
</div>

@code {
    private ThemeInfo theme = new ThemeInfo { ButtonClass = "btn-success" };
}
```

To make use of cascading values, components declare cascading parameters using the `[CascadingParameter]` attribute. Cascading values are bound to cascading parameters by type.

In the sample app, the `CascadingValuesParametersTheme` component binds the `ThemeInfo` cascading value to a cascading parameter. The parameter is used to set the CSS class for one of the buttons displayed by the component.

`CascadingValuesParametersTheme` component:

```
@page "/cascadingvaluesparameterstheme"
@layout CascadingValuesParametersLayout
@using BlazorSample.UIThemeClasses

<h1>Cascading Values & Parameters</h1>

<p>Current count: @currentCount</p>

<p>
    <button class="btn" @onclick="IncrementCount">
        Increment Counter (Unthemed)
    </button>
</p>

<p>
    <button class="btn @ThemeInfo.ButtonClass" @onclick="IncrementCount">
        Increment Counter (Themed)
    </button>
</p>

@code {
    private int currentCount = 0;

    [CascadingParameter]
    protected ThemeInfo ThemeInfo { get; set; }

    private void IncrementCount()
    {
        currentCount++;
    }
}
```

To cascade multiple values of the same type within the same subtree, provide a unique Name string to each CascadingValue<TValue> component and its corresponding `[CascadingParameter]` attribute. In the following example, two CascadingValue<TValue> components cascade different instances of `MyCascadingType` by name:

```
<CascadingValue Value="@parentCascadeParameter1" Name="CascadeParam1">
    <CascadingValue Value="@ParentCascadeParameter2" Name="CascadeParam2">
        ...
    </CascadingValue>
</CascadingValue>

@code {
    private MyCascadingType parentCascadeParameter1;

    [Parameter]
    public MyCascadingType ParentCascadeParameter2 { get; set; }

    ...
}
```

In a descendant component, the cascaded parameters receive their values from the corresponding cascaded values in the ancestor component by name:

```
...

@code {
    [CascadingParameter(Name = "CascadeParam1")]
    protected MyCascadingType ChildCascadeParameter1 { get; set; }

    [CascadingParameter(Name = "CascadeParam2")]
    protected MyCascadingType ChildCascadeParameter2 { get; set; }
}
```

TabSet example

Cascading parameters also enable components to collaborate across the component hierarchy. For example, consider the following `TabSet` example in the sample app.

The sample app has an `ITab` interface that tabs implement:

```
using Microsoft.AspNetCore.Components;

namespace BlazorSample.UIInterfaces
{
    public interface ITab
    {
        RenderFragment ChildContent { get; }
    }
}
```

The `CascadingValuesParametersTabSet` component uses the `TabSet` component, which contains several `Tab` components:

```
@page "/CascadingValuesParametersTabSet"

<TabSet>
    <Tab Title="First tab">
        <h4>Greetings from the first tab!</h4>

        <label>
            <input type="checkbox" @bind="showThirdTab" />
            Toggle third tab
        </label>
    </Tab>
    <Tab Title="Second tab">
        <h4>The second tab says Hello World!</h4>
    </Tab>

    @if (showThirdTab)
    {
        <Tab Title="Third tab">
            <h4>Welcome to the disappearing third tab!</h4>
            <p>Toggle this tab from the first tab.</p>
        </Tab>
    }
</TabSet>

@code {
    private bool showThirdTab;
}
```

The child `Tab` components aren't explicitly passed as parameters to the `TabSet`. Instead, the child `Tab` components are part of the child content of the `TabSet`. However, the `TabSet` still needs to know about each `Tab` component so that it can render the headers and the active tab. To enable this coordination without requiring additional code, the `TabSet` component *can provide itself as a cascading value* that is then picked up by the descendent `Tab` components.

`TabSet` component:

```
@using BlazorSample.UIInterfaces

<!-- Display the tab headers -->
<CascadingValue Value=this>
    <ul class="nav nav-tabs">
        @ChildContent
    </ul>
</CascadingValue>

<!-- Display body for only the active tab -->
<div class="nav-tabs-body p-4">
    @ActiveTab?.ChildContent
</div>

@code {
    [Parameter]
    public RenderFragment ChildContent { get; set; }

    public ITab ActiveTab { get; private set; }

    public void AddTab(ITab tab)
    {
        if (ActiveTab == null)
        {
            SetActiveTab(tab);
        }
    }

    public void SetActiveTab(ITab tab)
    {
        if (ActiveTab != tab)
        {
            ActiveTab = tab;
            StateHasChanged();
        }
    }
}
```

The descendent `Tab` components capture the containing `TabSet` as a cascading parameter, so the `Tab` components add themselves to the `TabSet` and coordinate on which tab is active.

`Tab` component:

```
@using BlazorSample.UIInterfaces
@implements ITab

<li>
    <a @onclick="ActivateTab" class="nav-link @TitleCssClass" role="button">
        @Title
    </a>
</li>

@code {
    [CascadingParameter]
    public TabSet ContainerTabSet { get; set; }

    [Parameter]
    public string Title { get; set; }

    [Parameter]
    public RenderFragment ChildContent { get; set; }

    private string TitleCssClass => ContainerTabSet.ActiveTab == this ? "active" : null;

    protected override void OnInitialized()
    {
        ContainerTabSet.AddTab(this);
    }

    private void ActivateTab()
    {
        ContainerTabSet.SetActiveTab(this);
    }
}
```

ASP.NET Core Blazor data binding

9/22/2020 • 6 minutes to read • Edit Online

By Luke Latham and Daniel Roth

Razor components provide data binding features via an HTML element attribute named `@bind` with a field, property, or Razor expression value.

The following example binds an `<input>` element to the `currentValue` field and an `<input>` element to the `CurrentValue` property:

```
<p>
    <input @bind="currentValue" /> Current value: @currentValue
</p>

<p>
    <input @bind="CurrentValue" /> Current value: @CurrentValue
</p>

@code {
    private string currentValue;

    private string CurrentValue { get; set; }
}
```

When one of the elements looses focus, its bound field or property is updated.

The text box is updated in the UI only when the component is rendered, not in response to changing the field's or property's value. Since components render themselves after event handler code executes, field and property updates are *usually* reflected in the UI immediately after an event handler is triggered.

Using `@bind` with the `CurrentValue` property (`<input @bind="CurrentValue" />`) is essentially equivalent to the following:

```
<input value="@CurrentValue"
    @onchange="@((ChangeEventArgs __e) => CurrentValue =
        __e.Value.ToString())" />

@code {
    private string CurrentValue { get; set; }
}
```

When the component is rendered, the `value` of the input element comes from the `CurrentValue` property. When the user types in the text box and changes element focus, the `onchange` event is fired and the `CurrentValue` property is set to the changed value. In reality, the code generation is more complex than that because `@bind` handles cases where type conversions are performed. In principle, `@bind` associates the current value of an expression with a `value` attribute and handles changes using the registered handler.

Bind a property or field on other events by also including an `@bind:event` attribute with an `event` parameter. The following example binds the `CurrentValue` property on the `oninput` event:

```
<input @bind="CurrentValue" @bind:event="oninput" />

@code {
    private string CurrentValue { get; set; }
}
```

Unlike `onchange`, which fires when the element loses focus, `oninput` fires when the value of the text box changes.

Attribute binding is case sensitive:

- `@bind` is valid.
- `@Bind` and `@BIND` are invalid.

Unparsable values

When a user provides an unparsable value to a databound element, the unparsable value is automatically reverted to its previous value when the bind event is triggered.

Consider the following scenario:

- An `<input>` element is bound to an `int` type with an initial value of `123`:

  ```
  <input @bind="inputValue" />

  @code {
      private int inputValue = 123;
  }
  ```

- The user updates the value of the element to `123.45` in the page and changes the element focus.

In the preceding scenario, the element's value is reverted to `123`. When the value `123.45` is rejected in favor of the original value of `123`, the user understands that their value wasn't accepted.

By default, binding applies to the element's `onchange` event (`@bind="{PROPERTY OR FIELD}"`). Use `@bind="{PROPERTY OR FIELD}" @bind:event={EVENT}` to trigger binding on a different event. For the `oninput` event (`@bind:event="oninput"`), the reversion occurs after any keystroke that introduces an unparsable value. When targeting the `oninput` event with an `int`-bound type, a user is prevented from typing a `.` character. A `.` character is immediately removed, so the user receives immediate feedback that only whole numbers are permitted. There are scenarios where reverting the value on the `oninput` event isn't ideal, such as when the user should be allowed to clear an unparsable `<input>` value. Alternatives include:

- Don't use the `oninput` event. Use the default `onchange` event (only specify `@bind="{PROPERTY OR FIELD}"`), where an invalid value isn't reverted until the element loses focus.
- Bind to a nullable type, such as `int?` or `string` and provide custom logic to handle invalid entries.
- Use a form validation component, such as InputNumber<TValue> or InputDate<TValue>. Form validation components have built-in support to manage invalid inputs. For more information, see ASP.NET Core Blazor forms and validation. Form validation components:
  - Permit the user to provide invalid input and receive validation errors on the associated EditContext.
  - Display validation errors in the UI without interfering with the user entering additional webform data.

Format strings

Data binding works with DateTime format strings using `@bind:format`. Other format expressions, such as currency or number formats, aren't available at this time.

```
<input @bind="startDate" @bind:format="yyyy-MM-dd" />

@code {
    private DateTime startDate = new DateTime(2020, 1, 1);
}
```

In the preceding code, the `<input>` element's field type (`type`) defaults to `text`. `@bind:format` is supported for binding the following .NET types:

- System.DateTime
- System.DateTime?
- System.DateTimeOffset
- System.DateTimeOffset?

The `@bind:format` attribute specifies the date format to apply to the `value` of the `<input>` element. The format is also used to parse the value when an `onchange` event occurs.

Specifying a format for the `date` field type isn't recommended because Blazor has built-in support to format dates. In spite of the recommendation, only use the `yyyy-MM-dd` date format for binding to function correctly if a format is supplied with the `date` field type:

```
<input type="date" @bind="startDate" @bind:format="yyyy-MM-dd">
```

Parent-to-child binding with component parameters

Component parameters permit binding properties and fields of a parent component with `@bind-{PROPERTY OR FIELD}` syntax.

The following `Child` component (`Shared/Child.razor`) has a `Year` component parameter and `YearChanged` callback:

```
<div class="card bg-light mt-3" style="width:18rem ">
    <div class="card-body">
        <h3 class="card-title">Child Component</h3>
        <p class="card-text">Child <code>Year</code>: @Year</p>
    </div>
</div>

@code {
    [Parameter]
    public int Year { get; set; }

    [Parameter]
    public EventCallback<int> YearChanged { get; set; }
}
```

The callback (EventCallback<TValue>) must be named as the component parameter name followed by the "`Changed`" suffix (`{PARAMETER NAME}Changed`). In the preceding example, the callback is named `YearChanged`. For more information on EventCallback<TValue>, see ASP.NET Core Blazor event handling.

In the following `Parent` component (`Parent.razor`), the `year` field is bound to the `Year` parameter of the child component:

```
@page "/Parent"

<h1>Parent Component</h1>

<p>Parent <code>year</code>: @year</p>

<button @onclick="UpdateYear">Update Parent <code>year</code></button>

<Child @bind-Year="year" />

@code {
    private Random r = new Random();
    private int year = 1979;

    private void UpdateYear()
    {
        year = r.Next(1950, 2021);
    }
}
```

The `Year` parameter is bindable because it has a companion `YearChanged` event that matches the type of the `Year` parameter.

By convention, a property can be bound to a corresponding event handler by including an `@bind-{PROPERTY}:event` attribute assigned to the handler. `<Child @bind-Year="year" />` is equivalent to writing:

```
<Child @bind-Year="year" @bind-Year:event="YearChanged" />
```

Child-to-parent binding with chained bind

A common scenario is chaining a data-bound parameter to a page element in the component's output. This scenario is called a *chained bind* because multiple levels of binding occur simultaneously.

A chained bind can't be implemented with `@bind` syntax in the child component. The event handler and value must be specified separately. A parent component, however, can use `@bind` syntax with the child component's parameter.

The following `PasswordField` component (`PasswordField.razor`):

- Sets an `<input>` element's value to a `password` field.
- Exposes changes of a `Password` property to a parent component with an `EventCallback` that passes in the current value of the child's `password` field as its argument.
- Uses the `onclick` event to trigger the `ToggleShowPassword` method. For more information, see ASP.NET Core Blazor event handling.

```
<h1>Provide your password</h1>

Password:

<input @oninput="OnPasswordChanged"
       required
       type="@(showPassword ? "text" : "password")"
       value="@password" />

<button class="btn btn-primary" @onclick="ToggleShowPassword">
    Show password
</button>

@code {
    private bool showPassword;
    private string password;

    [Parameter]
    public string Password { get; set; }

    [Parameter]
    public EventCallback<string> PasswordChanged { get; set; }

    private Task OnPasswordChanged(ChangeEventArgs e)
    {
        password = e.Value.ToString();

        return PasswordChanged.InvokeAsync(password);
    }

    private void ToggleShowPassword()
    {
        showPassword = !showPassword;
    }
}
```

The `PasswordField` component is used in another component:

```
@page "/Parent"

<h1>Parent Component</h1>

<PasswordField @bind-Password="password" />

@code {
    private string password;
}
```

Perform checks or trap errors in the method that invokes the binding's delegate. The following example provides immediate feedback to the user if a space is used in the password's value:

```
<h1>Child Component</h1>

Password:

<input @oninput="OnPasswordChanged"
       required
       type="@(showPassword ? "text" : "password")"
       value="@password" />

<button class="btn btn-primary" @onclick="ToggleShowPassword">
    Show password
</button>

<span class="text-danger">@validationMessage</span>

@code {
    private bool showPassword;
    private string password;
    private string validationMessage;

    [Parameter]
    public string Password { get; set; }

    [Parameter]
    public EventCallback<string> PasswordChanged { get; set; }

    private Task OnPasswordChanged(ChangeEventArgs e)
    {
        if (password.Contains(' '))
        {
            validationMessage = "Spaces not allowed!";

            return Task.CompletedTask;
        }
        else
        {
            validationMessage = string.Empty;

            return PasswordChanged.InvokeAsync(password);
        }
    }

    private void ToggleShowPassword()
    {
        showPassword = !showPassword;
    }
}
```

ASP.NET Core Blazor event handling

9/22/2020 • 6 minutes to read • Edit Online

By Luke Latham and Daniel Roth

Razor components provide event handling features. For an HTML element attribute named `@on{EVENT}` (for example, `@onclick`) with a delegate-typed value, a Razor component treats the attribute's value as an event handler.

The following code calls the `UpdateHeading` method when the button is selected in the UI:

```
<button class="btn btn-primary" @onclick="UpdateHeading">
    Update heading
</button>

@code {
    private void UpdateHeading(MouseEventArgs e)
    {
        ...
    }
}
```

The following code calls the `CheckChanged` method when the check box is changed in the UI:

```
<input type="checkbox" class="form-check-input" @onchange="CheckChanged" />

@code {
    private void CheckChanged()
    {
        ...
    }
}
```

Event handlers can also be asynchronous and return a Task. There's no need to manually call StateHasChanged. Exceptions are logged when they occur.

In the following example, `UpdateHeading` is called asynchronously when the button is selected:

```
<button class="btn btn-primary" @onclick="UpdateHeading">
    Update heading
</button>

@code {
    private async Task UpdateHeading(MouseEventArgs e)
    {
        ...
    }
}
```

Event argument types

For some events, event argument types are permitted. Specifying an event parameter in an event method definition is optional and only necessary if the event type is used in the method. In the following example, the `MouseEventArgs` event argument is used in the `ShowMessage` method to set message text:

```
private void ShowMessage(MouseEventArgs e)
{
    messageText = $"The mouse is at coordinates: {e.ScreenX}:{e.ScreenY}";
}
```

Supported EventArgs are shown in the following table.

EVENT	CLASS	DOM EVENTS AND NOTES
Clipboard	ClipboardEventArgs	`oncut`, `oncopy`, `onpaste`
Drag	DragEventArgs	`ondrag`, `ondragstart`, `ondragenter`, `ondragleave`, `ondragover`, `ondrop`, `ondragend` DataTransfer and DataTransferItem hold dragged item data.
Error	ErrorEventArgs	`onerror`
Event	EventArgs	*General* `onactivate`, `onbeforeactivate`, `onbeforedeactivate`, `ondeactivate`, `onfullscreenchange`, `onfullscreenerror`, `onloadeddata`, `onloadedmetadata`, `onpointerlockchange`, `onpointerlockerror`, `onreadystatechange`, `onscroll` *Clipboard* `onbeforecut`, `onbeforecopy`, `onbeforepaste` *Input* `oninvalid`, `onreset`, `onselect`, `onselectionchange`, `onselectstart`, `onsubmit` *Media* `oncanplay`, `oncanplaythrough`, `oncuechange`, `ondurationchange`, `onemptied`, `onended`, `onpause`, `onplay`, `onplaying`, `onratechange`, `onseeked`, `onseeking`, `onstalled`, `onstop`, `onsuspend`, `ontimeupdate`, `ontoggle`, `onvolumechange`, `onwaiting` EventHandlers holds attributes to configure the mappings between event names and event argument types.

EVENT	CLASS	DOM EVENTS AND NOTES
Focus	FocusEventArgs	`onfocus`, `onblur`, `onfocusin`, `onfocusout` Doesn't include support for `relatedTarget`.
Input	ChangeEventArgs	`onchange`, `oninput`
Keyboard	KeyboardEventArgs	`onkeydown`, `onkeypress`, `onkeyup`
Mouse	MouseEventArgs	`onclick`, `oncontextmenu`, `ondblclick`, `onmousedown`, `onmouseup`, `onmouseover`, `onmousemove`, `onmouseout`
Mouse pointer	PointerEventArgs	`onpointerdown`, `onpointerup`, `onpointercancel`, `onpointermove`, `onpointerover`, `onpointerout`, `onpointerenter`, `onpointerleave`, `ongotpointercapture`, `onlostpointercapture`
Mouse wheel	WheelEventArgs	`onwheel`, `onmousewheel`
Progress	ProgressEventArgs	`onabort`, `onload`, `onloadend`, `onloadstart`, `onprogress`, `ontimeout`
Touch	TouchEventArgs	`ontouchstart`, `ontouchend`, `ontouchmove`, `ontouchenter`, `ontouchleave`, `ontouchcancel` TouchPoint represents a single contact point on a touch-sensitive device.

EVENT	CLASS	DOM EVENTS AND NOTES
Clipboard	ClipboardEventArgs	`oncut`, `oncopy`, `onpaste`
Drag	DragEventArgs	`ondrag`, `ondragstart`, `ondragenter`, `ondragleave`, `ondragover`, `ondrop`, `ondragend` DataTransfer and DataTransferItem hold dragged item data.
Error	ErrorEventArgs	`onerror`

EVENT	CLASS	DOM EVENTS AND NOTES
Event	EventArgs	*General* `onactivate`, `onbeforeactivate`, `onbeforedeactivate`, `ondeactivate`, `onfullscreenchange`, `onfullscreenerror`, `onloadeddata`, `onloadedmetadata`, `onpointerlockchange`, `onpointerlockerror`, `onreadystatechange`, `onscroll` *Clipboard* `onbeforecut`, `onbeforecopy`, `onbeforepaste` *Input* `oninvalid`, `onreset`, `onselect`, `onselectionchange`, `onselectstart`, `onsubmit` *Media* `oncanplay`, `oncanplaythrough`, `oncuechange`, `ondurationchange`, `onemptied`, `onended`, `onpause`, `onplay`, `onplaying`, `onratechange`, `onseeked`, `onseeking`, `onstalled`, `onstop`, `onsuspend`, `ontimeupdate`, `onvolumechange`, `onwaiting` EventHandlers holds attributes to configure the mappings between event names and event argument types.
Focus	FocusEventArgs	`onfocus`, `onblur`, `onfocusin`, `onfocusout` Doesn't include support for `relatedTarget`.
Input	ChangeEventArgs	`onchange`, `oninput`
Keyboard	KeyboardEventArgs	`onkeydown`, `onkeypress`, `onkeyup`
Mouse	MouseEventArgs	`onclick`, `oncontextmenu`, `ondblclick`, `onmousedown`, `onmouseup`, `onmouseover`, `onmousemove`, `onmouseout`
Mouse pointer	PointerEventArgs	`onpointerdown`, `onpointerup`, `onpointercancel`, `onpointermove`, `onpointerover`, `onpointerout`, `onpointerenter`, `onpointerleave`, `ongotpointercapture`, `onlostpointercapture`
Mouse wheel	WheelEventArgs	`onwheel`, `onmousewheel`

EVENT	CLASS	DOM EVENTS AND NOTES
Progress	ProgressEventArgs	`onabort`, `onload`, `onloadend`, `onloadstart`, `onprogress`, `ontimeout`
Touch	TouchEventArgs	`ontouchstart`, `ontouchend`, `ontouchmove`, `ontouchenter`, `ontouchleave`, `ontouchcancel` TouchPoint represents a single contact point on a touch-sensitive device.

For more information, see the following resources:

- `EventArgs` classes in the ASP.NET Core reference source (dotnet/aspnetcore `master` branch). The `master` branch represents API under development for the *next* ASP.NET Core release. For the current release, select the appropriate GitHub repository branch (for example, `release/3.1`).
- MDN web docs: GlobalEventHandlers: Includes information on which HTML elements support each DOM event.

Lambda expressions

Lambda expressions can also be used:

```
<button @onclick="@(e => Console.WriteLine("Hello, world!"))">Say hello</button>
```

It's often convenient to close over additional values, such as when iterating over a set of elements. The following example creates three buttons, each of which calls `UpdateHeading` passing an event argument (MouseEventArgs) and its button number (`buttonNumber`) when selected in the UI:

```
<h2>@message</h2>

@for (var i = 1; i < 4; i++)
{
    var buttonNumber = i;

    <button class="btn btn-primary"
            @onclick="@(e => UpdateHeading(e, buttonNumber))">
        Button #@i
    </button>
}

@code {
    private string message = "Select a button to learn its position.";

    private void UpdateHeading(MouseEventArgs e, int buttonNumber)
    {
        message = $"You selected Button #{buttonNumber} at " +
            $"mouse position: {e.ClientX} X {e.ClientY}.";
    }
}
```

NOTE

Do **not** use a loop variable directly in a lambda expression, such as `i` in the preceding `for` loop example. Otherwise, the same variable is used by all lambda expressions, which results in use of the same value in all lambdas. Always capture the variable's value in a local variable and then use it. In the preceding example, the loop variable `i` is assigned to `buttonNumber`.

EventCallback

A common scenario with nested components is the desire to run a parent component's method when a child component event occurs. An `onclick` event occurring in the child component is a common use case. To expose events across components, use an EventCallback. A parent component can assign a callback method to a child component's EventCallback.

The `ChildComponent` in the sample app (`Components/ChildComponent.razor`) demonstrates how a button's `onclick` handler is set up to receive an EventCallback delegate from the sample's `ParentComponent`. The EventCallback is typed with `MouseEventArgs`, which is appropriate for an `onclick` event from a peripheral device:

```
<div class="panel panel-default">
    <div class="panel-heading">@Title</div>
    <div class="panel-body">@ChildContent</div>

    <button class="btn btn-primary" @onclick="OnClickCallback">
        Trigger a Parent component method
    </button>
</div>

@code {
    [Parameter]
    public string Title { get; set; }

    [Parameter]
    public RenderFragment ChildContent { get; set; }

    [Parameter]
    public EventCallback<MouseEventArgs> OnClickCallback { get; set; }
}
```

The `ParentComponent` sets the child's EventCallback<TValue> (`OnClickCallback`) to its `ShowMessage` method.

`Pages/ParentComponent.razor`:

```
@page "/ParentComponent"

<h1>Parent-child example</h1>

<ChildComponent Title="Panel Title from Parent"
                OnClickCallback="@ShowMessage">
    Content of the child component is supplied
    by the parent component.
</ChildComponent>

<p><b>@messageText</b></p>

@code {
    private string messageText;

    private void ShowMessage(MouseEventArgs e)
    {
        messageText = $"Blaze a new trail with Blazor! ({e.ScreenX}, {e.ScreenY})";
    }
}
```

When the button is selected in the `ChildComponent`:

- The `ParentComponent`'s `ShowMessage` method is called. `messageText` is updated and displayed in the `ParentComponent`.
- A call to `StateHasChanged` isn't required in the callback's method (`ShowMessage`). StateHasChanged is called automatically to rerender the `ParentComponent`, just as child events trigger component rerendering in event handlers that execute within the child.

EventCallback and EventCallback<TValue> permit asynchronous delegates. EventCallback is weakly typed and allows passing any type argument in `InvokeAsync(Object)`. EventCallback<TValue> is strongly typed and requires passing a `T` argument in `InvokeAsync(T)` that's assignable to `TValue`.

```
<ChildComponent
    OnClickCallback="@(async () => { await Task.Yield(); messageText = "Blaze It!"; })" />
```

Invoke an EventCallback or EventCallback<TValue> with InvokeAsync and await the Task:

```
await OnClickCallback.InvokeAsync(arg);
```

Use EventCallback and EventCallback<TValue> for event handling and binding component parameters.

Prefer the strongly typed EventCallback<TValue> over EventCallback. EventCallback<TValue> provides better error feedback to users of the component. Similar to other UI event handlers, specifying the event parameter is optional. Use EventCallback when there's no value passed to the callback.

Prevent default actions

Use the `@on{EVENT}:preventDefault` directive attribute to prevent the default action for an event.

When a key is selected on an input device and the element focus is on a text box, a browser normally displays the key's character in the text box. In the following example, the default behavior is prevented by specifying the `@onkeypress:preventDefault` directive attribute. The counter increments, and the + key isn't captured into the `<input>` element's value:

```
<input value="@count" @onkeypress="KeyHandler" @onkeypress:preventDefault />

@code {
    private int count = 0;

    private void KeyHandler(KeyboardEventArgs e)
    {
        if (e.Key == "+")
        {
            count++;
        }
    }
}
```

Specifying the `@on{EVENT}:preventDefault` attribute without a value is equivalent to `@on{EVENT}:preventDefault="true"`.

The value of the attribute can also be an expression. In the following example, `shouldPreventDefault` is a `bool` field set to either `true` or `false`:

```
<input @onkeypress:preventDefault="shouldPreventDefault" />
```

Stop event propagation

Use the `@on{EVENT}:stopPropagation` directive attribute to stop event propagation.

In the following example, selecting the check box prevents click events from the second child `<div>` from propagating to the parent `<div>`:

```
<label>
    <input @bind="stopPropagation" type="checkbox" />
    Stop Propagation
</label>

<div @onclick="OnSelectParentDiv">
    <h3>Parent div</h3>

    <div @onclick="OnSelectChildDiv">
        Child div that doesn't stop propagation when selected.
    </div>

    <div @onclick="OnSelectChildDiv" @onclick:stopPropagation="stopPropagation">
        Child div that stops propagation when selected.
    </div>
</div>

@code {
    private bool stopPropagation = false;

    private void OnSelectParentDiv() =>
        Console.WriteLine($"The parent div was selected. {DateTime.Now}");
    private void OnSelectChildDiv() =>
        Console.WriteLine($"A child div was selected. {DateTime.Now}");
}
```

ASP.NET Core Blazor lifecycle

9/22/2020 • 11 minutes to read • Edit Online

By Luke Latham and Daniel Roth

The Blazor framework includes synchronous and asynchronous lifecycle methods. Override lifecycle methods to perform additional operations on components during component initialization and rendering.

Lifecycle methods

Before parameters are set

SetParametersAsync sets parameters supplied by the component's parent in the render tree:

```
public override async Task SetParametersAsync(ParameterView parameters)
{
    await ...

    await base.SetParametersAsync(parameters);
}
```

ParameterView contains the set of parameter values for the component each time SetParametersAsync is called.

The default implementation of SetParametersAsync sets the value of each property with the `[Parameter]` or `[CascadingParameter]` attribute that has a corresponding value in the ParameterView. Parameters that don't have a corresponding value in ParameterView are left unchanged.

If `base.SetParametersAync` isn't invoked, the custom code can interpret the incoming parameters value in any way required. For example, there's no requirement to assign the incoming parameters to the properties on the class.

If any event handlers are set up, unhook them on disposal. For more information, see the Component disposal with `IDisposable` section.

Component initialization methods

OnInitializedAsync and OnInitialized are invoked when the component is initialized after having received its initial parameters from its parent component in SetParametersAsync.

Use OnInitializedAsync when the component performs an asynchronous operation and should refresh when the operation is completed.

For a synchronous operation, override OnInitialized:

```
protected override void OnInitialized()
{
    ...
}
```

To perform an asynchronous operation, override OnInitializedAsync and use the `await` operator on the operation:

```
protected override async Task OnInitializedAsync()
{
    await ...
}
```

Blazor Server apps that prerender their content call OnInitializedAsync ***twice***:

- Once when the component is initially rendered statically as part of the page.
- A second time when the browser establishes a connection back to the server.

To prevent developer code in OnInitializedAsync from running twice, see the Stateful reconnection after prerendering section.

While a Blazor Server app is prerendering, certain actions, such as calling into JavaScript, aren't possible because a connection with the browser hasn't been established. Components may need to render differently when prerendered. For more information, see the Detect when the app is prerendering section.

If any event handlers are set up, unhook them on disposal. For more information, see the Component disposal with `IDisposable` section.

After parameters are set

OnParametersSetAsync or OnParametersSet are called:

- After the component is initialized in OnInitialized or OnInitializedAsync.
- When the parent component re-renders and supplies:
  - Only known primitive immutable types of which at least one parameter has changed.
  - Any complex-typed parameters. The framework can't know whether the values of a complex-typed parameter have mutated internally, so it treats the parameter set as changed.

```
protected override async Task OnParametersSetAsync()
{
    await ...
}
```

> **NOTE**
> Asynchronous work when applying parameters and property values must occur during the OnParametersSetAsync lifecycle event.

```
protected override void OnParametersSet()
{
    ...
}
```

If any event handlers are set up, unhook them on disposal. For more information, see the Component disposal with `IDisposable` section.

After component render

OnAfterRenderAsync and OnAfterRender are called after a component has finished rendering. Element and component references are populated at this point. Use this stage to perform additional initialization steps using the rendered content, such as activating third-party JavaScript libraries that operate on the rendered DOM elements.

The `firstRender` parameter for OnAfterRenderAsync and OnAfterRender:

- Is set to `true` the first time that the component instance is rendered.
- Can be used to ensure that initialization work is only performed once.

```
protected override async Task OnAfterRenderAsync(bool firstRender)
{
    if (firstRender)
    {
        await ...
    }
}
```

> **NOTE**
>
> Asynchronous work immediately after rendering must occur during the OnAfterRenderAsync lifecycle event.
>
> Even if you return a Task from OnAfterRenderAsync, the framework doesn't schedule a further render cycle for your component once that task completes. This is to avoid an infinite render loop. It's different from the other lifecycle methods, which schedule a further render cycle once the returned task completes.

```
protected override void OnAfterRender(bool firstRender)
{
    if (firstRender)
    {
        ...
    }
}
```

OnAfterRender and OnAfterRenderAsync *aren't called during the prerendering process on the server*. The methods are called when the component is rendered interactively after prerendering is finished. When the app prerenders:

1. The component executes on the server to produce some static HTML markup in the HTTP response. During this phase, OnAfterRender and OnAfterRenderAsync aren't called.
2. When `blazor.server.js` or `blazor.webassembly.js` start up in the browser, the component is restarted in an interactive rendering mode. After a component is restarted, OnAfterRender and OnAfterRenderAsync **are** called because the app isn't inside the prerendering phase any longer.

If any event handlers are set up, unhook them on disposal. For more information, see the Component disposal with `IDisposable` section.

Suppress UI refreshing

Override ShouldRender to suppress UI refreshing. If the implementation returns `true`, the UI is refreshed:

```
protected override bool ShouldRender()
{
    var renderUI = true;

    return renderUI;
}
```

ShouldRender is called each time the component is rendered.

Even if ShouldRender is overridden, the component is always initially rendered.

For more information, see ASP.NET Core Blazor WebAssembly performance best practices.

State changes

StateHasChanged notifies the component that its state has changed. When applicable, calling StateHasChanged

causes the component to be rerendered.

StateHasChanged is called automatically for EventCallback methods. For more information, see ASP.NET Core Blazor event handling.

Handle incomplete async actions at render

Asynchronous actions performed in lifecycle events might not have completed before the component is rendered. Objects might be `null` or incompletely populated with data while the lifecycle method is executing. Provide rendering logic to confirm that objects are initialized. Render placeholder UI elements (for example, a loading message) while objects are `null`.

In the `FetchData` component of the Blazor templates, OnInitializedAsync is overridden to asychronously receive forecast data (`forecasts`). When `forecasts` is `null`, a loading message is displayed to the user. After the `Task` returned by OnInitializedAsync completes, the component is rerendered with the updated state.

`Pages/FetchData.razor` in the Blazor Server template:

```
@page "/fetchdata"
@using MyBlazorApp.Data
@inject WeatherForecastService ForecastService

<h1>Weather forecast</h1>

<p>This component demonstrates fetching data from a service.</p>

@if (forecasts == null)
{
    <p><em>Loading...</em></p>
}
else
{
    <table class="table">
        <!-- forecast data in table element content -->
    </table>
}

@code {
    private WeatherForecast[] forecasts;

    protected override async Task OnInitializedAsync()
    {
        forecasts = await ForecastService.GetForecastAsync(DateTime.Now);
    }
}
```

Handle errors

For information on handling errors during lifecycle method execution, see Handle errors in ASP.NET Core Blazor apps.

Stateful reconnection after prerendering

In a Blazor Server app when RenderMode is ServerPrerendered, the component is initially rendered statically as part of the page. Once the browser establishes a connection back to the server, the component is rendered *again*, and the component is now interactive. If the `OnInitialized{Async}` lifecycle method for initializing the component is present, the method is executed *twice*:

- When the component is prerendered statically.

- After the server connection has been established.

This can result in a noticeable change in the data displayed in the UI when the component is finally rendered.

To avoid the double-rendering scenario in a Blazor Server app:

- Pass in an identifier that can be used to cache the state during prerendering and to retrieve the state after the app restarts.
- Use the identifier during prerendering to save component state.
- Use the identifier after prerendering to retrieve the cached state.

The following code demonstrates an updated `WeatherForecastService` in a template-based Blazor Server app that avoids the double rendering:

```
public class WeatherForecastService
{
    private static readonly string[] summaries = new[]
    {
        "Freezing", "Bracing", "Chilly", "Cool", "Mild",
        "Warm", "Balmy", "Hot", "Sweltering", "Scorching"
    };

    public WeatherForecastService(IMemoryCache memoryCache)
    {
        MemoryCache = memoryCache;
    }

    public IMemoryCache MemoryCache { get; }

    public Task<WeatherForecast[]> GetForecastAsync(DateTime startDate)
    {
        return MemoryCache.GetOrCreateAsync(startDate, async e =>
        {
            e.SetOptions(new MemoryCacheEntryOptions
            {
                AbsoluteExpirationRelativeToNow =
                    TimeSpan.FromSeconds(30)
            });

            var rng = new Random();

            await Task.Delay(TimeSpan.FromSeconds(10));

            return Enumerable.Range(1, 5).Select(index => new WeatherForecast
            {
                Date = startDate.AddDays(index),
                TemperatureC = rng.Next(-20, 55),
                Summary = summaries[rng.Next(summaries.Length)]
            }).ToArray();
        });
    }
}
```

For more information on the RenderMode, see ASP.NET Core Blazor hosting model configuration.

Detect when the app is prerendering

While a Blazor Server app is prerendering, certain actions, such as calling into JavaScript, aren't possible because a connection with the browser hasn't been established. Components may need to render differently when prerendered.

To delay JavaScript interop calls until after the connection with the browser is established, you can use the

OnAfterRenderAsync component lifecycle event. This event is only called after the app is fully rendered and the client connection is established.

```
@using Microsoft.JSInterop
@inject IJSRuntime JSRuntime

<div @ref="divElement">Text during render</div>

@code {
    private ElementReference divElement;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            await JSRuntime.InvokeVoidAsync(
                "setElementText", divElement, "Text after render");
        }
    }
}
```

For the preceding example code, provide a `setElementText` JavaScript function inside the `<head>` element of `wwwroot/index.html` (Blazor WebAssembly) or `Pages/_Host.cshtml` (Blazor Server). The function is called with JSRuntimeExtensions.InvokeVoidAsync and doesn't return a value:

```
<script>
  window.setElementText = (element, text) => element.innerText = text;
</script>
```

WARNING

The preceding example modifies the Document Object Model (DOM) directly for demonstration purposes only. Directly modifying the DOM with JavaScript isn't recommended in most scenarios because JavaScript can interfere with Blazor's change tracking.

The following component demonstrates how to use JavaScript interop as part of a component's initialization logic in a way that's compatible with prerendering. The component shows that it's possible to trigger a rendering update from inside OnAfterRenderAsync. The developer must avoid creating an infinite loop in this scenario.

Where JSRuntime.InvokeAsync is called, `ElementRef` is only used in OnAfterRenderAsync and not in any earlier lifecycle method because there's no JavaScript element until after the component is rendered.

StateHasChanged is called to rerender the component with the new state obtained from the JavaScript interop call. The code doesn't create an infinite loop because `StateHasChanged` is only called when `infoFromJs` is `null`.

```
@page "/prerendered-interop"
@using Microsoft.AspNetCore.Components
@using Microsoft.JSInterop
@inject IJSRuntime JSRuntime

<p>
    Get value via JS interop call:
    <strong id="val-get-by-interop">@(infoFromJs ?? "No value yet")</strong>
</p>

Set value via JS interop call:
<div id="val-set-by-interop" @ref="divElement"></div>

@code {
    private string infoFromJs;
    private ElementReference divElement;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender && infoFromJs == null)
        {
            infoFromJs = await JSRuntime.InvokeAsync<string>(
                "setElementText", divElement, "Hello from interop call!");

            StateHasChanged();
        }
    }
}
```

For the preceding example code, provide a `setElementText` JavaScript function inside the `<head>` element of `wwwroot/index.html` (Blazor WebAssembly) or `Pages/_Host.cshtml` (Blazor Server). The function is called withIJSRuntime.InvokeAsync and returns a value:

```
<script>
  window.setElementText = (element, text) => {
    element.innerText = text;
    return text;
  };
</script>
```

WARNING

The preceding example modifies the Document Object Model (DOM) directly for demonstration purposes only. Directly modifying the DOM with JavaScript isn't recommended in most scenarios because JavaScript can interfere with Blazor's change tracking.

Component disposal with IDisposable

If a component implements IDisposable, the `Dispose` method is called when the component is removed from the UI. Disposal can occur at any time, including during component initialization. The following component uses `@implements IDisposable` and the `Dispose` method:

```
@using System
@implements IDisposable

...

@code {
    public void Dispose()
    {
        ...
    }
}
```

NOTE

Calling StateHasChanged in `Dispose` isn't supported. StateHasChanged might be invoked as part of tearing down the renderer, so requesting UI updates at that point isn't supported.

Unsubscribe event handlers from .NET events. The following Blazor form examples show how to unhook an event handler in the `Dispose` method:

- Private field and lambda approach

```
@implements IDisposable

<EditForm EditContext="@editContext">

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    ...
    private EventHandler<FieldChangedEventArgs> fieldChanged;

    protected override void OnInitialized()
    {
        editContext = new EditContext(...);

        fieldChanged = (_, __) =>
        {
            ...
        };

        editContext.OnFieldChanged += fieldChanged;
    }

    public void Dispose()
    {
        editContext.OnFieldChanged -= fieldChanged;
    }
}
```

- Private method approach

```
@implements IDisposable

<EditForm EditContext="@editContext">

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    ...

    protected override void OnInitialized()
    {
        editContext = new EditContext(...);
        editContext.OnFieldChanged += HandleFieldChanged;
    }

    private void HandleFieldChanged(object sender, FieldChangedEventArgs e)
    {
        ...
    }

    public void Dispose()
    {
        editContext.OnFieldChanged -= HandleFieldChanged;
    }
}
```

Cancelable background work

Components often perform long-running background work, such as making network calls (HttpClient) and interacting with databases. It's desirable to stop the background work to conserve system resources in several situations. For example, background asynchronous operations don't automatically stop when a user navigates away from a component.

Other reasons why background work items might require cancellation include:

- An executing background task was started with faulty input data or processing parameters.
- The current set of executing background work items must be replaced with a new set of work items.
- The priority of currently executing tasks must be changed.
- The app has to be shut down in order to redeploy it to the server.
- Server resources become limited, necessitating the rescheduling of background work items.

To implement a cancelable background work pattern in a component:

- Use a CancellationTokenSource and CancellationToken.
- On disposal of the component and at any point cancellation is desired by manually cancelling the token, call `CancellationTokenSource.Cancel` to signal that the background work should be cancelled.
- After the asynchronous call returns, call ThrowIfCancellationRequested on the token.

In the following example:

- `await Task.Delay(5000, cts.Token);` represents long-running asynchronous background work.
- `BackgroundResourceMethod` represents a long-running background method that shouldn't start if the `Resource` is disposed before the method is called.

```
@implements IDisposable
@using System.Threading

<button @onclick="LongRunningWork">Trigger long running work</button>

@code {
    private Resource resource = new Resource();
    private CancellationTokenSource cts = new CancellationTokenSource();

    protected async Task LongRunningWork()
    {
        await Task.Delay(5000, cts.Token);

        cts.Token.ThrowIfCancellationRequested();
        resource.BackgroundResourceMethod();
    }

    public void Dispose()
    {
        cts.Cancel();
        cts.Dispose();
        resource.Dispose();
    }

    private class Resource : IDisposable
    {
        private bool disposed;

        public void BackgroundResourceMethod()
        {
            if (disposed)
            {
                throw new ObjectDisposedException(nameof(Resource));
            }

            ...
        }

        public void Dispose()
        {
            disposed = true;
        }
    }
}
```

ASP.NET Core Blazor component virtualization

9/22/2020 • 3 minutes to read • Edit Online

By Daniel Roth

Improve the perceived performance of component rendering using the Blazor framework's built-in virtualization support. Virtualization is a technique for limiting UI rendering to just the parts that are currently visible. For example, virtualization is helpful when the app must render a long list or a table with many rows and only a subset of items is required to be visible at any given time. Blazor provides the `Virtualize` component that can be used to add virtualization to an app's components.

Without virtualization, a typical list or table-based component might use a C# `foreach` loop to render each item in the list or each row in the table:

```
<table>
    @foreach (var employee in employees)
    {
        <tr>
            <td>@employee.FirstName</td>
            <td>@employee.LastName</td>
            <td>@employee.JobTitle</td>
        </tr>
    }
</table>
```

If the list contains thousands of items, then rendering the list may take a long time. The user may experience a noticeable UI lag.

Instead of rendering each item in the list all at one time, replace the `foreach` loop with the `Virtualize` component and specify a fixed item source with `Items`. Only the items that are currently visible are rendered:

```
<table>
    <Virtualize Context="employee" Items="@employees">
        <tr>
            <td>@employee.FirstName</td>
            <td>@employee.LastName</td>
            <td>@employee.JobTitle</td>
        </tr>
    </Virtualize>
</table>
```

If not specifying a context to the component with `Context`, use the `context` value (`@context.{PROPERTY}`) in the item content template:

```
<table>
    <Virtualize Items="@employees">
        <tr>
            <td>@context.FirstName</td>
            <td>@context.LastName</td>
            <td>@context.JobTitle</td>
        </tr>
    </Virtualize>
</table>
```

The `Virtualize` component calculates how many items to render based on the height of the container and the size of the rendered items.

Item provider delegate

If you don't want to load all of the items into memory, you can specify an items provider delegate method to the component's `ItemsProvider` parameter that asynchronously retrieves the requested items on demand:

```
<table>
    <Virtualize Context="employee" ItemsProvider="@LoadEmployees">
         <tr>
            <td>@employee.FirstName</td>
            <td>@employee.LastName</td>
            <td>@employee.JobTitle</td>
        </tr>
    </Virtualize>
</table>
```

The items provider receives an `ItemsProviderRequest`, which specifies the required number of items starting at a specific start index. The items provider then retrieves the requested items from a database or other service and returns them as an `ItemsProviderResult<TItem>` along with a count of the total items. The items provider can choose to retrieve the items with each request or cache them so that they're readily available. Don't attempt to use an items provider and assign a collection to `Items` for the same `Virtualize` component.

The following example loads employees from an `EmployeeService`:

```
private async ValueTask<ItemsProviderResult<Employee>> LoadEmployees(
    ItemsProviderRequest request)
{
    var numEmployees = Math.Min(request.Count, totalEmployees - request.StartIndex);
    var employees = await EmployeesService.GetEmployeesAsync(request.StartIndex,
        numEmployees, request.CancellationToken);

    return new ItemsProviderResult<Employee>(employees, totalEmployees);
}
```

Placeholder

Because requesting items from a remote data source might take some time, you have the option to render a placeholder (`<Placeholder>...</Placeholder>`) until the item data is available:

```
<table>
    <Virtualize Context="employee" ItemsProvider="@LoadEmployees">
        <ItemContent>
            <tr>
                <td>@employee.FirstName</td>
                <td>@employee.LastName</td>
                <td>@employee.JobTitle</td>
            </tr>
        </ItemContent>
        <Placeholder>
            <tr>
                <td>Loading...</td>
            </tr>
        </Placeholder>
    </Virtualize>
</table>
```

Item size

The size of each item in pixels can be set with `ItemSize` (default: 50px):

```
<table>
    <Virtualize Context="employee" Items="@employees" ItemSize="25">
        ...
    </Virtualize>
</table>
```

Overscan count

`OverscanCount` determines how many additional items are rendered before and after the visible region. This setting helps to reduce the frequency of rendering during scrolling. However, higher values result in more elements rendered in the page (default: 3):

```
<table>
    <Virtualize Context="employee" Items="@employees" OverscanCount="4">
        ...
    </Virtualize>
</table>
```

For example, a grid or list that renders hundreds of rows containing components is processor intensive to render. Consider virtualizing a grid or list layout so that only a subset of the components is rendered at any given time. For an example of component subset rendering, see the following components in the `Virtualization` sample app (aspnet/samples GitHub repository):

- `Virtualize` component (`Shared/Virtualize.razor`): A component written in C# that implements ComponentBase to render a set of weather data rows based on user scrolling.
- `FetchData` component (`Pages/FetchData.razor`): Uses the `Virtualize` component to display 25 rows of weather data at a time.

State changes

When making changes to items rendered by the `Virtualize` component, call StateHasChanged to force re-evaluation and rerendering of the component.

ASP.NET Core Blazor templated components

9/22/2020 • 2 minutes to read • Edit Online

By Luke Latham and Daniel Roth

Templated components are components that accept one or more UI templates as parameters, which can then be used as part of the component's rendering logic. Templated components allow you to author higher-level components that are more reusable than regular components. A couple of examples include:

- A table component that allows a user to specify templates for the table's header, rows, and footer.
- A list component that allows a user to specify a template for rendering items in a list.

Template parameters

A templated component is defined by specifying one or more component parameters of type RenderFragment or RenderFragment<TValue>. A render fragment represents a segment of UI to render. RenderFragment<TValue> takes a type parameter that can be specified when the render fragment is invoked.

`TableTemplate` component:

```
@typeparam TItem

<table class="table">
    <thead>
        <tr>@TableHeader</tr>
    </thead>
    <tbody>
        @foreach (var item in Items)
        {
            <tr>@RowTemplate(item)</tr>
        }
    </tbody>
</table>

@code {
    [Parameter]
    public RenderFragment TableHeader { get; set; }

    [Parameter]
    public RenderFragment<TItem> RowTemplate { get; set; }

    [Parameter]
    public IReadOnlyList<TItem> Items { get; set; }
}
```

When using a templated component, the template parameters can be specified using child elements that match the names of the parameters (`TableHeader` and `RowTemplate` in the following example):

```
<TableTemplate Items="pets">
    <TableHeader>
        <th>ID</th>
        <th>Name</th>
    </TableHeader>
    <RowTemplate>
        <td>@context.PetId</td>
        <td>@context.Name</td>
    </RowTemplate>
</TableTemplate>
```

> **NOTE**
>
> Generic type constraints will be supported in a future release. For more information, see Allow generic type constraints (dotnet/aspnetcore #8433).

Template context parameters

Component arguments of type RenderFragment<TValue> passed as elements have an implicit parameter named `context` (for example from the preceding code sample, `@context.PetId`), but you can change the parameter name using the `Context` attribute on the child element. In the following example, the `RowTemplate` element's `Context` attribute specifies the `pet` parameter:

```
<TableTemplate Items="pets">
    <TableHeader>
        <th>ID</th>
        <th>Name</th>
    </TableHeader>
    <RowTemplate Context="pet">
        <td>@pet.PetId</td>
        <td>@pet.Name</td>
    </RowTemplate>
</TableTemplate>
```

Alternatively, you can specify the `Context` attribute on the component element. The specified `Context` attribute applies to all specified template parameters. This can be useful when you want to specify the content parameter name for implicit child content (without any wrapping child element). In the following example, the `Context` attribute appears on the `TableTemplate` element and applies to all template parameters:

```
<TableTemplate Items="pets" Context="pet">
    <TableHeader>
        <th>ID</th>
        <th>Name</th>
    </TableHeader>
    <RowTemplate>
        <td>@pet.PetId</td>
        <td>@pet.Name</td>
    </RowTemplate>
</TableTemplate>
```

Generic-typed components

Templated components are often generically typed. For example, a generic `ListViewTemplate` component can be used to render `IEnumerable<T>` values. To define a generic component, use the `@typeparam` directive to specify type parameters:

```
@typeparam TItem

<ul>
    @foreach (var item in Items)
    {
        @ItemTemplate(item)
    }
</ul>

@code {
    [Parameter]
    public RenderFragment<TItem> ItemTemplate { get; set; }

    [Parameter]
    public IReadOnlyList<TItem> Items { get; set; }
}
```

When using generic-typed components, the type parameter is inferred if possible:

```
<ListViewTemplate Items="pets">
    <ItemTemplate Context="pet">
        <li>@pet.Name</li>
    </ItemTemplate>
</ListViewTemplate>
```

Otherwise, the type parameter must be explicitly specified using an attribute that matches the name of the type parameter. In the following example, `TItem="Pet"` specifies the type:

```
<ListViewTemplate Items="pets" TItem="Pet">
    <ItemTemplate Context="pet">
        <li>@pet.Name</li>
    </ItemTemplate>
</ListViewTemplate>
```

Integrate ASP.NET Core Razor components into Razor Pages and MVC apps

9/22/2020 • 5 minutes to read • Edit Online

By Luke Latham and Daniel Roth

Razor components can be integrated into Razor Pages and MVC apps. When the page or view is rendered, components can be prerendered at the same time.

After preparing the app, use the guidance in the following sections depending on the app's requirements:

- Routable components: For components that are directly routable from user requests. Follow this guidance when visitors should be able to make an HTTP request in their browser for a component with an `@page` directive.
  - Use routable components in a Razor Pages app
  - Use routable components in an MVC app
- Render components from a page or view: For components that aren't directly routable from user requests. Follow this guidance when the app embeds components into existing pages and views with the Component Tag Helper.

Prepare the app

An existing Razor Pages or MVC app can integrate Razor components into pages and views:

1. In the app's layout file (`_Layout.cshtml`):
   - Add the following `<base>` tag to the `<head>` element:

     ```
     <base href="~/" />
     ```

     The `href` value (the *app base path*) in the preceding example assumes that the app resides at the root URL path (`/`). If the app is a sub-application, follow the guidance in the *App base path* section of the Host and deploy ASP.NET Core Blazor article.

     The `_Layout.cshtml` file is located in the *Pages/Shared* folder in a Razor Pages app or *Views/Shared* folder in an MVC app.

   - Add a `<script>` tag for the *blazor.server.js* script immediately before the closing `</body>` tag:

     ```
     <script src="_framework/blazor.server.js"></script>
     ```

     The framework adds the *blazor.server.js* script to the app. There's no need to manually add the script to the app.
2. Add an `_Imports.razor` file to the root folder of the project with the following content (change the last namespace, `MyAppNamespace`, to the namespace of the app):

```
@using System.Net.Http
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.Web
@using Microsoft.JSInterop
@using MyAppNamespace
```

3. In `Startup.ConfigureServices`, register the Blazor Server service:

```
services.AddServerSideBlazor();
```

4. In `Startup.Configure`, add the Blazor Hub endpoint to `app.UseEndpoints`:

```
endpoints.MapBlazorHub();
```

5. Integrate components into any page or view. For more information, see the Render components from a page or view section.

Use routable components in a Razor Pages app

This section pertains to adding components that are directly routable from user requests.

To support routable Razor components in Razor Pages apps:

1. Follow the guidance in the Prepare the app section.
2. Add an `App.razor` file to the project root with the following content:

```
@using Microsoft.AspNetCore.Components.Routing

<Router AppAssembly="@typeof(Program).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="routeData" />
    </Found>
    <NotFound>
        <h1>Page not found</h1>
        <p>Sorry, but there's nothing here!</p>
    </NotFound>
</Router>
```

3. Add a `_Host.cshtml` file to the `Pages` folder with the following content:

```
@page "/blazor"
@{
    Layout = "_Layout";
}

<app>
    <component type="typeof(App)" render-mode="ServerPrerendered" />
</app>
```

Components use the shared `_Layout.cshtml` file for their layout.

RenderMode configures whether the `App` component:

- Is prerendered into the page.
- Is rendered as static HTML on the page or if it includes the necessary information to bootstrap a Blazor app from the user agent.

RENDER MODE	DESCRIPTION
ServerPrerendered	Renders the `App` component into static HTML and includes a marker for a Blazor Server app. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Server	Renders a marker for a Blazor Server app. Output from the `App` component isn't included. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Static	Renders the `App` component into static HTML.

For more information on the Component Tag Helper, see Component Tag Helper in ASP.NET Core.

4. Add a low-priority route for the `_Host.cshtml` page to endpoint configuration in `Startup.Configure`:

```
app.UseEndpoints(endpoints =>
{
    ...

    endpoints.MapFallbackToPage("/_Host");
});
```

5. Add routable components to the app. For example:

```
@page "/counter"

<h1>Counter</h1>

...
```

For more information on namespaces, see the Component namespaces section.

Use routable components in an MVC app

This section pertains to adding components that are directly routable from user requests.

To support routable Razor components in MVC apps:

1. Follow the guidance in the Prepare the app section.
2. Add an `App.razor` file to the root of the project with the following content:

```
@using Microsoft.AspNetCore.Components.Routing

<Router AppAssembly="@typeof(Program).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="routeData" />
    </Found>
    <NotFound>
        <h1>Page not found</h1>
        <p>Sorry, but there's nothing here!</p>
    </NotFound>
</Router>
```

3. Add a `_Host.cshtml` file to the `Views/Home` folder with the following content:

```
@{
    Layout = "_Layout";
}

<app>
    <component type="typeof(App)" render-mode="ServerPrerendered" />
</app>
```

Components use the shared `_Layout.cshtml` file for their layout.

RenderMode configures whether the `App` component:

- Is prerendered into the page.
- Is rendered as static HTML on the page or if it includes the necessary information to bootstrap a Blazor app from the user agent.

RENDER MODE	DESCRIPTION
ServerPrerendered	Renders the `App` component into static HTML and includes a marker for a Blazor Server app. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Server	Renders a marker for a Blazor Server app. Output from the `App` component isn't included. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Static	Renders the `App` component into static HTML.

For more information on the Component Tag Helper, see Component Tag Helper in ASP.NET Core.

4. Add an action to the Home controller:

```
public IActionResult Blazor()
{
   return View("_Host");
}
```

5. Add a low-priority route for the controller action that returns the `_Host.cshtml` view to the endpoint configuration in `Startup.Configure`:

```
app.UseEndpoints(endpoints =>
{
    ...

    endpoints.MapFallbackToController("Blazor", "Home");
});
```

6. Create a `Pages` folder and add routable components to the app. For example:

```
@page "/counter"

<h1>Counter</h1>

...
```

For more information on namespaces, see the Component namespaces section.

Render components from a page or view

This section pertains to adding components to pages or views, where the components aren't directly routable from user requests.

To render a component from a page or view, use the Component Tag Helper.

Render stateful interactive components

Stateful interactive components can be added to a Razor page or view.

When the page or view renders:

- The component is prerendered with the page or view.
- The initial component state used for prerendering is lost.
- New component state is created when the SignalR connection is established.

The following Razor page renders a `Counter` component:

```
<h1>My Razor Page</h1>

<component type="typeof(Counter)" render-mode="ServerPrerendered"
    param-InitialValue="InitialValue" />

@functions {
    [BindProperty(SupportsGet=true)]
    public int InitialValue { get; set; }
}
```

For more information, see Component Tag Helper in ASP.NET Core.

Render noninteractive components

In the following Razor page, the `Counter` component is statically rendered with an initial value that's specified using a form. Since the component is statically rendered, the component isn't interactive:

```
<h1>My Razor Page</h1>

<form>
    <input type="number" asp-for="InitialValue" />
    <button type="submit">Set initial value</button>
</form>

<component type="typeof(Counter)" render-mode="Static"
    param-InitialValue="InitialValue" />

@functions {
    [BindProperty(SupportsGet=true)]
    public int InitialValue { get; set; }
}
```

For more information, see Component Tag Helper in ASP.NET Core.

Component namespaces

When using a custom folder to hold the app's components, add the namespace representing the folder to either the page/view or to the `_ViewImports.cshtml` file. In the following example:

- Change `MyAppNamespace` to the app's namespace.
- If a folder named *Components* isn't used to hold the components, change `Components` to the folder where the components reside.

```
@using MyAppNamespace.Components
```

The `_ViewImports.cshtml` file is located in the `Pages` folder of a Razor Pages app or the `Views` folder of an MVC app.

For more information, see Create and use ASP.NET Core Razor components.

ASP.NET Core Razor components class libraries

9/22/2020 • 5 minutes to read • Edit Online

By Simon Timms

Components can be shared in a Razor class library (RCL) across projects. A *Razor components class library* can be included from:

- Another project in the solution.
- A NuGet package.
- A referenced .NET library.

Just as components are regular .NET types, components provided by an RCL are normal .NET assemblies.

Create an RCL

- Visual Studio
- .NET Core CLI

1. Create a new project.
2. Select **Razor Class Library**. Select **Next**.
3. In the **Create a new Razor class library** dialog, select **Create**.
4. Provide a project name in the **Project name** field or accept the default project name. The examples in this topic use the project name `ComponentLibrary`. Select **Create**.
5. Add the RCL to a solution:
   a. Right-click the solution. Select **Add** > **Existing Project**.
   b. Navigate to the RCL's project file.
   c. Select the RCL's project file (`.csproj`).
6. Add a reference the RCL from the app:
   a. Right-click the app project. Select **Add** > **Reference**.
   b. Select the RCL project. Select **OK**.

> **NOTE**
> If the **Support pages and views** check box is selected when generating the RCL from the template, then also add an `_Imports.razor` file to root of the generated project with the following contents to enable Razor component authoring:
>
> ```
> @using Microsoft.AspNetCore.Components.Web
> ```
>
> Manually add the file the root of the generated project.

Consume a library component

In order to consume components defined in a library in another project, use either of the following approaches:

- Use the full type name with the namespace.
- Use Razor's `@using` directive. Individual components can be added by name.

In the following examples, `ComponentLibrary` is a component library containing the `Component1` component (

`Component1.razor`). The `Component1` component is an example component automatically added by the RCL project template when the library is created.

Reference the `Component1` component using its namespace:

```
<h1>Hello, world!</h1>

Welcome to your new app.

<ComponentLibrary.Component1 />
```

Alternatively, bring the library into scope with an `@using` directive and use the component without its namespace:

```
@using ComponentLibrary

<h1>Hello, world!</h1>

Welcome to your new app.

<Component1 />
```

Optionally, include the `@using ComponentLibrary` directive in the top-level `_Import.razor` file to make the library's components available to an entire project. Add the directive to an `_Import.razor` file at any level to apply the namespace to a single component or set of components within a folder.

To provide `Component1`'s `my-component` CSS class to the component, link to the library's stylesheet using the framework's `Link` component in `Component1.razor`:

```
<div class="my-component">
    <Link href="_content/ComponentLibrary/styles.css" rel="stylesheet" />

    <p>
        This Blazor component is defined in the <strong>ComponentLibrary</strong> package.
    </p>
</div>
```

To provide the stylesheet across the app, you can alternatively link to the library's stylesheet in the app's `wwwroot/index.html` file (Blazor WebAssembly) or `Pages/_Host.cshtml` file (Blazor Server):

```
<head>
    ...
    <link href="_content/ComponentLibrary/styles.css" rel="stylesheet" />
</head>
```

When the `Link` component is used in a child component, the linked asset is also available to any other child component of the parent component as long as the child with the `Link` component is rendered. The distinction between using the `Link` component in a child component and placing a `<link>` HTML tag in `wwwroot/index.html` or `Pages/_Host.cshtml` is that a framework component's rendered HTML tag:

- Can be modified by application state. A hard-coded `<link>` HTML tag can't be modified by application state.
- Is removed from the HTML `<head>` when the parent component is no longer rendered.

To provide `Component1`'s `my-component` CSS class, link to the library's stylesheet in the app's `wwwroot/index.html` file (Blazor WebAssembly) or `Pages/_Host.cshtml` file (Blazor Server):

```
<head>
    ...
    <link href="_content/ComponentLibrary/styles.css" rel="stylesheet" />
</head>
```

Create a Razor components class library with static assets

An RCL can include static assets. The static assets are available to any app that consumes the library. For more information, see Reusable Razor UI in class libraries with ASP.NET Core.

Supply components and static assets to multiple hosted Blazor apps

For more information, see Host and deploy ASP.NET Core Blazor WebAssembly.

Browser compatibility analyzer for Blazor WebAssembly

Blazor WebAssembly apps target the full .NET API surface area, but not all .NET APIs are supported on WebAssembly due to browser sandbox constraints. Unsupported APIs throw PlatformNotSupportedException when running on WebAssembly. A platform compatibility analyzer warns the developer when the app uses APIs that aren't supported by the app's target platforms. For Blazor WebAssembly apps, this means checking that APIs are supported in browsers. Annotating .NET framework APIs for the compatibility analyzer is an on-going process, so not all .NET framework API is currently annotated.

Blazor WebAssembly and Razor class library projects *automatically* enable browser compatibilty checks by adding `browser` as a supported platform with the `SupportedPlatform` MSBuild item. Library developers can manually add the `SupportedPlatform` item to a library's project file to enable the feature:

```
<ItemGroup>
  <SupportedPlatform Include="browser" />
</ItemGroup>
```

When authoring a library, indicate that a particular API isn't supported in browsers by specifying `browser` to UnsupportedOSPlatformAttribute:

```
[UnsupportedOSPlatform("browser")]
private static string GetLoggingDirectory()
{
    ...
}
```

For more information, see Annotating APIs as unsupported on specific platforms (dotnet/designs GitHub repository.

Blazor JavaScript isolation and object references

Blazor enables JavaScript isolation in standard JavaScript modules. JavaScript isolation provides the following benefits:

- Imported JavaScript no longer pollutes the global namespace.
- Consumers of the library and components aren't required to manually import the related JavaScript.

For more information, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.

Build, pack, and ship to NuGet

Because component libraries are standard .NET libraries, packaging and shipping them to NuGet is no different from packaging and shipping any library to NuGet. Packaging is performed using the `dotnet pack` command in a command shell:

```
dotnet pack
```

Upload the package to NuGet using the `dotnet nuget push` command in a command shell.

ASP.NET Core Blazor globalization and localization

9/22/2020 • 4 minutes to read • Edit Online

By Luke Latham and Daniel Roth

Razor components can be made accessible to users in multiple cultures and languages. The following .NET globalization and localization scenarios are available:

- .NET's resources system
- Culture-specific number and date formatting

A limited set of ASP.NET Core's localization scenarios are currently supported:

- IStringLocalizer and IStringLocalizer<T> *are supported* in Blazor apps.
- IHtmlLocalizer, IViewLocalizer, and Data Annotations localization are ASP.NET Core MVC scenarios and **not supported** in Blazor apps.

For more information, see Globalization and localization in ASP.NET Core.

Globalization

Blazor's `@bind` functionality performs formats and parses values for display based on the user's current culture.

The current culture can be accessed from the System.Globalization.CultureInfo.CurrentCulture property.

CultureInfo.InvariantCulture is used for the following field types (`<input type="{TYPE}" />`):

- `date`
- `number`

The preceding field types:

- Are displayed using their appropriate browser-based formatting rules.
- Can't contain free-form text.
- Provide user interaction characteristics based on the browser's implementation.

The following field types have specific formatting requirements and aren't currently supported by Blazor because they aren't supported by all major browsers:

- `datetime-local`
- `month`
- `week`

`@bind` supports the `@bind:culture` parameter to provide a System.Globalization.CultureInfo for parsing and formatting a value. Specifying a culture isn't recommended when using the `date` and `number` field types. `date` and `number` have built-in Blazor support that provides the required culture.

Localization

Blazor WebAssembly

Blazor WebAssembly apps set the culture using the user's language preference.

To explicitly configure the culture, set CultureInfo.DefaultThreadCurrentCulture and

CultureInfo.DefaultThreadCurrentUICulture in `Program.Main`.

By default, Blazor WebAssembly carries globalization resources required to display values, such as dates and currency, in the user's culture. If the app doesn't require localization, you may configure the app to support the invariant culture, which is based on the `en-US` culture:

```
<PropertyGroup>
  <InvariantGlobalization>true</InvariantGlobalization>
</PropertyGroup>
```

By default, the Intermediate Language (IL) Linker configuration for Blazor WebAssembly apps strips out internationalization information except for locales explicitly requested. For more information, see Configure the Linker for ASP.NET Core Blazor.

While the culture that Blazor selects by default might be sufficient for most users, consider offering a way for users to specify their preferred locale. For a Blazor WebAssembly sample app with a culture picker, see the `LocSample` localization sample app.

Blazor Server

Blazor Server apps are localized using Localization Middleware. The middleware selects the appropriate culture for users requesting resources from the app.

The culture can be set using one of the following approaches:

- Cookies
- Provide UI to choose the culture

For more information and examples, see Globalization and localization in ASP.NET Core.

Cookies

A localization culture cookie can persist the user's culture. The Localization Middleware reads the cookie on subsequent requests to set the user's culture.

Use of a cookie ensures that the WebSocket connection can correctly propagate the culture. If localization schemes are based on the URL path or query string, the scheme might not be able to work with WebSockets, thus fail to persist the culture. Therefore, use of a localization culture cookie is the recommended approach.

Any technique can be used to assign a culture if the culture is persisted in a localization cookie. If the app already has an established localization scheme for server-side ASP.NET Core, continue to use the app's existing localization infrastructure and set the localization culture cookie within the app's scheme.

The following example shows how to set the current culture in a cookie that can be read by the Localization Middleware. Create a Razor expression in the `Pages/_Host.cshtml` file immediately inside the opening `<body>` tag:

```
@using System.Globalization
@using Microsoft.AspNetCore.Localization

...

<body>
    @{
        this.HttpContext.Response.Cookies.Append(
            CookieRequestCultureProvider.DefaultCookieName,
            CookieRequestCultureProvider.MakeCookieValue(
                new RequestCulture(
                    CultureInfo.CurrentCulture,
                    CultureInfo.CurrentUICulture)));
    }

    ...
</body>
```

Localization is handled by the app in the following sequence of events:

1. The browser sends an initial HTTP request to the app.
2. The culture is assigned by the Localization Middleware.
3. The Razor expression in the `_Host` page (`_Host.cshtml`) persists the culture in a cookie as part of the response.
4. The browser opens a WebSocket connection to create an interactive Blazor Server session.
5. The Localization Middleware reads the cookie and assigns the culture.
6. The Blazor Server session begins with the correct culture.

Provide UI to choose the culture

To provide UI to allow a user to select a culture, a *redirect-based approach* is recommended. The process is similar to what happens in a web app when a user attempts to access a secure resource. The user is redirected to a sign-in page and then redirected back to the original resource.

The app persists the user's selected culture via a redirect to a controller. The controller sets the user's selected culture into a cookie and redirects the user back to the original URI.

Establish an HTTP endpoint on the server to set the user's selected culture in a cookie and perform the redirect back to the original URI:

```
[Route("[controller]/[action]")]
public class CultureController : Controller
{
    public IActionResult SetCulture(string culture, string redirectUri)
    {
        if (culture != null)
        {
            HttpContext.Response.Cookies.Append(
                CookieRequestCultureProvider.DefaultCookieName,
                CookieRequestCultureProvider.MakeCookieValue(
                    new RequestCulture(culture)));
        }

        return LocalRedirect(redirectUri);
    }
}
```

> **WARNING**
>
> Use the LocalRedirect action result to prevent open redirect attacks. For more information, see Prevent open redirect attacks in ASP.NET Core.

If the app isn't configured to process controller actions:

- Add MVC services to the service collection in `Startup.ConfigureServices`:

```
services.AddControllers();
```

- Add controller endpoint routing in `Startup.Configure`:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllers();
    endpoints.MapBlazorHub();
    endpoints.MapFallbackToPage("/_Host");
});
```

The following component shows an example of how to perform the initial redirection when the user selects a culture:

```
@inject NavigationManager NavigationManager

<h3>Select your language</h3>

<select @onchange="OnSelected">
    <option>Select...</option>
    <option value="en-US">English</option>
    <option value="fr-FR">Français</option>
</select>

@code {
    private void OnSelected(ChangeEventArgs e)
    {
        var culture = (string)e.Value;
        var uri = new Uri(NavigationManager.Uri)
            .GetComponents(UriComponents.PathAndQuery, UriFormat.Unescaped);
        var query = $"?culture={Uri.EscapeDataString(culture)}&" +
            $"redirectUri={Uri.EscapeDataString(uri)}";

        NavigationManager.NavigateTo("/Culture/SetCulture" + query, forceLoad: true);
    }
}
```

ASP.NET Core Blazor layouts

9/22/2020 • 4 minutes to read • Edit Online

By Rainer Stropek and Luke Latham

Some app elements, such as menus, copyright messages, and company logos, are usually part of app's overall layout and used by every component in the app. Copying the code of these elements into all of the components of an app isn't an efficient approach. Every time one of the elements requires an update, every component must be updated. Such duplication is difficult to maintain and can lead to inconsistent content over time. *Layouts* solve this problem.

Technically, a layout is just another component. A layout is defined in a Razor template or in C# code and can use data binding, dependency injection, and other component scenarios.

To turn a *component* into a *layout*, the component:

- Inherits from LayoutComponentBase, which defines a Body property for the rendered content inside the layout.
- Uses the Razor syntax `@Body` to specify the location in the layout markup where the content is rendered.

The following code sample shows the Razor template of a layout component, `MainLayout.razor`. The layout inherits LayoutComponentBase and sets the `@Body` between the navigation bar and the footer:

```
@inherits LayoutComponentBase

<header>
    <h1>Doctor Who&trade; Episode Database</h1>
</header>

<nav>
    <a href="masterlist">Master Episode List</a>
    <a href="search">Search</a>
    <a href="new">Add Episode</a>
</nav>

@Body

<footer>
    @TrademarkMessage
</footer>

@code {
    public string TrademarkMessage { get; set; } =
        "Doctor Who is a registered trademark of the BBC. " +
        "https://www.doctorwho.tv/";
}
```

`MainLayout` component

In an app based on one of the Blazor project templates, the `MainLayout` component (`MainLayout.razor`) is in the app's `Shared` folder:

```
@inherits LayoutComponentBase

<div class="sidebar">
    <NavMenu />
</div>

<div class="main">
    <div class="content px-4">
        @Body
    </div>
</div>
```

Default layout

Specify the default app layout in the Router component in the app's `App.razor` file. The following Router component, which is provided by the default Blazor templates, sets the default layout to the `MainLayout` component:

```
<Router AppAssembly="@typeof(Startup).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="@routeData" DefaultLayout="@typeof(MainLayout)" />
    </Found>
    <NotFound>
        <p>Sorry, there's nothing at this address.</p>
    </NotFound>
</Router>
```

To supply a default layout for NotFound content, specify a LayoutView for NotFound content:

```
<Router AppAssembly="@typeof(Startup).Assembly">
    <Found Context="routeData">
        <RouteView RouteData="@routeData" DefaultLayout="@typeof(MainLayout)" />
    </Found>
    <NotFound>
        <LayoutView Layout="@typeof(MainLayout)">
            <h1>Page not found</h1>
            <p>Sorry, there's nothing at this address.</p>
        </LayoutView>
    </NotFound>
</Router>
```

For more information on the Router component, see ASP.NET Core Blazor routing.

Specifying the layout as a default layout in the router is a useful practice because it can be overridden on a per-component or per-folder basis. Prefer using the router to set the app's default layout because it's the most general technique.

Specify a layout in a component

Use the Razor directive `@layout` to apply a layout to a component. The compiler converts `@layout` into a LayoutAttribute, which is applied to the component class.

The content of the following `MasterList` component is inserted into the `MasterLayout` at the position of `@Body`:

```
@layout MasterLayout
@page "/masterlist"

<h1>Master Episode List</h1>
```

Specifying the layout directly in a component overrides a *default layout* set in the router or an `@layout` directive imported from `_Imports.razor`.

Centralized layout selection

Every folder of an app can optionally contain a template file named `_Imports.razor`. The compiler includes the directives specified in the imports file in all of the Razor templates in the same folder and recursively in all of its subfolders. Therefore, an `_Imports.razor` file containing `@layout MyCoolLayout` ensures that all of the components in a folder use `MyCoolLayout`. There's no need to repeatedly add `@layout MyCoolLayout` to all of the `.razor` files within the folder and subfolders. `@using` directives are also applied to components in the same way.

The following `_Imports.razor` file imports:

- `MyCoolLayout`.
- All Razor components in the same folder and any subfolders.
- The `BlazorApp1.Data` namespace.

```
@layout MyCoolLayout
@using Microsoft.AspNetCore.Components
@using BlazorApp1.Data
```

The `_Imports.razor` file is similar to the _ViewImports.cshtml file for Razor views and pages but applied specifically to Razor component files.

Specifying a layout in `_Imports.razor` overrides a layout specified as the router's *default layout*.

WARNING

Do **not** add a Razor `@layout` directive to the root `_Imports.razor` file, which results in an infinite loop of layouts in the app. To control the default app layout, specify the layout in the `Router` component. For more information, see the Default layout section.

Nested layouts

Apps can consist of nested layouts. A component can reference a layout which in turn references another layout. For example, nesting layouts are used to create a multi-level menu structure.

The following example shows how to use nested layouts. The `EpisodesComponent.razor` file is the component to display. The component references the `MasterListLayout`:

```
@layout MasterListLayout
@page "/masterlist/episodes"

<h1>Episodes</h1>
```

The `MasterListLayout.razor` file provides the `MasterListLayout`. The layout references another layout, `MasterLayout`, where it's rendered. `EpisodesComponent` is rendered where `@Body` appears:

```
@layout MasterLayout
@inherits LayoutComponentBase

<nav>
    <!-- Menu structure of master list -->
    ...
</nav>

@Body
```

Finally, `MasterLayout` in `MasterLayout.razor` contains the top-level layout elements, such as the header, main menu, and footer. `MasterListLayout` with the `EpisodesComponent` is rendered where `@Body` appears:

```
@inherits LayoutComponentBase

<header>...</header>
<nav>...</nav>

@Body

<footer>
    @TrademarkMessage
</footer>

@code {
    public string TrademarkMessage { get; set; } =
        "Doctor Who is a registered trademark of the BBC. " +
        "https://www.doctorwho.tv/";
}
```

Share a Razor Pages layout with integrated components

When routable components are integrated into a Razor Pages app, the app's shared layout can be used with the components. For more information, see Integrate ASP.NET Core Razor components into Razor Pages and MVC apps.

- Layout in ASP.NET Core

ASP.NET Core Blazor forms and validation

9/22/2020 • 22 minutes to read • Edit Online

By Daniel Roth, Rémi Bourgarel, and Luke Latham

Forms and validation are supported in Blazor using data annotations.

The following `ExampleModel` type defines validation logic using data annotations:

```
using System.ComponentModel.DataAnnotations;

public class ExampleModel
{
    [Required]
    [StringLength(10, ErrorMessage = "Name is too long.")]
    public string Name { get; set; }
}
```

A form is defined using the EditForm component. The following form demonstrates typical elements, components, and Razor code:

```
<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <InputText id="name" @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }
}
```

In the preceding example:

- The form validates user input in the `name` field using the validation defined in the `ExampleModel` type. The model is created in the component's `@code` block and held in a private field (`exampleModel`). The field is assigned to the `Model` attribute of the `<EditForm>` element.
- The InputText component's `@bind-Value` binds:
  - The model property (`exampleModel.Name`) to the InputText component's `Value` property. For more information on property binding, see ASP.NET Core Blazor data binding.
  - A change event delegate to the InputText component's `ValueChanged` property.
- The DataAnnotationsValidator validator component attaches validation support using data annotations.
- The ValidationSummary component summarizes validation messages.
- `HandleValidSubmit` is triggered when the form successfully submits (passes validation).

Built-in forms components

A set of built-in components are available to receive and validate user input. Inputs are validated when they're changed and when a form is submitted. Available input components are shown in the following table.

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
`InputFile`	`<input type="file">`
InputNumber<TValue>	`<input type="number">`
`InputRadio`	`<input type="radio">`
`InputRadioGroup`	`<input type="radio">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

INPUT COMPONENT	RENDERED AS...
InputCheckbox	`<input type="checkbox">`
InputDate<TValue>	`<input type="date">`
InputNumber<TValue>	`<input type="number">`
InputSelect<TValue>	`<select>`
InputText	`<input>`
InputTextArea	`<textarea>`

> **NOTE**
>
> The `InputRadio` and `InputRadioGroup` components are available in ASP.NET Core 5.0 or later. For more information, select a 5.0 or later version of this article.

All of the input components, including EditForm, support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the rendered HTML element.

Input components provide default behavior for validating when a field is changed, including updating the field CSS class to reflect the field state. Some components include useful parsing logic. For example, InputDate<TValue> and InputNumber<TValue> handle unparseable values gracefully by registering unparseable values as validation errors. Types that can accept null values also support nullability of the target field (for example, `int?`).

The following `Starship` type defines validation logic using a larger set of properties and data annotations than the

earlier `ExampleModel`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    [Required]
    [StringLength(16, ErrorMessage = "Identifier too long (16 character limit).")]
    public string Identifier { get; set; }

    public string Description { get; set; }

    [Required]
    public string Classification { get; set; }

    [Range(1, 100000, ErrorMessage = "Accommodation invalid (1-100000).")]
    public int MaximumAccommodation { get; set; }

    [Required]
    [Range(typeof(bool), "true", "true",
        ErrorMessage = "This form disallows unapproved ships.")]
    public bool IsValidatedDesign { get; set; }

    [Required]
    public DateTime ProductionDate { get; set; }
}
```

In the preceding example, `Description` is optional because no data annotations are present.

The following form validates user input using the validation defined in the `Starship` model:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <p>
        <label>
            Identifier:
            <InputText @bind-Value="starship.Identifier" />
        </label>
    </p>
    <p>
        <label>
            Description (optional):
            <InputTextArea @bind-Value="starship.Description" />
        </label>
    </p>
    <p>
        <label>
            Primary Classification:
            <InputSelect @bind-Value="starship.Classification">
                <option value="">Select classification ...</option>
                <option value="Exploration">Exploration</option>
                <option value="Diplomacy">Diplomacy</option>
                <option value="Defense">Defense</option>
            </InputSelect>
        </label>
    </p>
    <p>
```

```
        <label>
            Maximum Accommodation:
            <InputNumber @bind-Value="starship.MaximumAccommodation" />
        </label>
    </p>
    <p>
        <label>
            Engineering Approval:
            <InputCheckbox @bind-Value="starship.IsValidatedDesign" />
        </label>
    </p>
    <p>
        <label>
            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" />
        </label>
    </p>

    <button type="submit">Submit</button>

    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        ...
    }
}
```

The EditForm creates an EditContext as a cascading value that tracks metadata about the edit process, including which fields have been modified and the current validation messages.

Assign **either** an EditContext **or** an EditForm.Model to an EditForm. Assignment of both isn't supported and generates a **runtime error**.

The EditForm provides convenient events for valid and invalid form submission:

- OnValidSubmit
- OnInvalidSubmit

Use OnSubmit to use custom code to trigger validation and check field values.

In the following example:

- The `HandleSubmit` method executes when the `Submit` button is selected.
- The form is validated by calling EditContext.Validate.
- Additional code is executed depending on the validation result. Place business logic in the method assigned to OnSubmit.

```
<EditForm EditContext="@editContext" OnSubmit="@HandleSubmit">

    ...

    <button type="submit">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
    }

    private async Task HandleSubmit()
    {
        var isValid = editContext.Validate();

        if (isValid)
        {
            ...
        }
        else
        {
            ...
        }
    }
}
```

NOTE

Framework API doesn't exist to clear validation messages directly from an EditContext. Therefore, we don't generally recommend adding validation messages to a new ValidationMessageStore in a form. To manage validation messages, use a validator component with your business logic validation code, as described in this article.

Display name support

This section applies to ASP.NET Core in .NET 5 Release Candidate 1 (RC1) or later.

The following built-in components support display names with the `DisplayName` parameter:

- InputDate<TValue>
- InputNumber<TValue>
- InputSelect<TValue>

In the following `InputDate` component example:

- The display name (`DisplayName`) is set to `birthday`.
- The component is bound to the `BirthDate` property as a `DateTime` type.

```
<InputDate @bind-Value="@BirthDate" DisplayName="birthday" />

@code {
    public DateTime BirthDate { get; set; }
}
```

If the user doesn't provide a date value, the validation error appears as:

```
The birthday must be a date.
```

Validator components

Validator components support form validation by managing a ValidationMessageStore for a form's EditContext.

The Blazor framework provides the DataAnnotationsValidator component to attach validation support to forms based on validation attributes (data annotations). Create custom validator components to process validation messages for different forms on the same page or the same form at different steps of form processing, for example client-side validation followed by server-side validation. The validator component example shown in this section, `CustomValidator`, is used in the following sections of this article:

- Business logic validation
- Server validation

> **NOTE**
>
> Custom data annotation validation attributes can be used instead of custom validator components in many cases. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, any custom attributes applied to the model must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Create a validator component from ComponentBase:

- The form's EditContext is a cascading parameter of the component.
- When the validator component is initialized, a new ValidationMessageStore is created to maintain a current list of form errors.
- The message store receives errors when developer code in the form's component calls the `DisplayErrors` method. The errors are passed to the `DisplayErrors` method in a `Dictionary<string, List<string>>`. In the dictionary, the key is the name of the form field that has one or more errors. The value is the error list.
- Messages are cleared when any of the following have occurred:
  - Validation is requested on the EditContext when the OnValidationRequested event is raised. All of the errors are cleared.
  - A field changes in the form when the OnFieldChanged event is raised. Only the errors for the field are cleared.
  - The `ClearErrors` method is called by developer code. All of the errors are cleared.

```
using System;
using System.Collections.Generic;
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.Forms;

namespace BlazorSample.Client
{
    public class CustomValidator : ComponentBase
    {
        private ValidationMessageStore messageStore;

        [CascadingParameter]
        private EditContext CurrentEditContext { get; set; }

        protected override void OnInitialized()
        {
            if (CurrentEditContext == null)
            {
                throw new InvalidOperationException(
                    $"{nameof(CustomValidator)} requires a cascading " +
                    $"parameter of type {nameof(EditContext)}. " +
                    $"For example, you can use {nameof(CustomValidator)} " +
                    $"inside an {nameof(EditForm)}.");
            }

            messageStore = new ValidationMessageStore(CurrentEditContext);

            CurrentEditContext.OnValidationRequested += (s, e) =>
                messageStore.Clear();
            CurrentEditContext.OnFieldChanged += (s, e) =>
                messageStore.Clear(e.FieldIdentifier);
        }

        public void DisplayErrors(Dictionary<string, List<string>> errors)
        {
            foreach (var err in errors)
            {
                messageStore.Add(CurrentEditContext.Field(err.Key), err.Value);
            }

            CurrentEditContext.NotifyValidationStateChanged();
        }

        public void ClearErrors()
        {
            messageStore.Clear();
            CurrentEditContext.NotifyValidationStateChanged();
        }
    }
}
```

Business logic validation

Business logic validation can be accomplished with a validator component that receives form errors in a dictionary.

In the following example:

- The `CustomValidator` component from the Validator components section of this article is used.
- The validation requires a value for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

When validation messages are set in the component, they're added to the validator's ValidationMessageStore and shown in the EditForm:

```
@page "/FormsValidation"

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    ...

</EditForm>

@code {
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private void HandleValidSubmit()
    {
        customValidator.ClearErrors();

        var errors = new Dictionary<string, List<string>>();

        if (starship.Classification == "Defense" &&
                string.IsNullOrEmpty(starship.Description))
        {
            errors.Add(nameof(starship.Description),
                new List<string>() { "For a 'Defense' ship classification, " +
                "'Description' is required." });
        }

        if (errors.Count() > 0)
        {
            customValidator.DisplayErrors(errors);
        }
        else
        {
            // Process the form
        }
    }
}
```

NOTE

As an alternative to using validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

Server validation

Server validation can be accomplished with a server validator component:

- Process client-side validation in the form with the DataAnnotationsValidator component.
- When the form passes client-side validation (OnValidSubmit is called), send the EditContext.Model to a backend server API for form processing.
- Process model validation on the server.
- The server API includes both the built-in framework data annotations validation and custom validation logic supplied by the developer. If validation passes on the server, process the form and send back a success status

code (*200 - OK*). If validation fails, return a failure status code (*400 - Bad Request*) and the field validation errors.

- Either disable the form on success or display the errors.

The following example is based on:

- A hosted Blazor solution created by the Blazor Hosted project template. The example can be used with any of the secure hosted Blazor solutions described in the Security and Identity documentation.
- The *Starfleet Starship Database* form example in the preceding Built-in forms components section.
- The Blazor framework's DataAnnotationsValidator component.
- The `CustomValidator` component shown in the Validator components section.

In the following example, the server API validates that a value is provided for the ship's description (`Description`) if the user selects the `Defense` ship classification (`Classification`).

Place the `Starship` model into the solution's `Shared` project so that both the client and server apps can use the model. Since the model requires data annotations, add a package reference for `System.ComponentModel.Annotations` to the `Shared` project's project file:

```
<ItemGroup>
  <PackageReference Include="System.ComponentModel.Annotations" Version="{VERSION}" />
</ItemGroup>
```

To determine the latest non-preview version of the package, see the package **Version History** at NuGet.org.

In the server API project, add a controller to process starship validation requests (`Controllers/StarshipValidation.cs`) and return failed validation messages:

```
using System;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Logging;
using BlazorSample.Shared;

namespace BlazorSample.Server.Controllers
{
    [Authorize]
    [ApiController]
    [Route("[controller]")]
    public class StarshipValidationController : ControllerBase
    {
        private readonly ILogger<StarshipValidationController> logger;

        public StarshipValidationController(
            ILogger<StarshipValidationController> logger)
        {
            this.logger = logger;
        }

        [HttpPost]
        public async Task<IActionResult> Post(Starship starship)
        {
            try
            {
                if (starship.Classification == "Defense" &&
                    string.IsNullOrEmpty(starship.Description))
                {
                    ModelState.AddModelError(nameof(starship.Description),
                        "For a 'Defense' ship " +
                        "classification, 'Description' is required.");
                }
                else
                {
                    // Process the form asynchronously
                    // async ...

                    return Ok(ModelState);
                }
            }
            catch (Exception ex)
            {
                logger.LogError("Validation Error: {MESSAGE}", ex.Message);
            }

            return BadRequest(ModelState);
        }
    }
}
```

When a model binding validation error occurs on the server, an `ApiController` (ApiControllerAttribute) normally returns a default bad request response with a ValidationProblemDetails. The response contains more data than just the validation errors, as shown in the following example when all of the fields of the *Starfleet Starship Database* form aren't submitted and the form fails validation:

```
{
  "title": "One or more validation errors occurred.",
  "status": 400,
  "errors": {
    "Identifier": ["The Identifier field is required."],
    "Classification": ["The Classification field is required."],
    "IsValidatedDesign": ["This form disallows unapproved ships."],
    "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
  }
}
```

If the server API returns the preceding default JSON response, it's possible for the client to parse the response to obtain the children of the `errors` node. However, it's inconvenient to parse the file. Parsing the JSON requires additional code after calling ReadFromJsonAsync in order to produce a `Dictionary<string, List<string>>` of errors for forms validation error processing. Ideally, the server API should only return the validation errors:

```
{
  "Identifier": ["The Identifier field is required."],
  "Classification": ["The Classification field is required."],
  "IsValidatedDesign": ["This form disallows unapproved ships."],
  "MaximumAccommodation": ["Accommodation invalid (1-100000)."]
}
```

To modify the server API's response to make it only return the validation errors, change the delegate that's invoked on actions that are annotated with ApiControllerAttribute in `Startup.ConfigureServices`. For the API endpoint (`/StarshipValidation`), return a BadRequestObjectResult with the ModelStateDictionary. For any other API endpoints, preserve the default behavior by returning the object result with a new ValidationProblemDetails:

```
using Microsoft.AspNetCore.Mvc;

...

services.AddControllersWithViews()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.InvalidModelStateResponseFactory = context =>
        {
            if (context.HttpContext.Request.Path == "/StarshipValidation")
            {
                return new BadRequestObjectResult(context.ModelState);
            }
            else
            {
                return new BadRequestObjectResult(
                    new ValidationProblemDetails(context.ModelState));
            }
        };
    });
```

For more information, see Handle errors in ASP.NET Core web APIs.

In the client project, add the validator component shown in the Validator components section.

In the client project, the *Starfleet Starship Database* form is updated to show server validation errors with help of the `CustomValidator` component. When the server API returns validation messages, they're added to the `CustomValidator` component's ValidationMessageStore. The errors are available in the form's EditContext for display by the form's ValidationSummary:

```
@page "/FormValidation"
```

```
@using System.Net
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@using Microsoft.Extensions.Logging
@using BlazorSample.Shared
@attribute [Authorize]
@inject HttpClient Http
@inject ILogger<FormValidation> Logger

<h1>Starfleet Starship Database</h1>

<h2>New Ship Entry Form</h2>

<EditForm Model="@starship" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <CustomValidator @ref="customValidator" />
    <ValidationSummary />

    <p>
        <label>
            Identifier:
            <InputText @bind-Value="starship.Identifier" disabled="@disabled" />
        </label>
    </p>

                disabled="@disabled" />
        </label>
    </p>
    <p>
        <label>
            Engineering Approval:
            <InputCheckbox @bind-Value="starship.IsValidatedDesign"
                disabled="@disabled" />
        </label>
    </p>
    <p>
        <label>
            Production Date:
            <InputDate @bind-Value="starship.ProductionDate" disabled="@disabled" />
        </label>
    </p>

    <button type="submit" disabled="@disabled">Submit</button>

    <p style="@messageStyles">
        @message
    </p>
```

```
    <p>
        <a href="http://www.startrek.com/">Star Trek</a>,
        &copy;1966-2019 CBS Studios, Inc. and
        <a href="https://www.paramount.com">Paramount Pictures</a>
    </p>
</EditForm>

@code {
    private bool disabled;
    private string message;
    private string messageStyles = "visibility:hidden";
    private CustomValidator customValidator;
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };

    private async Task HandleValidSubmit(EditContext editContext)
    {
        customValidator.ClearErrors();

        try
        {
            var response = await Http.PostAsJsonAsync<Starship>(
                "StarshipValidation", (Starship)editContext.Model);

            var errors = await response.Content
                .ReadFromJsonAsync<Dictionary<string, List<string>>>();

            if (response.StatusCode == HttpStatusCode.BadRequest &&
                errors.Count() > 0)
            {
                customValidator.DisplayErrors(errors);
            }
            else if (!response.IsSuccessStatusCode)
            {
                throw new HttpRequestException(
                    $"Validation failed. Status Code: {response.StatusCode}");
            }
            else
            {
                disabled = true;
                messageStyles = "color:green";
                message = "The form has been processed.";
            }
        }
        catch (AccessTokenNotAvailableException ex)
        {
            ex.Redirect();
        }
        catch (Exception ex)
        {
            Logger.LogError("Form processing error: {MESSAGE}", ex.Message);
            disabled = true;
            messageStyles = "color:red";
            message = "There was an error processing the form.";
        }
    }
}
```

NOTE

As an alternative to validation components, data annotation validation attributes can be used. Custom attributes applied to the form's model activate with the use of the DataAnnotationsValidator component. When used with server-side validation, the attributes must be executable on the server. For more information, see Model validation in ASP.NET Core MVC.

NOTE

The server-side validation approach in this section is suitable for any of the Blazor WebAssembly hosted solution examples in this documentation set:

- Azure Active Directory (AAD)
- Azure Active Directory (AAD) B2C
- Identity Server

InputText based on the input event

Use the InputText component to create a custom component that uses the `input` event instead of the `change` event.

In the following example, the `CustomInputText` component inherits the framework's `InputText` component and sets the event binding (CreateBinder) to the `oninput` event.

`Shared/CustomInputText.razor`:

```
@inherits InputText

<input
    @attributes="AdditionalAttributes"
    class="@CssClass"
    value="@CurrentValue"
    @oninput="EventCallback.Factory.CreateBinder<string>(
         this, __value => CurrentValueAsString = __value,
         CurrentValueAsString)" />
```

The `CustomInputText` component can be used anywhere InputText is used:

`Pages/TestForm.razor`:

```
@page "/testform"
@using System.ComponentModel.DataAnnotations;

<EditForm Model="@exampleModel" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <CustomInputText @bind-Value="exampleModel.Name" />

    <button type="submit">Submit</button>
</EditForm>

<p>
    CurrentValue: @exampleModel.Name
</p>

@code {
    private ExampleModel exampleModel = new ExampleModel();

    private void HandleValidSubmit()
    {
        ...
    }

    public class ExampleModel
    {
        [Required]
        [StringLength(10, ErrorMessage = "Name is too long.")]
        public string Name { get; set; }
    }
}
```

Radio buttons

Use `InputRadio` components with the `InputRadioGroup` component to create a radio button group. In the following example, properties are added to the `Starship` model described in the Built-in forms components section:

```
[Required]
[Range(typeof(Manufacturer), nameof(Manufacturer.SpaceX),
    nameof(Manufacturer.VirginGalactic), ErrorMessage = "Pick a manufacturer.")]
public Manufacturer Manufacturer { get; set; } = Manufacturer.Unknown;

[Required, EnumDataType(typeof(Color))]
public Color? Color { get; set; } = null;

[Required, EnumDataType(typeof(Engine))]
public Engine? Engine { get; set; } = null;
```

Add the following `enums` to the app. Create a new file to hold the `enums` or add the `enums` to the `Starship.cs` file. Make the `enums` accessible to the `Starship` model and the *Starfleet Starship Database* form:

```
public enum Manufacturer { SpaceX, NASA, ULA, Virgin, Unknown }
public enum Color { ImperialRed, SpacecruiserGreen, StarshipBlue, VoyagerOrange }
public enum Engine { Ion, Plasma, Fusion, Warp }
```

Update the *Starfleet Starship Database* form described in the Built-in forms components section. Add the components to produce:

- A radio button group for the ship manufacturer.

- A nested radio button group for ship color and engine.

```
<p>
    <InputRadioGroup @bind-Value="starship.Manufacturer">
        Manufacturer:
        <br>
        @foreach (var manufacturer in (Manufacturer[])Enum
            .GetValues(typeof(Manufacturer)))
        {
            <InputRadio Value="manufacturer" />
            @manufacturer
            <br>
        }
    </InputRadioGroup>
</p>

<p>
    Pick one color and one engine:
    <InputRadioGroup Name="engine" @bind-Value="starship.Engine">
        <InputRadioGroup Name="color" @bind-Value="starship.Color">
            <InputRadio Name="color" Value="Color.ImperialRed" />Imperial Red<br>
            <InputRadio Name="engine" Value="Engine.Ion" />Ion<br>
            <InputRadio Name="color" Value="Color.SpacecruiserGreen" />
                Spacecruiser Green<br>
            <InputRadio Name="engine" Value="Engine.Plasma" />Plasma<br>
            <InputRadio Name="color" Value="Color.StarshipBlue" />Starship Blue<br>
            <InputRadio Name="engine" Value="Engine.Fusion" />Fusion<br>
            <InputRadio Name="color" Value="Color.VoyagerOrange" />
                Voyager Orange<br>
            <InputRadio Name="engine" Value="Engine.Warp" />Warp<br>
        </InputRadioGroup>
    </InputRadioGroup>
</p>
```

> **NOTE**
>
> If `Name` is omitted, `InputRadio` components are grouped by their most recent ancestor.

When working with radio buttons in a form, data binding is handled differently than other elements because radio buttons are evaluated as a group. The value of each radio button is fixed, but the value of the radio button group is the value of the selected radio button. The following example shows how to:

- Handle data binding for a radio button group.
- Support validation using a custom `InputRadio` component.

```
@using System.Globalization
@typeparam TValue
@inherits InputBase<TValue>

<input @attributes="AdditionalAttributes" type="radio" value="@SelectedValue"
       checked="@(SelectedValue.Equals(Value))" @onchange="OnChange" />

@code {
    [Parameter]
    public TValue SelectedValue { get; set; }

    private void OnChange(ChangeEventArgs args)
    {
        CurrentValueAsString = args.Value.ToString();
    }

    protected override bool TryParseValueFromString(string value,
        out TValue result, out string errorMessage)
    {
        var success = BindConverter.TryConvertTo<TValue>(
            value, CultureInfo.CurrentCulture, out var parsedValue);
        if (success)
        {
            result = parsedValue;
            errorMessage = null;

            return true;
        }
        else
        {
            result = default;
            errorMessage = $"{FieldIdentifier.FieldName} field isn't valid.";

            return false;
        }
    }
}
```

The following EditForm uses the preceding `InputRadio` component to obtain and validate a rating from the user:

```
@page "/RadioButtonExample"
@using System.ComponentModel.DataAnnotations

<h1>Radio Button Group Test</h1>

<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    @for (int i = 1; i <= 5; i++)
    {
        <label>
            <InputRadio name="rate" SelectedValue="i" @bind-Value="model.Rating" />
            @i
        </label>
    }

    <button type="submit">Submit</button>
</EditForm>

<p>You chose: @model.Rating</p>

@code {
    private Model model = new Model();

    private void HandleValidSubmit()
    {
        ...
    }

    public class Model
    {
        [Range(1, 5)]
        public int Rating { get; set; }
    }
}
```

Binding `<select>` element options to C# object `null` values

There's no sensible way to represent a `<select>` element option value as a C# object `null` value, because:

- HTML attributes can't have `null` values. The closest equivalent to `null` in HTML is absence of the HTML `value` attribute from the `<option>` element.
- When selecting an `<option>` with no `value` attribute, the browser treats the value as the *text content* of that `<option>`'s element.

The Blazor framework doesn't attempt to suppress the default behavior because it would involve:

- Creating a chain of special-case workarounds in the framework.
- Breaking changes to current framework behavior.

The most plausible `null` equivalent in HTML is an *empty string* `value`. The Blazor framework handles `null` to empty string conversions for two-way binding to a `<select>`'s value.

The Blazor framework doesn't automatically handle `null` to empty string conversions when attempting two-way binding to a `<select>`'s value. For more information, see Fix binding `<select>` to a null value (dotnet/aspnetcore #23221).

Validation support

The DataAnnotationsValidator component attaches validation support using data annotations to the cascaded

EditContext. Enabling support for validation using data annotations requires this explicit gesture. To use a different validation system than data annotations, replace the DataAnnotationsValidator with a custom implementation. The ASP.NET Core implementation is available for inspection in the reference source: `DataAnnotationsValidator` / `AddDataAnnotationsValidation`. The preceding links to reference source provide code from the repository's `master` branch, which represents the product unit's current development for the next release of ASP.NET Core. To select the branch for a different release, use the GitHub branch selector (for example `release/3.1`).

Blazor performs two types of validation:

- *Field validation* is performed when the user tabs out of a field. During field validation, the DataAnnotationsValidator component associates all reported validation results with the field.
- *Model validation* is performed when the user submits the form. During model validation, the DataAnnotationsValidator component attempts to determine the field based on the member name that the validation result reports. Validation results that aren't associated with an individual member are associated with the model rather than a field.

Validation Summary and Validation Message components

The ValidationSummary component summarizes all validation messages, which is similar to the Validation Summary Tag Helper:

```
<ValidationSummary />
```

Output validation messages for a specific model with the `Model` parameter:

```
<ValidationSummary Model="@starship" />
```

The ValidationMessage<TValue> component displays validation messages for a specific field, which is similar to the Validation Message Tag Helper. Specify the field for validation with the `For` attribute and a lambda expression naming the model property:

```
<ValidationMessage For="@(() => starship.MaximumAccommodation)" />
```

The ValidationMessage<TValue> and ValidationSummary components support arbitrary attributes. Any attribute that doesn't match a component parameter is added to the generated `<div>` or `<ul>` element.

Control the style of validation messages in the app's stylesheet (`wwwroot/css/app.css` or `wwwroot/css/site.css`). The default `validation-message` class sets the text color of validation messages to red:

```
.validation-message {
    color: red;
}
```

Custom validation attributes

To ensure that a validation result is correctly associated with a field when using a custom validation attribute, pass the validation context's MemberName when creating the ValidationResult:

```
using System;
using System.ComponentModel.DataAnnotations;

private class CustomValidator : ValidationAttribute
{
    protected override ValidationResult IsValid(object value,
        ValidationContext validationContext)
    {
        ...

        return new ValidationResult("Validation message to user.",
            new[] { validationContext.MemberName });
    }
}
```

NOTE

ValidationContext.GetService is `null`. Injecting services for validation in the `IsValid` method isn't supported.

Custom validation class attributes

Custom validation class names are useful when integrating with CSS frameworks, such as Bootstrap. To specify custom validation class names, create a class derived from `FieldCssClassProvider` and set the class on the EditContext instance:

```
var editContext = new EditContext(model);
editContext.SetFieldCssClassProvider(new MyFieldClassProvider());

...

private class MyFieldClassProvider : FieldCssClassProvider
{
    public override string GetFieldCssClass(EditContext editContext,
        in FieldIdentifier fieldIdentifier)
    {
        var isValid = !editContext.GetValidationMessages(fieldIdentifier).Any();

        return isValid ? "good field" : "bad field";
    }
}
```

Blazor data annotations validation package

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` is a package that fills validation experience gaps using the DataAnnotationsValidator component. The package is currently *experimental*.

NOTE

The `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package has a latest version of *release candidate* at Nuget.org. Continue to use the *experimental* release candidate package at this time. The package's assembly might be moved to either the framework or the runtime in a future release. Watch the Announcements GitHub repository, the dotnet/aspnetcore GitHub repository, or this topic section for further updates.

[CompareProperty] attribute

The CompareAttribute doesn't work well with the DataAnnotationsValidator component because it doesn't associate the validation result with a specific member. This can result in inconsistent behavior between field-level validation and when the entire model is validated on a submit. The

`Microsoft.AspNetCore.Components.DataAnnotations.Validation` *experimental* package introduces an additional validation attribute, `ComparePropertyAttribute`, that works around these limitations. In a Blazor app, `[CompareProperty]` is a direct replacement for the `[Compare]` attribute.

Nested models, collection types, and complex types

Blazor provides support for validating form input using data annotations with the built-in DataAnnotationsValidator. However, the DataAnnotationsValidator only validates top-level properties of the model bound to the form that aren't collection- or complex-type properties.

To validate the bound model's entire object graph, including collection- and complex-type properties, use the `ObjectGraphDataAnnotationsValidator` provided by the *experimental* `Microsoft.AspNetCore.Components.DataAnnotations.Validation` package:

```
<EditForm Model="@model" OnValidSubmit="@HandleValidSubmit">
    <ObjectGraphDataAnnotationsValidator />
    ...
</EditForm>
```

Annotate model properties with `[ValidateComplexType]`. In the following model classes, the `ShipDescription` class contains additional data annotations to validate when the model is bound to the form:

`Starship.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class Starship
{
    ...

    [ValidateComplexType]
    public ShipDescription ShipDescription { get; set; } =
        new ShipDescription();

    ...
}
```

`ShipDescription.cs`:

```
using System;
using System.ComponentModel.DataAnnotations;

public class ShipDescription
{
    [Required]
    [StringLength(40, ErrorMessage = "Description too long (40 char).")]
    public string ShortDescription { get; set; }

    [Required]
    [StringLength(240, ErrorMessage = "Description too long (240 char).")]
    public string LongDescription { get; set; }
}
```

Enable the submit button based on form validation

To enable and disable the submit button based on form validation:

- Use the form's EditContext to assign the model when the component is initialized.
- Validate the form in the context's OnFieldChanged callback to enable and disable the submit button.

- Unhook the event handler in the `Dispose` method. For more information, see ASP.NET Core Blazor lifecycle.

> **NOTE**
> When using an EditContext, don't also assign a Model to the EditForm.

```
@implements IDisposable

<EditForm EditContext="@editContext">
    <DataAnnotationsValidator />
    <ValidationSummary />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private Starship starship = new Starship() { ProductionDate = DateTime.UtcNow };
    private bool formInvalid = true;
    private EditContext editContext;

    protected override void OnInitialized()
    {
        editContext = new EditContext(starship);
        editContext.OnFieldChanged += HandleFieldChanged;
    }

    private void HandleFieldChanged(object sender, FieldChangedEventArgs e)
    {
        formInvalid = !editContext.Validate();
        StateHasChanged();
    }

    public void Dispose()
    {
        editContext.OnFieldChanged -= HandleFieldChanged;
    }
}
```

In the preceding example, set `formInvalid` to `false` if:

- The form is preloaded with valid default values.
- You want the submit button enabled when the form loads.

A side effect of the preceding approach is that a ValidationSummary component is populated with invalid fields after the user interacts with any one field. This scenario can be addressed in either of the following ways:

- Don't use a ValidationSummary component on the form.
- Make the ValidationSummary component visible when the submit button is selected (for example, in a `HandleValidSubmit` method).

```
<EditForm EditContext="@editContext" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary style="@displaySummary" />

    ...

    <button type="submit" disabled="@formInvalid">Submit</button>
</EditForm>

@code {
    private string displaySummary = "display:none";

    ...

    private void HandleValidSubmit()
    {
        displaySummary = "display:block";
    }
}
```

Troubleshoot

> InvalidOperationException: EditForm requires a Model parameter, or an EditContext parameter, but not both.

Confirm that the EditForm has a Model **or** EditContext. Don't use both for the same form.

When assigning a Model to the form, confirm that the model type is instantiated, as the following example shows:

```
private ExampleModel exampleModel = new ExampleModel();
```

ASP.NET Core Blazor file uploads

9/22/2020 • 2 minutes to read • Edit Online

By Daniel Roth

Use the `InputFile` component to read browser file data into .NET code, including for file uploads. The `InputFile` component renders as an HTML input of type `file`.

By default, the user selects single files. Add the `multiple` attribute to permit the user to upload multiple files at once. When one or more files is selected by the user, the `InputFile` component fires an `OnChange` event and passes in an `InputFileChangeEventArgs` that provides access to the selected file list and details about each file.

A component that receives an image file can call the `RequestImageFileAsync` convenience method on the file to resize the image data within the browser's JavaScript runtime before the image is streamed into the app.

The following example demonstrates multiple image file upload in a component:

```
<h3>Upload PNG images</h3>

<p>
    <InputFile OnChange="@OnInputFileChange" multiple />
</p>

@if (imageDataUrls.Count > 0)
{
    <h3>Images</h3>

    <div class="card" style="width:30rem;">
        <div class="card-body">
            @foreach (var imageDataUrl in imageDataUrls)
            {
                <img class="rounded m-1" src="@imageDataUrl" />
            }
        </div>
    </div>
}

@code {
    IList<string> imageDataUrls = new List<string>();

    private async Task OnInputFileChange(InputFileChangeEventArgs e)
    {
        var imageFiles = e.GetMultipleFiles();
        var format = "image/png";

        foreach (var imageFile in imageFiles)
        {
            var resizedImageFile = await imageFile.RequestImageFileAsync(format,
                100, 100);
            var buffer = new byte[resizedImageFile.Size];
            await resizedImageFile.OpenReadStream().ReadAsync(buffer);
            var imageDataUrl =
                $"data:{format};base64,{Convert.ToBase64String(buffer)}";
            imageDataUrls.Add(imageDataUrl);
        }
    }
}
```

To read data from a user-selected file, call `OpenReadStream` on the file and read from the returned stream. In a Blazor WebAssembly app, the data is streamed directly into the .NET code within the browser. In a Blazor Server app, the file data is streamed into .NET code on the server as the file is read from the stream.

Call JavaScript functions from .NET methods in ASP.NET Core Blazor

9/22/2020 • 16 minutes to read • Edit Online

By Javier Calvarro Nelson, Daniel Roth, and Luke Latham

A Blazor app can invoke JavaScript functions from .NET methods and .NET methods from JavaScript functions. These scenarios are called *JavaScript interoperability* (*JS interop*).

This article covers invoking JavaScript functions from .NET. For information on how to call .NET methods from JavaScript, see Call .NET methods from JavaScript functions in ASP.NET Core Blazor.

View or download sample code (how to download)

To call into JavaScript from .NET, use the IJSRuntime abstraction. To issue JS interop calls, inject the IJSRuntime abstraction in your component. InvokeAsync takes an identifier for the JavaScript function that you wish to invoke along with any number of JSON-serializable arguments. The function identifier is relative to the global scope (`window`). If you wish to call `window.someScope.someFunction` , the identifier is `someScope.someFunction` . There's no need to register the function before it's called. The return type `T` must also be JSON serializable. `T` should match the .NET type that best maps to the JSON type returned.

For Blazor Server apps with prerendering enabled, calling into JavaScript isn't possible during the initial prerendering. JavaScript interop calls must be deferred until after the connection with the browser is established. For more information, see the Detect when a Blazor Server app is prerendering section.

The following example is based on `TextDecoder` , a JavaScript-based decoder. The example demonstrates how to invoke a JavaScript function from a C# method that offloads a requirement from developer code to an existing JavaScript API. The JavaScript function accepts a byte array from a C# method, decodes the array, and returns the text to the component for display.

Inside the `<head>` element of `wwwroot/index.html` (Blazor WebAssembly) or `Pages/_Host.cshtml` (Blazor Server), provide a JavaScript function that uses `TextDecoder` to decode a passed array and return the decoded value:

```
<script>
  window.convertArray = (win1251Array) => {
    var win1251decoder = new TextDecoder('windows-1251');
    var bytes = new Uint8Array(win1251Array);
    var decodedArray = win1251decoder.decode(bytes);
    console.log(decodedArray);
    return decodedArray;
  };
</script>
```

JavaScript code, such as the code shown in the preceding example, can also be loaded from a JavaScript file (`.js`) with a reference to the script file:

```
<script src="exampleJsInterop.js"></script>
```

The following component:

- Invokes the `convertArray` JavaScript function using `JSRuntime` when a component button (`Convert Array`) is selected.

- After the JavaScript function is called, the passed array is converted into a string. The string is returned to the component for display.

```
@page "/call-js-example"
@inject IJSRuntime JSRuntime;

<h1>Call JavaScript Function Example</h1>

<button type="button" class="btn btn-primary" @onclick="ConvertArray">
    Convert Array
</button>

<p class="mt-2" style="font-size:1.6em">
    <span class="badge badge-success">
        @convertedText
    </span>
</p>

@code {
    // Quote (c)2005 Universal Pictures: Serenity
    // https://www.uphe.com/movies/serenity
    // David Krumholtz on IMDB: https://www.imdb.com/name/nm0472710/

    private MarkupString convertedText =
        new MarkupString("Select the <b>Convert Array</b> button.");

    private uint[] quoteArray = new uint[]
        {
            60, 101, 109, 62, 67, 97, 110, 39, 116, 32, 115, 116, 111, 112, 32,
            116, 104, 101, 32, 115, 105, 103, 110, 97, 108, 44, 32, 77, 97,
            108, 46, 60, 47, 101, 109, 62, 32, 45, 32, 77, 114, 46, 32, 85, 110,
            105, 118, 101, 114, 115, 101, 10, 10,
        };

    private async Task ConvertArray()
    {
        var text =
            await JSRuntime.InvokeAsync<string>("convertArray", quoteArray);

        convertedText = new MarkupString(text);
    }
}
```

IJSRuntime

To use the IJSRuntime abstraction, adopt any of the following approaches:

- Inject the IJSRuntime abstraction into the Razor component (`.razor`):

  ```
  @inject IJSRuntime JSRuntime

  @code {
      protected override void OnInitialized()
      {
          StocksService.OnStockTickerUpdated += stockUpdate =>
          {
              JSRuntime.InvokeVoidAsync("handleTickerChanged",
                  stockUpdate.symbol, stockUpdate.price);
          };
      }
  }
  ```

  Inside the `<head>` element of `wwwroot/index.html` (Blazor WebAssembly) or `Pages/_Host.cshtml` (Blazor

Server), provide a `handleTickerChanged` JavaScript function. The function is called with JSRuntimeExtensions.InvokeVoidAsync and doesn't return a value:

```
<script>
  window.handleTickerChanged = (symbol, price) => {
    // ... client-side processing/display code ...
  };
</script>
```

- Inject the IJSRuntime abstraction into a class (`.cs`):

```
public class JsInteropClasses
{
    private readonly IJSRuntime jsRuntime;

    public JsInteropClasses(IJSRuntime jsRuntime)
    {
        this.jsRuntime = jsRuntime;
    }

    public ValueTask<string> TickerChanged(string data)
    {
        return jsRuntime.InvokeAsync<string>(
            "handleTickerChanged",
            stockUpdate.symbol,
            stockUpdate.price);
    }
}
```

Inside the `<head>` element of `wwwroot/index.html` (Blazor WebAssembly) or `Pages/_Host.cshtml` (Blazor Server), provide a `handleTickerChanged` JavaScript function. The function is called with `JSRuntime.InvokeAsync` and returns a value:

```
<script>
  window.handleTickerChanged = (symbol, price) => {
    // ... client-side processing/display code ...
    return 'Done!';
  };
</script>
```

- For dynamic content generation with BuildRenderTree, use the `[Inject]` attribute:

```
[Inject]
IJSRuntime JSRuntime { get; set; }
```

In the client-side sample app that accompanies this topic, two JavaScript functions are available to the app that interact with the DOM to receive user input and display a welcome message:

- `showPrompt` : Produces a prompt to accept user input (the user's name) and returns the name to the caller.
- `displayWelcome` : Assigns a welcome message from the caller to a DOM object with an `id` of `welcome` .

`wwwroot/exampleJsInterop.js` :

```
window.exampleJsFunctions = {
  showPrompt: function (text) {
    return prompt(text, 'Type your name here');
  },
  displayWelcome: function (welcomeMessage) {
    document.getElementById('welcome').innerText = welcomeMessage;
  },
  returnArrayAsyncJs: function () {
    DotNet.invokeMethodAsync('BlazorSample', 'ReturnArrayAsync')
      .then(data => {
        data.push(4);
          console.log(data);
      });
  },
  sayHello: function (dotnetHelper) {
    return dotnetHelper.invokeMethodAsync('SayHello')
      .then(r => console.log(r));
  }
};
```

Place the `<script>` tag that references the JavaScript file in the `wwwroot/index.html` file (Blazor WebAssembly) or `Pages/_Host.cshtml` file (Blazor Server).

`wwwroot/index.html` (Blazor WebAssembly):

```
<!DOCTYPE html>
<html lang="en">

<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0, maximum-scale=1.0, user-
scalable=no" />
    <title>Blazor WebAssembly Sample</title>
    <base href="/" />
    <link href="css/bootstrap/bootstrap.min.css" rel="stylesheet" />
    <link href="css/app.css" rel="stylesheet" />
</head>

<body>
    <app>Loading...</app>

    <div id="blazor-error-ui">
        An unhandled error has occurred.
        <a href="" class="reload">Reload</a>
        <a class="dismiss">🗙</a>
    </div>
    <script src="_framework/blazor.webassembly.js"></script>
    <script src="exampleJsInterop.js"></script>
</body>

</html>
```

`Pages/_Host.cshtml` (Blazor Server):

```
@page "/"
@namespace BlazorSample.Pages
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@{
    Layout = null;
}

<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>Blazor Server Sample</title>
    <base href="~/" />
    <link rel="stylesheet" href="css/bootstrap/bootstrap.min.css" />
    <link href="css/site.css" rel="stylesheet" />
</head>
<body>
    <app>
        <component type="typeof(App)" render-mode="ServerPrerendered" />
    </app>

    <div id="blazor-error-ui">
        <environment include="Staging,Production">
            An error has occurred. This application may no longer respond until reloaded.
        </environment>
        <environment include="Development">
            An unhandled exception has occurred. See browser dev tools for details.
        </environment>
        <a href="" class="reload">Reload</a>
        <a class="dismiss">🗙</a>
    </div>

    <script src="_framework/blazor.server.js"></script>
    <script src="exampleJsInterop.js"></script>
</body>
</html>
```

Don't place a `<script>` tag in a component file because the `<script>` tag can't be updated dynamically.

.NET methods interop with the JavaScript functions in the `exampleJsInterop.js` file by calling IJSRuntime.InvokeAsync.

The IJSRuntime abstraction is asynchronous to allow for Blazor Server scenarios. If the app is a Blazor WebAssembly app and you want to invoke a JavaScript function synchronously, downcast to IJSInProcessRuntime and call Invoke instead. We recommend that most JS interop libraries use the async APIs to ensure that the libraries are available in all scenarios.

> **NOTE**
>
> To enable JavaScript isolation in standard JavaScript modules, see the Blazor JavaScript isolation and object references section.

The sample app includes a component to demonstrate JS interop. The component:

- Receives user input via a JavaScript prompt.
- Returns the text to the component for processing.
- Calls a second JavaScript function that interacts with the DOM to display a welcome message.

`Pages/JsInterop.razor`:

```
@page "/JSInterop"
@using {APP ASSEMBLY}.JsInteropClasses
@inject IJSRuntime JSRuntime

<h1>JavaScript Interop</h1>

<h2>Invoke JavaScript functions from .NET methods</h2>

<button type="button" class="btn btn-primary" @onclick="TriggerJsPrompt">
    Trigger JavaScript Prompt
</button>

<h3 id="welcome" style="color:green;font-style:italic"></h3>

@code {
    public async Task TriggerJsPrompt()
    {
        var name = await JSRuntime.InvokeAsync<string>(
                "exampleJsFunctions.showPrompt",
                "What's your name?");

        await JSRuntime.InvokeVoidAsync(
                "exampleJsFunctions.displayWelcome",
                $"Hello {name}! Welcome to Blazor!");
    }
}
```

The placeholder `{APP ASSEMBLY}` is the app's app assembly name (for example, `BlazorSample`).

1. When `TriggerJsPrompt` is executed by selecting the component's `Trigger JavaScript Prompt` button, the JavaScript `showPrompt` function provided in the `wwwroot/exampleJsInterop.js` file is called.
2. The `showPrompt` function accepts user input (the user's name), which is HTML-encoded and returned to the component. The component stores the user's name in a local variable, `name`.
3. The string stored in `name` is incorporated into a welcome message, which is passed to a JavaScript function, `displayWelcome`, which renders the welcome message into a heading tag.

Call a void JavaScript function

JavaScript functions that return void(0)/void 0 or undefined are called with JSRuntimeExtensions.InvokeVoidAsync.

Detect when a Blazor Server app is prerendering

While a Blazor Server app is prerendering, certain actions, such as calling into JavaScript, aren't possible because a connection with the browser hasn't been established. Components may need to render differently when prerendered.

To delay JavaScript interop calls until after the connection with the browser is established, you can use the OnAfterRenderAsync component lifecycle event. This event is only called after the app is fully rendered and the client connection is established.

```
@using Microsoft.JSInterop
@inject IJSRuntime JSRuntime

<div @ref="divElement">Text during render</div>

@code {
    private ElementReference divElement;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            await JSRuntime.InvokeVoidAsync(
                "setElementText", divElement, "Text after render");
        }
    }
}
```

For the preceding example code, provide a `setElementText` JavaScript function inside the `<head>` element of `wwwroot/index.html` (Blazor WebAssembly) or `Pages/_Host.cshtml` (Blazor Server). The function is called with JSRuntimeExtensions.InvokeVoidAsync and doesn't return a value:

```
<script>
  window.setElementText = (element, text) => element.innerText = text;
</script>
```

WARNING

The preceding example modifies the Document Object Model (DOM) directly for demonstration purposes only. Directly modifying the DOM with JavaScript isn't recommended in most scenarios because JavaScript can interfere with Blazor's change tracking.

The following component demonstrates how to use JavaScript interop as part of a component's initialization logic in a way that's compatible with prerendering. The component shows that it's possible to trigger a rendering update from inside OnAfterRenderAsync. The developer must avoid creating an infinite loop in this scenario.

Where JSRuntime.InvokeAsync is called, `ElementRef` is only used in OnAfterRenderAsync and not in any earlier lifecycle method because there's no JavaScript element until after the component is rendered.

StateHasChanged is called to rerender the component with the new state obtained from the JavaScript interop call. The code doesn't create an infinite loop because `StateHasChanged` is only called when `infoFromJs` is `null`.

```
@page "/prerendered-interop"
@using Microsoft.AspNetCore.Components
@using Microsoft.JSInterop
@inject IJSRuntime JSRuntime

<p>
    Get value via JS interop call:
    <strong id="val-get-by-interop">@(infoFromJs ?? "No value yet")</strong>
</p>

Set value via JS interop call:
<div id="val-set-by-interop" @ref="divElement"></div>

@code {
    private string infoFromJs;
    private ElementReference divElement;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender && infoFromJs == null)
        {
            infoFromJs = await JSRuntime.InvokeAsync<string>(
                "setElementText", divElement, "Hello from interop call!");

            StateHasChanged();
        }
    }
}
```

For the preceding example code, provide a `setElementText` JavaScript function inside the `<head>` element of `wwwroot/index.html` (Blazor WebAssembly) or `Pages/_Host.cshtml` (Blazor Server). The function is called withIJSRuntime.InvokeAsync and returns a value:

```
<script>
  window.setElementText = (element, text) => {
    element.innerText = text;
    return text;
  };
</script>
```

WARNING

The preceding example modifies the Document Object Model (DOM) directly for demonstration purposes only. Directly modifying the DOM with JavaScript isn't recommended in most scenarios because JavaScript can interfere with Blazor's change tracking.

Capture references to elements

Some JS interop scenarios require references to HTML elements. For example, a UI library may require an element reference for initialization, or you might need to call command-like APIs on an element, such as `focus` or `play`.

Capture references to HTML elements in a component using the following approach:

- Add an `@ref` attribute to the HTML element.
- Define a field of type ElementReference whose name matches the value of the `@ref` attribute.

The following example shows capturing a reference to the `username` `<input>` element:

```
<input @ref="username" ... />

@code {
    ElementReference username;
}
```

WARNING

Only use an element reference to mutate the contents of an empty element that doesn't interact with Blazor. This scenario is useful when a third-party API supplies content to the element. Because Blazor doesn't interact with the element, there's no possibility of a conflict between Blazor's representation of the element and the DOM.

In the following example, it's *dangerous* to mutate the contents of the unordered list (`ul`) because Blazor interacts with the DOM to populate this element's list items (`<li>`):

```
<ul ref="MyList">
    @foreach (var item in Todos)
    {
        <li>@item.Text</li>
    }
</ul>
```

If JS interop mutates the contents of element `MyList` and Blazor attempts to apply diffs to the element, the diffs won't match the DOM.

As far as .NET code is concerned, an ElementReference is an opaque handle. The *only* thing you can do with ElementReference is pass it through to JavaScript code via JS interop. When you do so, the JavaScript-side code receives an `HTMLElement` instance, which it can use with normal DOM APIs.

For example, the following code defines a .NET extension method that enables setting the focus on an element:

`exampleJsInterop.js`:

```
window.exampleJsFunctions = {
  focusElement : function (element) {
    element.focus();
  }
}
```

To call a JavaScript function that doesn't return a value, use JSRuntimeExtensions.InvokeVoidAsync. The following code sets the focus on the username input by calling the preceding JavaScript function with the captured ElementReference:

```
@inject IJSRuntime JSRuntime

<input @ref="username" />
<button @onclick="SetFocus">Set focus on username</button>

@code {
    private ElementReference username;

    public async Task SetFocus()
    {
        await JSRuntime.InvokeVoidAsync(
            "exampleJsFunctions.focusElement", username);
    }
}
```

To use an extension method, create a static extension method that receives the IJSRuntime instance:

```
public static async Task Focus(this ElementReference elementRef, IJSRuntime jsRuntime)
{
    await jsRuntime.InvokeVoidAsync(
        "exampleJsFunctions.focusElement", elementRef);
}
```

The `Focus` method is called directly on the object. The following example assumes that the `Focus` method is available from the `JsInteropClasses` namespace:

```
@inject IJSRuntime JSRuntime
@using JsInteropClasses

<input @ref="username" />
<button @onclick="SetFocus">Set focus on username</button>

@code {
    private ElementReference username;

    public async Task SetFocus()
    {
        await username.Focus(JSRuntime);
    }
}
```

IMPORTANT

The `username` variable is only populated after the component is rendered. If an unpopulated ElementReference is passed to JavaScript code, the JavaScript code receives a value of `null`. To manipulate element references after the component has finished rendering (to set the initial focus on an element) use the `OnAfterRenderAsync` or `OnAfterRender` component lifecycle methods.

When working with generic types and returning a value, use ValueTask<TResult>:

```
public static ValueTask<T> GenericMethod<T>(this ElementReference elementRef,
    IJSRuntime jsRuntime)
{
    return jsRuntime.InvokeAsync<T>(
        "exampleJsFunctions.doSomethingGeneric", elementRef);
}
```

`GenericMethod` is called directly on the object with a type. The following example assumes that the `GenericMethod` is available from the `JsInteropClasses` namespace:

```
@inject IJSRuntime JSRuntime
@using JsInteropClasses

<input @ref="username" />
<button @onclick="OnClickMethod">Do something generic</button>

<p>
    returnValue: @returnValue
</p>

@code {
    private ElementReference username;
    private string returnValue;

    private async Task OnClickMethod()
    {
        returnValue = await username.GenericMethod<string>(JSRuntime);
    }
}
```

Reference elements across components

An ElementReference is only guaranteed valid in a component's OnAfterRender method (and an element reference is a `struct`), so an element reference can't be passed between components.

For a parent component to make an element reference available to other components, the parent component can:

- Allow child components to register callbacks.
- Invoke the registered callbacks during the OnAfterRender event with the passed element reference. Indirectly, this approach allows child components to interact with the parent's element reference.

The following Blazor WebAssembly example illustrates the approach.

In the `<head>` of `wwwroot/index.html`:

```
<style>
    .red { color: red }
</style>
```

In the `<body>` of `wwwroot/index.html`:

```
<script>
    function setElementClass(element, className) {
        /** @type {HTMLElement} **/
        var myElement = element;
        myElement.classList.add(className);
    }
</script>
```

`Pages/Index.razor` (parent component):

```
@page "/"

<h1 @ref="title">Hello, world!</h1>

Welcome to your new app.

<SurveyPrompt Parent="this" Title="How is Blazor working for you?" />
```

`Pages/Index.razor.cs`:

```
using System;
using System.Collections.Generic;
using Microsoft.AspNetCore.Components;

namespace {APP ASSEMBLY}.Pages
{
    public partial class Index :
        ComponentBase, IObservable<ElementReference>, IDisposable
    {
        private bool disposing;
        private IList<IObserver<ElementReference>> subscriptions =
            new List<IObserver<ElementReference>>();
        private ElementReference title;

        protected override void OnAfterRender(bool firstRender)
        {
            base.OnAfterRender(firstRender);

            foreach (var subscription in subscriptions)
            {
                try
                {
                    subscription.OnNext(title);
                }
                catch (Exception)
                {
                    throw;
                }
            }
        }

        public void Dispose()
        {
            disposing = true;

            foreach (var subscription in subscriptions)
            {
                try
                {
                    subscription.OnCompleted();
                }
                catch (Exception)
                {
                }
            }

            subscriptions.Clear();
        }

        public IDisposable Subscribe(IObserver<ElementReference> observer)
        {
            if (disposing)
            {
                throw new InvalidOperationException("Parent being disposed");
            }

            subscriptions.Add(observer);

            return new Subscription(observer, this);
        }

        private class Subscription : IDisposable
        {
            public Subscription(IObserver<ElementReference> observer, Index self)
            {
                Observer = observer;
```

```
                Self = self;
            }

            public IObserver<ElementReference> Observer { get; }
            public Index Self { get; }

            public void Dispose()
            {
                Self.subscriptions.Remove(Observer);
            }
        }
    }
}
```

The placeholder `{APP ASSEMBLY}` is the app's app assembly name (for example, `BlazorSample`).

`Shared/SurveyPrompt.razor` (child component):

```
@inject IJSRuntime JS

<div class="alert alert-secondary mt-4" role="alert">
    <span class="oi oi-pencil mr-2" aria-hidden="true"></span>
    <strong>@Title</strong>

    <span class="text-nowrap">
        Please take our
        <a target="_blank" class="font-weight-bold"
            href="https://go.microsoft.com/fwlink/?linkid=2109206">brief survey</a>
    </span>
    and tell us what you think.
</div>

@code {
    [Parameter]
    public string Title { get; set; }
}
```

`Shared/SurveyPrompt.razor.cs`:

```
using System;
using Microsoft.AspNetCore.Components;

namespace {APP ASSEMBLY}.Shared
{
    public partial class SurveyPrompt :
        ComponentBase, IObserver<ElementReference>, IDisposable
    {
        private IDisposable subscription = null;

        [Parameter]
        public IObservable<ElementReference> Parent { get; set; }

        protected override void OnParametersSet()
        {
            base.OnParametersSet();

            if (subscription != null)
            {
                subscription.Dispose();
            }

            subscription = Parent.Subscribe(this);
        }

        public void OnCompleted()
        {
            subscription = null;
        }

        public void OnError(Exception error)
        {
            subscription = null;
        }

        public void OnNext(ElementReference value)
        {
            JS.InvokeAsync<object>(
                "setElementClass", new object[] { value, "red" });
        }

        public void Dispose()
        {
            subscription?.Dispose();
        }
    }
}
```

The placeholder `{APP ASSEMBLY}` is the app's app assembly name (for example, `BlazorSample`).

Harden JS interop calls

JS interop may fail due to networking errors and should be treated as unreliable. By default, a Blazor Server app times out JS interop calls on the server after one minute. If an app can tolerate a more aggressive timeout, set the timeout using one of the following approaches:

- Globally in `Startup.ConfigureServices`, specify the timeout:

  ```
  services.AddServerSideBlazor(
      options => options.JSInteropDefaultCallTimeout = TimeSpan.FromSeconds({SECONDS}));
  ```

- Per-invocation in component code, a single call can specify the timeout:

```
var result = await JSRuntime.InvokeAsync<string>("MyJSOperation",
    TimeSpan.FromSeconds({SECONDS}), new[] { "Arg1" });
```

For more information on resource exhaustion, see Threat mitigation guidance for ASP.NET Core Blazor Server.

Share interop code in a class library

JS interop code can be included in a class library, which allows you to share the code in a NuGet package.

The class library handles embedding JavaScript resources in the built assembly. The JavaScript files are placed in the `wwwroot` folder. The tooling takes care of embedding the resources when the library is built.

The built NuGet package is referenced in the app's project file the same way that any NuGet package is referenced. After the package is restored, app code can call into JavaScript as if it were C#.

For more information, see ASP.NET Core Razor components class libraries.

Avoid circular object references

Objects that contain circular references can't be serialized on the client for either:

- .NET method calls.
- JavaScript method calls from C# when the return type has circular references.

For more information, see the following issues:

- Circular references are not supported, take two (dotnet/aspnetcore #20525)
- Proposal: Add mechanism to handle circular references when serializing (dotnet/runtime #30820)

Blazor JavaScript isolation and object references

Blazor enables JavaScript isolation in standard JavaScript modules. JavaScript isolation provides the following benefits:

- Imported JavaScript no longer pollutes the global namespace.
- Consumers of a library and components aren't required to import the related JavaScript.

For example, the following JavaScript module exports a JavaScript function for showing a browser prompt:

```
export function showPrompt(message) {
  return prompt(message, 'Type anything here');
}
```

Add the preceding JavaScript module to a .NET library as a static web asset (`wwwroot/exampleJsInterop.js`) and then import the module into the .NET code using the IJSRuntime service. The service is injected as `jsRuntime` (not shown) for the following example:

```
var module = await jsRuntime.InvokeAsync<JSObjectReference>(
    "import", "./_content/MyComponents/exampleJsInterop.js");
```

The `import` identifier in the preceding example is a special identifier used specifically for importing a JavaScript module. Specify the module using its stable static web asset path: `_content/{LIBRARY NAME}/{PATH UNDER WWWROOT}`. The placeholder `{LIBRARY NAME}` is the library name. The placeholder `{PATH UNDER WWWROOT}` is the path to the script under `wwwroot` .

IJSRuntime imports the module as a `JSObjectReference`, which represents a reference to a JavaScript object from .NET code. Use the `JSObjectReference` to invoke exported JavaScript functions from the module:

```
public async ValueTask<string> Prompt(string message)
{
    return await module.InvokeAsync<string>("showPrompt", message);
}
```

Call .NET methods from JavaScript functions in ASP.NET Core Blazor

9/22/2020 • 8 minutes to read • Edit Online

By Javier Calvarro Nelson, Daniel Roth, Shashikant Rudrawadi, and Luke Latham

A Blazor app can invoke JavaScript functions from .NET methods and .NET methods from JavaScript functions. These scenarios are called *JavaScript interoperability* (*JS interop*).

This article covers invoking .NET methods from JavaScript. For information on how to call JavaScript functions from .NET, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.

View or download sample code (how to download)

Static .NET method call

To invoke a static .NET method from JavaScript, use the `DotNet.invokeMethod` or `DotNet.invokeMethodAsync` functions. Pass in the identifier of the static method you wish to call, the name of the assembly containing the function, and any arguments. The asynchronous version is preferred to support Blazor Server scenarios. The .NET method must be public, static, and have the `[JSInvokable]` attribute. Calling open generic methods isn't currently supported.

The sample app includes a C# method to return an `int` array. The `[JSInvokable]` attribute is applied to the method.

`Pages/JsInterop.razor`:

```
<button type="button" class="btn btn-primary"
        onclick="exampleJsFunctions.returnArrayAsyncJs()">
    Trigger .NET static method ReturnArrayAsync
</button>

@code {
    [JSInvokable]
    public static Task<int[]> ReturnArrayAsync()
    {
        return Task.FromResult(new int[] { 1, 2, 3 });
    }
}
```

JavaScript served to the client invokes the C# .NET method.

`wwwroot/exampleJsInterop.js`:

```
window.exampleJsFunctions = {
  showPrompt: function (text) {
    return prompt(text, 'Type your name here');
  },
  displayWelcome: function (welcomeMessage) {
    document.getElementById('welcome').innerText = welcomeMessage;
  },
  returnArrayAsyncJs: function () {
    DotNet.invokeMethodAsync('BlazorSample', 'ReturnArrayAsync')
      .then(data => {
        data.push(4);
          console.log(data);
      });
  },
  sayHello: function (dotnetHelper) {
    return dotnetHelper.invokeMethodAsync('SayHello')
      .then(r => console.log(r));
  }
};
```

When the `Trigger .NET static method ReturnArrayAsync` button is selected, examine the console output in the browser's web developer tools.

The console output is:

```
Array(4) [ 1, 2, 3, 4 ]
```

The fourth array value is pushed to the array (`data.push(4);`) returned by `ReturnArrayAsync` .

By default, the method identifier is the method name, but you can specify a different identifier using the `[JSInvokable]` attribute constructor:

```
@code {
    [JSInvokable("DifferentMethodName")]
    public static Task<int[]> ReturnArrayAsync()
    {
        return Task.FromResult(new int[] { 1, 2, 3 });
    }
}
```

In the client-side JavaScript file:

```
returnArrayAsyncJs: function () {
  DotNet.invokeMethodAsync('{APP ASSEMBLY}', 'DifferentMethodName')
    .then(data => {
      data.push(4);
      console.log(data);
    });
}
```

The placeholder `{APP ASSEMBLY}` is the app's app assembly name (for example, `BlazorSample`).

Instance method call

You can also call .NET instance methods from JavaScript. To invoke a .NET instance method from JavaScript:

- Pass the .NET instance by reference to JavaScript:
  - Make a static call to DotNetObjectReference.Create.

    - Wrap the instance in a DotNetObjectReference instance and call Create on the DotNetObjectReference instance. Dispose of DotNetObjectReference objects (an example appears later in this section).
- Invoke .NET instance methods on the instance using the `invokeMethod` or `invokeMethodAsync` functions. The .NET instance can also be passed as an argument when invoking other .NET methods from JavaScript.

> **NOTE**
>
> The sample app logs messages to the client-side console. For the following examples demonstrated by the sample app, examine the browser's console output in the browser's developer tools.

When the `Trigger .NET instance method HelloHelper.SayHello` button is selected, `ExampleJsInterop.CallHelloHelperSayHello` is called and passes a name, `Blazor`, to the method.

`Pages/JsInterop.razor`:

```
<button type="button" class="btn btn-primary" @onclick="TriggerNetInstanceMethod">
    Trigger .NET instance method HelloHelper.SayHello
</button>

@code {
    public async Task TriggerNetInstanceMethod()
    {
        var exampleJsInterop = new ExampleJsInterop(JSRuntime);
        await exampleJsInterop.CallHelloHelperSayHello("Blazor");
    }
}
```

`CallHelloHelperSayHello` invokes the JavaScript function `sayHello` with a new instance of `HelloHelper`.

`JsInteropClasses/ExampleJsInterop.cs`:

```
public class ExampleJsInterop : IDisposable
{
    private readonly IJSRuntime jsRuntime;
    private DotNetObjectReference<HelloHelper> objRef;

    public ExampleJsInterop(IJSRuntime jsRuntime)
    {
        this.jsRuntime = jsRuntime;
    }

    public ValueTask<string> CallHelloHelperSayHello(string name)
    {
        objRef = DotNetObjectReference.Create(new HelloHelper(name));

        return jsRuntime.InvokeAsync<string>(
            "exampleJsFunctions.sayHello",
            objRef);
    }

    public void Dispose()
    {
        objRef?.Dispose();
    }
}
```

`wwwroot/exampleJsInterop.js`:

```
window.exampleJsFunctions = {
  showPrompt: function (text) {
    return prompt(text, 'Type your name here');
  },
  displayWelcome: function (welcomeMessage) {
    document.getElementById('welcome').innerText = welcomeMessage;
  },
  returnArrayAsyncJs: function () {
    DotNet.invokeMethodAsync('BlazorSample', 'ReturnArrayAsync')
      .then(data => {
        data.push(4);
          console.log(data);
      });
  },
  sayHello: function (dotnetHelper) {
    return dotnetHelper.invokeMethodAsync('SayHello')
      .then(r => console.log(r));
  }
};
```

The name is passed to `HelloHelper`'s constructor, which sets the `HelloHelper.Name` property. When the JavaScript function `sayHello` is executed, `HelloHelper.SayHello` returns the `Hello, {Name}!` message, which is written to the console by the JavaScript function.

`JsInteropClasses/HelloHelper.cs`:

```
public class HelloHelper
{
    public HelloHelper(string name)
    {
        Name = name;
    }

    public string Name { get; set; }

    [JSInvokable]
    public string SayHello() => $"Hello, {Name}!";
}
```

Console output in the browser's web developer tools:

```
Hello, Blazor!
```

To avoid a memory leak and allow garbage collection on a component that creates a DotNetObjectReference, adopt one of the following approaches:

- Dispose of the object in the class that created the DotNetObjectReference instance:

```
public class ExampleJsInterop : IDisposable
{
    private readonly IJSRuntime jsRuntime;
    private DotNetObjectReference<HelloHelper> objRef;

    public ExampleJsInterop(IJSRuntime jsRuntime)
    {
        this.jsRuntime = jsRuntime;
    }

    public ValueTask<string> CallHelloHelperSayHello(string name)
    {
        objRef = DotNetObjectReference.Create(new HelloHelper(name));

        return jsRuntime.InvokeAsync<string>(
            "exampleJsFunctions.sayHello",
            objRef);
    }

    public void Dispose()
    {
        objRef?.Dispose();
    }
}
```

The preceding pattern shown in the `ExampleJsInterop` class can also be implemented in a component:

```
@page "/JSInteropComponent"
@using {APP ASSEMBLY}.JsInteropClasses
@implements IDisposable
@inject IJSRuntime JSRuntime

<h1>JavaScript Interop</h1>

<button type="button" class="btn btn-primary" @onclick="TriggerNetInstanceMethod">
    Trigger .NET instance method HelloHelper.SayHello
</button>

@code {
    private DotNetObjectReference<HelloHelper> objRef;

    public async Task TriggerNetInstanceMethod()
    {
        objRef = DotNetObjectReference.Create(new HelloHelper("Blazor"));

        await JSRuntime.InvokeAsync<string>(
            "exampleJsFunctions.sayHello",
            objRef);
    }

    public void Dispose()
    {
        objRef?.Dispose();
    }
}
```

The placeholder `{APP ASSEMBLY}` is the app's app assembly name (for example, `BlazorSample`).

- When the component or class doesn't dispose of the DotNetObjectReference, dispose of the object on the client by calling `.dispose()`:

```
window.myFunction = (dotnetHelper) => {
  dotnetHelper.invokeMethodAsync('{APP ASSEMBLY}', 'MyMethod');
  dotnetHelper.dispose();
}
```

Component instance method call

To invoke a component's .NET methods:

- Use the `invokeMethod` or `invokeMethodAsync` function to make a static method call to the component.
- The component's static method wraps the call to its instance method as an invoked Action.

> **NOTE**
>
> For Blazor Server apps, where several users might be concurrently using the same component, use a helper class to invoke instance methods.
>
> For more information, see the Component instance method helper class section.

In the client-side JavaScript:

```
function updateMessageCallerJS() {
  DotNet.invokeMethodAsync('{APP ASSEMBLY}', 'UpdateMessageCaller');
}
```

The placeholder `{APP ASSEMBLY}` is the app's app assembly name (for example, `BlazorSample`).

`Pages/JSInteropComponent.razor`:

```
@page "/JSInteropComponent"

<p>
    Message: @message
</p>

<p>
    <button onclick="updateMessageCallerJS()">Call JS Method</button>
</p>

@code {
    private static Action action;
    private string message = "Select the button.";

    protected override void OnInitialized()
    {
        action = UpdateMessage;
    }

    private void UpdateMessage()
    {
        message = "UpdateMessage Called!";
        StateHasChanged();
    }

    [JSInvokable]
    public static void UpdateMessageCaller()
    {
        action.Invoke();
    }
}
```

To pass arguments to the instance method:

- Add parameters to the JS method invocation. In the following example, a name is passed to the method. Additional parameters can be added to the list as needed.

  ```
  function updateMessageCallerJS(name) {
    DotNet.invokeMethodAsync('{APP ASSEMBLY}', 'UpdateMessageCaller', name);
  }
  ```

  The placeholder `{APP ASSEMBLY}` is the app's app assembly name (for example, `BlazorSample`).

- Provide the correct types to the Action for the parameters. Provide the parameter list to the C# methods. Invoke the Action (`UpdateMessage`) with the parameters (`action.Invoke(name)`).

  `Pages/JSInteropComponent.razor`:

```
@page "/JSInteropComponent"

<p>
    Message: @message
</p>

<p>
    <button onclick="updateMessageCallerJS('Sarah Jane')">
        Call JS Method
    </button>
</p>

@code {
    private static Action<string> action;
    private string message = "Select the button.";

    protected override void OnInitialized()
    {
        action = UpdateMessage;
    }

    private void UpdateMessage(string name)
    {
        message = $"{name}, UpdateMessage Called!";
        StateHasChanged();
    }

    [JSInvokable]
    public static void UpdateMessageCaller(string name)
    {
        action.Invoke(name);
    }
}
```

Output `message` when the **Call JS Method** button is selected:

```
Sarah Jane, UpdateMessage Called!
```

Component instance method helper class

The helper class is used to invoke an instance method as an Action. Helper classes are useful when:

- Several components of the same type are rendered on the same page.
- A Blazor Server app is used, where multiple users might be using a component concurrently.

In the following example:

- The `JSInteropExample` component contains several `ListItem` components.
- Each `ListItem` component is composed of a message and a button.
- When a `ListItem` component button is selected, that `ListItem`'s `UpdateMessage` method changes the list item text and hides the button.

`MessageUpdateInvokeHelper.cs`:

```
using System;
using Microsoft.JSInterop;

public class MessageUpdateInvokeHelper
{
    private Action action;

    public MessageUpdateInvokeHelper(Action action)
    {
        this.action = action;
    }

    [JSInvokable("{APP ASSEMBLY}")]
    public void UpdateMessageCaller()
    {
        action.Invoke();
    }
}
```

The placeholder `{APP ASSEMBLY}` is the app's app assembly name (for example, `BlazorSample`).

In the client-side JavaScript:

```
window.updateMessageCallerJS = (dotnetHelper) => {
    dotnetHelper.invokeMethodAsync('{APP ASSEMBLY}', 'UpdateMessageCaller');
    dotnetHelper.dispose();
}
```

The placeholder `{APP ASSEMBLY}` is the app's app assembly name (for example, `BlazorSample`).

`Shared/ListItem.razor`:

```
@inject IJSRuntime JsRuntime

<li>
    @message
    <button @onclick="InteropCall" style="display:@display">InteropCall</button>
</li>

@code {
    private string message = "Select one of these list item buttons.";
    private string display = "inline-block";
    private MessageUpdateInvokeHelper messageUpdateInvokeHelper;

    protected override void OnInitialized()
    {
        messageUpdateInvokeHelper = new MessageUpdateInvokeHelper(UpdateMessage);
    }

    protected async Task InteropCall()
    {
        await JsRuntime.InvokeVoidAsync("updateMessageCallerJS",
            DotNetObjectReference.Create(messageUpdateInvokeHelper));
    }

    private void UpdateMessage()
    {
        message = "UpdateMessage Called!";
        display = "none";
        StateHasChanged();
    }
}
```

`Pages/JSInteropExample.razor`:

```
@page "/JSInteropExample"

<h1>List of components</h1>

<ul>
    <ListItem />
    <ListItem />
    <ListItem />
    <ListItem />
</ul>
```

Share interop code in a class library

JS interop code can be included in a class library, which allows you to share the code in a NuGet package.

The class library handles embedding JavaScript resources in the built assembly. The JavaScript files are placed in the `wwwroot` folder. The tooling takes care of embedding the resources when the library is built.

The built NuGet package is referenced in the app's project file the same way that any NuGet package is referenced. After the package is restored, app code can call into JavaScript as if it were C#.

For more information, see ASP.NET Core Razor components class libraries.

Avoid circular object references

Objects that contain circular references can't be serialized on the client for either:

- .NET method calls.
- JavaScript method calls from C# when the return type has circular references.

For more information, see the following issues:

- Circular references are not supported, take two (dotnet/aspnetcore #20525)
- Proposal: Add mechanism to handle circular references when serializing (dotnet/runtime #30820)

Additional resources

- Call JavaScript functions from .NET methods in ASP.NET Core Blazor
- `InteropComponent.razor` example (dotnet/AspNetCore GitHub repository, 3.1 release branch)

Call a web API from ASP.NET Core Blazor

9/22/2020 • 8 minutes to read • Edit Online

By Luke Latham, Daniel Roth, and Juan De la Cruz

> **NOTE**
> This topic applies to Blazor WebAssembly. Blazor Server apps call web APIs using HttpClient instances, typically created using IHttpClientFactory. For guidance that applies to Blazor Server, see Make HTTP requests using IHttpClientFactory in ASP.NET Core.

Blazor WebAssembly apps call web APIs using a preconfigured HttpClient service. Compose requests, which can include JavaScript Fetch API options, using Blazor JSON helpers or with HttpRequestMessage. The HttpClient service in Blazor WebAssembly apps is focused on making requests back to the server of origin. The guidance in this topic only pertains to Blazor WebAssembly apps.

View or download sample code (how to download): Select the `BlazorWebAssemblySample` app.

See the following components in the `BlazorWebAssemblySample` sample app:

- Call Web API (`Pages/CallWebAPI.razor`)
- HTTP Request Tester (`Components/HTTPRequestTester.razor`)

Packages

Reference the `System.Net.Http.Json` NuGet package in the project file.

Add the HttpClient service

In `Program.Main`, add an HttpClient service if it doesn't already exist:

```
builder.Services.AddScoped(sp =>
    new HttpClient
    {
        BaseAddress = new Uri(builder.HostEnvironment.BaseAddress)
    });
```

HttpClient and JSON helpers

In a Blazor WebAssembly app, `HttpClient` is available as a preconfigured service for making requests back to the origin server.

A Blazor Server app doesn't include an HttpClient service by default. Provide an HttpClient to the app using the `HttpClient` factory infrastructure.

HttpClient and JSON helpers are also used to call third-party web API endpoints. HttpClient is implemented using the browser Fetch API and is subject to its limitations, including enforcement of the same origin policy.

The client's base address is set to the originating server's address. Inject an HttpClient instance using the `@inject` directive:

```
@using System.Net.Http
@inject HttpClient Http
```

In the following examples, a Todo web API processes create, read, update, and delete (CRUD) operations. The examples are based on a `TodoItem` class that stores the:

- ID (`Id`, `long`): Unique ID of the item.
- Name (`Name`, `string`): Name of the item.
- Status (`IsComplete`, `bool`): Indication if the Todo item is finished.

```
private class TodoItem
{
    public long Id { get; set; }
    public string Name { get; set; }
    public bool IsComplete { get; set; }
}
```

JSON helper methods send requests to a URI (a web API in the following examples) and process the response:

- GetFromJsonAsync: Sends an HTTP GET request and parses the JSON response body to create an object.

  In the following code, the `todoItems` are displayed by the component. The `GetTodoItems` method is triggered when the component is finished rendering (`OnInitializedAsync`). See the sample app for a complete example.

  ```
  @using System.Net.Http
  @inject HttpClient Http

  @code {
      private TodoItem[] todoItems;

      protected override async Task OnInitializedAsync() =>
          todoItems = await Http.GetFromJsonAsync<TodoItem[]>("api/TodoItems");
  }
  ```

- PostAsJsonAsync: Sends an HTTP POST request, including JSON-encoded content, and parses the JSON response body to create an object.

  In the following code, `newItemName` is provided by a bound element of the component. The `AddItem` method is triggered by selecting a `<button>` element. See the sample app for a complete example.

  ```
  @using System.Net.Http
  @inject HttpClient Http

  <input @bind="newItemName" placeholder="New Todo Item" />
  <button @onclick="@AddItem">Add</button>

  @code {
      private string newItemName;

      private async Task AddItem()
      {
          var addItem = new TodoItem { Name = newItemName, IsComplete = false };
          await Http.PostAsJsonAsync("api/TodoItems", addItem);
      }
  }
  ```

  Calls to PostAsJsonAsync return an HttpResponseMessage. To deserialize the JSON content from the

response message, use the `ReadFromJsonAsync<T>` extension method:

```
var content = response.Content.ReadFromJsonAsync<WeatherForecast>();
```

- PutAsJsonAsync: Sends an HTTP PUT request, including JSON-encoded content.

  In the following code, `editItem` values for `Name` and `IsCompleted` are provided by bound elements of the component. The item's `Id` is set when the item is selected in another part of the UI and `EditItem` is called. The `SaveItem` method is triggered by selecting the Save `<button>` element. See the sample app for a complete example.

```
@using System.Net.Http
@inject HttpClient Http

<input type="checkbox" @bind="editItem.IsComplete" />
<input @bind="editItem.Name" />
<button @onclick="@SaveItem">Save</button>

@code {
    private TodoItem editItem = new TodoItem();

    private void EditItem(long id)
    {
        editItem = todoItems.Single(i => i.Id == id);
    }

    private async Task SaveItem() =>
        await Http.PutAsJsonAsync($"api/TodoItems/{editItem.Id}, editItem);
}
```

  Calls to PutAsJsonAsync return an HttpResponseMessage. To deserialize the JSON content from the response message, use the ReadFromJsonAsync extension method:

```
var content = response.Content.ReadFromJsonAsync<WeatherForecast>();
```

System.Net.Http includes additional extension methods for sending HTTP requests and receiving HTTP responses. HttpClient.DeleteAsync is used to send an HTTP DELETE request to a web API.

In the following code, the Delete `<button>` element calls the `DeleteItem` method. The bound `<input>` element supplies the `id` of the item to delete. See the sample app for a complete example.

```
@using System.Net.Http
@inject HttpClient Http

<input @bind="id" />
<button @onclick="@DeleteItem">Delete</button>

@code {
    private long id;

    private async Task DeleteItem() =>
        await Http.DeleteAsync($"api/TodoItems/{id}");
}
```

Named HttpClient with IHttpClientFactory

IHttpClientFactory services and the configuration of a named HttpClient are supported.

Reference the `Microsoft.Extensions.Http` NuGet package in the project file.

`Program.Main` (`Program.cs`):

```
builder.Services.AddHttpClient("ServerAPI", client =>
    client.BaseAddress = new Uri(builder.HostEnvironment.BaseAddress));
```

`FetchData` component (`Pages/FetchData.razor`):

```
@inject IHttpClientFactory ClientFactory

...

@code {
    private WeatherForecast[] forecasts;

    protected override async Task OnInitializedAsync()
    {
        var client = ClientFactory.CreateClient("ServerAPI");

        forecasts = await client.GetFromJsonAsync<WeatherForecast[]>(
            "WeatherForecast");
    }
}
```

Typed HttpClient

Typed HttpClient uses one or more of the app's HttpClient instances, default or named, to return data from one or more web API endpoints.

`WeatherForecastClient.cs` :

```
using System.Net.Http;
using System.Net.Http.Json;
using System.Threading.Tasks;

public class WeatherForecastClient
{
    private readonly HttpClient client;

    public WeatherForecastClient(HttpClient client)
    {
        this.client = client;
    }

    public async Task<WeatherForecast[]> GetForecastAsync()
    {
        var forecasts = new WeatherForecast[0];

        try
        {
            forecasts = await client.GetFromJsonAsync<WeatherForecast[]>(
                "WeatherForecast");
        }
        catch
        {
            ...
        }

        return forecasts;
    }
}
```

`Program.Main` (`Program.cs`):

```
builder.Services.AddHttpClient<WeatherForecastClient>(client =>
    client.BaseAddress = new Uri(builder.HostEnvironment.BaseAddress));
```

Components inject the typed HttpClient to call the web API.

`FetchData` component (`Pages/FetchData.razor`):

```
@inject WeatherForecastClient Client

...

@code {
    private WeatherForecast[] forecasts;

    protected override async Task OnInitializedAsync()
    {
        forecasts = await Client.GetForecastAsync();
    }
}
```

`HttpClient` and `HttpRequestMessage` with Fetch API request options

When running on WebAssembly in a Blazor WebAssembly app, `HttpClient` (API documentation) and HttpRequestMessage can be used to customize requests. For example, you can specify the HTTP method and request headers. The following component makes a `POST` request to a To Do List API endpoint on the server and shows the response body:

```
@page "/todorequest"
@using System.Net.Http
@using System.Net.Http.Headers
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject HttpClient Http
@inject IAccessTokenProvider TokenProvider

<h1>ToDo Request</h1>

<button @onclick="PostRequest">Submit POST request</button>

<p>Response body returned by the server:</p>

<p>@responseBody</p>

@code {
    private string responseBody;

    private async Task PostRequest()
    {
        var requestMessage = new HttpRequestMessage()
        {
            Method = new HttpMethod("POST"),
            RequestUri = new Uri("https://localhost:10000/api/TodoItems"),
            Content =
                JsonContent.Create(new TodoItem
                {
                    Name = "My New Todo Item",
                    IsComplete = false
                })
        };

        var tokenResult = await TokenProvider.RequestAccessToken();

        if (tokenResult.TryGetToken(out var token))
        {
            requestMessage.Headers.Authorization =
                new AuthenticationHeaderValue("Bearer", token.Value);

            requestMessage.Content.Headers.TryAddWithoutValidation(
                "x-custom-header", "value");

            var response = await Http.SendAsync(requestMessage);
            var responseStatusCode = response.StatusCode;

            responseBody = await response.Content.ReadAsStringAsync();
        }
    }

    public class TodoItem
    {
        public long Id { get; set; }
        public string Name { get; set; }
        public bool IsComplete { get; set; }
    }
}
```

.NET WebAssembly's implementation of HttpClient uses WindowOrWorkerGlobalScope.fetch(). Fetch allows configuring several request-specific options.

HTTP fetch request options can be configured with HttpRequestMessage extension methods shown in the following table.

EXTENSION METHOD	FETCH REQUEST PROPERTY
SetBrowserRequestCredentials	`credentials`
SetBrowserRequestCache	`cache`
SetBrowserRequestMode	`mode`
SetBrowserRequestIntegrity	`integrity`

You can set additional options using the more generic SetBrowserRequestOption extension method.

The HTTP response is typically buffered in a Blazor WebAssembly app to enable support for sync reads on the response content. To enable support for response streaming, use the SetBrowserResponseStreamingEnabled extension method on the request.

To include credentials in a cross-origin request, use the SetBrowserRequestCredentials extension method:

```
requestMessage.SetBrowserRequestCredentials(BrowserRequestCredentials.Include);
```

For more information on Fetch API options, see MDN web docs: WindowOrWorkerGlobalScope.fetch():Parameters.

Handle errors

When errors occur while interacting with a web API, they can be handled by developer code. For example, GetFromJsonAsync expects a JSON response from the server API with a `Content-Type` of `application/json`. If the response isn't in JSON format, content validation throws a NotSupportedException.

In the following example, the URI endpoint for the weather forecast data request is misspelled. The URI should be to `WeatherForecast` but appears in the call as `WeatherForcast` (missing "e").

The GetFromJsonAsync call expects JSON to be returned, but the server returns HTML for an unhandled exception on the server with a `Content-Type` of `text/html`. The unhandled exception occurs on the server because the path isn't found and middleware can't serve a page or view for the request.

In OnInitializedAsync on the client, NotSupportedException is thrown when the response content is validated as non-JSON. The exception is caught in the `catch` block, where custom logic could log the error or present a friendly error message to the user:

```
protected override async Task OnInitializedAsync()
{
    try
    {
        forecasts = await Http.GetFromJsonAsync<WeatherForecast[]>(
            "WeatherForcast");
    }
    catch (NotSupportedException exception)
    {
        ...
    }
}
```

> **NOTE**
>
> The preceding example is for demonstration purposes. A web API server app can be configured to return JSON even when an endpoint doesn't exist or an unhandled exception on the server occurs.

For more information, see Handle errors in ASP.NET Core Blazor apps.

Cross-origin resource sharing (CORS)

Browser security prevents a webpage from making requests to a different domain than the one that served the webpage. This restriction is called the *same-origin policy*. The same-origin policy prevents a malicious site from reading sensitive data from another site. To make requests from the browser to an endpoint with a different origin, the *endpoint* must enable cross-origin resource sharing (CORS).

The Blazor WebAssembly sample app (BlazorWebAssemblySample) demonstrates the use of CORS in the Call Web API component (`Pages/CallWebAPI.razor`).

For more information on CORS with secure requests in Blazor apps, see ASP.NET Core Blazor WebAssembly additional security scenarios.

For general information on CORS with ASP.NET Core apps, see Enable Cross-Origin Requests (CORS) in ASP.NET Core.

ASP.NET Core Blazor authentication and authorization

9/22/2020 • 10 minutes to read • Edit Online

By Steve Sanderson and Luke Latham

ASP.NET Core supports the configuration and management of security in Blazor apps.

Security scenarios differ between Blazor Server and Blazor WebAssembly apps. Because Blazor Server apps run on the server, authorization checks are able to determine:

- The UI options presented to a user (for example, which menu entries are available to a user).
- Access rules for areas of the app and components.

Blazor WebAssembly apps run on the client. Authorization is *only* used to determine which UI options to show. Since client-side checks can be modified or bypassed by a user, a Blazor WebAssembly app can't enforce authorization access rules.

Razor Pages authorization conventions don't apply to routable Razor components. If a non-routable Razor component is embedded in a page, the page's authorization conventions indirectly affect the Razor component along with the rest of the page's content.

> **NOTE**
> SignInManager<TUser> and UserManager<TUser> aren't supported in Razor components.

Authentication

Blazor uses the existing ASP.NET Core authentication mechanisms to establish the user's identity. The exact mechanism depends on how the Blazor app is hosted, Blazor WebAssembly or Blazor Server.

Blazor WebAssembly authentication

In Blazor WebAssembly apps, authentication checks can be bypassed because all client-side code can be modified by users. The same is true for all client-side app technologies, including JavaScript SPA frameworks or native apps for any operating system.

Add the following:

- A package reference for `Microsoft.AspNetCore.Components.Authorization` to the app's project file.
- The `Microsoft.AspNetCore.Components.Authorization` namespace to the app's `_Imports.razor` file.

To handle authentication, use of a built-in or custom AuthenticationStateProvider service is covered in the following sections.

For more information on creating apps and configuration, see Secure ASP.NET Core Blazor WebAssembly.

Blazor Server authentication

Blazor Server apps operate over a real-time connection that's created using SignalR. Authentication in SignalR-based apps is handled when the connection is established. Authentication can be based on a cookie or some other bearer token.

The built-in AuthenticationStateProvider service for Blazor Server apps obtains authentication state data from

ASP.NET Core's `HttpContext.User`. This is how authentication state integrates with existing ASP.NET Core authentication mechanisms.

For more information on creating apps and configuration, see Secure ASP.NET Core Blazor Server apps.

AuthenticationStateProvider service

AuthenticationStateProvider is the underlying service used by the AuthorizeView component and CascadingAuthenticationState component to get the authentication state.

You don't typically use AuthenticationStateProvider directly. Use the `AuthorizeView` component or `Task<AuthenticationState>` approaches described later in this article. The main drawback to using AuthenticationStateProvider directly is that the component isn't notified automatically if the underlying authentication state data changes.

The AuthenticationStateProvider service can provide the current user's ClaimsPrincipal data, as shown in the following example:

```
@page "/"
@using System.Security.Claims
@using Microsoft.AspNetCore.Components.Authorization
@inject AuthenticationStateProvider AuthenticationStateProvider

<h3>ClaimsPrincipal Data</h3>

<button @onclick="GetClaimsPrincipalData">Get ClaimsPrincipal Data</button>

<p>@_authMessage</p>

@if (_claims.Count() > 0)
{
    <ul>
        @foreach (var claim in _claims)
        {
            <li>@claim.Type: @claim.Value</li>
        }
    </ul>
}

<p>@_surnameMessage</p>

@code {
    private string _authMessage;
    private string _surnameMessage;
    private IEnumerable<Claim> _claims = Enumerable.Empty<Claim>();

    private async Task GetClaimsPrincipalData()
    {
        var authState = await AuthenticationStateProvider.GetAuthenticationStateAsync();
        var user = authState.User;

        if (user.Identity.IsAuthenticated)
        {
            _authMessage = $"{user.Identity.Name} is authenticated.";
            _claims = user.Claims;
            _surnameMessage =
                $"Surname: {user.FindFirst(c => c.Type == ClaimTypes.Surname)?.Value}";
        }
        else
        {
            _authMessage = "The user is NOT authenticated.";
        }
    }
}
```

If `user.Identity.IsAuthenticated` is `true` and because the user is a ClaimsPrincipal, claims can be enumerated and membership in roles evaluated.

For more information on dependency injection (DI) and services, see ASP.NET Core Blazor dependency injection and Dependency injection in ASP.NET Core.

Implement a custom AuthenticationStateProvider

If the app requires a custom provider, implement AuthenticationStateProvider and override `GetAuthenticationStateAsync`:

```
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Components.Authorization;

public class CustomAuthStateProvider : AuthenticationStateProvider
{
    public override Task<AuthenticationState> GetAuthenticationStateAsync()
    {
        var identity = new ClaimsIdentity(new[]
        {
            new Claim(ClaimTypes.Name, "mrfibuli"),
        }, "Fake authentication type");

        var user = new ClaimsPrincipal(identity);

        return Task.FromResult(new AuthenticationState(user));
    }
}
```

In a Blazor WebAssembly app, the `CustomAuthStateProvider` service is registered in `Main` of `Program.cs`:

```
using Microsoft.AspNetCore.Components.Authorization;

...

builder.Services.AddScoped<AuthenticationStateProvider, CustomAuthStateProvider>();
```

In a Blazor Server app, the `CustomAuthStateProvider` service is registered in `Startup.ConfigureServices`:

```
using Microsoft.AspNetCore.Components.Authorization;

...

services.AddScoped<AuthenticationStateProvider, CustomAuthStateProvider>();
```

Using the `CustomAuthStateProvider` in the preceding example, all users are authenticated with the username `mrfibuli`.

Expose the authentication state as a cascading parameter

If authentication state data is required for procedural logic, such as when performing an action triggered by the user, obtain the authentication state data by defining a cascading parameter of type `Task<` AuthenticationState `>`:

```
@page "/"

<button @onclick="LogUsername">Log username</button>

<p>@_authMessage</p>

@code {
    [CascadingParameter]
    private Task<AuthenticationState> authenticationStateTask { get; set; }

    private string _authMessage;

    private async Task LogUsername()
    {
        var authState = await authenticationStateTask;
        var user = authState.User;

        if (user.Identity.IsAuthenticated)
        {
            _authMessage = $"{user.Identity.Name} is authenticated.";
        }
        else
        {
            _authMessage = "The user is NOT authenticated.";
        }
    }
}
```

If `user.Identity.IsAuthenticated` is `true`, claims can be enumerated and membership in roles evaluated.

Set up the `Task<` AuthenticationState `>` cascading parameter using the AuthorizeRouteView and CascadingAuthenticationState components in the `App` component (`App.razor`):

```
<CascadingAuthenticationState>
    <Router AppAssembly="@typeof(Program).Assembly">
        <Found Context="routeData">
            <AuthorizeRouteView RouteData="@routeData"
                DefaultLayout="@typeof(MainLayout)" />
        </Found>
        <NotFound>
            <LayoutView Layout="@typeof(MainLayout)">
                <p>Sorry, there's nothing at this address.</p>
            </LayoutView>
        </NotFound>
    </Router>
</CascadingAuthenticationState>
```

In a Blazor WebAssembly App, add services for options and authorization to `Program.Main`:

```
builder.Services.AddOptions();
builder.Services.AddAuthorizationCore();
```

In a Blazor Server app, services for options and authorization are already present, so no further action is required.

Authorization

After a user is authenticated, *authorization* rules are applied to control what the user can do.

Access is typically granted or denied based on whether:

- A user is authenticated (signed in).

- A user is in a *role*.
- A user has a *claim*.
- A *policy* is satisfied.

Each of these concepts is the same as in an ASP.NET Core MVC or Razor Pages app. For more information on ASP.NET Core security, see the articles under ASP.NET Core Security and Identity.

AuthorizeView component

The AuthorizeView component selectively displays UI depending on whether the user is authorized to see it. This approach is useful when you only need to *display* data for the user and don't need to use the user's identity in procedural logic.

The component exposes a `context` variable of type AuthenticationState, which you can use to access information about the signed-in user:

```
<AuthorizeView>
    <h1>Hello, @context.User.Identity.Name!</h1>
    <p>You can only see this content if you're authenticated.</p>
</AuthorizeView>
```

You can also supply different content for display if the user isn't authenticated:

```
<AuthorizeView>
    <Authorized>
        <h1>Hello, @context.User.Identity.Name!</h1>
        <p>You can only see this content if you're authenticated.</p>
    </Authorized>
    <NotAuthorized>
        <h1>Authentication Failure!</h1>
        <p>You're not signed in.</p>
    </NotAuthorized>
</AuthorizeView>
```

The AuthorizeView component can be used in the `NavMenu` component (`Shared/NavMenu.razor`) to display a list item (`<li>...</li>`) for a `NavLink` component (NavLink), but note that this approach only removes the list item from the rendered output. It doesn't prevent the user from navigating to the component.

The content of `<Authorized>` and `<NotAuthorized>` tags can include arbitrary items, such as other interactive components.

Authorization conditions, such as roles or policies that control UI options or access, are covered in the Authorization section.

If authorization conditions aren't specified, AuthorizeView uses a default policy and treats:

- Authenticated (signed-in) users as authorized.
- Unauthenticated (signed-out) users as unauthorized.

Role-based and policy-based authorization

The AuthorizeView component supports *role-based* or *policy-based* authorization.

For role-based authorization, use the Roles parameter:

```
<AuthorizeView Roles="admin, superuser">
    <p>You can only see this if you're an admin or superuser.</p>
</AuthorizeView>
```

For more information, see Role-based authorization in ASP.NET Core.

For policy-based authorization, use the Policy parameter:

```
<AuthorizeView Policy="content-editor">
    <p>You can only see this if you satisfy the "content-editor" policy.</p>
</AuthorizeView>
```

Claims-based authorization is a special case of policy-based authorization. For example, you can define a policy that requires users to have a certain claim. For more information, see Policy-based authorization in ASP.NET Core.

These APIs can be used in either Blazor Server or Blazor WebAssembly apps.

If neither Roles nor Policy is specified, AuthorizeView uses the default policy.

Content displayed during asynchronous authentication

Blazor allows for authentication state to be determined *asynchronously*. The primary scenario for this approach is in Blazor WebAssembly apps that make a request to an external endpoint for authentication.

While authentication is in progress, AuthorizeView displays no content by default. To display content while authentication occurs, use the `<Authorizing>` tag:

```
<AuthorizeView>
    <Authorized>
        <h1>Hello, @context.User.Identity.Name!</h1>
        <p>You can only see this content if you're authenticated.</p>
    </Authorized>
    <Authorizing>
        <h1>Authentication in progress</h1>
        <p>You can only see this content while authentication is in progress.</p>
    </Authorizing>
</AuthorizeView>
```

This approach isn't normally applicable to Blazor Server apps. Blazor Server apps know the authentication state as soon as the state is established. Authorizing content can be provided in a Blazor Server app's AuthorizeView component, but the content is never displayed.

[Authorize] attribute

The `[Authorize]` attribute can be used in Razor components:

```
@page "/"
@attribute [Authorize]

You can only see this if you're signed in.
```

IMPORTANT

Only use `[Authorize]` on `@page` components reached via the Blazor Router. Authorization is only performed as an aspect of routing and *not* for child components rendered within a page. To authorize the display of specific parts within a page, use AuthorizeView instead.

The `[Authorize]` attribute also supports role-based or policy-based authorization. For role-based authorization, use the Roles parameter:

```
@page "/"
@attribute [Authorize(Roles = "admin, superuser")]

<p>You can only see this if you're in the 'admin' or 'superuser' role.</p>
```

For policy-based authorization, use the Policy parameter:

```
@page "/"
@attribute [Authorize(Policy = "content-editor")]

<p>You can only see this if you satisfy the 'content-editor' policy.</p>
```

If neither Roles nor Policy is specified, `[Authorize]` uses the default policy, which by default is to treat:

- Authenticated (signed-in) users as authorized.
- Unauthenticated (signed-out) users as unauthorized.

Customize unauthorized content with the Router component

The Router component, in conjunction with the AuthorizeRouteView component, allows the app to specify custom content if:

- Content isn't found.
- The user fails an `[Authorize]` condition applied to the component. The `[Authorize]` attribute is covered in the `[Authorize]` attribute section.
- Asynchronous authentication is in progress.

In the default Blazor Server project template, the `App` component (`App.razor`) demonstrates how to set custom content:

```
<CascadingAuthenticationState>
    <Router AppAssembly="@typeof(Program).Assembly">
        <Found Context="routeData">
            <AuthorizeRouteView RouteData="@routeData"
                DefaultLayout="@typeof(MainLayout)">
                <NotAuthorized>
                    <h1>Sorry</h1>
                    <p>You're not authorized to reach this page.</p>
                    <p>You may need to log in as a different user.</p>
                </NotAuthorized>
                <Authorizing>
                    <h1>Authentication in progress</h1>
                    <p>Only visible while authentication is in progress.</p>
                </Authorizing>
            </AuthorizeRouteView>
        </Found>
        <NotFound>
            <LayoutView Layout="@typeof(MainLayout)">
                <h1>Sorry</h1>
                <p>Sorry, there's nothing at this address.</p>
            </LayoutView>
        </NotFound>
    </Router>
</CascadingAuthenticationState>
```

The content of `<NotFound>`, `<NotAuthorized>`, and `<Authorizing>` tags can include arbitrary items, such as other interactive components.

If the `<NotAuthorized>` tag isn't specified, the AuthorizeRouteView uses the following fallback message:

```
Not authorized.
```

Notification about authentication state changes

If the app determines that the underlying authentication state data has changed (for example, because the user signed out or another user has changed their roles), a custom `AuthenticationStateProvider` can optionally invoke the method NotifyAuthenticationStateChanged on the AuthenticationStateProvider base class. This notifies consumers of the authentication state data (for example, AuthorizeView) to rerender using the new data.

Procedural logic

If the app is required to check authorization rules as part of procedural logic, use a cascaded parameter of type `Task<` AuthenticationState `>` to obtain the user's ClaimsPrincipal. `Task<` AuthenticationState `>` can be combined with other services, such as `IAuthorizationService`, to evaluate policies.

```
@using Microsoft.AspNetCore.Authorization
@inject IAuthorizationService AuthorizationService

<button @onclick="@DoSomething">Do something important</button>

@code {
    [CascadingParameter]
    private Task<AuthenticationState> authenticationStateTask { get; set; }

    private async Task DoSomething()
    {
        var user = (await authenticationStateTask).User;

        if (user.Identity.IsAuthenticated)
        {
            // Perform an action only available to authenticated (signed-in) users.
        }

        if (user.IsInRole("admin"))
        {
            // Perform an action only available to users in the 'admin' role.
        }

        if ((await AuthorizationService.AuthorizeAsync(user, "content-editor"))
            .Succeeded)
        {
            // Perform an action only available to users satisfying the
            // 'content-editor' policy.
        }
    }
}
```

NOTE

In a Blazor WebAssembly app component, add the Microsoft.AspNetCore.Authorization and Microsoft.AspNetCore.Components.Authorization namespaces:

```
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.Authorization
```

These namespaces can be provided globally by adding them to the app's `_Imports.razor` file.

Troubleshoot errors

Common errors:

- **Authorization requires a cascading parameter of type `Task\<AuthenticationState>`. Consider using `CascadingAuthenticationState` to supply this.**
- **`null` value is received for `authenticationStateTask`**

It's likely that the project wasn't created using a Blazor Server template with authentication enabled. Wrap a `<CascadingAuthenticationState>` around some part of the UI tree, for example in the `App` component (`App.razor`) as follows:

```
<CascadingAuthenticationState>
    <Router AppAssembly="typeof(Startup).Assembly">
        ...
    </Router>
</CascadingAuthenticationState>
```

The CascadingAuthenticationState supplies the `Task<` AuthenticationState `>` cascading parameter, which in turn it receives from the underlying AuthenticationStateProvider DI service.

Secure ASP.NET Core Blazor WebAssembly

9/22/2020 • 5 minutes to read • Edit Online

By Javier Calvarro Nelson

Blazor WebAssembly apps are secured in the same manner as Single Page Applications (SPAs). There are several approaches for authenticating users to SPAs, but the most common and comprehensive approach is to use an implementation based on the OAuth 2.0 protocol, such as OpenID Connect (OIDC).

Authentication library

Blazor WebAssembly supports authenticating and authorizing apps using OIDC via the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` library. The library provides a set of primitives for seamlessly authenticating against ASP.NET Core backends. The library integrates ASP.NET Core Identity with API authorization support built on top of Identity Server. The library can authenticate against any third-party Identity Provider (IP) that supports OIDC, which are called OpenID Providers (OP).

The authentication support in Blazor WebAssembly is built on top of the `oidc-client.js` library, which is used to handle the underlying authentication protocol details.

Other options for authenticating SPAs exist, such as the use of SameSite cookies. However, the engineering design of Blazor WebAssembly is settled on OAuth and OIDC as the best option for authentication in Blazor WebAssembly apps. Token-based authentication based on JSON Web Tokens (JWTs) was chosen over cookie-based authentication for functional and security reasons:

- Using a token-based protocol offers a smaller attack surface area, as the tokens aren't sent in all requests.
- Server endpoints don't require protection against Cross-Site Request Forgery (CSRF) because the tokens are sent explicitly. This allows you to host Blazor WebAssembly apps alongside MVC or Razor pages apps.
- Tokens have narrower permissions than cookies. For example, tokens can't be used to manage the user account or change a user's password unless such functionality is explicitly implemented.
- Tokens have a short lifetime, one hour by default, which limits the attack window. Tokens can also be revoked at any time.
- Self-contained JWTs offer guarantees to the client and server about the authentication process. For example, a client has the means to detect and validate that the tokens it receives are legitimate and were emitted as part of a given authentication process. If a third party attempts to switch a token in the middle of the authentication process, the client can detect the switched token and avoid using it.
- Tokens with OAuth and OIDC don't rely on the user agent behaving correctly to ensure that the app is secure.
- Token-based protocols, such as OAuth and OIDC, allow for authenticating and authorizing hosted and standalone apps with the same set of security characteristics.

Authentication process with OIDC

The `Microsoft.AspNetCore.Components.WebAssembly.Authentication` library offers several primitives to implement authentication and authorization using OIDC. In broad terms, authentication works as follows:

- When an anonymous user selects the login button or requests a page with the `[Authorize]` attribute applied, the user is redirected to the app's login page (`/authentication/login`).
- In the login page, the authentication library prepares for a redirect to the authorization endpoint. The authorization endpoint is outside of the Blazor WebAssembly app and can be hosted at a separate origin. The endpoint is responsible for determining whether the user is authenticated and for issuing one or more tokens

in response. The authentication library provides a login callback to receive the authentication response.
    - If the user isn't authenticated, the user is redirected to the underlying authentication system, which is usually ASP.NET Core Identity.
    - If the user was already authenticated, the authorization endpoint generates the appropriate tokens and redirects the browser back to the login callback endpoint (`/authentication/login-callback`).
- When the Blazor WebAssembly app loads the login callback endpoint (`/authentication/login-callback`), the authentication response is processed.
    - If the authentication process completes successfully, the user is authenticated and optionally sent back to the original protected URL that the user requested.
    - If the authentication process fails for any reason, the user is sent to the login failed page (`/authentication/login-failed`), and an error is displayed.

`Authentication` component

The `Authentication` component (`Pages/Authentication.razor`) handles remote authentication operations and permits the app to:

- Configure app routes for authentication states.
- Set UI content for authentication states.
- Manage authentication state.

Authentication actions, such as registering or signing in a user, are passed to the Blazor framework's RemoteAuthenticatorViewCore<TAuthenticationState> component, which persists and controls state across authentication operations.

For more information and examples, see ASP.NET Core Blazor WebAssembly additional security scenarios.

Authorization

In Blazor WebAssembly apps, authorization checks can be bypassed because all client-side code can be modified by users. The same is true for all client-side app technologies, including JavaScript SPA frameworks or native apps for any operating system.

Always perform authorization checks on the server within any API endpoints accessed by your client-side app.

Require authorization for the entire app

Apply the `[Authorize]` attribute (API documentation) to each Razor component of the app using one of the following approaches:

- Use the `@attribute` directive in the `_Imports.razor` file:

```
@using Microsoft.AspNetCore.Authorization
@attribute [Authorize]
```

- Add the attribute to each Razor component in the `Pages` folder.

> **NOTE**
>
> Setting an AuthorizationOptions.FallbackPolicy to a policy with RequireAuthenticatedUser is **not** supported.

Refresh tokens

Refresh tokens can't be secured client-side in Blazor WebAssembly apps. Therefore, refresh tokens shouldn't be sent to the app for direct use.

Refresh tokens can be maintained and used by the server-side app in a Hosted Blazor WebAssembly solution to access third-party APIs. For more information, see ASP.NET Core Blazor WebAssembly additional security scenarios.

Establish claims for users

Apps often require claims for users based on a web API call to a server. For example, claims are frequently used to establish authorization in an app. In these scenarios, the app requests an access token to access the service and uses the token to obtain the user data for the claims. For examples, see the following resources:

- Additional scenarios: Customize the user
- ASP.NET Core Blazor WebAssembly with Azure Active Directory groups and roles

Implementation guidance

Articles under this *Overview* provide information on authenticating users in Blazor WebAssembly apps against specific providers.

Standalone Blazor WebAssembly apps:

- General guidance for OIDC providers and the WebAssembly Authentication Library
- Microsoft Accounts
- Azure Active Directory (AAD)
- Azure Active Directory (AAD) B2C

Hosted Blazor WebAssembly apps:

- Azure Active Directory (AAD)
- Azure Active Directory (AAD) B2C
- Identity Server

For further guidance on configuration, see ASP.NET Core Blazor WebAssembly additional security scenarios.

Secure an ASP.NET Core Blazor WebAssembly standalone app with the Authentication library

9/22/2020 • 7 minutes to read • Edit Online

By Javier Calvarro Nelson and Luke Latham

For Azure Active Directory (AAD) and Azure Active Directory B2C (AAD B2C), don't follow the guidance in this topic. See the AAD and AAD B2C topics in this table of contents node.

To create a standalone Blazor WebAssembly app that uses `Microsoft.AspNetCore.Components.WebAssembly.Authentication` library, follow the guidance for your choice of tooling.

- Visual Studio
- Visual Studio Code / .NET Core CLI
- Visual Studio for Mac

To create a new Blazor WebAssembly project with an authentication mechanism:

1. After choosing the **Blazor WebAssembly App** template in the **Create a new ASP.NET Core Web Application** dialog, select **Change** under **Authentication**.
2. Select **Individual User Accounts** with the **Store user accounts in-app** option to store users within the app using ASP.NET Core's Identity system.

Authentication package

When an app is created to use Individual User Accounts, the app automatically receives a package reference for the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package in the app's project file. The package provides a set of primitives that help the app authenticate users and obtain tokens to call protected APIs.

If adding authentication to an app, manually add the package to the app's project file:

```
<PackageReference
  Include="Microsoft.AspNetCore.Components.WebAssembly.Authentication"
  Version="{VERSION}" />
```

For the placeholder `{VERSION}`, the latest stable version of the package that matches the app's shared framework version can be found in the package's **Version History** at NuGet.org.

Authentication service support

Support for authenticating users is registered in the service container with the AddOidcAuthentication extension method provided by the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package. This method sets up the services required for the app to interact with the Identity Provider (IP).

`Program.cs`:

```
builder.Services.AddOidcAuthentication(options =>
{
    builder.Configuration.Bind("Local", options.ProviderOptions);
});
```

Configuration is supplied by the `wwwroot/appsettings.json` file:

```
{
    "Local": {
        "Authority": "{AUTHORITY}",
        "ClientId": "{CLIENT ID}"
    }
}
```

Authentication support for standalone apps is offered using OpenID Connect (OIDC). The AddOidcAuthentication method accepts a callback to configure the parameters required to authenticate an app using OIDC. The values required for configuring the app can be obtained from the OIDC-compliant IP. Obtain the values when you register the app, which typically occurs in their online portal.

Access token scopes

The Blazor WebAssembly template doesn't automatically configure the app to request an access token for a secure API. To provision an access token as part of the sign-in flow, add the scope to the default token scopes of the OidcProviderOptions:

```
builder.Services.AddOidcAuthentication(options =>
{
    ...
    options.ProviderOptions.DefaultScopes.Add("{SCOPE URI}");
});
```

NOTE

If the Azure portal provides the scope URI for the app and the app throws an unhandled exception when it receives a *401 Unauthorized* response from the API, try using a scope URI that doesn't include the scheme and host. For example, the Azure portal may provide one of the following scope URI formats:

- `https://{TENANT}.onmicrosoft.com/{API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}`
- `api://{SERVER API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}`

Try supplying the scope URI without the scheme and host:

```
options.ProviderOptions.DefaultAccessTokenScopes.Add(
    "{SERVER API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}");
```

For example:

```
options.ProviderOptions.DefaultAccessTokenScopes.Add(
    "41451fa7-82d9-4673-8fa5-69eff5a761fd/API.Access");
```

For more information, see the following sections of the *Additional scenarios* article:

- Request additional access tokens
- Attach tokens to outgoing requests

Imports file

The Microsoft.AspNetCore.Components.Authorization namespace is made available throughout the app via the `_Imports.razor` file:

```
@using System.Net.Http
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.Web
@using Microsoft.AspNetCore.Components.WebAssembly.Http
@using Microsoft.JSInterop
@using {APPLICATION ASSEMBLY}
@using {APPLICATION ASSEMBLY}.Shared
```

Index page

The Index page (`wwwroot/index.html`) page includes a script that defines the `AuthenticationService` in JavaScript. `AuthenticationService` handles the low-level details of the OIDC protocol. The app internally calls methods defined in the script to perform the authentication operations.

```
<script src="_content/Microsoft.AspNetCore.Components.WebAssembly.Authentication/
    AuthenticationService.js"></script>
```

App component

The `App` component (`App.razor`) is similar to the `App` component found in Blazor Server apps:

- The CascadingAuthenticationState component manages exposing the AuthenticationState to the rest of the app.
- The AuthorizeRouteView component makes sure that the current user is authorized to access a given page or otherwise renders the `RedirectToLogin` component.
- The `RedirectToLogin` component manages redirecting unauthorized users to the login page.

```
<CascadingAuthenticationState>
    <Router AppAssembly="@typeof(Program).Assembly">
        <Found Context="routeData">
            <AuthorizeRouteView RouteData="@routeData"
                DefaultLayout="@typeof(MainLayout)">
                <NotAuthorized>
                    @if (!context.User.Identity.IsAuthenticated)
                    {
                        <RedirectToLogin />
                    }
                    else
                    {
                        <p>
                            You are not authorized to access
                            this resource.
                        </p>
                    }
                </NotAuthorized>
            </AuthorizeRouteView>
        </Found>
        <NotFound>
            <LayoutView Layout="@typeof(MainLayout)">
                <p>Sorry, there's nothing at this address.</p>
            </LayoutView>
        </NotFound>
    </Router>
</CascadingAuthenticationState>
```

RedirectToLogin component

The `RedirectToLogin` component (`Shared/RedirectToLogin.razor`):

- Manages redirecting unauthorized users to the login page.
- Preserves the current URL that the user is attempting to access so that they can be returned to that page if authentication is successful.

```
@inject NavigationManager Navigation
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@code {
    protected override void OnInitialized()
    {
        Navigation.NavigateTo($"authentication/login?returnUrl=" +
            Uri.EscapeDataString(Navigation.Uri));
    }
}
```

LoginDisplay component

The `LoginDisplay` component (`Shared/LoginDisplay.razor`) is rendered in the `MainLayout` component (`Shared/MainLayout.razor`) and manages the following behaviors:

- For authenticated users:
  - Displays the current username.
  - Offers a button to log out of the app.
- For anonymous users, offers the option to log in.

```
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject NavigationManager Navigation
@inject SignOutSessionStateManager SignOutManager

<AuthorizeView>
    <Authorized>
        Hello, @context.User.Identity.Name!
        <button class="nav-link btn btn-link" @onclick="BeginSignOut">
            Log out
        </button>
    </Authorized>
    <NotAuthorized>
        <a href="authentication/login">Log in</a>
    </NotAuthorized>
</AuthorizeView>

@code {
    private async Task BeginSignOut(MouseEventArgs args)
    {
        await SignOutManager.SetSignOutState();
        Navigation.NavigateTo("authentication/logout");
    }
}
```

Authentication component

The page produced by the `Authentication` component (`Pages/Authentication.razor`) defines the routes required for handling different authentication stages.

The RemoteAuthenticatorView component:

- Is provided by the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package.
- Manages performing the appropriate actions at each stage of authentication.

```
@page "/authentication/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action" />

@code {
    [Parameter]
    public string Action { get; set; }
}
```

Troubleshoot

Cookies and site data

Cookies and site data can persist across app updates and interfere with testing and troubleshooting. Clear the following when making app code changes, user account changes with the provider, or provider app configuration changes:

- User sign-in cookies
- App cookies
- Cached and stored site data

One approach to prevent lingering cookies and site data from interfering with testing and troubleshooting is to:

- Configure a browser
  - Use a browser for testing that you can configure to delete all cookie and site data each time the browser is closed.
  - Make sure that the browser is closed manually or by the IDE between any change to the app, test user, or provider configuration.
- Use a custom command to open a browser in incognito or private mode in Visual Studio:
  - Open **Browse With** dialog box from Visual Studio's **Run** button.
  - Select the **Add** button.
  - Provide the path to your browser in the **Program** field. The following executable paths are typical installation locations for Windows 10. If your browser is installed in a different location or you aren't using Windows 10, provide the path to the browser's executable.
    - Microsoft Edge: `C:\Program Files (x86)\Microsoft\Edge\Application\msedge.exe`
    - Google Chrome: `C:\Program Files (x86)\Google\Chrome\Application\chrome.exe`
    - Mozilla Firefox: `C:\Program Files\Mozilla Firefox\firefox.exe`
  - In the **Arguments** field, provide the command-line option that the browser uses to open in incognito or private mode. Some browsers require the URL of the app.
    - Microsoft Edge: `-inprivate`
    - Google Chrome: `--incognito --new-window https://localhost:5001`
    - Mozilla Firefox: `-private -url https://localhost:5001`
  - Provide a name in the **Friendly name** field. For example, `Firefox Auth Testing`.
  - Select the **OK** button.
  - To avoid having to select the browser profile for each iteration of testing with an app, set the profile as the default with the **Set as Default** button.
  - Make sure that the browser is closed by the IDE between any change to the app, test user, or provider configuration.

Run the Server app

When testing and troubleshooting a hosted Blazor app, make sure that you're running the app from the `Server` project. For example in Visual Studio, confirm that the Server project is highlighted in **Solution Explorer** before you start the app with any of the following approaches:

- Select the **Run** button.
- Use **Debug** > **Start Debugging** from the menu.
- Press F5.

Inspect the content of a JSON Web Token (JWT)

To decode a JSON Web Token (JWT), use Microsoft's jwt.ms tool. Values in the UI never leave your browser.

Secure an ASP.NET Core Blazor WebAssembly standalone app with Microsoft Accounts

9/22/2020 • 8 minutes to read • Edit Online

By Javier Calvarro Nelson and Luke Latham

To create a standalone Blazor WebAssembly app that uses Microsoft Accounts with Azure Active Directory (AAD) for authentication:

Create an AAD tenant and web application

Register a AAD app in the **Azure Active Directory** > **App registrations** area of the Azure portal:

1. Provide a **Name** for the app (for example, **Blazor Standalone AAD Microsoft Accounts**).
2. In **Supported account types**, select **Accounts in any organizational directory**.
3. Leave the **Redirect URI** drop down set to **Web** and provide the following redirect URI: `https://localhost:{PORT}/authentication/login-callback`. The default port for an app running on Kestrel is 5001. If the app is run on a different Kestrel port, use the app's port. For IIS Express, the randomly generated port for the app can be found in the app's properties in the **Debug** panel. Since the app doesn't exist at this point and the IIS Express port isn't known, return to this step after the app is created and update the redirect URI. A remark appears later in this topic to remind IIS Express users to update the redirect URI.
4. Disable the **Permissions** > **Grant admin consent to openid and offline_access permissions** check box.
5. Select **Register**.

Record the Application (client) ID (for example, `41451fa7-82d9-4673-8fa5-69eff5a761fd`).

In **Authentication** > **Platform configurations** > **Web**:

1. Confirm the **Redirect URI** of `https://localhost:{PORT}/authentication/login-callback` is present.
2. For **Implicit grant**, select the check boxes for **Access tokens** and **ID tokens**.
3. The remaining defaults for the app are acceptable for this experience.
4. Select the **Save** button.

Create the app. Replace the placeholders in the following command with the information recorded earlier and execute the following command in a command shell:

```
dotnet new blazorwasm -au SingleOrg --client-id "{CLIENT ID}" --tenant-id "common" -o {APP NAME}
```

PLACEHOLDER	AZURE PORTAL NAME	EXAMPLE
`{APP NAME}`	—	`BlazorSample`
`{CLIENT ID}`	Application (client) ID	`41451fa7-82d9-4673-8fa5-69eff5a761fd`

The output location specified with the `-o|--output` option creates a project folder if it doesn't exist and becomes part of the app's name.

> **NOTE**
>
> In the Azure portal, the app's **Authentication** > **Platform configurations** > **Web** > **Redirect URI** is configured for port 5001 for apps that run on the Kestrel server with default settings.
>
> If the app is run on a random IIS Express port, the port for the app can be found in the app's properties in the **Debug** panel.
>
> If the port wasn't configured earlier with the app's known port, return to the app's registration in the Azure portal and update the redirect URI with the correct port.

After creating the app, you should be able to:

- Log into the app using a Microsoft account.
- Request access tokens for Microsoft APIs. For more information, see:
  - Access token scopes
  - Quickstart: Configure an application to expose web APIs.

Authentication package

When an app is created to use Work or School Accounts (`SingleOrg`), the app automatically receives a package reference for the Microsoft Authentication Library (`Microsoft.Authentication.WebAssembly.Msal`). The package provides a set of primitives that help the app authenticate users and obtain tokens to call protected APIs.

If adding authentication to an app, manually add the package to the app's project file:

```
<PackageReference Include="Microsoft.Authentication.WebAssembly.Msal"
  Version="{VERSION}" />
```

For the placeholder `{VERSION}`, the latest stable version of the package that matches the app's shared framework version can be found in the package's **Version History** at NuGet.org.

The `Microsoft.Authentication.WebAssembly.Msal` package transitively adds the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package to the app.

Authentication service support

Support for authenticating users is registered in the service container with the AddMsalAuthentication extension method provided by the `Microsoft.Authentication.WebAssembly.Msal` package. This method sets up all of the services required for the app to interact with the Identity Provider (IP).

`Program.cs`:

```
builder.Services.AddMsalAuthentication(options =>
{
    builder.Configuration.Bind("AzureAd", options.ProviderOptions.Authentication);
});
```

The AddMsalAuthentication method accepts a callback to configure the parameters required to authenticate an app. The values required for configuring the app can be obtained from the AAD configuration when you register the app.

Configuration is supplied by the `wwwroot/appsettings.json` file:

```
{
  "AzureAd": {
    "Authority": "https://login.microsoftonline.com/common",
    "ClientId": "{CLIENT ID}",
    "ValidateAuthority": true
  }
}
```

Example:

```
{
  "AzureAd": {
    "Authority": "https://login.microsoftonline.com/common",
    "ClientId": "41451fa7-82d9-4673-8fa5-69eff5a761fd",
    "ValidateAuthority": true
  }
}
```

Access token scopes

The Blazor WebAssembly template doesn't automatically configure the app to request an access token for a secure API. To provision an access token as part of the sign-in flow, add the scope to the default access token scopes of the MsalProviderOptions:

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.DefaultAccessTokenScopes.Add("{SCOPE URI}");
});
```

NOTE

If the Azure portal provides the scope URI for the app and the app throws an unhandled exception when it receives a *401 Unauthorized* response from the API, try using a scope URI that doesn't include the scheme and host. For example, the Azure portal may provide one of the following scope URI formats:

- `https://{TENANT}.onmicrosoft.com/{API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}`
- `api://{SERVER API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}`

Try supplying the scope URI without the scheme and host:

```
options.ProviderOptions.DefaultAccessTokenScopes.Add(
    "{SERVER API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}");
```

For example:

```
options.ProviderOptions.DefaultAccessTokenScopes.Add(
    "41451fa7-82d9-4673-8fa5-69eff5a761fd/API.Access");
```

For more information, see the following sections of the *Additional scenarios* article:

- Request additional access tokens
- Attach tokens to outgoing requests

Login mode

The framework defaults to pop-up login mode and falls back to redirect login mode if a pop-up can't be opened. Configure MSAL to use redirect login mode by setting the `LoginMode` property of MsalProviderOptions to `redirect`:

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.LoginMode = "redirect";
});
```

The default setting is `popup`, and the string value isn't case sensitive.

Imports file

The Microsoft.AspNetCore.Components.Authorization namespace is made available throughout the app via the `_Imports.razor` file:

```
@using System.Net.Http
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.Web
@using Microsoft.AspNetCore.Components.WebAssembly.Http
@using Microsoft.JSInterop
@using {APPLICATION ASSEMBLY}
@using {APPLICATION ASSEMBLY}.Shared
```

Index page

The Index page (`wwwroot/index.html`) page includes a script that defines the `AuthenticationService` in JavaScript. `AuthenticationService` handles the low-level details of the OIDC protocol. The app internally calls methods defined in the script to perform the authentication operations.

```
<script src="_content/Microsoft.Authentication.WebAssembly.Msal/
    AuthenticationService.js"></script>
```

App component

The `App` component (`App.razor`) is similar to the `App` component found in Blazor Server apps:

- The CascadingAuthenticationState component manages exposing the AuthenticationState to the rest of the app.
- The AuthorizeRouteView component makes sure that the current user is authorized to access a given page or otherwise renders the `RedirectToLogin` component.
- The `RedirectToLogin` component manages redirecting unauthorized users to the login page.

```
<CascadingAuthenticationState>
    <Router AppAssembly="@typeof(Program).Assembly">
        <Found Context="routeData">
            <AuthorizeRouteView RouteData="@routeData"
                DefaultLayout="@typeof(MainLayout)">
                <NotAuthorized>
                    @if (!context.User.Identity.IsAuthenticated)
                    {
                        <RedirectToLogin />
                    }
                    else
                    {
                        <p>
                            You are not authorized to access
                            this resource.
                        </p>
                    }
                </NotAuthorized>
            </AuthorizeRouteView>
        </Found>
        <NotFound>
            <LayoutView Layout="@typeof(MainLayout)">
                <p>Sorry, there's nothing at this address.</p>
            </LayoutView>
        </NotFound>
    </Router>
</CascadingAuthenticationState>
```

RedirectToLogin component

The `RedirectToLogin` component (`Shared/RedirectToLogin.razor`):

- Manages redirecting unauthorized users to the login page.
- Preserves the current URL that the user is attempting to access so that they can be returned to that page if authentication is successful.

```
@inject NavigationManager Navigation
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@code {
    protected override void OnInitialized()
    {
        Navigation.NavigateTo($"authentication/login?returnUrl=" +
            Uri.EscapeDataString(Navigation.Uri));
    }
}
```

LoginDisplay component

The `LoginDisplay` component (`Shared/LoginDisplay.razor`) is rendered in the `MainLayout` component (`Shared/MainLayout.razor`) and manages the following behaviors:

- For authenticated users:
  - Displays the current username.
  - Offers a button to log out of the app.
- For anonymous users, offers the option to log in.

```
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject NavigationManager Navigation
@inject SignOutSessionStateManager SignOutManager

<AuthorizeView>
    <Authorized>
        Hello, @context.User.Identity.Name!
        <button class="nav-link btn btn-link" @onclick="BeginLogout">
            Log out
        </button>
    </Authorized>
    <NotAuthorized>
        <a href="authentication/login">Log in</a>
    </NotAuthorized>
</AuthorizeView>

@code {
    private async Task BeginLogout(MouseEventArgs args)
    {
        await SignOutManager.SetSignOutState();
        Navigation.NavigateTo("authentication/logout");
    }
}
```

Authentication component

The page produced by the `Authentication` component (`Pages/Authentication.razor`) defines the routes required for handling different authentication stages.

The RemoteAuthenticatorView component:

- Is provided by the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package.
- Manages performing the appropriate actions at each stage of authentication.

```
@page "/authentication/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action" />

@code {
    [Parameter]
    public string Action { get; set; }
}
```

Troubleshoot

Cookies and site data

Cookies and site data can persist across app updates and interfere with testing and troubleshooting. Clear the following when making app code changes, user account changes with the provider, or provider app configuration changes:

- User sign-in cookies
- App cookies
- Cached and stored site data

One approach to prevent lingering cookies and site data from interfering with testing and troubleshooting is to:

- Configure a browser

    - Use a browser for testing that you can configure to delete all cookie and site data each time the browser is closed.
    - Make sure that the browser is closed manually or by the IDE between any change to the app, test user, or provider configuration.
- Use a custom command to open a browser in incognito or private mode in Visual Studio:
    - Open **Browse With** dialog box from Visual Studio's **Run** button.
    - Select the **Add** button.
    - Provide the path to your browser in the **Program** field. The following executable paths are typical installation locations for Windows 10. If your browser is installed in a different location or you aren't using Windows 10, provide the path to the browser's executable.
        - Microsoft Edge: `C:\Program Files (x86)\Microsoft\Edge\Application\msedge.exe`
        - Google Chrome: `C:\Program Files (x86)\Google\Chrome\Application\chrome.exe`
        - Mozilla Firefox: `C:\Program Files\Mozilla Firefox\firefox.exe`
    - In the **Arguments** field, provide the command-line option that the browser uses to open in incognito or private mode. Some browsers require the URL of the app.
        - Microsoft Edge: `-inprivate`
        - Google Chrome: `--incognito --new-window https://localhost:5001`
        - Mozilla Firefox: `-private -url https://localhost:5001`
    - Provide a name in the **Friendly name** field. For example, `Firefox Auth Testing`.
    - Select the **OK** button.
    - To avoid having to select the browser profile for each iteration of testing with an app, set the profile as the default with the **Set as Default** button.
    - Make sure that the browser is closed by the IDE between any change to the app, test user, or provider configuration.

Run the Server app

When testing and troubleshooting a hosted Blazor app, make sure that you're running the app from the `Server` project. For example in Visual Studio, confirm that the Server project is highlighted in **Solution Explorer** before you start the app with any of the following approaches:

- Select the **Run** button.
- Use **Debug** > **Start Debugging** from the menu.
- Press F5.

Inspect the content of a JSON Web Token (JWT)

To decode a JSON Web Token (JWT), use Microsoft's jwt.ms tool. Values in the UI never leave your browser.

Secure an ASP.NET Core Blazor WebAssembly standalone app with Azure Active Directory

9/22/2020 • 8 minutes to read • Edit Online

By Javier Calvarro Nelson and Luke Latham

To create a standalone Blazor WebAssembly app that uses Azure Active Directory (AAD) for authentication:

Create an AAD tenant and web application:

Register a AAD app in the **Azure Active Directory** > **App registrations** area of the Azure portal:

1. Provide a **Name** for the app (for example, **Blazor Standalone AAD**).
2. Choose a **Supported account types**. You may select **Accounts in this organizational directory only** for this experience.
3. Leave the **Redirect URI** drop down set to **Web** and provide the following redirect URI: `https://localhost:{PORT}/authentication/login-callback`. The default port for an app running on Kestrel is 5001. If the app is run on a different Kestrel port, use the app's port. For IIS Express, the randomly generated port for the app can be found in the app's properties in the **Debug** panel. Since the app doesn't exist at this point and the IIS Express port isn't known, return to this step after the app is created and update the redirect URI. A remark appears later in this topic to remind IIS Express users to update the redirect URI.
4. Disable the **Permissions** > **Grant admin consent to openid and offline_access permissions** check box.
5. Select **Register**.

Record the following information:

- Application (client) ID (for example, `41451fa7-82d9-4673-8fa5-69eff5a761fd`)
- Directory (tenant) ID (for example, `e86c78e2-8bb4-4c41-aefd-918e0565a45e`)

In **Authentication** > **Platform configurations** > **Web**:

1. Confirm the **Redirect URI** of `https://localhost:{PORT}/authentication/login-callback` is present.
2. For **Implicit grant**, select the check boxes for **Access tokens** and **ID tokens**.
3. The remaining defaults for the app are acceptable for this experience.
4. Select the **Save** button.

Create the app in an empty folder. Replace the placeholders in the following command with the information recorded earlier and execute the command in a command shell:

```
dotnet new blazorwasm -au SingleOrg --client-id "{CLIENT ID}" -o {APP NAME} --tenant-id "{TENANT ID}"
```

PLACEHOLDER	AZURE PORTAL NAME	EXAMPLE
`{APP NAME}`	—	`BlazorSample`
`{CLIENT ID}`	Application (client) ID	`41451fa7-82d9-4673-8fa5-69eff5a761fd`
`{TENANT ID}`	Directory (tenant) ID	`e86c78e2-8bb4-4c41-aefd-918e0565a45e`

The output location specified with the `-o|--output` option creates a project folder if it doesn't exist and becomes part of the app's name.

> **NOTE**
>
> In the Azure portal, the app's **Authentication** > **Platform configurations** > **Web** > **Redirect URI** is configured for port 5001 for apps that run on the Kestrel server with default settings.
>
> If the app is run on a random IIS Express port, the port for the app can be found in the app's properties in the **Debug** panel.
>
> If the port wasn't configured earlier with the app's known port, return to the app's registration in the Azure portal and update the redirect URI with the correct port.

After creating the app, you should be able to:

- Log into the app using an AAD user account.
- Request access tokens for Microsoft APIs. For more information, see:
  - Access token scopes
  - Quickstart: Configure an application to expose web APIs.

Authentication package

When an app is created to use Work or School Accounts (`SingleOrg`), the app automatically receives a package reference for the Microsoft Authentication Library (`Microsoft.Authentication.WebAssembly.Msal`). The package provides a set of primitives that help the app authenticate users and obtain tokens to call protected APIs.

If adding authentication to an app, manually add the package to the app's project file:

```
<PackageReference Include="Microsoft.Authentication.WebAssembly.Msal"
  Version="{VERSION}" />
```

For the placeholder `{VERSION}`, the latest stable version of the package that matches the app's shared framework version can be found in the package's **Version History** at NuGet.org.

The `Microsoft.Authentication.WebAssembly.Msal` package transitively adds the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package to the app.

Authentication service support

Support for authenticating users is registered in the service container with the AddMsalAuthentication extension method provided by the `Microsoft.Authentication.WebAssembly.Msal` package. This method sets up the services required for the app to interact with the Identity Provider (IP).

`Program.cs`:

```
builder.Services.AddMsalAuthentication(options =>
{
    builder.Configuration.Bind("AzureAd", options.ProviderOptions.Authentication);
});
```

The AddMsalAuthentication method accepts a callback to configure the parameters required to authenticate an app. The values required for configuring the app can be obtained from the AAD configuration when you register the app.

Configuration is supplied by the `wwwroot/appsettings.json` file:

```
{
  "AzureAd": {
    "Authority": "https://login.microsoftonline.com/{TENANT ID}",
    "ClientId": "{CLIENT ID}",
    "ValidateAuthority": true
  }
}
```

Example:

```
{
  "AzureAd": {
    "Authority": "https://login.microsoftonline.com/e86c78e2-...-918e0565a45e",
    "ClientId": "41451fa7-82d9-4673-8fa5-69eff5a761fd",
    "ValidateAuthority": true
  }
}
```

Access token scopes

The Blazor WebAssembly template doesn't automatically configure the app to request an access token for a secure API. To provision an access token as part of the sign-in flow, add the scope to the default access token scopes of the MsalProviderOptions:

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.DefaultAccessTokenScopes.Add("{SCOPE URI}");
});
```

NOTE

If the Azure portal provides the scope URI for the app and the app throws an unhandled exception when it receives a *401 Unauthorized* response from the API, try using a scope URI that doesn't include the scheme and host. For example, the Azure portal may provide one of the following scope URI formats:

- `https://{TENANT}.onmicrosoft.com/{API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}`
- `api://{SERVER API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}`

Try supplying the scope URI without the scheme and host:

```
options.ProviderOptions.DefaultAccessTokenScopes.Add(
    "{SERVER API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}");
```

For example:

```
options.ProviderOptions.DefaultAccessTokenScopes.Add(
    "41451fa7-82d9-4673-8fa5-69eff5a761fd/API.Access");
```

For more information, see the following sections of the *Additional scenarios* article:

- Request additional access tokens
- Attach tokens to outgoing requests

Login mode

The framework defaults to pop-up login mode and falls back to redirect login mode if a pop-up can't be opened. Configure MSAL to use redirect login mode by setting the `LoginMode` property of MsalProviderOptions to `redirect`:

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.LoginMode = "redirect";
});
```

The default setting is `popup`, and the string value isn't case sensitive.

Imports file

The Microsoft.AspNetCore.Components.Authorization namespace is made available throughout the app via the `_Imports.razor` file:

```
@using System.Net.Http
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.Web
@using Microsoft.AspNetCore.Components.WebAssembly.Http
@using Microsoft.JSInterop
@using {APPLICATION ASSEMBLY}
@using {APPLICATION ASSEMBLY}.Shared
```

Index page

The Index page (`wwwroot/index.html`) page includes a script that defines the `AuthenticationService` in JavaScript. `AuthenticationService` handles the low-level details of the OIDC protocol. The app internally calls methods defined in the script to perform the authentication operations.

```
<script src="_content/Microsoft.Authentication.WebAssembly.Msal/
    AuthenticationService.js"></script>
```

App component

The `App` component (`App.razor`) is similar to the `App` component found in Blazor Server apps:

- The CascadingAuthenticationState component manages exposing the AuthenticationState to the rest of the app.
- The AuthorizeRouteView component makes sure that the current user is authorized to access a given page or otherwise renders the `RedirectToLogin` component.
- The `RedirectToLogin` component manages redirecting unauthorized users to the login page.

```
<CascadingAuthenticationState>
    <Router AppAssembly="@typeof(Program).Assembly">
        <Found Context="routeData">
            <AuthorizeRouteView RouteData="@routeData"
                DefaultLayout="@typeof(MainLayout)">
                <NotAuthorized>
                    @if (!context.User.Identity.IsAuthenticated)
                    {
                        <RedirectToLogin />
                    }
                    else
                    {
                        <p>
                            You are not authorized to access
                            this resource.
                        </p>
                    }
                </NotAuthorized>
            </AuthorizeRouteView>
        </Found>
        <NotFound>
            <LayoutView Layout="@typeof(MainLayout)">
                <p>Sorry, there's nothing at this address.</p>
            </LayoutView>
        </NotFound>
    </Router>
</CascadingAuthenticationState>
```

RedirectToLogin component

The `RedirectToLogin` component (`Shared/RedirectToLogin.razor`):

- Manages redirecting unauthorized users to the login page.
- Preserves the current URL that the user is attempting to access so that they can be returned to that page if authentication is successful.

```
@inject NavigationManager Navigation
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@code {
    protected override void OnInitialized()
    {
        Navigation.NavigateTo($"authentication/login?returnUrl=" +
            Uri.EscapeDataString(Navigation.Uri));
    }
}
```

LoginDisplay component

The `LoginDisplay` component (`Shared/LoginDisplay.razor`) is rendered in the `MainLayout` component (`Shared/MainLayout.razor`) and manages the following behaviors:

- For authenticated users:
  - Displays the current username.
  - Offers a button to log out of the app.
- For anonymous users, offers the option to log in.

```
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject NavigationManager Navigation
@inject SignOutSessionStateManager SignOutManager

<AuthorizeView>
    <Authorized>
        Hello, @context.User.Identity.Name!
        <button class="nav-link btn btn-link" @onclick="BeginLogout">
            Log out
        </button>
    </Authorized>
    <NotAuthorized>
        <a href="authentication/login">Log in</a>
    </NotAuthorized>
</AuthorizeView>

@code {
    private async Task BeginLogout(MouseEventArgs args)
    {
        await SignOutManager.SetSignOutState();
        Navigation.NavigateTo("authentication/logout");
    }
}
```

Authentication component

The page produced by the `Authentication` component (`Pages/Authentication.razor`) defines the routes required for handling different authentication stages.

The RemoteAuthenticatorView component:

- Is provided by the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package.
- Manages performing the appropriate actions at each stage of authentication.

```
@page "/authentication/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action" />

@code {
    [Parameter]
    public string Action { get; set; }
}
```

Troubleshoot

Cookies and site data

Cookies and site data can persist across app updates and interfere with testing and troubleshooting. Clear the following when making app code changes, user account changes with the provider, or provider app configuration changes:

- User sign-in cookies
- App cookies
- Cached and stored site data

One approach to prevent lingering cookies and site data from interfering with testing and troubleshooting is to:

- Configure a browser

    - Use a browser for testing that you can configure to delete all cookie and site data each time the browser is closed.
    - Make sure that the browser is closed manually or by the IDE between any change to the app, test user, or provider configuration.
- Use a custom command to open a browser in incognito or private mode in Visual Studio:
    - Open **Browse With** dialog box from Visual Studio's **Run** button.
    - Select the **Add** button.
    - Provide the path to your browser in the **Program** field. The following executable paths are typical installation locations for Windows 10. If your browser is installed in a different location or you aren't using Windows 10, provide the path to the browser's executable.
        - Microsoft Edge: `C:\Program Files (x86)\Microsoft\Edge\Application\msedge.exe`
        - Google Chrome: `C:\Program Files (x86)\Google\Chrome\Application\chrome.exe`
        - Mozilla Firefox: `C:\Program Files\Mozilla Firefox\firefox.exe`
    - In the **Arguments** field, provide the command-line option that the browser uses to open in incognito or private mode. Some browsers require the URL of the app.
        - Microsoft Edge: `-inprivate`
        - Google Chrome: `--incognito --new-window https://localhost:5001`
        - Mozilla Firefox: `-private -url https://localhost:5001`
    - Provide a name in the **Friendly name** field. For example, `Firefox Auth Testing`.
    - Select the **OK** button.
    - To avoid having to select the browser profile for each iteration of testing with an app, set the profile as the default with the **Set as Default** button.
    - Make sure that the browser is closed by the IDE between any change to the app, test user, or provider configuration.

Run the Server app

When testing and troubleshooting a hosted Blazor app, make sure that you're running the app from the `Server` project. For example in Visual Studio, confirm that the Server project is highlighted in **Solution Explorer** before you start the app with any of the following approaches:

- Select the **Run** button.
- Use **Debug** > **Start Debugging** from the menu.
- Press F5.

Inspect the content of a JSON Web Token (JWT)

To decode a JSON Web Token (JWT), use Microsoft's jwt.ms tool. Values in the UI never leave your browser.

Secure an ASP.NET Core Blazor WebAssembly standalone app with Azure Active Directory B2C

9/22/2020 • 9 minutes to read • Edit Online

By Javier Calvarro Nelson and Luke Latham

To create a standalone Blazor WebAssembly app that uses Azure Active Directory (AAD) B2C for authentication:

Follow the guidance in the following topics to create a tenant and register a web app in the Azure Portal:

Create an AAD B2C tenant

Record the following information:

- AAD B2C instance (for example, `https://contoso.b2clogin.com/`, which includes the trailing slash): The instance is the scheme and host of an Azure B2C app registration, which can be found by opening the **Endpoints** window from the **App registrations** page in the Azure portal.
- AAD B2C Primary/Publisher/Tenant domain (for example, `contoso.onmicrosoft.com`): The domain is available as the **Publisher domain** in the **Branding** blade of the Azure portal for the registered app.

Follow the guidance in Tutorial: Register an application in Azure Active Directory B2C again to register an AAD app for the *Client app* and then do the following:

1. In **Azure Active Directory** > **App registrations**, select **New registration**.
2. Provide a **Name** for the app (for example, **Blazor Standalone AAD B2C**).
3. For **Supported account types**, select the multi-tenant option: **Accounts in any organizational directory or any identity provider. For authenticating users with Azure AD B2C.**
4. Leave the **Redirect URI** drop down set to **Web** and provide the following redirect URI: `https://localhost:{PORT}/authentication/login-callback`. The default port for an app running on Kestrel is 5001. If the app is run on a different Kestrel port, use the app's port. For IIS Express, the randomly generated port for the app can be found in the app's properties in the **Debug** panel. Since the app doesn't exist at this point and the IIS Express port isn't known, return to this step after the app is created and update the redirect URI. A remark appears later in this topic to remind IIS Express users to update the redirect URI.
5. Confirm that **Permissions** > **Grant admin consent to openid and offline_access permissions** is enabled.
6. Select **Register**.

Record the Application (client) ID (for example, `41451fa7-82d9-4673-8fa5-69eff5a761fd`).

In **Authentication** > **Platform configurations** > **Web**:

1. Confirm the **Redirect URI** of `https://localhost:{PORT}/authentication/login-callback` is present.
2. For **Implicit grant**, select the check boxes for **Access tokens** and **ID tokens**.
3. The remaining defaults for the app are acceptable for this experience.
4. Select the **Save** button.

In **Home** > **Azure AD B2C** > **User flows**:

Create a sign-up and sign-in user flow

At a minimum, select the **Application claims** > **Display Name** user attribute to populate the `context.User.Identity.Name` in the `LoginDisplay` component (`Shared/LoginDisplay.razor`).

Record the sign-up and sign-in user flow name created for the app (for example, `B2C_1_signupsignin`).

In an empty folder, replace the placeholders in the following command with the information recorded earlier and execute the command in a command shell:

```
dotnet new blazorwasm -au IndividualB2C --aad-b2c-instance "{AAD B2C INSTANCE}" --client-id "{CLIENT ID}" --
domain "{TENANT DOMAIN}" -o {APP NAME} -ssp "{SIGN UP OR SIGN IN POLICY}"
```

PLACEHOLDER	AZURE PORTAL NAME	EXAMPLE
`{AAD B2C INSTANCE}`	Instance	`https://contoso.b2clogin.com/`
`{APP NAME}`	—	`BlazorSample`
`{CLIENT ID}`	Application (client) ID	`41451fa7-82d9-4673-8fa5-69eff5a761fd`
`{SIGN UP OR SIGN IN POLICY}`	Sign-up/sign-in user flow	`B2C_1_signupsignin1`
`{TENANT DOMAIN}`	Primary/Publisher/Tenant domain	`contoso.onmicrosoft.com`

The output location specified with the `-o|--output` option creates a project folder if it doesn't exist and becomes part of the app's name.

> **NOTE**
>
> In the Azure portal, the app's **Authentication** > **Platform configurations** > **Web** > **Redirect URI** is configured for port 5001 for apps that run on the Kestrel server with default settings.
>
> If the app is run on a random IIS Express port, the port for the app can be found in the app's properties in the **Debug** panel.
>
> If the port wasn't configured earlier with the app's known port, return to the app's registration in the Azure portal and update the redirect URI with the correct port.

After creating the app, you should be able to:

- Log into the app using an AAD user account.
- Request access tokens for Microsoft APIs. For more information, see:
  - Access token scopes
  - Quickstart: Configure an application to expose web APIs.

Authentication package

When an app is created to use an Individual B2C Account (`IndividualB2C`), the app automatically receives a package reference for the Microsoft Authentication Library (`Microsoft.Authentication.WebAssembly.Msal`). The package provides a set of primitives that help the app authenticate users and obtain tokens to call protected APIs.

If adding authentication to an app, manually add the package to the app's project file:

```
<PackageReference Include="Microsoft.Authentication.WebAssembly.Msal"
  Version="{VERSION}" />
```

For the placeholder `{VERSION}`, the latest stable version of the package that matches the app's shared framework version can be found in the package's **Version History** at NuGet.org.

The `Microsoft.Authentication.WebAssembly.Msal` package transitively adds the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package to the app.

Authentication service support

Support for authenticating users is registered in the service container with the AddMsalAuthentication extension method provided by the `Microsoft.Authentication.WebAssembly.Msal` package. This method sets up all of the services required for the app to interact with the Identity Provider (IP).

`Program.cs`:

```
builder.Services.AddMsalAuthentication(options =>
{
    builder.Configuration.Bind("AzureAdB2C", options.ProviderOptions.Authentication);
});
```

The AddMsalAuthentication method accepts a callback to configure the parameters required to authenticate an app. The values required for configuring the app can be obtained from the AAD configuration when you register the app.

Configuration is supplied by the `wwwroot/appsettings.json` file:

```
{
  "AzureAdB2C": {
    "Authority": "{AAD B2C INSTANCE}{DOMAIN}/{SIGN UP OR SIGN IN POLICY}",
    "ClientId": "{CLIENT ID}",
    "ValidateAuthority": false
  }
}
```

Example:

```
{
  "AzureAdB2C": {
    "Authority": "https://contoso.b2clogin.com/contoso.onmicrosoft.com/B2C_1_signupsignin1",
    "ClientId": "41451fa7-82d9-4673-8fa5-69eff5a761fd",
    "ValidateAuthority": false
  }
}
```

Access token scopes

The Blazor WebAssembly template doesn't automatically configure the app to request an access token for a secure API. To provision an access token as part of the sign-in flow, add the scope to the default access token scopes of the MsalProviderOptions:

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.DefaultAccessTokenScopes.Add("{SCOPE URI}");
});
```

NOTE

If the Azure portal provides the scope URI for the app and the app throws an unhandled exception when it receives a *401 Unauthorized* response from the API, try using a scope URI that doesn't include the scheme and host. For example, the Azure portal may provide one of the following scope URI formats:

- `https://{TENANT}.onmicrosoft.com/{API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}`
- `api://{SERVER API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}`

Try supplying the scope URI without the scheme and host:

```
options.ProviderOptions.DefaultAccessTokenScopes.Add(
    "{SERVER API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}");
```

For example:

```
options.ProviderOptions.DefaultAccessTokenScopes.Add(
    "41451fa7-82d9-4673-8fa5-69eff5a761fd/API.Access");
```

For more information, see the following sections of the *Additional scenarios* article:

- Request additional access tokens
- Attach tokens to outgoing requests

Login mode

The framework defaults to pop-up login mode and falls back to redirect login mode if a pop-up can't be opened. Configure MSAL to use redirect login mode by setting the `LoginMode` property of MsalProviderOptions to `redirect`:

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.LoginMode = "redirect";
});
```

The default setting is `popup`, and the string value isn't case sensitive.

Imports file

The Microsoft.AspNetCore.Components.Authorization namespace is made available throughout the app via the `_Imports.razor` file:

```
@using System.Net.Http
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.Web
@using Microsoft.AspNetCore.Components.WebAssembly.Http
@using Microsoft.JSInterop
@using {APPLICATION ASSEMBLY}
@using {APPLICATION ASSEMBLY}.Shared
```

Index page

The Index page (`wwwroot/index.html`) page includes a script that defines the `AuthenticationService` in JavaScript. `AuthenticationService` handles the low-level details of the OIDC protocol. The app internally calls methods defined in the script to perform the authentication operations.

```
<script src="_content/Microsoft.Authentication.WebAssembly.Msal/
    AuthenticationService.js"></script>
```

App component

The `App` component (`App.razor`) is similar to the `App` component found in Blazor Server apps:

- The CascadingAuthenticationState component manages exposing the AuthenticationState to the rest of the app.
- The AuthorizeRouteView component makes sure that the current user is authorized to access a given page or otherwise renders the `RedirectToLogin` component.
- The `RedirectToLogin` component manages redirecting unauthorized users to the login page.

```
<CascadingAuthenticationState>
    <Router AppAssembly="@typeof(Program).Assembly">
        <Found Context="routeData">
            <AuthorizeRouteView RouteData="@routeData"
                DefaultLayout="@typeof(MainLayout)">
                <NotAuthorized>
                    @if (!context.User.Identity.IsAuthenticated)
                    {
                        <RedirectToLogin />
                    }
                    else
                    {
                        <p>
                            You are not authorized to access
                            this resource.
                        </p>
                    }
                </NotAuthorized>
            </AuthorizeRouteView>
        </Found>
        <NotFound>
            <LayoutView Layout="@typeof(MainLayout)">
                <p>Sorry, there's nothing at this address.</p>
            </LayoutView>
        </NotFound>
    </Router>
</CascadingAuthenticationState>
```

RedirectToLogin component

The `RedirectToLogin` component (`Shared/RedirectToLogin.razor`):

- Manages redirecting unauthorized users to the login page.
- Preserves the current URL that the user is attempting to access so that they can be returned to that page if authentication is successful.

```
@inject NavigationManager Navigation
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@code {
    protected override void OnInitialized()
    {
        Navigation.NavigateTo($"authentication/login?returnUrl=" +
            Uri.EscapeDataString(Navigation.Uri));
    }
}
```

LoginDisplay component

The `LoginDisplay` component (`Shared/LoginDisplay.razor`) is rendered in the `MainLayout` component (`Shared/MainLayout.razor`) and manages the following behaviors:

- For authenticated users:
  - Displays the current username.
  - Offers a button to log out of the app.
- For anonymous users, offers the option to log in.

```
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject NavigationManager Navigation
@inject SignOutSessionStateManager SignOutManager

<AuthorizeView>
    <Authorized>
        Hello, @context.User.Identity.Name!
        <button class="nav-link btn btn-link" @onclick="BeginLogout">
            Log out
        </button>
    </Authorized>
    <NotAuthorized>
        <a href="authentication/login">Log in</a>
    </NotAuthorized>
</AuthorizeView>

@code {
    private async Task BeginLogout(MouseEventArgs args)
    {
        await SignOutManager.SetSignOutState();
        Navigation.NavigateTo("authentication/logout");
    }
}
```

Authentication component

The page produced by the `Authentication` component (`Pages/Authentication.razor`) defines the routes required for handling different authentication stages.

The RemoteAuthenticatorView component:

- Is provided by the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package.
- Manages performing the appropriate actions at each stage of authentication.

```
@page "/authentication/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action" />

@code {
    [Parameter]
    public string Action { get; set; }
}
```

Custom user flows

The Microsoft Authentication Library (Microsoft.Authentication.WebAssembly.Msal, NuGet package) doesn't support AAD B2C user flows by default. Create custom user flows in developer code.

For more information on how to build a challenge for a custom user flow, see User flows in Azure Active Directory B2C.

Troubleshoot

Cookies and site data

Cookies and site data can persist across app updates and interfere with testing and troubleshooting. Clear the following when making app code changes, user account changes with the provider, or provider app configuration changes:

- User sign-in cookies
- App cookies
- Cached and stored site data

One approach to prevent lingering cookies and site data from interfering with testing and troubleshooting is to:

- Configure a browser
  - Use a browser for testing that you can configure to delete all cookie and site data each time the browser is closed.
  - Make sure that the browser is closed manually or by the IDE between any change to the app, test user, or provider configuration.
- Use a custom command to open a browser in incognito or private mode in Visual Studio:
  - Open **Browse With** dialog box from Visual Studio's **Run** button.
  - Select the **Add** button.
  - Provide the path to your browser in the **Program** field. The following executable paths are typical installation locations for Windows 10. If your browser is installed in a different location or you aren't using Windows 10, provide the path to the browser's executable.
    - Microsoft Edge: `C:\Program Files (x86)\Microsoft\Edge\Application\msedge.exe`
    - Google Chrome: `C:\Program Files (x86)\Google\Chrome\Application\chrome.exe`
    - Mozilla Firefox: `C:\Program Files\Mozilla Firefox\firefox.exe`
  - In the **Arguments** field, provide the command-line option that the browser uses to open in incognito or private mode. Some browsers require the URL of the app.
    - Microsoft Edge: `-inprivate`
    - Google Chrome: `--incognito --new-window https://localhost:5001`
    - Mozilla Firefox: `-private -url https://localhost:5001`
  - Provide a name in the **Friendly name** field. For example, `Firefox Auth Testing`.
  - Select the **OK** button.

- To avoid having to select the browser profile for each iteration of testing with an app, set the profile as the default with the **Set as Default** button.
- Make sure that the browser is closed by the IDE between any change to the app, test user, or provider configuration.

Run the Server app

When testing and troubleshooting a hosted Blazor app, make sure that you're running the app from the `Server` project. For example in Visual Studio, confirm that the Server project is highlighted in **Solution Explorer** before you start the app with any of the following approaches:

- Select the **Run** button.
- Use **Debug** > **Start Debugging** from the menu.
- Press F5.

Inspect the content of a JSON Web Token (JWT)

To decode a JSON Web Token (JWT), use Microsoft's jwt.ms tool. Values in the UI never leave your browser.

Secure an ASP.NET Core Blazor WebAssembly hosted app with Azure Active Directory

9/22/2020 • 14 minutes to read • Edit Online

By Javier Calvarro Nelson and Luke Latham

This article describes how to create a hosted Blazor WebAssembly app that uses Azure Active Directory (AAD) for authentication.

Register apps in AAD and create solution

Create a tenant

Follow the guidance in Quickstart: Set up a tenant to create a tenant in AAD.

Register a server API app

Follow the guidance in Quickstart: Register an application with the Microsoft identity platform and subsequent Azure AAD topics to register an AAD app for the *Server API app* and then do the following:

1. In **Azure Active Directory** > **App registrations**, select **New registration**.
2. Provide a **Name** for the app (for example, **Blazor Server AAD**).
3. Choose a **Supported account types**. You may select **Accounts in this organizational directory only** (single tenant) for this experience.
4. The *Server API app* doesn't require a **Redirect URI** in this scenario, so leave the drop down set to **Web** and don't enter a redirect URI.
5. Disable the **Permissions** > **Grant admin consent to openid and offline_access permissions** check box.
6. Select **Register**.

Record the following information:

- *Server API app* Application (client) ID (for example, `41451fa7-82d9-4673-8fa5-69eff5a761fd`)
- Directory (tenant) ID (for example, `e86c78e2-8bb4-4c41-aefd-918e0565a45e`)
- AAD Primary/Publisher/Tenant domain (for example, `contoso.onmicrosoft.com`): The domain is available as the **Publisher domain** in the **Branding** blade of the Azure portal for the registered app.

In **API permissions**, remove the **Microsoft Graph** > **User.Read** permission, as the app doesn't require sign in or user profile access.

In **Expose an API**:

1. Select **Add a scope**.
2. Select **Save and continue**.
3. Provide a **Scope name** (for example, `API.Access`).
4. Provide an **Admin consent display name** (for example, `Access API`).
5. Provide an **Admin consent description** (for example, `Allows the app to access server app API endpoints.`).
6. Confirm that the **State** is set to **Enabled**.
7. Select **Add scope**.

Record the following information:

- App ID URI (for example, `https://contoso.onmicrosoft.com/41451fa7-82d9-4673-8fa5-69eff5a761fd`, `api://41451fa7-82d9-4673-8fa5-69eff5a761fd`, or the custom value that you provided)
- Scope name (for example, `API.Access`)

The App ID URI might require a special configuration in the client app, which is described in the Access token scopes section later in this topic.

Register a client app

Follow the guidance in Quickstart: Register an application with the Microsoft identity platform and subsequent Azure AAD topics to register a AAD app for the *Client app* and then do the following:

1. In **Azure Active Directory** > **App registrations**, select **New registration**.
2. Provide a **Name** for the app (for example, **Blazor Client AAD**).
3. Choose a **Supported account types**. You may select **Accounts in this organizational directory only** (single tenant) for this experience.
4. Leave the **Redirect URI** drop down set to **Web** and provide the following redirect URI: `https://localhost:{PORT}/authentication/login-callback`. The default port for an app running on Kestrel is 5001. If the app is run on a different Kestrel port, use the app's port. For IIS Express, the randomly generated port for the app can be found in the Server app's properties in the **Debug** panel. Since the app doesn't exist at this point and the IIS Express port isn't known, return to this step after the app is created and update the redirect URI. A remark appears in the Create the app section to remind IIS Express users to update the redirect URI.
5. Disable the **Permissions** > **Grant admin consent to openid and offline_access permissions** check box.
6. Select **Register**.

Record the *Client app* Application (client) ID (for example, `4369008b-21fa-427c-abaa-9b53bf58e538`).

In **Authentication** > **Platform configurations** > **Web**:

1. Confirm the **Redirect URI** of `https://localhost:{PORT}/authentication/login-callback` is present.
2. For **Implicit grant**, select the check boxes for **Access tokens** and **ID tokens**.
3. The remaining defaults for the app are acceptable for this experience.
4. Select the **Save** button.

In **API permissions**:

1. Confirm that the app has **Microsoft Graph** > **User.Read** permission.
2. Select **Add a permission** followed by **My APIs**.
3. Select the *Server API app* from the **Name** column (for example, **Blazor Server AAD**).
4. Open the **API** list.
5. Enable access to the API (for example, `API.Access`).
6. Select **Add permissions**.
7. Select the **Grant admin consent for {TENANT NAME}** button. Select **Yes** to confirm.

Create the app

In an empty folder, replace the placeholders in the following command with the information recorded earlier and execute the command in a command shell:

```
dotnet new blazorwasm -au SingleOrg --api-client-id "{SERVER API APP CLIENT ID}" --app-id-uri "{SERVER API APP ID URI}" --client-id "{CLIENT APP CLIENT ID}" --default-scope "{DEFAULT SCOPE}" --domain "{TENANT DOMAIN}" -ho -o {APP NAME} --tenant-id "{TENANT ID}"
```

PLACEHOLDER	AZURE PORTAL NAME	EXAMPLE
`{APP NAME}`	—	`BlazorSample`
`{CLIENT APP CLIENT ID}`	Application (client) ID for the *Client app*	`4369008b-21fa-427c-abaa-9b53bf58e538`
`{DEFAULT SCOPE}`	Scope name	`API.Access`
`{SERVER API APP CLIENT ID}`	Application (client) ID for the *Server API app*	`41451fa7-82d9-4673-8fa5-69eff5a761fd`
`{SERVER API APP ID URI}`	Application ID URI (see note)	`41451fa7-82d9-4673-8fa5-69eff5a761fd`
`{TENANT DOMAIN}`	Primary/Publisher/Tenant domain	`contoso.onmicrosoft.com`
`{TENANT ID}`	Directory (tenant) ID	`e86c78e2-8bb4-4c41-aefd-918e0565a45e`

The output location specified with the `-o|--output` option creates a project folder if it doesn't exist and becomes part of the app's name.

> **NOTE**
>
> Pass the App ID URI to the `app-id-uri` option, but note a configuration change might be required in the client app, which is described in the Access token scopes section.

> **NOTE**
>
> In the Azure portal, the *Client app's* **Authentication** > **Platform configurations** > **Web** > **Redirect URI** is configured for port 5001 for apps that run on the Kestrel server with default settings.
>
> If the *Client app* is run on a random IIS Express port, the port for the app can be found in the *Server API app's* properties in the **Debug** panel.
>
> If the port wasn't configured earlier with the *Client app's* known port, return to the *Client app's* registration in the Azure portal and update the redirect URI with the correct port.

Server app configuration

This section pertains to the solution's `Server` app.

Authentication package

The support for authenticating and authorizing calls to ASP.NET Core Web APIs is provided by the `Microsoft.AspNetCore.Authentication.AzureAD.UI` package:

```
<PackageReference Include="Microsoft.AspNetCore.Authentication.AzureAD.UI"
  Version="{VERSION}" />
```

For the placeholder `{VERSION}`, the latest stable version of the package that matches the app's shared framework version can be found in the package's **Version History** at NuGet.org.

Authentication service support

The `AddAuthentication` method sets up authentication services within the app and configures the JWT Bearer handler as the default authentication method. The AddAzureADBearer method sets up the specific parameters in the JWT Bearer handler required to validate tokens emitted by the Azure Active Directory:

```
services.AddAuthentication(AzureADDefaults.BearerAuthenticationScheme)
    .AddAzureADBearer(options => Configuration.Bind("AzureAd", options));
```

UseAuthentication and UseAuthorization ensure that:

- The app attempts to parse and validate tokens on incoming requests.
- Any request attempting to access a protected resource without proper credentials fails.

```
app.UseAuthentication();
app.UseAuthorization();
```

User.Identity.Name

By default, the Server app API populates `User.Identity.Name` with the value from the `http://schemas.xmlsoap.org/ws/2005/05/identity/claims/name` claim type (for example, `2d64b3da-d9d5-42c6-9352-53d8df33d770@contoso.onmicrosoft.com`).

To configure the app to receive the value from the `name` claim type, configure the TokenValidationParameters.NameClaimType of the JwtBearerOptions in `Startup.ConfigureServices`:

```
using Microsoft.AspNetCore.Authentication.JwtBearer;

...

services.Configure<JwtBearerOptions>(
    AzureADDefaults.JwtBearerAuthenticationScheme, options =>
    {
        options.TokenValidationParameters.NameClaimType = "name";
    });
```

App settings

The `appsettings.json` file contains the options to configure the JWT bearer handler used to validate access tokens:

```
{
  "AzureAd": {
    "Instance": "https://login.microsoftonline.com/",
    "Domain": "{DOMAIN}",
    "TenantId": "{TENANT ID}",
    "ClientId": "{SERVER API APP CLIENT ID}",
  }
}
```

Example:

```
{
  "AzureAd": {
    "Instance": "https://login.microsoftonline.com/",
    "Domain": "contoso.onmicrosoft.com",
    "TenantId": "e86c78e2-8bb4-4c41-aefd-918e0565a45e",
    "ClientId": "41451fa7-82d9-4673-8fa5-69eff5a761fd",
  }
}
```

WeatherForecast controller

The WeatherForecast controller (*Controllers/WeatherForecastController.cs*) exposes a protected API with the `[Authorize]` attribute applied to the controller. It's **important** to understand that:

- The `[Authorize]` attribute in this API controller is the only thing that protect this API from unauthorized access.
- The `[Authorize]` attribute used in the Blazor WebAssembly app only serves as a hint to the app that the user should be authorized for the app to work correctly.

```
[Authorize]
[ApiController]
[Route("[controller]")]
public class WeatherForecastController : ControllerBase
{
    [HttpGet]
    public IEnumerable<WeatherForecast> Get()
    {
        ...
    }
}
```

Client app configuration

This section pertains to the solution's `Client` app.

Authentication package

When an app is created to use Work or School Accounts (`SingleOrg`), the app automatically receives a package reference for the Microsoft Authentication Library (`Microsoft.Authentication.WebAssembly.Msal`). The package provides a set of primitives that help the app authenticate users and obtain tokens to call protected APIs.

If adding authentication to an app, manually add the package to the app's project file:

```
<PackageReference Include="Microsoft.Authentication.WebAssembly.Msal"
  Version="{VERSION}" />
```

For the placeholder `{VERSION}` , the latest stable version of the package that matches the app's shared framework version can be found in the package's **Version History** at NuGet.org.

The `Microsoft.Authentication.WebAssembly.Msal` package transitively adds the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package to the app.

Authentication service support

Support for HttpClient instances is added that include access tokens when making requests to the server project.

`Program.cs` :

```
builder.Services.AddHttpClient("{APP ASSEMBLY}.ServerAPI", client =>
        client.BaseAddress = new Uri(builder.HostEnvironment.BaseAddress))
    .AddHttpMessageHandler<BaseAddressAuthorizationMessageHandler>();

builder.Services.AddScoped(sp => sp.GetRequiredService<IHttpClientFactory>()
    .CreateClient("{APP ASSEMBLY}.ServerAPI"));
```

The placeholder `{APP ASSEMBLY}` is the app's assembly name (for example, `BlazorSample.ServerAPI`).

Support for authenticating users is registered in the service container with the AddMsalAuthentication extension method provided by the `Microsoft.Authentication.WebAssembly.Msal` package. This method sets up the services required for the app to interact with the Identity Provider (IP).

`Program.cs`:

```
builder.Services.AddMsalAuthentication(options =>
{
    builder.Configuration.Bind("AzureAd", options.ProviderOptions.Authentication);
    options.ProviderOptions.DefaultAccessTokenScopes.Add("{SCOPE URI}");
});
```

The AddMsalAuthentication method accepts a callback to configure the parameters required to authenticate an app. The values required for configuring the app can be obtained from the Azure Portal AAD configuration when you register the app.

Configuration is supplied by the `wwwroot/appsettings.json` file:

```
{
  "AzureAd": {
    "Authority": "https://login.microsoftonline.com/{TENANT ID}",
    "ClientId": "{CLIENT APP CLIENT ID}",
    "ValidateAuthority": true
  }
}
```

Example:

```
{
  "AzureAd": {
    "Authority": "https://login.microsoftonline.com/e86c78e2-...-918e0565a45e",
    "ClientId": "4369008b-21fa-427c-abaa-9b53bf58e538",
    "ValidateAuthority": true
  }
}
```

Access token scopes

The default access token scopes represent the list of access token scopes that are:

- Included by default in the sign in request.
- Used to provision an access token immediately after authentication.

All scopes must belong to the same app per Azure Active Directory rules. Additional scopes can be added for additional API apps as needed:

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.DefaultAccessTokenScopes.Add("{SCOPE URI}");
});
```

NOTE

If the Azure portal provides the scope URI for the app and the app throws an unhandled exception when it receives a *401 Unauthorized* response from the API, try using a scope URI that doesn't include the scheme and host. For example, the Azure portal may provide one of the following scope URI formats:

- `https://{TENANT}.onmicrosoft.com/{API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}`
- `api://{SERVER API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}`

Try supplying the scope URI without the scheme and host:

```
options.ProviderOptions.DefaultAccessTokenScopes.Add(
    "{SERVER API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}");
```

For example:

```
options.ProviderOptions.DefaultAccessTokenScopes.Add(
    "41451fa7-82d9-4673-8fa5-69eff5a761fd/API.Access");
```

For more information, see the following sections of the *Additional scenarios* article:

- Request additional access tokens
- Attach tokens to outgoing requests

Login mode

The framework defaults to pop-up login mode and falls back to redirect login mode if a pop-up can't be opened. Configure MSAL to use redirect login mode by setting the `LoginMode` property of MsalProviderOptions to `redirect`:

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.LoginMode = "redirect";
});
```

The default setting is `popup`, and the string value isn't case sensitive.

Imports file

The Microsoft.AspNetCore.Components.Authorization namespace is made available throughout the app via the `_Imports.razor` file:

```
@using System.Net.Http
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.Web
@using Microsoft.AspNetCore.Components.WebAssembly.Http
@using Microsoft.JSInterop
@using {APPLICATION ASSEMBLY}.Client
@using {APPLICATION ASSEMBLY}.Client.Shared
```

Index page

The Index page (`wwwroot/index.html`) page includes a script that defines the `AuthenticationService` in JavaScript. `AuthenticationService` handles the low-level details of the OIDC protocol. The app internally calls methods defined in the script to perform the authentication operations.

```
<script src="_content/Microsoft.Authentication.WebAssembly.Msal/
    AuthenticationService.js"></script>
```

App component

The `App` component (`App.razor`) is similar to the `App` component found in Blazor Server apps:

- The CascadingAuthenticationState component manages exposing the AuthenticationState to the rest of the app.
- The AuthorizeRouteView component makes sure that the current user is authorized to access a given page or otherwise renders the `RedirectToLogin` component.
- The `RedirectToLogin` component manages redirecting unauthorized users to the login page.

```
<CascadingAuthenticationState>
    <Router AppAssembly="@typeof(Program).Assembly">
        <Found Context="routeData">
            <AuthorizeRouteView RouteData="@routeData"
                DefaultLayout="@typeof(MainLayout)">
                <NotAuthorized>
                    @if (!context.User.Identity.IsAuthenticated)
                    {
                        <RedirectToLogin />
                    }
                    else
                    {
                        <p>
                            You are not authorized to access
                            this resource.
                        </p>
                    }
                </NotAuthorized>
            </AuthorizeRouteView>
        </Found>
        <NotFound>
            <LayoutView Layout="@typeof(MainLayout)">
                <p>Sorry, there's nothing at this address.</p>
            </LayoutView>
        </NotFound>
    </Router>
</CascadingAuthenticationState>
```

RedirectToLogin component

The `RedirectToLogin` component (`Shared/RedirectToLogin.razor`):

- Manages redirecting unauthorized users to the login page.
- Preserves the current URL that the user is attempting to access so that they can be returned to that page if authentication is successful.

```
@inject NavigationManager Navigation
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@code {
    protected override void OnInitialized()
    {
        Navigation.NavigateTo($"authentication/login?returnUrl=" +
            Uri.EscapeDataString(Navigation.Uri));
    }
}
```

LoginDisplay component

The `LoginDisplay` component (`Shared/LoginDisplay.razor`) is rendered in the `MainLayout` component (`Shared/MainLayout.razor`) and manages the following behaviors:

- For authenticated users:
  - Displays the current username.
  - Offers a button to log out of the app.
- For anonymous users, offers the option to log in.

```
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject NavigationManager Navigation
@inject SignOutSessionStateManager SignOutManager

<AuthorizeView>
    <Authorized>
        Hello, @context.User.Identity.Name!
        <button class="nav-link btn btn-link" @onclick="BeginLogout">
            Log out
        </button>
    </Authorized>
    <NotAuthorized>
        <a href="authentication/login">Log in</a>
    </NotAuthorized>
</AuthorizeView>

@code {
    private async Task BeginLogout(MouseEventArgs args)
    {
        await SignOutManager.SetSignOutState();
        Navigation.NavigateTo("authentication/logout");
    }
}
```

Authentication component

The page produced by the `Authentication` component (`Pages/Authentication.razor`) defines the routes required for handling different authentication stages.

The RemoteAuthenticatorView component:

- Is provided by the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package.
- Manages performing the appropriate actions at each stage of authentication.

```
@page "/authentication/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action" />

@code {
    [Parameter]
    public string Action { get; set; }
}
```

FetchData component

The `FetchData` component shows how to:

- Provision an access token.
- Use the access token to call a protected resource API in the *Server* app.

The `@attribute [Authorize]` directive indicates to the Blazor WebAssembly authorization system that the user must be authorized in order to visit this component. The presence of the attribute in the `Client` app doesn't prevent the API on the server from being called without proper credentials. The `Server` app also must use `[Authorize]` on the appropriate endpoints to correctly protect them.

IAccessTokenProvider.RequestAccessToken takes care of requesting an access token that can be added to the request to call the API. If the token is cached or the service is able to provision a new access token without user interaction, the token request succeeds. Otherwise, the token request fails with an AccessTokenNotAvailableException, which is caught in a `try-catch` statement.

In order to obtain the actual token to include in the request, the app must check that the request succeeded by calling `tokenResult.TryGetToken(out var token)`.

If the request was successful, the token variable is populated with the access token. The AccessToken.Value property of the token exposes the literal string to include in the `Authorization` request header.

If the request failed because the token couldn't be provisioned without user interaction, the token result contains a redirect URL. Navigating to this URL takes the user to the login page and back to the current page after a successful authentication.

```
@page "/fetchdata"
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@using {APP NAMESPACE}.Shared
@attribute [Authorize]
@inject HttpClient Http

...

@code {
    private WeatherForecast[] forecasts;

    protected override async Task OnInitializedAsync()
    {
        try
        {
            forecasts = await Http.GetFromJsonAsync<WeatherForecast[]>("WeatherForecast");
        }
        catch (AccessTokenNotAvailableException exception)
        {
            exception.Redirect();
        }
    }
}
```

Run the app

Run the app from the Server project. When using Visual Studio, either:

- Set the **Startup Projects** drop down list in the toolbar to the *Server API app* and select the **Run** button.
- Select the Server project in **Solution Explorer** and select the **Run** button in the toolbar or start the app from the **Debug** menu.

Troubleshoot

Cookies and site data

Cookies and site data can persist across app updates and interfere with testing and troubleshooting. Clear the following when making app code changes, user account changes with the provider, or provider app configuration changes:

- User sign-in cookies
- App cookies
- Cached and stored site data

One approach to prevent lingering cookies and site data from interfering with testing and troubleshooting is to:

- Configure a browser
  - Use a browser for testing that you can configure to delete all cookie and site data each time the browser is closed.
  - Make sure that the browser is closed manually or by the IDE between any change to the app, test user, or provider configuration.
- Use a custom command to open a browser in incognito or private mode in Visual Studio:
  - Open **Browse With** dialog box from Visual Studio's **Run** button.
  - Select the **Add** button.
  - Provide the path to your browser in the **Program** field. The following executable paths are typical installation locations for Windows 10. If your browser is installed in a different location or you aren't using Windows 10, provide the path to the browser's executable.

    - Microsoft Edge: `C:\Program Files (x86)\Microsoft\Edge\Application\msedge.exe`
    - Google Chrome: `C:\Program Files (x86)\Google\Chrome\Application\chrome.exe`
    - Mozilla Firefox: `C:\Program Files\Mozilla Firefox\firefox.exe`
  - In the **Arguments** field, provide the command-line option that the browser uses to open in incognito or private mode. Some browsers require the URL of the app.
    - Microsoft Edge: `-inprivate`
    - Google Chrome: `--incognito --new-window https://localhost:5001`
    - Mozilla Firefox: `-private -url https://localhost:5001`
  - Provide a name in the **Friendly name** field. For example, `Firefox Auth Testing`.
  - Select the **OK** button.
  - To avoid having to select the browser profile for each iteration of testing with an app, set the profile as the default with the **Set as Default** button.
  - Make sure that the browser is closed by the IDE between any change to the app, test user, or provider configuration.

Run the Server app

When testing and troubleshooting a hosted Blazor app, make sure that you're running the app from the `Server` project. For example in Visual Studio, confirm that the Server project is highlighted in **Solution Explorer** before you start the app with any of the following approaches:

- Select the **Run** button.
- Use **Debug** > **Start Debugging** from the menu.
- Press F5.

Inspect the content of a JSON Web Token (JWT)

To decode a JSON Web Token (JWT), use Microsoft's jwt.ms tool. Values in the UI never leave your browser.

Secure an ASP.NET Core Blazor WebAssembly hosted app with Azure Active Directory B2C

9/22/2020 • 15 minutes to read • Edit Online

By Javier Calvarro Nelson and Luke Latham

This article describes how to create a hosted Blazor WebAssembly app that uses Azure Active Directory (AAD) B2C for authentication.

Register apps in AAD B2C and create solution

Create a tenant

Follow the guidance in Tutorial: Create an Azure Active Directory B2C tenant to create an AAD B2C tenant.

Record the AAD B2C instance (for example, `https://contoso.b2clogin.com/`, which includes the trailing slash). The instance is the scheme and host of an Azure B2C app registration, which can be found by opening the **Endpoints** window from the **App registrations** page in the Azure portal.

Register a server API app

Follow the guidance in Tutorial: Register an application in Azure Active Directory B2C to register an AAD app for the *Server API app* and then do the following:

1. In **Azure Active Directory** > **App registrations**, select **New registration**.
2. Provide a **Name** for the app (for example, **Blazor Server AAD B2C**).
3. For **Supported account types**, select the multi-tenant option: **Accounts in any organizational directory or any identity provider. For authenticating users with Azure AD B2C.**
4. The *Server API app* doesn't require a **Redirect URI** in this scenario, so leave the drop down set to **Web** and don't enter a redirect URI.
5. Confirm that **Permissions** > **Grant admin consent to openid and offline_access permissions** is enabled.
6. Select **Register**.

Record the following information:

- *Server API app* Application (client) ID (for example, `41451fa7-82d9-4673-8fa5-69eff5a761fd`)
- AAD Primary/Publisher/Tenant domain (for example, `contoso.onmicrosoft.com`): The domain is available as the **Publisher domain** in the **Branding** blade of the Azure portal for the registered app.

In **Expose an API**:

1. Select **Add a scope**.
2. Select **Save and continue**.
3. Provide a **Scope name** (for example, `API.Access`).
4. Provide an **Admin consent display name** (for example, `Access API`).
5. Provide an **Admin consent description** (for example, `Allows the app to access server app API endpoints.`).
6. Confirm that the **State** is set to **Enabled**.
7. Select **Add scope**.

Record the following information:

- App ID URI (for example, `https://contoso.onmicrosoft.com/41451fa7-82d9-4673-8fa5-69eff5a761fd`, `api://41451fa7-82d9-4673-8fa5-69eff5a761fd`, or the custom value that you provided)
- Scope name (for example, `API.Access`)

The App ID URI might require a special configuration in the client app, which is described in the Access token scopes section later in this topic.

Register a client app

Follow the guidance in Tutorial: Register an application in Azure Active Directory B2C again to register an AAD app for the *Client app* and then do the following:

1. In **Azure Active Directory** > **App registrations**, select **New registration**.
2. Provide a **Name** for the app (for example, **Blazor Client AAD B2C**).
3. For **Supported account types**, select the multi-tenant option: **Accounts in any organizational directory or any identity provider. For authenticating users with Azure AD B2C.**
4. Leave the **Redirect URI** drop down set to **Web** and provide the following redirect URI: `https://localhost:{PORT}/authentication/login-callback`. The default port for an app running on Kestrel is 5001. If the app is run on a different Kestrel port, use the app's port. For IIS Express, the randomly generated port for the app can be found in the Server app's properties in the **Debug** panel. Since the app doesn't exist at this point and the IIS Express port isn't known, return to this step after the app is created and update the redirect URI. A remark appears in the Create the app section to remind IIS Express users to update the redirect URI.
5. Confirm that **Permissions** > **Grant admin consent to openid and offline_access permissions** is enabled.
6. Select **Register**.

Record the Application (client) ID (for example, `4369008b-21fa-427c-abaa-9b53bf58e538`).

In **Authentication** > **Platform configurations** > **Web**:

1. Confirm the **Redirect URI** of `https://localhost:{PORT}/authentication/login-callback` is present.
2. For **Implicit grant**, select the check boxes for **Access tokens** and **ID tokens**.
3. The remaining defaults for the app are acceptable for this experience.
4. Select the **Save** button.

In **API permissions**:

1. Select **Add a permission** followed by **My APIs**.
2. Select the *Server API app* from the **Name** column (for example, **Blazor Server AAD B2C**).
3. Open the **API** list.
4. Enable access to the API (for example, `API.Access`).
5. Select **Add permissions**.
6. Select the **Grant admin consent for {TENANT NAME}** button. Select **Yes** to confirm.

In **Home** > **Azure AD B2C** > **User flows**:

Create a sign-up and sign-in user flow

At a minimum, select the **Application claims** > **Display Name** user attribute to populate the `context.User.Identity.Name` in the `LoginDisplay` component (`Shared/LoginDisplay.razor`).

Record the sign-up and sign-in user flow name created for the app (for example, `B2C_1_signupsignin`).

Create the app

Replace the placeholders in the following command with the information recorded earlier and execute the command in a command shell:

```
dotnet new blazorwasm -au IndividualB2C --aad-b2c-instance "{AAD B2C INSTANCE}" --api-client-id "{SERVER API APP CLIENT ID}" --app-id-uri "{SERVER API APP ID URI}" --client-id "{CLIENT APP CLIENT ID}" --default-scope "{DEFAULT SCOPE}" --domain "{TENANT DOMAIN}" -ho -o {APP NAME} -ssp "{SIGN UP OR SIGN IN POLICY}"
```

PLACEHOLDER	AZURE PORTAL NAME	EXAMPLE
`{AAD B2C INSTANCE}`	Instance	`https://contoso.b2clogin.com/`
`{APP NAME}`	—	`BlazorSample`
`{CLIENT APP CLIENT ID}`	Application (client) ID for the *Client app*	`4369008b-21fa-427c-abaa-9b53bf58e538`
`{DEFAULT SCOPE}`	Scope name	`API.Access`
`{SERVER API APP CLIENT ID}`	Application (client) ID for the *Server API app*	`41451fa7-82d9-4673-8fa5-69eff5a761fd`
`{SERVER API APP ID URI}`	Application ID URI (see note)	`41451fa7-82d9-4673-8fa5-69eff5a761fd`
`{SIGN UP OR SIGN IN POLICY}`	Sign-up/sign-in user flow	`B2C_1_signupsignin1`
`{TENANT DOMAIN}`	Primary/Publisher/Tenant domain	`contoso.onmicrosoft.com`

The output location specified with the `-o|--output` option creates a project folder if it doesn't exist and becomes part of the app's name.

> **NOTE**
>
> Pass the App ID URI to the `app-id-uri` option, but note a configuration change might be required in the client app, which is described in the Access token scopes section.
>
> Additionally, the scope set up by the Hosted Blazor template might have the App ID URI host repeated. Confirm that the scope configured for the `DefaultAccessTokenScopes` collection is correct in `Program.Main` (`Program.cs`) of the *Client app*.

> **NOTE**
>
> In the Azure portal, the *Client app's* **Authentication** > **Platform configurations** > **Web** > **Redirect URI** is configured for port 5001 for apps that run on the Kestrel server with default settings.
>
> If the *Client app* is run on a random IIS Express port, the port for the app can be found in the *Server API app's* properties in the **Debug** panel.
>
> If the port wasn't configured earlier with the *Client app's* known port, return to the *Client app's* registration in the Azure portal and update the redirect URI with the correct port.

Server app configuration

This section pertains to the solution's `Server` *app.*

Authentication package

The support for authenticating and authorizing calls to ASP.NET Core Web APIs is provided by the `Microsoft.AspNetCore.Authentication.AzureADB2C.UI` package:

```
<PackageReference Include="Microsoft.AspNetCore.Authentication.AzureADB2C.UI"
  Version="{VERSION}" />
```

For the placeholder `{VERSION}`, the latest stable version of the package that matches the app's shared framework version can be found in the package's **Version History** at NuGet.org.

Authentication service support

The `AddAuthentication` method sets up authentication services within the app and configures the JWT Bearer handler as the default authentication method. The AddAzureADB2CBearer method sets up the specific parameters in the JWT Bearer handler required to validate tokens emitted by the Azure Active Directory B2C:

```
services.AddAuthentication(AzureADB2CDefaults.BearerAuthenticationScheme)
    .AddAzureADB2CBearer(options => Configuration.Bind("AzureAdB2C", options));
```

UseAuthentication and UseAuthorization ensure that:

- The app attempts to parse and validate tokens on incoming requests.
- Any request attempting to access a protected resource without proper credentials fails.

```
app.UseAuthentication();
app.UseAuthorization();
```

User.Identity.Name

By default, the `User.Identity.Name` isn't populated.

To configure the app to receive the value from the `name` claim type, configure the TokenValidationParameters.NameClaimType of the JwtBearerOptions in `Startup.ConfigureServices`:

```
using Microsoft.AspNetCore.Authentication.JwtBearer;

...

services.Configure<JwtBearerOptions>(
    AzureADB2CDefaults.JwtBearerAuthenticationScheme, options =>
    {
        options.TokenValidationParameters.NameClaimType = "name";
    });
```

App settings

The `appsettings.json` file contains the options to configure the JWT bearer handler used to validate access tokens.

```
{
  "AzureAdB2C": {
    "Instance": "https://{TENANT}.b2clogin.com/",
    "ClientId": "{SERVER API APP CLIENT ID}",
    "Domain": "{TENANT DOMAIN}",
    "SignUpSignInPolicyId": "{SIGN UP OR SIGN IN POLICY}"
  }
}
```

Example:

```
{
  "AzureAdB2C": {
    "Instance": "https://contoso.b2clogin.com/",
    "ClientId": "41451fa7-82d9-4673-8fa5-69eff5a761fd",
    "Domain": "contoso.onmicrosoft.com",
    "SignUpSignInPolicyId": "B2C_1_signupsignin1",
  }
}
```

WeatherForecast controller

The WeatherForecast controller (*Controllers/WeatherForecastController.cs*) exposes a protected API with the `[Authorize]` attribute applied to the controller. It's **important** to understand that:

- The `[Authorize]` attribute in this API controller is the only thing that protect this API from unauthorized access.
- The `[Authorize]` attribute used in the Blazor WebAssembly app only serves as a hint to the app that the user should be authorized for the app to work correctly.

```
[Authorize]
[ApiController]
[Route("[controller]")]
public class WeatherForecastController : ControllerBase
{
    [HttpGet]
    public IEnumerable<WeatherForecast> Get()
    {
        ...
    }
}
```

Client app configuration

This section pertains to the solution's `Client` app.

Authentication package

When an app is created to use an Individual B2C Account (`IndividualB2C`), the app automatically receives a package reference for the Microsoft Authentication Library (`Microsoft.Authentication.WebAssembly.Msal`). The package provides a set of primitives that help the app authenticate users and obtain tokens to call protected APIs.

If adding authentication to an app, manually add the package to the app's project file:

```
<PackageReference Include="Microsoft.Authentication.WebAssembly.Msal"
  Version="{VERSION}" />
```

For the placeholder `{VERSION}` , the latest stable version of the package that matches the app's shared framework version can be found in the package's **Version History** at NuGet.org.

The `Microsoft.Authentication.WebAssembly.Msal` package transitively adds the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package to the app.

Authentication service support

Support for HttpClient instances is added that include access tokens when making requests to the server project.

`Program.cs`:

```
builder.Services.AddHttpClient("{APP ASSEMBLY}.ServerAPI", client =>
    client.BaseAddress = new Uri(builder.HostEnvironment.BaseAddress))
    .AddHttpMessageHandler<BaseAddressAuthorizationMessageHandler>();

builder.Services.AddScoped(sp => sp.GetRequiredService<IHttpClientFactory>()
    .CreateClient("{APP ASSEMBLY}.ServerAPI"));
```

The placeholder `{APP ASSEMBLY}` is the app's assembly name (for example, `BlazorSample.ServerAPI`).

Support for authenticating users is registered in the service container with the AddMsalAuthentication extension method provided by the `Microsoft.Authentication.WebAssembly.Msal` package. This method sets up the services required for the app to interact with the Identity Provider (IP).

`Program.cs`:

```
builder.Services.AddMsalAuthentication(options =>
{
    builder.Configuration.Bind("AzureAdB2C", options.ProviderOptions.Authentication);
    options.ProviderOptions.DefaultAccessTokenScopes.Add("{SCOPE URI}");
});
```

The AddMsalAuthentication method accepts a callback to configure the parameters required to authenticate an app. The values required for configuring the app can be obtained from the Azure Portal AAD configuration when you register the app.

Configuration is supplied by the `wwwroot/appsettings.json` file:

```
{
  "AzureAdB2C": {
    "Authority": "{AAD B2C INSTANCE}{TENANT DOMAIN}/{SIGN UP OR SIGN IN POLICY}",
    "ClientId": "{CLIENT APP CLIENT ID}",
    "ValidateAuthority": false
  }
}
```

Example:

```
{
  "AzureAdB2C": {
    "Authority": "https://contoso.b2clogin.com/contoso.onmicrosoft.com/B2C_1_signupsignin1",
    "ClientId": "4369008b-21fa-427c-abaa-9b53bf58e538",
    "ValidateAuthority": false
  }
}
```

Access token scopes

The default access token scopes represent the list of access token scopes that are:

- Included by default in the sign in request.
- Used to provision an access token immediately after authentication.

All scopes must belong to the same app per Azure Active Directory rules. Additional scopes can be added for additional API apps as needed:

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.DefaultAccessTokenScopes.Add("{SCOPE URI}");
});
```

NOTE

If the Azure portal provides the scope URI for the app and the app throws an unhandled exception when it receives a *401 Unauthorized* response from the API, try using a scope URI that doesn't include the scheme and host. For example, the Azure portal may provide one of the following scope URI formats:

- `https://{TENANT}.onmicrosoft.com/{API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}`
- `api://{SERVER API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}`

Try supplying the scope URI without the scheme and host:

```
options.ProviderOptions.DefaultAccessTokenScopes.Add(
    "{SERVER API CLIENT ID OR CUSTOM VALUE}/{SCOPE NAME}");
```

For example:

```
options.ProviderOptions.DefaultAccessTokenScopes.Add(
    "41451fa7-82d9-4673-8fa5-69eff5a761fd/API.Access");
```

For more information, see the following sections of the *Additional scenarios* article:

- Request additional access tokens
- Attach tokens to outgoing requests

Login mode

The framework defaults to pop-up login mode and falls back to redirect login mode if a pop-up can't be opened. Configure MSAL to use redirect login mode by setting the `LoginMode` property of MsalProviderOptions to `redirect`:

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.LoginMode = "redirect";
});
```

The default setting is `popup`, and the string value isn't case sensitive.

Imports file

The Microsoft.AspNetCore.Components.Authorization namespace is made available throughout the app via the `_Imports.razor` file:

```
@using System.Net.Http
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.Web
@using Microsoft.AspNetCore.Components.WebAssembly.Http
@using Microsoft.JSInterop
@using {APPLICATION ASSEMBLY}.Client
@using {APPLICATION ASSEMBLY}.Client.Shared
```

Index page

The Index page (`wwwroot/index.html`) page includes a script that defines the `AuthenticationService` in JavaScript. `AuthenticationService` handles the low-level details of the OIDC protocol. The app internally calls methods defined in the script to perform the authentication operations.

```
<script src="_content/Microsoft.Authentication.WebAssembly.Msal/
    AuthenticationService.js"></script>
```

App component

The `App` component (`App.razor`) is similar to the `App` component found in Blazor Server apps:

- The CascadingAuthenticationState component manages exposing the AuthenticationState to the rest of the app.
- The AuthorizeRouteView component makes sure that the current user is authorized to access a given page or otherwise renders the `RedirectToLogin` component.
- The `RedirectToLogin` component manages redirecting unauthorized users to the login page.

```
<CascadingAuthenticationState>
    <Router AppAssembly="@typeof(Program).Assembly">
        <Found Context="routeData">
            <AuthorizeRouteView RouteData="@routeData"
                DefaultLayout="@typeof(MainLayout)">
                <NotAuthorized>
                    @if (!context.User.Identity.IsAuthenticated)
                    {
                        <RedirectToLogin />
                    }
                    else
                    {
                        <p>
                            You are not authorized to access
                            this resource.
                        </p>
                    }
                </NotAuthorized>
            </AuthorizeRouteView>
        </Found>
        <NotFound>
            <LayoutView Layout="@typeof(MainLayout)">
                <p>Sorry, there's nothing at this address.</p>
            </LayoutView>
        </NotFound>
    </Router>
</CascadingAuthenticationState>
```

RedirectToLogin component

The `RedirectToLogin` component (`Shared/RedirectToLogin.razor`):

- Manages redirecting unauthorized users to the login page.
- Preserves the current URL that the user is attempting to access so that they can be returned to that page if authentication is successful.

```
@inject NavigationManager Navigation
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@code {
    protected override void OnInitialized()
    {
        Navigation.NavigateTo($"authentication/login?returnUrl=" +
            Uri.EscapeDataString(Navigation.Uri));
    }
}
```

LoginDisplay component

The `LoginDisplay` component (`Shared/LoginDisplay.razor`) is rendered in the `MainLayout` component (`Shared/MainLayout.razor`) and manages the following behaviors:

- For authenticated users:
  - Displays the current username.
  - Offers a button to log out of the app.
- For anonymous users, offers the option to log in.

```
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject NavigationManager Navigation
@inject SignOutSessionStateManager SignOutManager

<AuthorizeView>
    <Authorized>
        Hello, @context.User.Identity.Name!
        <button class="nav-link btn btn-link" @onclick="BeginLogout">
            Log out
        </button>
    </Authorized>
    <NotAuthorized>
        <a href="authentication/login">Log in</a>
    </NotAuthorized>
</AuthorizeView>

@code {
    private async Task BeginLogout(MouseEventArgs args)
    {
        await SignOutManager.SetSignOutState();
        Navigation.NavigateTo("authentication/logout");
    }
}
```

Authentication component

The page produced by the `Authentication` component (`Pages/Authentication.razor`) defines the routes required for handling different authentication stages.

The RemoteAuthenticatorView component:

- Is provided by the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package.
- Manages performing the appropriate actions at each stage of authentication.

```
@page "/authentication/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action" />

@code {
    [Parameter]
    public string Action { get; set; }
}
```

FetchData component

The `FetchData` component shows how to:

- Provision an access token.
- Use the access token to call a protected resource API in the *Server* app.

The `@attribute [Authorize]` directive indicates to the Blazor WebAssembly authorization system that the user must be authorized in order to visit this component. The presence of the attribute in the `Client` app doesn't prevent the API on the server from being called without proper credentials. The `Server` app also must use `[Authorize]` on the appropriate endpoints to correctly protect them.

IAccessTokenProvider.RequestAccessToken takes care of requesting an access token that can be added to the request to call the API. If the token is cached or the service is able to provision a new access token without user interaction, the token request succeeds. Otherwise, the token request fails with an AccessTokenNotAvailableException, which is caught in a `try-catch` statement.

In order to obtain the actual token to include in the request, the app must check that the request succeeded by calling `tokenResult.TryGetToken(out var token)`.

If the request was successful, the token variable is populated with the access token. The AccessToken.Value property of the token exposes the literal string to include in the `Authorization` request header.

If the request failed because the token couldn't be provisioned without user interaction, the token result contains a redirect URL. Navigating to this URL takes the user to the login page and back to the current page after a successful authentication.

```
@page "/fetchdata"
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@using {APP NAMESPACE}.Shared
@attribute [Authorize]
@inject HttpClient Http

...

@code {
    private WeatherForecast[] forecasts;

    protected override async Task OnInitializedAsync()
    {
        try
        {
            forecasts = await Http.GetFromJsonAsync<WeatherForecast[]>("WeatherForecast");
        }
        catch (AccessTokenNotAvailableException exception)
        {
            exception.Redirect();
        }
    }
}
```

Run the app

Run the app from the Server project. When using Visual Studio, either:

- Set the **Startup Projects** drop down list in the toolbar to the *Server API app* and select the **Run** button.
- Select the Server project in **Solution Explorer** and select the **Run** button in the toolbar or start the app from the **Debug** menu.

Custom user flows

The Microsoft Authentication Library (Microsoft.Authentication.WebAssembly.Msal, NuGet package) doesn't support AAD B2C user flows by default. Create custom user flows in developer code.

For more information on how to build a challenge for a custom user flow, see User flows in Azure Active Directory B2C.

Troubleshoot

Cookies and site data

Cookies and site data can persist across app updates and interfere with testing and troubleshooting. Clear the following when making app code changes, user account changes with the provider, or provider app configuration changes:

- User sign-in cookies
- App cookies
- Cached and stored site data

One approach to prevent lingering cookies and site data from interfering with testing and troubleshooting is to:

- Configure a browser
  - Use a browser for testing that you can configure to delete all cookie and site data each time the browser is closed.
  - Make sure that the browser is closed manually or by the IDE between any change to the app, test user,

or provider configuration.

- Use a custom command to open a browser in incognito or private mode in Visual Studio:
  - Open **Browse With** dialog box from Visual Studio's **Run** button.
  - Select the **Add** button.
  - Provide the path to your browser in the **Program** field. The following executable paths are typical installation locations for Windows 10. If your browser is installed in a different location or you aren't using Windows 10, provide the path to the browser's executable.
    - Microsoft Edge: `C:\Program Files (x86)\Microsoft\Edge\Application\msedge.exe`
    - Google Chrome: `C:\Program Files (x86)\Google\Chrome\Application\chrome.exe`
    - Mozilla Firefox: `C:\Program Files\Mozilla Firefox\firefox.exe`
  - In the **Arguments** field, provide the command-line option that the browser uses to open in incognito or private mode. Some browsers require the URL of the app.
    - Microsoft Edge: `-inprivate`
    - Google Chrome: `--incognito --new-window https://localhost:5001`
    - Mozilla Firefox: `-private -url https://localhost:5001`
  - Provide a name in the **Friendly name** field. For example, `Firefox Auth Testing`.
  - Select the **OK** button.
  - To avoid having to select the browser profile for each iteration of testing with an app, set the profile as the default with the **Set as Default** button.
  - Make sure that the browser is closed by the IDE between any change to the app, test user, or provider configuration.

Run the Server app

When testing and troubleshooting a hosted Blazor app, make sure that you're running the app from the `Server` project. For example in Visual Studio, confirm that the Server project is highlighted in **Solution Explorer** before you start the app with any of the following approaches:

- Select the **Run** button.
- Use **Debug** > **Start Debugging** from the menu.
- Press F5.

Inspect the content of a JSON Web Token (JWT)

To decode a JSON Web Token (JWT), use Microsoft's jwt.ms tool. Values in the UI never leave your browser.

Secure an ASP.NET Core Blazor WebAssembly hosted app with Identity Server

9/22/2020 • 13 minutes to read • Edit Online

By Javier Calvarro Nelson and Luke Latham

This article explains how to create a hosted Blazor WebAssembly app that uses IdentityServer to authenticate users and API calls.

> **NOTE**
> To configure a standalone or hosted Blazor WebAssembly app to use an existing, external Identity Server instance, follow the guidance in Secure an ASP.NET Core Blazor WebAssembly standalone app with the Authentication library.

- Visual Studio
- Visual Studio Code / .NET Core CLI
- Visual Studio for Mac

To create a new Blazor WebAssembly project with an authentication mechanism:

1. After choosing the **Blazor WebAssembly App** template in the **Create a new ASP.NET Core Web Application** dialog, select **Change** under **Authentication**.
2. Select **Individual User Accounts** with the **Store user accounts in-app** option to store users within the app using ASP.NET Core's Identity system.
3. Select the **ASP.NET Core hosted** check box in the **Advanced** section.

Server app configuration

The following sections describe additions to the project when authentication support is included.

Startup class

The `Startup` class has the following additions.

- In `Startup.ConfigureServices`:
  - ASP.NET Core Identity:

```
services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlite(
        Configuration.GetConnectionString("DefaultConnection")));

services.AddDefaultIdentity<ApplicationUser>(options =>
        options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
```

  - IdentityServer with an additional AddApiAuthorization helper method that sets up default ASP.NET Core conventions on top of IdentityServer:

```
services.AddIdentityServer()
    .AddApiAuthorization<ApplicationUser, ApplicationDbContext>();
```

- Authentication with an additional AddIdentityServerJwt helper method that configures the app to validate JWT tokens produced by IdentityServer:

```
services.AddAuthentication()
    .AddIdentityServerJwt();
```

- In `Startup.Configure`:
  - The IdentityServer middleware exposes the OpenID Connect (OIDC) endpoints:

```
app.UseIdentityServer();
```

  - The Authentication middleware is responsible for validating request credentials and setting the user on the request context:

```
app.UseAuthentication();
```

  - Authorization Middleware enables authorization capabilities:

```
app.UseAuthentication();
app.UseAuthorization();
```

AddApiAuthorization

The AddApiAuthorization helper method configures IdentityServer for ASP.NET Core scenarios. IdentityServer is a powerful and extensible framework for handling app security concerns. IdentityServer exposes unnecessary complexity for the most common scenarios. Consequently, a set of conventions and configuration options is provided that we consider a good starting point. Once your authentication needs change, the full power of IdentityServer is available to customize authentication to suit an app's requirements.

AddIdentityServerJwt

The AddIdentityServerJwt helper method configures a policy scheme for the app as the default authentication handler. The policy is configured to allow Identity to handle all requests routed to any subpath in the Identity URL space `/Identity`. The JwtBearerHandler handles all other requests. Additionally, this method:

- Registers an `{APPLICATION NAME}API` API resource with IdentityServer with a default scope of `{APPLICATION NAME}API`.
- Configures the JWT Bearer Token Middleware to validate tokens issued by IdentityServer for the app.

WeatherForecastController

In the `WeatherForecastController` (`Controllers/WeatherForecastController.cs`), the `[Authorize]` attribute is applied to the class. The attribute indicates that the user must be authorized based on the default policy to access the resource. The default authorization policy is configured to use the default authentication scheme, which is set up by AddIdentityServerJwt. The helper method configures JwtBearerHandler as the default handler for requests to the app.

ApplicationDbContext

In the `ApplicationDbContext` (`Data/ApplicationDbContext.cs`), DbContext extends ApiAuthorizationDbContext<TUser> to include the schema for IdentityServer.

ApiAuthorizationDbContext<TUser> is derived from IdentityDbContext.

To gain full control of the database schema, inherit from one of the available Identity DbContext classes and configure the context to include the Identity schema by calling `builder.ConfigurePersistedGrantContext(_operationalStoreOptions.Value)` in the OnModelCreating method.

OidcConfigurationController

In the `OidcConfigurationController` (`Controllers/OidcConfigurationController.cs`), the client endpoint is provisioned to serve OIDC parameters.

App settings

In the app settings file (`appsettings.json`) at the project root, the `IdentityServer` section describes the list of configured clients. In the following example, there's a single client. The client name corresponds to the app name and is mapped by convention to the OAuth `ClientId` parameter. The profile indicates the app type being configured. The profile is used internally to drive conventions that simplify the configuration process for the server.

```
"IdentityServer": {
  "Clients": {
    "{APP ASSEMBLY}.Client": {
      "Profile": "IdentityServerSPA"
    }
  }
}
```

The placeholder `{APP ASSEMBLY}` is the app's assembly name (for example, `BlazorSample.Client`).

Client app configuration

Authentication package

When an app is created to use Individual User Accounts (`Individual`), the app automatically receives a package reference for the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package in the app's project file. The package provides a set of primitives that help the app authenticate users and obtain tokens to call protected APIs.

If adding authentication to an app, manually add the package to the app's project file:

```
<PackageReference
  Include="Microsoft.AspNetCore.Components.WebAssembly.Authentication"
  Version="{VERSION}" />
```

For the placeholder `{VERSION}`, the latest stable version of the package that matches the app's shared framework version can be found in the package's **Version History** at NuGet.org.

`HttpClient` configuration

In `Program.Main` (`Program.cs`), a named HttpClient (`HostIS.ServerAPI`) is configured to supply HttpClient instances that include access tokens when making requests to the server API:

```
builder.Services.AddHttpClient("HostIS.ServerAPI",
        client => client.BaseAddress = new Uri(builder.HostEnvironment.BaseAddress))
    .AddHttpMessageHandler<BaseAddressAuthorizationMessageHandler>();

builder.Services.AddScoped(sp => sp.GetRequiredService<IHttpClientFactory>()
    .CreateClient("HostIS.ServerAPI"));
```

> **NOTE**
>
> If you're configuring a Blazor WebAssembly app to use an existing Identity Server instance that isn't part of a hosted Blazor solution, change the HttpClient base address registration from IWebAssemblyHostEnvironment.BaseAddress (`builder.HostEnvironment.BaseAddress`) to the server app's API authorization endpoint URL.

API authorization support

The support for authenticating users is plugged into the service container by the extension method provided inside the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package. This method sets up the services required by the app to interact with the existing authorization system.

```
builder.Services.AddApiAuthorization();
```

By default, configuration for the app is loaded by convention from `_configuration/{client-id}`. By convention, the client ID is set to the app's assembly name. This URL can be changed to point to a separate endpoint by calling the overload with options.

Imports file

The Microsoft.AspNetCore.Components.Authorization namespace is made available throughout the app via the `_Imports.razor` file:

```
@using System.Net.Http
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.Web
@using Microsoft.AspNetCore.Components.WebAssembly.Http
@using Microsoft.JSInterop
@using {APPLICATION ASSEMBLY}.Client
@using {APPLICATION ASSEMBLY}.Client.Shared
```

Index page

The Index page (`wwwroot/index.html`) page includes a script that defines the `AuthenticationService` in JavaScript. `AuthenticationService` handles the low-level details of the OIDC protocol. The app internally calls methods defined in the script to perform the authentication operations.

```
<script src="_content/Microsoft.AspNetCore.Components.WebAssembly.Authentication/
    AuthenticationService.js"></script>
```

App component

The `App` component (`App.razor`) is similar to the `App` component found in Blazor Server apps:

- The CascadingAuthenticationState component manages exposing the AuthenticationState to the rest of the app.
- The AuthorizeRouteView component makes sure that the current user is authorized to access a given page or otherwise renders the `RedirectToLogin` component.
- The `RedirectToLogin` component manages redirecting unauthorized users to the login page.

```
<CascadingAuthenticationState>
    <Router AppAssembly="@typeof(Program).Assembly">
        <Found Context="routeData">
            <AuthorizeRouteView RouteData="@routeData"
                DefaultLayout="@typeof(MainLayout)">
                <NotAuthorized>
                    @if (!context.User.Identity.IsAuthenticated)
                    {
                        <RedirectToLogin />
                    }
                    else
                    {
                        <p>
                            You are not authorized to access
                            this resource.
                        </p>
                    }
                </NotAuthorized>
            </AuthorizeRouteView>
        </Found>
        <NotFound>
            <LayoutView Layout="@typeof(MainLayout)">
                <p>Sorry, there's nothing at this address.</p>
            </LayoutView>
        </NotFound>
    </Router>
</CascadingAuthenticationState>
```

RedirectToLogin component

The `RedirectToLogin` component (`Shared/RedirectToLogin.razor`):

- Manages redirecting unauthorized users to the login page.
- Preserves the current URL that the user is attempting to access so that they can be returned to that page if authentication is successful.

```
@inject NavigationManager Navigation
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@code {
    protected override void OnInitialized()
    {
        Navigation.NavigateTo($"authentication/login?returnUrl=" +
            Uri.EscapeDataString(Navigation.Uri));
    }
}
```

LoginDisplay component

The `LoginDisplay` component (`Shared/LoginDisplay.razor`) is rendered in the `MainLayout` component (`Shared/MainLayout.razor`) and manages the following behaviors:

- For authenticated users:
  - Displays the current user name.
  - Offers a link to the user profile page in ASP.NET Core Identity.
  - Offers a button to log out of the app.
- For anonymous users:
  - Offers the option to register.
  - Offers the option to log in.

```
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject NavigationManager Navigation
@inject SignOutSessionStateManager SignOutManager

<AuthorizeView>
    <Authorized>
        <a href="authentication/profile">Hello, @context.User.Identity.Name!</a>
        <button class="nav-link btn btn-link" @onclick="BeginSignOut">
            Log out
        </button>
    </Authorized>
    <NotAuthorized>
        <a href="authentication/register">Register</a>
        <a href="authentication/login">Log in</a>
    </NotAuthorized>
</AuthorizeView>

@code {
    private async Task BeginSignOut(MouseEventArgs args)
    {
        await SignOutManager.SetSignOutState();
        Navigation.NavigateTo("authentication/logout");
    }
}
```

Authentication component

The page produced by the `Authentication` component (`Pages/Authentication.razor`) defines the routes required for handling different authentication stages.

The RemoteAuthenticatorView component:

- Is provided by the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` package.
- Manages performing the appropriate actions at each stage of authentication.

```
@page "/authentication/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action" />

@code {
    [Parameter]
    public string Action { get; set; }
}
```

FetchData component

The `FetchData` component shows how to:

- Provision an access token.
- Use the access token to call a protected resource API in the *Server* app.

The `@attribute [Authorize]` directive indicates to the Blazor WebAssembly authorization system that the user must be authorized in order to visit this component. The presence of the attribute in the `Client` app doesn't prevent the API on the server from being called without proper credentials. The `Server` app also must use `[Authorize]` on the appropriate endpoints to correctly protect them.

IAccessTokenProvider.RequestAccessToken takes care of requesting an access token that can be added to the request to call the API. If the token is cached or the service is able to provision a new access token without user interaction, the token request succeeds. Otherwise, the token request fails with an

AccessTokenNotAvailableException, which is caught in a `try-catch` statement.

In order to obtain the actual token to include in the request, the app must check that the request succeeded by calling `tokenResult.TryGetToken(out var token)`.

If the request was successful, the token variable is populated with the access token. The AccessToken.Value property of the token exposes the literal string to include in the `Authorization` request header.

If the request failed because the token couldn't be provisioned without user interaction, the token result contains a redirect URL. Navigating to this URL takes the user to the login page and back to the current page after a successful authentication.

```
@page "/fetchdata"
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@using {APP NAMESPACE}.Shared
@attribute [Authorize]
@inject HttpClient Http

...

@code {
    private WeatherForecast[] forecasts;

    protected override async Task OnInitializedAsync()
    {
        try
        {
            forecasts = await Http.GetFromJsonAsync<WeatherForecast[]>("WeatherForecast");
        }
        catch (AccessTokenNotAvailableException exception)
        {
            exception.Redirect();
        }
    }
}
```

Run the app

Run the app from the Server project. When using Visual Studio, either:

- Set the **Startup Projects** drop down list in the toolbar to the *Server API app* and select the **Run** button.
- Select the Server project in **Solution Explorer** and select the **Run** button in the toolbar or start the app from the **Debug** menu.

Name and role claim with API authorization

Custom user factory

In the Client app, create a custom user factory. Identity Server sends multiple roles as a JSON array in a single `role` claim. A single role is sent as a string value in the claim. The factory creates an individual `role` claim for each of the user's roles.

`CustomUserFactory.cs`:

```
using System.Linq;
using System.Security.Claims;
using System.Text.Json;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication.Internal;

public class CustomUserFactory
    : AccountClaimsPrincipalFactory<RemoteUserAccount>
{
    public CustomUserFactory(IAccessTokenProviderAccessor accessor)
        : base(accessor)
    {
    }

    public async override ValueTask<ClaimsPrincipal> CreateUserAsync(
        RemoteUserAccount account,
        RemoteAuthenticationUserOptions options)
    {
        var user = await base.CreateUserAsync(account, options);

        if (user.Identity.IsAuthenticated)
        {
            var identity = (ClaimsIdentity)user.Identity;
            var roleClaims = identity.FindAll(identity.RoleClaimType);

            if (roleClaims != null && roleClaims.Any())
            {
                foreach (var existingClaim in roleClaims)
                {
                    identity.RemoveClaim(existingClaim);
                }

                var rolesElem = account.AdditionalProperties[identity.RoleClaimType];

                if (rolesElem is JsonElement roles)
                {
                    if (roles.ValueKind == JsonValueKind.Array)
                    {
                        foreach (var role in roles.EnumerateArray())
                        {
                            identity.AddClaim(new Claim(options.RoleClaim, role.GetString()));
                        }
                    }
                    else
                    {
                        identity.AddClaim(new Claim(options.RoleClaim, roles.GetString()));
                    }
                }
            }
        }

        return user;
    }
}
```

In the Client app, register the factory in `Program.Main` (`Program.cs`):

```
builder.Services.AddApiAuthorization()
    .AddAccountClaimsPrincipalFactory<CustomUserFactory>();
```

In the Server app, call AddRoles on the Identity builder, which adds role-related services:

```
using Microsoft.AspNetCore.Identity;

...

services.AddDefaultIdentity<ApplicationUser>(options =>
    options.SignIn.RequireConfirmedAccount = true)
    .AddRoles<IdentityRole>()
    .AddEntityFrameworkStores<ApplicationDbContext>();
```

Configure Identity Server

Use **one** of the following approaches:

- API authorization options
- Profile Service

API authorization options

In the Server app:

- Configure Identity Server to put the `name` and `role` claims into the ID token and access token.
- Prevent the default mapping for roles in the JWT token handler.

```
using System.IdentityModel.Tokens.Jwt;
using System.Linq;

...

services.AddIdentityServer()
    .AddApiAuthorization<ApplicationUser, ApplicationDbContext>(options => {
        options.IdentityResources["openid"].UserClaims.Add("name");
        options.ApiResources.Single().UserClaims.Add("name");
        options.IdentityResources["openid"].UserClaims.Add("role");
        options.ApiResources.Single().UserClaims.Add("role");
    });

JwtSecurityTokenHandler.DefaultInboundClaimTypeMap.Remove("role");
```

Profile Service

In the Server app, create a `ProfileService` implementation.

`ProfileService.cs`:

```
using IdentityModel;
using IdentityServer4.Models;
using IdentityServer4.Services;
using System.Threading.Tasks;

public class ProfileService : IProfileService
{
    public ProfileService()
    {
    }

    public Task GetProfileDataAsync(ProfileDataRequestContext context)
    {
        var nameClaim = context.Subject.FindAll(JwtClaimTypes.Name);
        context.IssuedClaims.AddRange(nameClaim);

        var roleClaims = context.Subject.FindAll(JwtClaimTypes.Role);
        context.IssuedClaims.AddRange(roleClaims);

        return Task.CompletedTask;
    }

    public Task IsActiveAsync(IsActiveContext context)
    {
        return Task.CompletedTask;
    }
}
```

In the Server app, register the Profile Service in `Startup.ConfigureServices`:

```
using IdentityServer4.Services;

...

services.AddTransient<IProfileService, ProfileService>();
```

Use authorization mechanisms

In the Client app, component authorization approaches are functional at this point. Any of the authorization mechanisms in components can use a role to authorize the user:

- `AuthorizeView` component (Example: `<AuthorizeView Roles="admin">`)
- `[Authorize]` attribute directive (AuthorizeAttribute) (Example: `@attribute [Authorize(Roles = "admin")]`)
- Procedural logic (Example: `if (user.IsInRole("admin")) { ... }`)

  Multiple role tests are supported:

  ```
  if (user.IsInRole("admin") && user.IsInRole("developer"))
  {
      ...
  }
  ```

`User.Identity.Name` is populated in the Client app with the user's user name, which is usually their sign-in email address.

UserManager and SignInManager

Set the user identifier claim type when a Server app requires:

- UserManager<TUser> or SignInManager<TUser> in an API endpoint.
- IdentityUser details, such as the user's name, email address, or lockout end time.

In `Startup.ConfigureServices`:

```
using System.Security.Claims;

...

services.Configure<IdentityOptions>(options =>
    options.ClaimsIdentity.UserIdClaimType = ClaimTypes.NameIdentifier);
```

The following `WeatherForecastController` logs the UserName when the `Get` method is called:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Identity;
using Microsoft.Extensions.Logging;
using {APP NAMESPACE}.Server.Models;
using {APP NAMESPACE}.Shared;

namespace {APP NAMESPACE}.Server.Controllers
{
    [Authorize]
    [ApiController]
    [Route("[controller]")]
    public class WeatherForecastController : ControllerBase
    {
        private readonly UserManager<ApplicationUser> userManager;

        private static readonly string[] Summaries = new[]
        {
            "Freezing", "Bracing", "Chilly", "Cool", "Mild", "Warm",
            "Balmy", "Hot", "Sweltering", "Scorching"
        };

        private readonly ILogger<WeatherForecastController> logger;

        public WeatherForecastController(ILogger<WeatherForecastController> logger,
            UserManager<ApplicationUser> userManager)
        {
            this.logger = logger;
            this.userManager = userManager;
        }

        [HttpGet]
        public async Task<IEnumerable<WeatherForecast>> Get()
        {
            var rng = new Random();

            var user = await userManager.GetUserAsync(User);

            if (user != null)
            {
                logger.LogInformation($"User.Identity.Name: {user.UserName}");
            }

            return Enumerable.Range(1, 5).Select(index => new WeatherForecast
            {
                Date = DateTime.Now.AddDays(index),
                TemperatureC = rng.Next(-20, 55),
                Summary = Summaries[rng.Next(Summaries.Length)]
            })
            .ToArray();
        }
    }
}
```

Troubleshoot

Cookies and site data

Cookies and site data can persist across app updates and interfere with testing and troubleshooting. Clear the following when making app code changes, user account changes with the provider, or provider app configuration changes:

- User sign-in cookies
- App cookies
- Cached and stored site data

One approach to prevent lingering cookies and site data from interfering with testing and troubleshooting is to:

- Configure a browser
  - Use a browser for testing that you can configure to delete all cookie and site data each time the browser is closed.
  - Make sure that the browser is closed manually or by the IDE between any change to the app, test user, or provider configuration.
- Use a custom command to open a browser in incognito or private mode in Visual Studio:
  - Open **Browse With** dialog box from Visual Studio's **Run** button.
  - Select the **Add** button.
  - Provide the path to your browser in the **Program** field. The following executable paths are typical installation locations for Windows 10. If your browser is installed in a different location or you aren't using Windows 10, provide the path to the browser's executable.
    - Microsoft Edge: `C:\Program Files (x86)\Microsoft\Edge\Application\msedge.exe`
    - Google Chrome: `C:\Program Files (x86)\Google\Chrome\Application\chrome.exe`
    - Mozilla Firefox: `C:\Program Files\Mozilla Firefox\firefox.exe`
  - In the **Arguments** field, provide the command-line option that the browser uses to open in incognito or private mode. Some browsers require the URL of the app.
    - Microsoft Edge: `-inprivate`
    - Google Chrome: `--incognito --new-window https://localhost:5001`
    - Mozilla Firefox: `-private -url https://localhost:5001`
  - Provide a name in the **Friendly name** field. For example, `Firefox Auth Testing`.
  - Select the **OK** button.
  - To avoid having to select the browser profile for each iteration of testing with an app, set the profile as the default with the **Set as Default** button.
  - Make sure that the browser is closed by the IDE between any change to the app, test user, or provider configuration.

Run the Server app

When testing and troubleshooting a hosted Blazor app, make sure that you're running the app from the `Server` project. For example in Visual Studio, confirm that the Server project is highlighted in **Solution Explorer** before you start the app with any of the following approaches:

- Select the **Run** button.
- Use **Debug** > **Start Debugging** from the menu.
- Press F5.

Inspect the content of a JSON Web Token (JWT)

To decode a JSON Web Token (JWT), use Microsoft's jwt.ms tool. Values in the UI never leave your browser.

Attach tokens to outgoing requests

AuthorizationMessageHandler is a DelegatingHandler used to attach access tokens to outgoing HttpResponseMessage instances. Tokens are acquired using the IAccessTokenProvider service, which is registered by the framework. If a token can't be acquired, an AccessTokenNotAvailableException is thrown. AccessTokenNotAvailableException has a Redirect method that can be used to navigate the user to the identity provider to acquire a new token.

For convenience, the framework provides the BaseAddressAuthorizationMessageHandler preconfigured with the app's base address as an authorized URL. **Access tokens are only added when the request URI is within the app's base URI.** When outgoing request URIs aren't within the app's base URI, use a custom `AuthorizationMessageHandler` class (*recommended*) or configure the `AuthorizationMessageHandler`.

> **NOTE**
> In addition to the client app configuration for server API access, the server API must also allow cross-origin requests (CORS) when the client and the server don't reside at the same base address. For more information on server-side CORS configuration, see the Cross-origin resource sharing (CORS) section later in this article.

In the following example:

- AddHttpClient adds IHttpClientFactory and related services to the service collection and configures a named HttpClient (`ServerAPI`). HttpClient.BaseAddress is the base address of the resource URI when sending requests. IHttpClientFactory is provided by the `Microsoft.Extensions.Http` NuGet package.
- BaseAddressAuthorizationMessageHandler is the DelegatingHandler used to attach access tokens to outgoing HttpResponseMessage instances. Access tokens are only added when the request URI is within the app's base URI.
- IHttpClientFactory.CreateClient creates and configures an HttpClient instance for outgoing requests using the configuration that corresponds to the named HttpClient (`ServerAPI`).

```
using System.Net.Http;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

...

builder.Services.AddHttpClient("ServerAPI",
        client => client.BaseAddress = new Uri("https://www.example.com/base"))
    .AddHttpMessageHandler<BaseAddressAuthorizationMessageHandler>();

builder.Services.AddScoped(sp => sp.GetRequiredService<IHttpClientFactory>()
    .CreateClient("ServerAPI"));
```

For a Blazor app based on the Blazor WebAssembly Hosted project template, request URIs are within the app's base URI by default. Therefore, IWebAssemblyHostEnvironment.BaseAddress (

`new Uri(builder.HostEnvironment.BaseAddress)`) is assigned to the HttpClient.BaseAddress in an app generated from the project template.

The configured HttpClient is used to make authorized requests using the `try-catch` pattern:

```
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject HttpClient Client

...

protected override async Task OnInitializedAsync()
{
    private ExampleType[] examples;

    try
    {
        examples =
            await Client.GetFromJsonAsync<ExampleType[]>("ExampleAPIMethod");

        ...
    }
    catch (AccessTokenNotAvailableException exception)
    {
        exception.Redirect();
    }
}
```

Custom `AuthorizationMessageHandler` class

This guidance in this section is recommended for client apps that make outgoing requests to URIs that aren't within the app's base URI.

In the following example, a custom class extends AuthorizationMessageHandler for use as the DelegatingHandler for an HttpClient. ConfigureHandler configures this handler to authorize outbound HTTP requests using an access token. The access token is only attached if at least one of the authorized URLs is a base of the request URI (HttpRequestMessage.RequestUri).

```
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

public class CustomAuthorizationMessageHandler : AuthorizationMessageHandler
{
    public CustomAuthorizationMessageHandler(IAccessTokenProvider provider,
        NavigationManager navigationManager)
        : base(provider, navigationManager)
    {
        ConfigureHandler(
            authorizedUrls: new[] { "https://www.example.com/base" },
            scopes: new[] { "example.read", "example.write" });
    }
}
```

In `Program.Main` (`Program.cs`), `CustomAuthorizationMessageHandler` is registered as a scoped service and is configured as the DelegatingHandler for outgoing HttpResponseMessage instances made by a named HttpClient:

```
builder.Services.AddScoped<CustomAuthorizationMessageHandler>();

builder.Services.AddHttpClient("ServerAPI",
        client => client.BaseAddress = new Uri("https://www.example.com/base"))
    .AddHttpMessageHandler<CustomAuthorizationMessageHandler>();
```

For a Blazor app based on the Blazor WebAssembly Hosted project template, IWebAssemblyHostEnvironment.BaseAddress (`new Uri(builder.HostEnvironment.BaseAddress)`) is assigned to the HttpClient.BaseAddress by default.

The configured HttpClient is used to make authorized requests using the `try-catch` pattern. Where the client is created with CreateClient (`Microsoft.Extensions.Http` package), the HttpClient is supplied instances that include access tokens when making requests to the server API. If the request URI is a relative URI, as it is in the following example (`ExampleAPIMethod`), it's combined with the BaseAddress when the client app makes the request:

```
@inject IHttpClientFactory ClientFactory

...

@code {
    private ExampleType[] examples;

    protected override async Task OnInitializedAsync()
    {
        try
        {
            var client = ClientFactory.CreateClient("ServerAPI");

            examples =
                await client.GetFromJsonAsync<ExampleType[]>("ExampleAPIMethod");
        }
        catch (AccessTokenNotAvailableException exception)
        {
            exception.Redirect();
        }
    }
}
```

Configure `AuthorizationMessageHandler`

AuthorizationMessageHandler can be configured with authorized URLs, scopes, and a return URL using the ConfigureHandler method. ConfigureHandler configures the handler to authorize outbound HTTP requests using an access token. The access token is only attached if at least one of the authorized URLs is a base of the request URI (HttpRequestMessage.RequestUri). If the request URI is a relative URI, it's combined with the BaseAddress.

In the following example, AuthorizationMessageHandler configures an HttpClient in `Program.Main` (`Program.cs`):

```
using System.Net.Http;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

...

builder.Services.AddScoped(sp => new HttpClient(
    sp.GetRequiredService<AuthorizationMessageHandler>()
    .ConfigureHandler(
        authorizedUrls: new[] { "https://www.example.com/base" },
        scopes: new[] { "example.read", "example.write" }))
    {
        BaseAddress = new Uri("https://www.example.com/base")
    });
```

For a Blazor app based on the Blazor WebAssembly Hosted project template, IWebAssemblyHostEnvironment.BaseAddress is assigned to the following by default:

- The HttpClient.BaseAddress (`new Uri(builder.HostEnvironment.BaseAddress)`).
- A URL of the `authorizedUrls` array.

Graph API example

In the following example, a named HttpClient for Graph API is used to obtain a user's mobile phone number to process a call. After adding the Microsoft Graph API `User.Read` permission in the AAD area of the Azure portal, the scope is configured for the named client in the standalone app or Client app of a hosted Blazor solution.

> **NOTE**
>
> The example in this section obtains Graph API data for the user in *component code*. To create user claims from Graph API, see the following resources:
>
> - Customize the user section
> - ASP.NET Core Blazor WebAssembly with Azure Active Directory groups and roles

`GraphAuthorizationMessageHandler.cs`:

```
public class GraphAPIAuthorizationMessageHandler : AuthorizationMessageHandler
{
    public GraphAPIAuthorizationMessageHandler(IAccessTokenProvider provider,
        NavigationManager navigationManager)
        : base(provider, navigationManager)
    {
        ConfigureHandler(
            authorizedUrls: new[] { "https://graph.microsoft.com" },
            scopes: new[] { "https://graph.microsoft.com/User.Read" });
    }
}
```

In `Program.Main` (`Program.cs`):

```
builder.Services.AddScoped<GraphAPIAuthorizationMessageHandler>();

builder.Services.AddHttpClient("GraphAPI",
        client => client.BaseAddress = new Uri("https://graph.microsoft.com"))
    .AddHttpMessageHandler<GraphAPIAuthorizationMessageHandler>();
```

In a Razor component (`Pages/CallUser.razor`):

```
@page "/CallUser"
```

```
@page "/CallUser"
@using System.ComponentModel.DataAnnotations
@using System.Text.Json.Serialization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@using Microsoft.Extensions.Logging
@inject IAccessTokenProvider TokenProvider
@inject IHttpClientFactory ClientFactory
@inject ILogger<CallUser> Logger
@inject ICallProcessor CallProcessor

<h3>Call User</h3>

<EditForm Model="@callInfo" OnValidSubmit="@HandleValidSubmit">
    <DataAnnotationsValidator />
    <ValidationSummary />

    <p>
        <label>
            Message:
            <InputTextArea @bind-Value="callInfo.Message" />
        </label>
    </p>

    <button type="submit">Place call</button>

    <p>
        @formStatus
    </p>
</EditForm>

@code {
    private string formStatus;
    private CallInfo callInfo = new CallInfo();

    private async Task HandleValidSubmit()
    {
        var tokenResult = await TokenProvider.RequestAccessToken(
            new AccessTokenRequestOptions
            {
                Scopes = new[] { "https://graph.microsoft.com/User.Read" }
            });

        if (tokenResult.TryGetToken(out var token))
        {
            var client = ClientFactory.CreateClient("GraphAPI");

            var userInfo = await client.GetFromJsonAsync<UserInfo>("v1.0/me");

            if (userInfo != null)
            {
                CallProcessor.Send(userInfo.MobilePhone, callInfo.Message);

                formStatus = "Form successfully processed.";
                Logger.LogInformation(
                    $"Form successfully processed at {DateTime.UtcNow}. " +
                    $"Mobile Phone: {userInfo.MobilePhone}");
            }
        }
        else
        {
            formStatus = "There was a problem processing the form.";
            Logger.LogError("Token failure");
        }
    }

    private class CallInfo
    {
        [Required]
        [StringLength(1000, ErrorMessage = "Message too long (1,000 char limit)")]
```

```
        public string Message { get; set; }
    }

    private class UserInfo
    {
        [JsonPropertyName("mobilePhone")]
        public string MobilePhone { get; set; }
    }
}
```

> **NOTE**
>
> In the preceding example, the developer implements the custom `ICallProcessor` (`CallProcessor`) to queue and then place automated calls.

Typed `HttpClient`

A typed client can be defined that handles all of the HTTP and token acquisition concerns within a single class.

`WeatherForecastClient.cs`:

```
using System.Net.Http;
using System.Net.Http.Json;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
using static {APP ASSEMBLY}.Data;

public class WeatherForecastClient
{
    private readonly HttpClient client;

    public WeatherForecastClient(HttpClient client)
    {
        this.client = client;
    }

    public async Task<WeatherForecast[]> GetForecastAsync()
    {
        var forecasts = new WeatherForecast[0];

        try
        {
            forecasts = await client.GetFromJsonAsync<WeatherForecast[]>(
                "WeatherForecast");
        }
        catch (AccessTokenNotAvailableException exception)
        {
            exception.Redirect();
        }

        return forecasts;
    }
}
```

The placeholder `{APP ASSEMBLY}` is the app's assembly name (for example, `using static BlazorSample.Data;`).

`Program.Main` (`Program.cs`):

```
using System.Net.Http;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

...

builder.Services.AddHttpClient<WeatherForecastClient>(
        client => client.BaseAddress = new Uri("https://www.example.com/base"))
    .AddHttpMessageHandler<BaseAddressAuthorizationMessageHandler>();
```

For a Blazor app based on the Blazor WebAssembly Hosted project template, IWebAssemblyHostEnvironment.BaseAddress (`new Uri(builder.HostEnvironment.BaseAddress)`) is assigned to the HttpClient.BaseAddress by default.

`FetchData` component (`Pages/FetchData.razor`):

```
@inject WeatherForecastClient Client

...

protected override async Task OnInitializedAsync()
{
    forecasts = await Client.GetForecastAsync();
}
```

Configure the `HttpClient` handler

The handler can be further configured with ConfigureHandler for outbound HTTP requests.

`Program.Main` (`Program.cs`):

```
builder.Services.AddHttpClient<WeatherForecastClient>(
        client => client.BaseAddress = new Uri("https://www.example.com/base"))
    .AddHttpMessageHandler(sp => sp.GetRequiredService<AuthorizationMessageHandler>()
    .ConfigureHandler(
        authorizedUrls: new [] { "https://www.example.com/base" },
        scopes: new[] { "example.read", "example.write" }));
```

For a Blazor app based on the Blazor WebAssembly Hosted project template, IWebAssemblyHostEnvironment.BaseAddress is assigned to the following by default:

- The HttpClient.BaseAddress (`new Uri(builder.HostEnvironment.BaseAddress)`).
- A URL of the `authorizedUrls` array.

Unauthenticated or unauthorized web API requests in an app with a secure default client

If the Blazor WebAssembly app ordinarily uses a secure default HttpClient, the app can also make unauthenticated or unauthorized web API requests by configuring a named HttpClient:

`Program.Main` (`Program.cs`):

```
builder.Services.AddHttpClient("ServerAPI.NoAuthenticationClient",
    client => client.BaseAddress = new Uri("https://www.example.com/base"));
```

For a Blazor app based on the Blazor WebAssembly Hosted project template,

IWebAssemblyHostEnvironment.BaseAddress (`new Uri(builder.HostEnvironment.BaseAddress)`) is assigned to the HttpClient.BaseAddress by default.

The preceding registration is in addition to the existing secure default HttpClient registration.

A component creates the HttpClient from the IHttpClientFactory (`Microsoft.Extensions.Http` package) to make unauthenticated or unauthorized requests:

```
@inject IHttpClientFactory ClientFactory

...

@code {
    private WeatherForecast[] forecasts;

    protected override async Task OnInitializedAsync()
    {
        var client = ClientFactory.CreateClient("ServerAPI.NoAuthenticationClient");

        forecasts = await client.GetFromJsonAsync<WeatherForecast[]>(
            "WeatherForecastNoAuthentication");
    }
}
```

> **NOTE**
>
> The controller in the server API, `WeatherForecastNoAuthenticationController` for the preceding example, isn't marked with the `[Authorize]` attribute.

The decision whether to use a secure client or an insecure client as the default HttpClient instance is up to the developer. One way to make this decision is to consider the number of authenticated versus unauthenticated endpoints that the app contacts. If the majority of the app's requests are to secure API endpoints, use the authenticated HttpClient instance as the default. Otherwise, register the unauthenticated HttpClient instance as the default.

An alternative approach to using the IHttpClientFactory is to create a typed client for unauthenticated access to anonymous endpoints.

Request additional access tokens

Access tokens can be manually obtained by calling `IAccessTokenProvider.RequestAccessToken`. In the following example, an additional scope is required by an app for the default HttpClient. The Microsoft Authentication Library (MSAL) example configures the scope with `MsalProviderOptions`:

`Program.Main` (`Program.cs`):

```
builder.Services.AddMsalAuthentication(options =>
{
    ...

    options.ProviderOptions.AdditionalScopesToConsent.Add("{CUSTOM SCOPE 1}");
    options.ProviderOptions.AdditionalScopesToConsent.Add("{CUSTOM SCOPE 2}");
}
```

The `{CUSTOM SCOPE 1}` and `{CUSTOM SCOPE 2}` placeholders in the preceding example are custom scopes.

The `IAccessTokenProvider.RequestToken` method provides an overload that allows an app to provision an access

token with a given set of scopes.

In a Razor component:

```
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject IAccessTokenProvider TokenProvider

...

var tokenResult = await TokenProvider.RequestAccessToken(
    new AccessTokenRequestOptions
    {
        Scopes = new[] { "{CUSTOM SCOPE 1}", "{CUSTOM SCOPE 2}" }
    });

if (tokenResult.TryGetToken(out var token))
{
    ...
}
```

The `{CUSTOM SCOPE 1}` and `{CUSTOM SCOPE 2}` placeholders in the preceding example are custom scopes.

AccessTokenResult.TryGetToken returns:

- `true` with the `token` for use.
- `false` if the token isn't retrieved.

Cross-origin resource sharing (CORS)

When sending credentials (authorization cookies/headers) on CORS requests, the `Authorization` header must be allowed by the CORS policy.

The following policy includes configuration for:

- Request origins (`http://localhost:5000`, `https://localhost:5001`).
- Any method (verb).
- `Content-Type` and `Authorization` headers. To allow a custom header (for example, `x-custom-header`), list the header when calling WithHeaders.
- Credentials set by client-side JavaScript code (`credentials` property set to `include`).

```
app.UseCors(policy =>
    policy.WithOrigins("http://localhost:5000", "https://localhost:5001")
    .AllowAnyMethod()
    .WithHeaders(HeaderNames.ContentType, HeaderNames.Authorization, "x-custom-header")
    .AllowCredentials());
```

A hosted Blazor solution based on the Blazor Hosted project template uses the same base address for the client and server apps. The client app's HttpClient.BaseAddress is set to a URI of `builder.HostEnvironment.BaseAddress` by default. CORS configuration is **not** required in the default configuration of a hosted app created from the Blazor Hosted project template. Additional client apps that aren't hosted by the server project and don't share the server app's base address **do** require CORS configuration in the server project.

For more information, see Enable Cross-Origin Requests (CORS) in ASP.NET Core and the sample app's HTTP Request Tester component (`Components/HTTPRequestTester.razor`).

Handle token request errors

When a Single Page Application (SPA) authenticates a user using OpenID Connect (OIDC), the authentication

state is maintained locally within the SPA and in the Identity Provider (IP) in the form of a session cookie that's set as a result of the user providing their credentials.
