public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc(options =>
    {
        options.MaxReceiveMessageSize = 16 * 1024 * 1024; // 16 MB
    });
}
```

For more information on configuration, see gRPC for .NET configuration.

Logging

C-core-based apps rely on the `GrpcEnvironment` to configure the logger for debugging purposes. The ASP.NET Core stack provides this functionality through the Logging API. For example, a logger can be added to the gRPC service via constructor injection:

```
public class GreeterService : Greeter.GreeterBase
{
    public GreeterService(ILogger<GreeterService> logger)
    {
    }
}
```

HTTPS

C-core-based apps configure HTTPS through the Server.Ports property. A similar concept is used to configure servers in ASP.NET Core. For example, Kestrel uses endpoint configuration for this functionality.

gRPC Interceptors vs Middleware

ASP.NET Core middleware offers similar functionalities compared to interceptors in C-core-based gRPC apps. ASP.NET Core middleware and interceptors are conceptually similar. Both:

- Are used to construct a pipeline that handles a gRPC request.
- Allow work to be performed before or after the next component in the pipeline.
- Provide access to `HttpContext`:
  - In middleware the `HttpContext` is a parameter.
  - In interceptors the `HttpContext` can be accessed using the `ServerCallContext` parameter with the `ServerCallContext.GetHttpContext` extension method. Note that this feature is specific to interceptors running in ASP.NET Core.

gRPC Interceptor differences from ASP.NET Core Middleware:

- Interceptors:
  - Operate on the gRPC layer of abstraction using the ServerCallContext.
  - Provide access to:
    - The deserialized message sent to a call.
    - The message being returned from the call before it is serialized.
  - Can catch and handle exceptions thrown from gRPC services.
- Middleware:
  - Runs before gRPC interceptors.
  - Operates on the underlying HTTP/2 messages.
  - Can only access bytes from the request and response streams.

gRPC for Windows Communication Foundation (WCF) developers

9/22/2020 • 3 minutes to read • Edit Online

This article provides a summary of why ASP.NET Core gRPC is a good fit for Windows Communication Foundation (WCF) developers who want to migrate to modern architectures and platforms.

Comparison to WCF

Although the implementation and approach are different for gRPC, the experience of developing and consuming services with gRPC should be intuitive for WCF developers. WCF and gRPC are RPC (remote procedure call) frameworks with the same goals:

- Make it possible to code as though the client and server are on the same platform.
- Provide a simplified portable networking API.

Both platforms share the requirement of declaring and implementing an interface, although the process for declaring the interface is different. The many types of RPC calls that gRPC supports map well to the bindings available to WCF services. For more information and examples, see Migrate a WCF solution to gRPC.

Benefits of gRPC

gRPC provides a better framework than other approaches for the following reasons.

Performance

gRPC uses HTTP/2. In contrast to HTTP/1.1, HTTP/2:

- Is a smaller, faster binary protocol.
- Is more efficient for computers to parse.
- Supports multiplexing requests over a single connection. Multiplexing enables multiple requests to be sent over one connection without requests blocking each other. In HTTP/1.1, the blocking is known as "head-of-line (HOL) blocking."

gRPC uses Protobuf, an efficient binary format, to serialize messages. Protobuf messages are:

- Fast to serialize and deserialize.
- Use less bandwidth than text-based formats.

gRPC is a good solution for mobile devices and networks with bandwidth restrictions.

Interoperability

There are gRPC tools and libraries for all major programming languages and platforms, including .NET, Java, Python, Go, C++, Node.js, Swift, Dart, Ruby, and PHP. Thanks to the Protobuf binary wire format and the efficient code generation for each platform, developers can build cross-platform, performant apps.

Usability and productivity

gRPC is a comprehensive RPC solution. It works consistently across multiple languages and platforms. It also provides excellent tooling, with much of the boilerplate code automatically generated. Like WCF, gRPC automatically generates messages and a strongly typed client. Developer time is freed up to focus on business logic.

Streaming

gRPC has full bidirectional streaming, which provides similar functionality to WCF's full duplex services. gRPC streaming can operate over regular internet connections, load balancers, and service meshes.

Deadlines, timeouts, and cancellation

gRPC allows clients to specify a maximum time for an RPC to finish. If the specified deadline is exceeded, the server can cancel the operation independently of the client. Deadlines and cancellations can be propagated through subsequent gRPC calls to help enforce resource usage limits. Clients can stop operations when a deadline is exceeded, or earlier if necessary. For example, clients can stop operations because of a user interaction.

Security

gRPC can use TLS and HTTP/2 to provide an end-to-end encrypted connection between the client and the server. Support for client certificate authentication further increases security and trust between client and server.

gRPC as a migration path for WCF to .NET Core and .NET 5

.NET Core and .NET 5 marks a shift in the way that Microsoft delivers remote communication solutions to developers who want to deliver services across a range of platforms. .NET Core and .NET 5 support calling WCF services, but won't offer server-side support for hosting WCF.

There are two recommended paths for modernizing WCF apps:

- gRPC is built on modern technologies and has emerged as the most popular choice across the developer community for RPC apps. Starting with .NET Core 3.0, modern .NET platforms have excellent support for gRPC. Migrating WCF services to use gRPC helps provide the RPC features, performance, an interoperability needed in modern apps.
- CoreWCF is a community effort to bring support for hosting WCF services to .NET Core and .NET 5. A preview release is available and the project is working towards being production ready. CoreWCF only supports a subset of WCF's features, and .NET Framework apps that migrate to use it will need code changes and testing to be successful. CoreWCF is a good choice if an app has to maintain compatibility with existing clients that call WCF services.

Get started

Compare gRPC services with HTTP APIs

9/22/2020 • 5 minutes to read • Edit Online

By James Newton-King

This article explains how gRPC services compare to HTTP APIs with JSON (including ASP.NET Core web APIs). The technology used to provide an API for your app is an important choice, and gRPC offers unique benefits compared to HTTP APIs. This article discusses the strengths and weaknesses of gRPC and recommends scenarios for using gRPC over other technologies.

High-level comparison

The following table offers a high-level comparison of features between gRPC and HTTP APIs with JSON.

FEATURE	GRPC	HTTP APIS WITH JSON
Contract	Required (*.proto*)	Optional (OpenAPI)
Protocol	HTTP/2	HTTP
Payload	Protobuf (small, binary)	JSON (large, human readable)
Prescriptiveness	Strict specification	Loose. Any HTTP is valid.
Streaming	Client, server, bi-directional	Client, server
Browser support	No (requires grpc-web)	Yes
Security	Transport (TLS)	Transport (TLS)
Client code-generation	Yes	OpenAPI + third-party tooling

gRPC strengths

Performance

gRPC messages are serialized using Protobuf, an efficient binary message format. Protobuf serializes very quickly on the server and client. Protobuf serialization results in small message payloads, important in limited bandwidth scenarios like mobile apps.

gRPC is designed for HTTP/2, a major revision of HTTP that provides significant performance benefits over HTTP 1.x:

- Binary framing and compression. HTTP/2 protocol is compact and efficient both in sending and receiving.
- Multiplexing of multiple HTTP/2 calls over a single TCP connection. Multiplexing eliminates head-of-line blocking.

HTTP/2 is not exclusive to gRPC. Many request types, including HTTP APIs with JSON, can use HTTP/2 and benefit from its performance improvements.

Code generation

All gRPC frameworks provide first-class support for code generation. A core file to gRPC development is the .proto file, which defines the contract of gRPC services and messages. From this file gRPC frameworks will code generate a service base class, messages, and a complete client.

By sharing the *.proto* file between the server and client, messages and client code can be generated from end to end. Code generation of the client eliminates duplication of messages on the client and server, and creates a strongly-typed client for you. Not having to write a client saves significant development time in applications with many services.

Strict specification

A formal specification for HTTP API with JSON doesn't exist. Developers debate the best format of URLs, HTTP verbs, and response codes.

The gRPC specification is prescriptive about the format a gRPC service must follow. gRPC eliminates debate and saves developer time because gRPC is consistent across platforms and implementations.

Streaming

HTTP/2 provides a foundation for long-lived, real-time communication streams. gRPC provides first-class support for streaming through HTTP/2.

A gRPC service supports all streaming combinations:

- Unary (no streaming)
- Server to client streaming
- Client to server streaming
- Bi-directional streaming

Deadline/timeouts and cancellation

gRPC allows clients to specify how long they are willing to wait for an RPC to complete. The deadline is sent to the server, and the server can decide what action to take if it exceeds the deadline. For example, the server might cancel in-progress gRPC/HTTP/database requests on timeout.

Propagating the deadline and cancellation through child gRPC calls helps enforce resource usage limits.

gRPC recommended scenarios

gRPC is well suited to the following scenarios:

- **Microservices**: gRPC is designed for low latency and high throughput communication. gRPC is great for lightweight microservices where efficiency is critical.
- **Point-to-point real-time communication**: gRPC has excellent support for bi-directional streaming. gRPC services can push messages in real-time without polling.
- **Polyglot environments**: gRPC tooling supports all popular development languages, making gRPC a good choice for multi-language environments.
- **Network constrained environments**: gRPC messages are serialized with Protobuf, a lightweight message format. A gRPC message is always smaller than an equivalent JSON message.
- **Inter-process communication (IPC)**: IPC transports such as Unix domain sockets and named pipes can be used with gRPC to communicate between apps on the same machine. For more information, see Inter-process communication with gRPC.

gRPC weaknesses

Limited browser support

It's impossible to directly call a gRPC service from a browser today. gRPC heavily uses HTTP/2 features and no browser provides the level of control required over web requests to support a gRPC client. For example, browsers

do not allow a caller to require that HTTP/2 be used, or provide access to underlying HTTP/2 frames.

There are two common approaches to bring gRPC to browser apps:

- gRPC-Web is an additional technology from the gRPC team that provides gRPC support in the browser. gRPC-Web allows browser apps to benefit from the high-performance and low network usage of gRPC. Not all of gRPC's features are supported by gRPC-Web. Client and bi-directional streaming isn't supported, and there is limited support for server streaming.

  .NET Core has support for gRPC-Web. For more information, see Use gRPC in browser apps.

- RESTful JSON Web APIs can be automatically created from gRPC services by annotating the *.proto* file with HTTP metadata. This allows an app to support both gRPC and JSON web APIs, without duplicating effort of building separate services for both.

  .NET Core has experimental support for creating JSON web APIs from gRPC services. For more information, see Create JSON Web APIs from gRPC.

Not human readable

HTTP API requests are sent as text and can be read and created by humans.

gRPC messages are encoded with Protobuf by default. While Protobuf is efficient to send and receive, its binary format isn't human readable. Protobuf requires the message's interface description specified in the *.proto* file to properly deserialize. Additional tooling is required to analyze Protobuf payloads on the wire and to compose requests by hand.

Features such as server reflection and the gRPC command line tool exist to assist with binary Protobuf messages. Also, Protobuf messages support conversion to and from JSON. The built-in JSON conversion provides an efficient way to convert Protobuf messages to and from human readable form when debugging.

Alternative framework scenarios

Other frameworks are recommended over gRPC in the following scenarios:

- **Browser accessible APIs**: gRPC isn't fully supported in the browser. gRPC-Web can offer browser support, but it has limitations and introduces a server proxy.
- **Broadcast real-time communication**: gRPC supports real-time communication via streaming, but the concept of broadcasting a message out to registered connections doesn't exist. For example in a chat room scenario where new chat messages should be sent to all clients in the chat room, each gRPC call is required to individually stream new chat messages to the client. SignalR is a useful framework for this scenario. SignalR has the concept of persistent connections and built-in support for broadcasting messages.

Troubleshoot gRPC on .NET Core

9/22/2020 • 4 minutes to read • Edit Online

By James Newton-King

This document discusses commonly encountered problems when developing gRPC apps on .NET.

Mismatch between client and service SSL/TLS configuration

The gRPC template and samples use Transport Layer Security (TLS) to secure gRPC services by default. gRPC clients need to use a secure connection to call secured gRPC services successfully.

You can verify the ASP.NET Core gRPC service is using TLS in the logs written on app start. The service will be listening on an HTTPS endpoint:

```
info: Microsoft.Hosting.Lifetime[0]
      Now listening on: https://localhost:5001
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
```

The .NET Core client must use `https` in the server address to make calls with a secured connection:

```
static async Task Main(string[] args)
{
    // The port number(5001) must match the port of the gRPC server.
    var channel = GrpcChannel.ForAddress("https://localhost:5001");
    var client = new Greet.GreeterClient(channel);
}
```

All gRPC client implementations support TLS. gRPC clients from other languages typically require the channel configured with `SslCredentials`. `SslCredentials` specifies the certificate that the client will use, and it must be used instead of insecure credentials. For examples of configuring the different gRPC client implementations to use TLS, see gRPC Authentication.

Call a gRPC service with an untrusted/invalid certificate

The .NET gRPC client requires the service to have a trusted certificate. The following error message is returned when calling a gRPC service without a trusted certificate:

> Unhandled exception. System.Net.Http.HttpRequestException: The SSL connection could not be established, see inner exception. ---> System.Security.Authentication.AuthenticationException: The remote certificate is invalid according to the validation procedure.

You may see this error if you are testing your app locally and the ASP.NET Core HTTPS development certificate is not trusted. For instructions to fix this issue, see Trust the ASP.NET Core HTTPS development certificate on Windows and macOS.

If you are calling a gRPC service on another machine and are unable to trust the certificate then the gRPC client can be configured to ignore the invalid certificate. The following code uses HttpClientHandler.ServerCertificateCustomValidationCallback to allow calls without a trusted certificate:

```
var httpHandler = new HttpClientHandler();
// Return `true` to allow certificates that are untrusted/invalid
httpHandler.ServerCertificateCustomValidationCallback =
    HttpClientHandler.DangerousAcceptAnyServerCertificateValidator;

var channel = GrpcChannel.ForAddress("https://localhost:5001",
    new GrpcChannelOptions { HttpHandler = httpHandler });
var client = new Greet.GreeterClient(channel);
```

WARNING

Untrusted certificates should only be used during app development. Production apps should always use valid certificates.

Call insecure gRPC services with .NET Core client

Additional configuration is required to call insecure gRPC services with the .NET Core client. The gRPC client must set the `System.Net.Http.SocketsHttpHandler.Http2UnencryptedSupport` switch to `true` and use `http` in the server address:

```
// This switch must be set before creating the GrpcChannel/HttpClient.
AppContext.SetSwitch(
    "System.Net.Http.SocketsHttpHandler.Http2UnencryptedSupport", true);

// The port number(5000) must match the port of the gRPC server.
var channel = GrpcChannel.ForAddress("http://localhost:5000");
var client = new Greet.GreeterClient(channel);
```

Unable to start ASP.NET Core gRPC app on macOS

Kestrel doesn't support HTTP/2 with TLS on macOS and older Windows versions such as Windows 7. The ASP.NET Core gRPC template and samples use TLS by default. You'll see the following error message when you attempt to start the gRPC server:

> Unable to bind to https://localhost:5001 on the IPv4 loopback interface: 'HTTP/2 over TLS is not supported on macOS due to missing ALPN support.'.

To work around this issue, configure Kestrel and the gRPC client to use HTTP/2 *without* TLS. You should only do this during development. Not using TLS will result in gRPC messages being sent without encryption.

Kestrel must configure an HTTP/2 endpoint without TLS in *Program.cs*:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.ConfigureKestrel(options =>
            {
                // Setup a HTTP/2 endpoint without TLS.
                options.ListenLocalhost(5000, o => o.Protocols =
                    HttpProtocols.Http2);
            });
            webBuilder.UseStartup<Startup>();
        });
```

When an HTTP/2 endpoint is configured without TLS, the endpoint's ListenOptions.Protocols must be set to

`HttpProtocols.Http2`. `HttpProtocols.Http1AndHttp2` can't be used because TLS is required to negotiate HTTP/2. Without TLS, all connections to the endpoint default to HTTP/1.1, and gRPC calls fail.

The gRPC client must also be configured to not use TLS. For more information, see Call insecure gRPC services with .NET Core client.

> **WARNING**
> HTTP/2 without TLS should only be used during app development. Production apps should always use transport security. For more information, see Security considerations in gRPC for ASP.NET Core.

gRPC C# assets are not code generated from .proto files

gRPC code generation of concrete clients and service base classes requires protobuf files and tooling to be referenced from a project. You must include:

- *.proto* files you want to use in the `<Protobuf>` item group. Imported *.proto* files must be referenced by the project.
- Package reference to the gRPC tooling package Grpc.Tools.

For more information on generating gRPC C# assets, see gRPC services with C#.

An ASP.NET Core web app hosting gRPC services only needs the service base class generated:

```
<ItemGroup>
  <Protobuf Include="Protos\greet.proto" GrpcServices="Server" />
</ItemGroup>
```

A gRPC client app making gRPC calls only needs the concrete client generated:

```
<ItemGroup>
  <Protobuf Include="Protos\greet.proto" GrpcServices="Client" />
</ItemGroup>
```

WPF projects unable to generate gRPC C# assets from .proto files

WPF projects have a known issue that prevents gRPC code generation from working correctly. Any gRPC types generated in a WPF project by referencing `Grpc.Tools` and *.proto* files will create compilation errors when used:

> error CS0246: The type or namespace name 'MyGrpcServices' could not be found (are you missing a using directive or an assembly reference?)

You can workaround this issue by:

1. Create a new .NET Core class library project.
2. In the new project, add references to enable C# code generation from **.proto* files:
   - Add a package reference to Grpc.Tools package.
   - Add **.proto* files to the `<Protobuf>` item group.
3. In the WPF application, add a reference to the new project.

The WPF application can use the gRPC generated types from the new class library project.

WARNING

ASP.NET Core gRPC is not currently supported on Azure App Service or IIS. The HTTP/2 implementation of Http.Sys does not support HTTP response trailing headers which gRPC relies on. For more information, see this GitHub issue.

Razor Pages unit tests in ASP.NET Core

9/22/2020 • 19 minutes to read • Edit Online

ASP.NET Core supports unit tests of Razor Pages apps. Tests of the data access layer (DAL) and page models help ensure:

- Parts of a Razor Pages app work independently and together as a unit during app construction.
- Classes and methods have limited scopes of responsibility.
- Additional documentation exists on how the app should behave.
- Regressions, which are errors brought about by updates to the code, are found during automated building and deployment.

This topic assumes that you have a basic understanding of Razor Pages apps and unit tests. If you're unfamiliar with Razor Pages apps or test concepts, see the following topics:

- Introduction to Razor Pages in ASP.NET Core
- Tutorial: Get started with Razor Pages in ASP.NET Core
- Unit testing C# in .NET Core using dotnet test and xUnit

View or download sample code (how to download)

The sample project is composed of two apps:

APP	PROJECT FOLDER	DESCRIPTION
Message app	*src/RazorPagesTestSample*	Allows a user to add a message, delete one message, delete all messages, and analyze messages (find the average number of words per message).
Test app	*tests/RazorPagesTestSample.Tests*	Used to unit test the DAL and Index page model of the message app.

The tests can be run using the built-in test features of an IDE, such as Visual Studio or Visual Studio for Mac. If using Visual Studio Code or the command line, execute the following command at a command prompt in the *tests/RazorPagesTestSample.Tests* folder:

```
dotnet test
```

Message app organization

The message app is a Razor Pages message system with the following characteristics:

- The Index page of the app (*Pages/Index.cshtml* and *Pages/Index.cshtml.cs*) provides a UI and page model methods to control the addition, deletion, and analysis of messages (find the average number of words per message).
- A message is described by the `Message` class (*Data/Message.cs*) with two properties: `Id` (key) and `Text` (message). The `Text` property is required and limited to 200 characters.
- Messages are stored using Entity Framework's in-memory database†.
- The app contains a DAL in its database context class, `AppDbContext` (*Data/AppDbContext.cs*). The DAL methods

are marked `virtual`, which allows mocking the methods for use in the tests.

- If the database is empty on app startup, the message store is initialized with three messages. These *seeded messages* are also used in tests.

†The EF topic, Test with InMemory, explains how to use an in-memory database for tests with MSTest. This topic uses the xUnit test framework. Test concepts and test implementations across different test frameworks are similar but not identical.

Although the sample app doesn't use the repository pattern and isn't an effective example of the Unit of Work (UoW) pattern, Razor Pages supports these patterns of development. For more information, see Designing the infrastructure persistence layer and Test controller logic in ASP.NET Core (the sample implements the repository pattern).

Test app organization

The test app is a console app inside the *tests/RazorPagesTestSample.Tests* folder.

TEST APP FOLDER	DESCRIPTION
UnitTests	• *DataAccessLayerTest.cs* contains the unit tests for the DAL. • *IndexPageTests.cs* contains the unit tests for the Index page model.
Utilities	Contains the `TestDbContextOptions` method used to create new database context options for each DAL unit test so that the database is reset to its baseline condition for each test.

The test framework is xUnit. The object mocking framework is Moq.

Unit tests of the data access layer (DAL)

The message app has a DAL with four methods contained in the `AppDbContext` class (*src/RazorPagesTestSample/Data/AppDbContext.cs*). Each method has one or two unit tests in the test app.

DAL METHOD	FUNCTION
`GetMessagesAsync`	Obtains a `List<Message>` from the database sorted by the `Text` property.
`AddMessageAsync`	Adds a `Message` to the database.
`DeleteAllMessagesAsync`	Deletes all `Message` entries from the database.
`DeleteMessageAsync`	Deletes a single `Message` from the database by `Id`.

Unit tests of the DAL require DbContextOptions when creating a new `AppDbContext` for each test. One approach to creating the `DbContextOptions` for each test is to use a DbContextOptionsBuilder:

```
var optionsBuilder = new DbContextOptionsBuilder<AppDbContext>()
    .UseInMemoryDatabase("InMemoryDb");

using (var db = new AppDbContext(optionsBuilder.Options))
{
    // Use the db here in the unit test.
}
```

The problem with this approach is that each test receives the database in whatever state the previous test left it. This can be problematic when trying to write atomic unit tests that don't interfere with each other. To force the `AppDbContext` to use a new database context for each test, supply a `DbContextOptions` instance that's based on a new service provider. The test app shows how to do this using its `Utilities` class method `TestDbContextOptions` (*tests/RazorPagesTestSample.Tests/Utilities/Utilities.cs*):

```
public static DbContextOptions<AppDbContext> TestDbContextOptions()
{
    // Create a new service provider to create a new in-memory database.
    var serviceProvider = new ServiceCollection()
        .AddEntityFrameworkInMemoryDatabase()
        .BuildServiceProvider();

    // Create a new options instance using an in-memory database and
    // IServiceProvider that the context should resolve all of its
    // services from.
    var builder = new DbContextOptionsBuilder<AppDbContext>()
        .UseInMemoryDatabase("InMemoryDb")
        .UseInternalServiceProvider(serviceProvider);

    return builder.Options;
}
```

Using the `DbContextOptions` in the DAL unit tests allows each test to run atomically with a fresh database instance:

```
using (var db = new AppDbContext(Utilities.TestDbContextOptions()))
{
    // Use the db here in the unit test.
}
```

Each test method in the `DataAccessLayerTest` class (*UnitTests/DataAccessLayerTest.cs*) follows a similar Arrange-Act-Assert pattern:

1. Arrange: The database is configured for the test and/or the expected outcome is defined.
2. Act: The test is executed.
3. Assert: Assertions are made to determine if the test result is a success.

For example, the `DeleteMessageAsync` method is responsible for removing a single message identified by its `Id` (*src/RazorPagesTestSample/Data/AppDbContext.cs*):

```
public async virtual Task DeleteMessageAsync(int id)
{
    var message = await Messages.FindAsync(id);

    if (message != null)
    {
        Messages.Remove(message);
        await SaveChangesAsync();
    }
}
```

There are two tests for this method. One test checks that the method deletes a message when the message is present in the database. The other method tests that the database doesn't change if the message `Id` for deletion doesn't exist. The `DeleteMessageAsync_MessageIsDeleted_WhenMessageIsFound` method is shown below:

```
[Fact]
public async Task DeleteMessageAsync_MessageIsDeleted_WhenMessageIsFound()
{
    using (var db = new AppDbContext(Utilities.TestDbContextOptions()))
    {
        // Arrange
        var seedMessages = AppDbContext.GetSeedingMessages();
        await db.AddRangeAsync(seedMessages);
        await db.SaveChangesAsync();
        var recId = 1;
        var expectedMessages =
            seedMessages.Where(message => message.Id != recId).ToList();

        // Act
        await db.DeleteMessageAsync(recId);

        // Assert
        var actualMessages = await db.Messages.AsNoTracking().ToListAsync();
        Assert.Equal(
            expectedMessages.OrderBy(m => m.Id).Select(m => m.Text),
            actualMessages.OrderBy(m => m.Id).Select(m => m.Text));
    }
}
```

First, the method performs the Arrange step, where preparation for the Act step takes place. The seeding messages are obtained and held in `seedMessages`. The seeding messages are saved into the database. The message with an `Id` of `1` is set for deletion. When the `DeleteMessageAsync` method is executed, the expected messages should have all of the messages except for the one with an `Id` of `1`. The `expectedMessages` variable represents this expected outcome.

```
// Arrange
var seedMessages = AppDbContext.GetSeedingMessages();
await db.AddRangeAsync(seedMessages);
await db.SaveChangesAsync();
var recId = 1;
var expectedMessages =
    seedMessages.Where(message => message.Id != recId).ToList();
```

The method acts: The `DeleteMessageAsync` method is executed passing in the `recId` of `1`:

```
// Act
await db.DeleteMessageAsync(recId);
```

Finally, the method obtains the `Messages` from the context and compares it to the `expectedMessages` asserting that the two are equal:

```
// Assert
var actualMessages = await db.Messages.AsNoTracking().ToListAsync();
Assert.Equal(
    expectedMessages.OrderBy(m => m.Id).Select(m => m.Text),
    actualMessages.OrderBy(m => m.Id).Select(m => m.Text));
```

In order to compare that the two `List<Message>` are the same:

- The messages are ordered by `Id`.
- Message pairs are compared on the `Text` property.

A similar test method, `DeleteMessageAsync_NoMessageIsDeleted_WhenMessageIsNotFound` checks the result of attempting to delete a message that doesn't exist. In this case, the expected messages in the database should be equal to the actual messages after the `DeleteMessageAsync` method is executed. There should be no change to the database's content:

```
[Fact]
public async Task DeleteMessageAsync_NoMessageIsDeleted_WhenMessageIsNotFound()
{
    using (var db = new AppDbContext(Utilities.TestDbContextOptions()))
    {
        // Arrange
        var expectedMessages = AppDbContext.GetSeedingMessages();
        await db.AddRangeAsync(expectedMessages);
        await db.SaveChangesAsync();
        var recId = 4;

        // Act
        try
        {
            await db.DeleteMessageAsync(recId);
        }
        catch
        {
            // recId doesn't exist
        }

        // Assert
        var actualMessages = await db.Messages.AsNoTracking().ToListAsync();
        Assert.Equal(
            expectedMessages.OrderBy(m => m.Id).Select(m => m.Text),
            actualMessages.OrderBy(m => m.Id).Select(m => m.Text));
    }
}
```

Unit tests of the page model methods

Another set of unit tests is responsible for tests of page model methods. In the message app, the Index page models are found in the `IndexModel` class in *src/RazorPagesTestSample/Pages/Index.cshtml.cs*.

PAGE MODEL METHOD	FUNCTION
`OnGetAsync`	Obtains the messages from the DAL for the UI using the `GetMessagesAsync` method.
`OnPostAddMessageAsync`	If the ModelState is valid, calls `AddMessageAsync` to add a message to the database.
`OnPostDeleteAllMessagesAsync`	Calls `DeleteAllMessagesAsync` to delete all of the messages in the database.
`OnPostDeleteMessageAsync`	Executes `DeleteMessageAsync` to delete a message with the `Id` specified.
`OnPostAnalyzeMessagesAsync`	If one or more messages are in the database, calculates the average number of words per message.

The page model methods are tested using seven tests in the `IndexPageTests` class (*tests/RazorPagesTestSample.Tests/UnitTests/IndexPageTests.cs*). The tests use the familiar Arrange-Assert-Act pattern. These tests focus on:

- Determining if the methods follow the correct behavior when the ModelState is invalid.
- Confirming the methods produce the correct IActionResult.
- Checking that property value assignments are made correctly.

This group of tests often mock the methods of the DAL to produce expected data for the Act step where a page model method is executed. For example, the `GetMessagesAsync` method of the `AppDbContext` is mocked to produce output. When a page model method executes this method, the mock returns the result. The data doesn't come from the database. This creates predictable, reliable test conditions for using the DAL in the page model tests.

The `OnGetAsync_PopulatesThePageModel_WithAListOfMessages` test shows how the `GetMessagesAsync` method is mocked for the page model:

```
var mockAppDbContext = new Mock<AppDbContext>(optionsBuilder.Options);
var expectedMessages = AppDbContext.GetSeedingMessages();
mockAppDbContext.Setup(
    db => db.GetMessagesAsync()).Returns(Task.FromResult(expectedMessages));
var pageModel = new IndexModel(mockAppDbContext.Object);
```

When the `OnGetAsync` method is executed in the Act step, it calls the page model's `GetMessagesAsync` method.

Unit test Act step (*tests/RazorPagesTestSample.Tests/UnitTests/IndexPageTests.cs*):

```
// Act
await pageModel.OnGetAsync();
```

`IndexPage` page model's `OnGetAsync` method (*src/RazorPagesTestSample/Pages/Index.cshtml.cs*):

```
public async Task OnGetAsync()
{
    Messages = await _db.GetMessagesAsync();
}
```

The `GetMessagesAsync` method in the DAL doesn't return the result for this method call. The mocked version of the method returns the result.

In the `Assert` step, the actual messages (`actualMessages`) are assigned from the `Messages` property of the page model. A type check is also performed when the messages are assigned. The expected and actual messages are compared by their `Text` properties. The test asserts that the two `List<Message>` instances contain the same messages.

```
// Assert
var actualMessages = Assert.IsAssignableFrom<List<Message>>(pageModel.Messages);
Assert.Equal(
    expectedMessages.OrderBy(m => m.Id).Select(m => m.Text),
    actualMessages.OrderBy(m => m.Id).Select(m => m.Text));
```

Other tests in this group create page model objects that include the DefaultHttpContext, the ModelStateDictionary, an ActionContext to establish the `PageContext`, a `ViewDataDictionary`, and a `PageContext`. These are useful in conducting tests. For example, the message app establishes a `ModelState` error with AddModelError to check that a valid PageResult is returned when `OnPostAddMessageAsync` is executed:

```
[Fact]
public async Task OnPostAddMessageAsync_ReturnsAPageResult_WhenModelStateIsInvalid()
{
    // Arrange
    var optionsBuilder = new DbContextOptionsBuilder<AppDbContext>()
        .UseInMemoryDatabase("InMemoryDb");
    var mockAppDbContext = new Mock<AppDbContext>(optionsBuilder.Options);
    var expectedMessages = AppDbContext.GetSeedingMessages();
    mockAppDbContext.Setup(db => db.GetMessagesAsync()).Returns(Task.FromResult(expectedMessages));
    var httpContext = new DefaultHttpContext();
    var modelState = new ModelStateDictionary();
    var actionContext = new ActionContext(httpContext, new RouteData(), new PageActionDescriptor(),
modelState);
    var modelMetadataProvider = new EmptyModelMetadataProvider();
    var viewData = new ViewDataDictionary(modelMetadataProvider, modelState);
    var tempData = new TempDataDictionary(httpContext, Mock.Of<ITempDataProvider>());
    var pageContext = new PageContext(actionContext)
    {
        ViewData = viewData
    };
    var pageModel = new IndexModel(mockAppDbContext.Object)
    {
        PageContext = pageContext,
        TempData = tempData,
        Url = new UrlHelper(actionContext)
    };
    pageModel.ModelState.AddModelError("Message.Text", "The Text field is required.");

    // Act
    var result = await pageModel.OnPostAddMessageAsync();

    // Assert
    Assert.IsType<PageResult>(result);
}
```

ASP.NET Core supports unit tests of Razor Pages apps. Tests of the data access layer (DAL) and page models help ensure:

- Parts of a Razor Pages app work independently and together as a unit during app construction.
- Classes and methods have limited scopes of responsibility.
- Additional documentation exists on how the app should behave.
- Regressions, which are errors brought about by updates to the code, are found during automated building and deployment.

This topic assumes that you have a basic understanding of Razor Pages apps and unit tests. If you're unfamiliar with Razor Pages apps or test concepts, see the following topics:

- Introduction to Razor Pages in ASP.NET Core
- Tutorial: Get started with Razor Pages in ASP.NET Core
- Unit testing C# in .NET Core using dotnet test and xUnit

View or download sample code (how to download)

The sample project is composed of two apps:

APP	PROJECT FOLDER	DESCRIPTION
Message app	*src/RazorPagesTestSample*	Allows a user to add a message, delete one message, delete all messages, and analyze messages (find the average number of words per message).
Test app	*tests/RazorPagesTestSample.Tests*	Used to unit test the DAL and Index page model of the message app.

The tests can be run using the built-in test features of an IDE, such as Visual Studio or Visual Studio for Mac. If using Visual Studio Code or the command line, execute the following command at a command prompt in the *tests/RazorPagesTestSample.Tests* folder:

```
dotnet test
```

Message app organization

The message app is a Razor Pages message system with the following characteristics:

- The Index page of the app (*Pages/Index.cshtml* and *Pages/Index.cshtml.cs*) provides a UI and page model methods to control the addition, deletion, and analysis of messages (find the average number of words per message).
- A message is described by the `Message` class (*Data/Message.cs*) with two properties: `Id` (key) and `Text` (message). The `Text` property is required and limited to 200 characters.
- Messages are stored using Entity Framework's in-memory database†.
- The app contains a DAL in its database context class, `AppDbContext` (*Data/AppDbContext.cs*). The DAL methods are marked `virtual`, which allows mocking the methods for use in the tests.
- If the database is empty on app startup, the message store is initialized with three messages. These *seeded messages* are also used in tests.

†The EF topic, Test with InMemory, explains how to use an in-memory database for tests with MSTest. This topic uses the xUnit test framework. Test concepts and test implementations across different test frameworks are similar but not identical.

Although the sample app doesn't use the repository pattern and isn't an effective example of the Unit of Work (UoW) pattern, Razor Pages supports these patterns of development. For more information, see Designing the infrastructure persistence layer and Test controller logic in ASP.NET Core (the sample implements the repository pattern).

Test app organization

The test app is a console app inside the *tests/RazorPagesTestSample.Tests* folder.

TEST APP FOLDER	DESCRIPTION
UnitTests	• *DataAccessLayerTest.cs* contains the unit tests for the DAL. • *IndexPageTests.cs* contains the unit tests for the Index page model.
Utilities	Contains the `TestDbContextOptions` method used to create new database context options for each DAL unit test so that the database is reset to its baseline condition for each test.

The test framework is xUnit. The object mocking framework is Moq.

Unit tests of the data access layer (DAL)

The message app has a DAL with four methods contained in the `AppDbContext` class (*src/RazorPagesTestSample/Data/AppDbContext.cs*). Each method has one or two unit tests in the test app.

DAL METHOD	FUNCTION
`GetMessagesAsync`	Obtains a `List<Message>` from the database sorted by the `Text` property.
`AddMessageAsync`	Adds a `Message` to the database.
`DeleteAllMessagesAsync`	Deletes all `Message` entries from the database.
`DeleteMessageAsync`	Deletes a single `Message` from the database by `Id`.

Unit tests of the DAL require DbContextOptions when creating a new `AppDbContext` for each test. One approach to creating the `DbContextOptions` for each test is to use a DbContextOptionsBuilder:

```
var optionsBuilder = new DbContextOptionsBuilder<AppDbContext>()
    .UseInMemoryDatabase("InMemoryDb");

using (var db = new AppDbContext(optionsBuilder.Options))
{
    // Use the db here in the unit test.
}
```

The problem with this approach is that each test receives the database in whatever state the previous test left it. This can be problematic when trying to write atomic unit tests that don't interfere with each other. To force the `AppDbContext` to use a new database context for each test, supply a `DbContextOptions` instance that's based on a new service provider. The test app shows how to do this using its `Utilities` class method `TestDbContextOptions` (*tests/RazorPagesTestSample.Tests/Utilities/Utilities.cs*):

```
public static DbContextOptions<AppDbContext> TestDbContextOptions()
{
    // Create a new service provider to create a new in-memory database.
    var serviceProvider = new ServiceCollection()
        .AddEntityFrameworkInMemoryDatabase()
        .BuildServiceProvider();

    // Create a new options instance using an in-memory database and
    // IServiceProvider that the context should resolve all of its
    // services from.
    var builder = new DbContextOptionsBuilder<AppDbContext>()
        .UseInMemoryDatabase("InMemoryDb")
        .UseInternalServiceProvider(serviceProvider);

    return builder.Options;
}
```

Using the `DbContextOptions` in the DAL unit tests allows each test to run atomically with a fresh database instance:

```
using (var db = new AppDbContext(Utilities.TestDbContextOptions()))
{
    // Use the db here in the unit test.
}
```

Each test method in the `DataAccessLayerTest` class (*UnitTests/DataAccessLayerTest.cs*) follows a similar Arrange-Act-Assert pattern:

1. Arrange: The database is configured for the test and/or the expected outcome is defined.
2. Act: The test is executed.
3. Assert: Assertions are made to determine if the test result is a success.

For example, the `DeleteMessageAsync` method is responsible for removing a single message identified by its `Id` (*src/RazorPagesTestSample/Data/AppDbContext.cs*):

```
public async virtual Task DeleteMessageAsync(int id)
{
    var message = await Messages.FindAsync(id);

    if (message != null)
    {
        Messages.Remove(message);
        await SaveChangesAsync();
    }
}
```

There are two tests for this method. One test checks that the method deletes a message when the message is present in the database. The other method tests that the database doesn't change if the message `Id` for deletion doesn't exist. The `DeleteMessageAsync_MessageIsDeleted_WhenMessageIsFound` method is shown below:

```
[Fact]
public async Task DeleteMessageAsync_MessageIsDeleted_WhenMessageIsFound()
{
    using (var db = new AppDbContext(Utilities.TestDbContextOptions()))
    {
        // Arrange
        var seedMessages = AppDbContext.GetSeedingMessages();
        await db.AddRangeAsync(seedMessages);
        await db.SaveChangesAsync();
        var recId = 1;
        var expectedMessages =
            seedMessages.Where(message => message.Id != recId).ToList();

        // Act
        await db.DeleteMessageAsync(recId);

        // Assert
        var actualMessages = await db.Messages.AsNoTracking().ToListAsync();
        Assert.Equal(
            expectedMessages.OrderBy(m => m.Id).Select(m => m.Text),
            actualMessages.OrderBy(m => m.Id).Select(m => m.Text));
    }
}
```

First, the method performs the Arrange step, where preparation for the Act step takes place. The seeding messages are obtained and held in `seedMessages`. The seeding messages are saved into the database. The message with an `Id` of `1` is set for deletion. When the `DeleteMessageAsync` method is executed, the expected messages should have all of the messages except for the one with an `Id` of `1`. The `expectedMessages` variable represents this expected outcome.

```
// Arrange
var seedMessages = AppDbContext.GetSeedingMessages();
await db.AddRangeAsync(seedMessages);
await db.SaveChangesAsync();
var recId = 1;
var expectedMessages =
    seedMessages.Where(message => message.Id != recId).ToList();
```

The method acts: The `DeleteMessageAsync` method is executed passing in the `recId` of `1`:

```
// Act
await db.DeleteMessageAsync(recId);
```

Finally, the method obtains the `Messages` from the context and compares it to the `expectedMessages` asserting that the two are equal:

```
// Assert
var actualMessages = await db.Messages.AsNoTracking().ToListAsync();
Assert.Equal(
    expectedMessages.OrderBy(m => m.Id).Select(m => m.Text),
    actualMessages.OrderBy(m => m.Id).Select(m => m.Text));
```

In order to compare that the two `List<Message>` are the same:

- The messages are ordered by `Id`.
- Message pairs are compared on the `Text` property.

A similar test method, `DeleteMessageAsync_NoMessageIsDeleted_WhenMessageIsNotFound` checks the result of

attempting to delete a message that doesn't exist. In this case, the expected messages in the database should be equal to the actual messages after the `DeleteMessageAsync` method is executed. There should be no change to the database's content:

```
[Fact]
public async Task DeleteMessageAsync_NoMessageIsDeleted_WhenMessageIsNotFound()
{
    using (var db = new AppDbContext(Utilities.TestDbContextOptions()))
    {
        // Arrange
        var expectedMessages = AppDbContext.GetSeedingMessages();
        await db.AddRangeAsync(expectedMessages);
        await db.SaveChangesAsync();
        var recId = 4;

        // Act
        await db.DeleteMessageAsync(recId);

        // Assert
        var actualMessages = await db.Messages.AsNoTracking().ToListAsync();
        Assert.Equal(
            expectedMessages.OrderBy(m => m.Id).Select(m => m.Text),
            actualMessages.OrderBy(m => m.Id).Select(m => m.Text));
    }
}
```

Unit tests of the page model methods

Another set of unit tests is responsible for tests of page model methods. In the message app, the Index page models are found in the `IndexModel` class in *src/RazorPagesTestSample/Pages/Index.cshtml.cs*.

PAGE MODEL METHOD	FUNCTION
`OnGetAsync`	Obtains the messages from the DAL for the UI using the `GetMessagesAsync` method.
`OnPostAddMessageAsync`	If the ModelState is valid, calls `AddMessageAsync` to add a message to the database.
`OnPostDeleteAllMessagesAsync`	Calls `DeleteAllMessagesAsync` to delete all of the messages in the database.
`OnPostDeleteMessageAsync`	Executes `DeleteMessageAsync` to delete a message with the `Id` specified.
`OnPostAnalyzeMessagesAsync`	If one or more messages are in the database, calculates the average number of words per message.

The page model methods are tested using seven tests in the `IndexPageTests` class (*tests/RazorPagesTestSample.Tests/UnitTests/IndexPageTests.cs*). The tests use the familiar Arrange-Assert-Act pattern. These tests focus on:

- Determining if the methods follow the correct behavior when the ModelState is invalid.
- Confirming the methods produce the correct IActionResult.
- Checking that property value assignments are made correctly.

This group of tests often mock the methods of the DAL to produce expected data for the Act step where a page

model method is executed. For example, the `GetMessagesAsync` method of the `AppDbContext` is mocked to produce output. When a page model method executes this method, the mock returns the result. The data doesn't come from the database. This creates predictable, reliable test conditions for using the DAL in the page model tests.

The `OnGetAsync_PopulatesThePageModel_WithAListOfMessages` test shows how the `GetMessagesAsync` method is mocked for the page model:

```
var mockAppDbContext = new Mock<AppDbContext>(optionsBuilder.Options);
var expectedMessages = AppDbContext.GetSeedingMessages();
mockAppDbContext.Setup(
    db => db.GetMessagesAsync()).Returns(Task.FromResult(expectedMessages));
var pageModel = new IndexModel(mockAppDbContext.Object);
```

When the `OnGetAsync` method is executed in the Act step, it calls the page model's `GetMessagesAsync` method.

Unit test Act step (*tests/RazorPagesTestSample.Tests/UnitTests/IndexPageTests.cs*):

```
// Act
await pageModel.OnGetAsync();
```

`IndexPage` page model's `OnGetAsync` method (*src/RazorPagesTestSample/Pages/Index.cshtml.cs*):

```
public async Task OnGetAsync()
{
    Messages = await _db.GetMessagesAsync();
}
```

The `GetMessagesAsync` method in the DAL doesn't return the result for this method call. The mocked version of the method returns the result.

In the `Assert` step, the actual messages (`actualMessages`) are assigned from the `Messages` property of the page model. A type check is also performed when the messages are assigned. The expected and actual messages are compared by their `Text` properties. The test asserts that the two `List<Message>` instances contain the same messages.

```
// Assert
var actualMessages = Assert.IsAssignableFrom<List<Message>>(pageModel.Messages);
Assert.Equal(
    expectedMessages.OrderBy(m => m.Id).Select(m => m.Text),
    actualMessages.OrderBy(m => m.Id).Select(m => m.Text));
```

Other tests in this group create page model objects that include the DefaultHttpContext, the ModelStateDictionary, an ActionContext to establish the `PageContext`, a `ViewDataDictionary`, and a `PageContext`. These are useful in conducting tests. For example, the message app establishes a `ModelState` error with AddModelError to check that a valid PageResult is returned when `OnPostAddMessageAsync` is executed:

```
[Fact]
public async Task OnPostAddMessageAsync_ReturnsAPageResult_WhenModelStateIsInvalid()
{
    // Arrange
    var optionsBuilder = new DbContextOptionsBuilder<AppDbContext>()
        .UseInMemoryDatabase("InMemoryDb");
    var mockAppDbContext = new Mock<AppDbContext>(optionsBuilder.Options);
    var expectedMessages = AppDbContext.GetSeedingMessages();
    mockAppDbContext.Setup(db => db.GetMessagesAsync()).Returns(Task.FromResult(expectedMessages));
    var httpContext = new DefaultHttpContext();
    var modelState = new ModelStateDictionary();
    var actionContext = new ActionContext(httpContext, new RouteData(), new PageActionDescriptor(),
modelState);
    var modelMetadataProvider = new EmptyModelMetadataProvider();
    var viewData = new ViewDataDictionary(modelMetadataProvider, modelState);
    var tempData = new TempDataDictionary(httpContext, Mock.Of<ITempDataProvider>());
    var pageContext = new PageContext(actionContext)
    {
        ViewData = viewData
    };
    var pageModel = new IndexModel(mockAppDbContext.Object)
    {
        PageContext = pageContext,
        TempData = tempData,
        Url = new UrlHelper(actionContext)
    };
    pageModel.ModelState.AddModelError("Message.Text", "The Text field is required.");

    // Act
    var result = await pageModel.OnPostAddMessageAsync();

    // Assert
    Assert.IsType<PageResult>(result);
}
```

Unit test controller logic in ASP.NET Core

9/22/2020 • 25 minutes to read • Edit Online

By Steve Smith

Unit tests involve testing a part of an app in isolation from its infrastructure and dependencies. When unit testing controller logic, only the contents of a single action are tested, not the behavior of its dependencies or of the framework itself.

Unit testing controllers

Set up unit tests of controller actions to focus on the controller's behavior. A controller unit test avoids scenarios such as filters, routing, and model binding. Tests that cover the interactions among components that collectively respond to a request are handled by *integration tests*. For more information on integration tests, see Integration tests in ASP.NET Core.

If you're writing custom filters and routes, unit test them in isolation, not as part of tests on a particular controller action.

To demonstrate controller unit tests, review the following controller in the sample app.

View or download sample code (how to download)

The Home controller displays a list of brainstorming sessions and allows the creation of new brainstorming sessions with a POST request:

```
public class HomeController : Controller
{
    private readonly IBrainstormSessionRepository _sessionRepository;

    public HomeController(IBrainstormSessionRepository sessionRepository)
    {
        _sessionRepository = sessionRepository;
    }

    public async Task<IActionResult> Index()
    {
        var sessionList = await _sessionRepository.ListAsync();

        var model = sessionList.Select(session => new StormSessionViewModel()
        {
            Id = session.Id,
            DateCreated = session.DateCreated,
            Name = session.Name,
            IdeaCount = session.Ideas.Count
        });

        return View(model);
    }

    public class NewSessionModel
    {
        [Required]
        public string SessionName { get; set; }
    }

    [HttpPost]
    public async Task<IActionResult> Index(NewSessionModel model)
    {
        if (!ModelState.IsValid)
        {
            return BadRequest(ModelState);
        }
        else
        {
            await _sessionRepository.AddAsync(new BrainstormSession()
            {
                DateCreated = DateTimeOffset.Now,
                Name = model.SessionName
            });
        }

        return RedirectToAction(actionName: nameof(Index));
    }
}
```

The preceding controller:

- Follows the Explicit Dependencies Principle.
- Expects dependency injection (DI) to provide an instance of `IBrainstormSessionRepository`.
- Can be tested with a mocked `IBrainstormSessionRepository` service using a mock object framework, such as Moq. A *mocked object* is a fabricated object with a predetermined set of property and method behaviors used for testing. For more information, see Introduction to integration tests.

The `HTTP GET Index` method has no looping or branching and only calls one method. The unit test for this action:

- Mocks the `IBrainstormSessionRepository` service using the `GetTestSessions` method. `GetTestSessions` creates two mock brainstorm sessions with dates and session names.
- Executes the `Index` method.

- Makes assertions on the result returned by the method:
  - A ViewResult is returned.
  - The ViewDataDictionary.Model is a `StormSessionViewModel`.
  - There are two brainstorming sessions stored in the `ViewDataDictionary.Model`.

```
[Fact]
public async Task Index_ReturnsAViewResult_WithAListOfBrainstormSessions()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.ListAsync())
        .ReturnsAsync(GetTestSessions());
    var controller = new HomeController(mockRepo.Object);

    // Act
    var result = await controller.Index();

    // Assert
    var viewResult = Assert.IsType<ViewResult>(result);
    var model = Assert.IsAssignableFrom<IEnumerable<StormSessionViewModel>>(
        viewResult.ViewData.Model);
    Assert.Equal(2, model.Count());
}
```

```
private List<BrainstormSession> GetTestSessions()
{
    var sessions = new List<BrainstormSession>();
    sessions.Add(new BrainstormSession()
    {
        DateCreated = new DateTime(2016, 7, 2),
        Id = 1,
        Name = "Test One"
    });
    sessions.Add(new BrainstormSession()
    {
        DateCreated = new DateTime(2016, 7, 1),
        Id = 2,
        Name = "Test Two"
    });
    return sessions;
}
```

The Home controller's `HTTP POST Index` method tests verifies that:

- When ModelState.IsValid is `false`, the action method returns a *400 Bad Request* ViewResult with the appropriate data.
- When `ModelState.IsValid` is `true`:
  - The `Add` method on the repository is called.
  - A RedirectToActionResult is returned with the correct arguments.

An invalid model state is tested by adding errors using AddModelError as shown in the first test below:

```
[Fact]
public async Task IndexPost_ReturnsBadRequestResult_WhenModelStateIsInvalid()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.ListAsync())
        .ReturnsAsync(GetTestSessions());
    var controller = new HomeController(mockRepo.Object);
    controller.ModelState.AddModelError("SessionName", "Required");
    var newSession = new HomeController.NewSessionModel();

    // Act
    var result = await controller.Index(newSession);

    // Assert
    var badRequestResult = Assert.IsType<BadRequestObjectResult>(result);
    Assert.IsType<SerializableError>(badRequestResult.Value);
}

[Fact]
public async Task IndexPost_ReturnsARedirectAndAddsSession_WhenModelStateIsValid()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.AddAsync(It.IsAny<BrainstormSession>()))
        .Returns(Task.CompletedTask)
        .Verifiable();
    var controller = new HomeController(mockRepo.Object);
    var newSession = new HomeController.NewSessionModel()
    {
        SessionName = "Test Name"
    };

    // Act
    var result = await controller.Index(newSession);

    // Assert
    var redirectToActionResult = Assert.IsType<RedirectToActionResult>(result);
    Assert.Null(redirectToActionResult.ControllerName);
    Assert.Equal("Index", redirectToActionResult.ActionName);
    mockRepo.Verify();
}
```

When ModelState isn't valid, the same `ViewResult` is returned as for a GET request. The test doesn't attempt to pass in an invalid model. Passing an invalid model isn't a valid approach, since model binding isn't running (although an integration test does use model binding). In this case, model binding isn't tested. These unit tests are only testing the code in the action method.

The second test verifies that when the `ModelState` is valid:

- A new `BrainstormSession` is added (via the repository).
- The method returns a `RedirectToActionResult` with the expected properties.

Mocked calls that aren't called are normally ignored, but calling `Verifiable` at the end of the setup call allows mock validation in the test. This is performed with the call to `mockRepo.Verify`, which fails the test if the expected method wasn't called.

> **NOTE**
>
> The Moq library used in this sample makes it possible to mix verifiable, or "strict", mocks with non-verifiable mocks (also called "loose" mocks or stubs). Learn more about customizing Mock behavior with Moq.

SessionController in the sample app displays information related to a particular brainstorming session. The controller includes logic to deal with invalid `id` values (there are two `return` scenarios in the following example to cover these scenarios). The final `return` statement returns a new `StormSessionViewModel` to the view (*Controllers/SessionController.cs*):

```
public class SessionController : Controller
{
    private readonly IBrainstormSessionRepository _sessionRepository;

    public SessionController(IBrainstormSessionRepository sessionRepository)
    {
        _sessionRepository = sessionRepository;
    }

    public async Task<IActionResult> Index(int? id)
    {
        if (!id.HasValue)
        {
            return RedirectToAction(actionName: nameof(Index),
                controllerName: "Home");
        }

        var session = await _sessionRepository.GetByIdAsync(id.Value);
        if (session == null)
        {
            return Content("Session not found.");
        }

        var viewModel = new StormSessionViewModel()
        {
            DateCreated = session.DateCreated,
            Name = session.Name,
            Id = session.Id
        };

        return View(viewModel);
    }
}
```

The unit tests include one test for each `return` scenario in the Session controller `Index` action:

```
[Fact]
public async Task IndexReturnsARedirectToIndexHomeWhenIdIsNull()
{
    // Arrange
    var controller = new SessionController(sessionRepository: null);

    // Act
    var result = await controller.Index(id: null);

    // Assert
    var redirectToActionResult =
        Assert.IsType<RedirectToActionResult>(result);
    Assert.Equal("Home", redirectToActionResult.ControllerName);
    Assert.Equal("Index", redirectToActionResult.ActionName);
}

[Fact]
public async Task IndexReturnsContentWithSessionNotFoundWhenSessionNotFound()
{
    // Arrange
    int testSessionId = 1;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new SessionController(mockRepo.Object);

    // Act
    var result = await controller.Index(testSessionId);

    // Assert
    var contentResult = Assert.IsType<ContentResult>(result);
    Assert.Equal("Session not found.", contentResult.Content);
}

[Fact]
public async Task IndexReturnsViewResultWithStormSessionViewModel()
{
    // Arrange
    int testSessionId = 1;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSessions().FirstOrDefault(
            s => s.Id == testSessionId));
    var controller = new SessionController(mockRepo.Object);

    // Act
    var result = await controller.Index(testSessionId);

    // Assert
    var viewResult = Assert.IsType<ViewResult>(result);
    var model = Assert.IsType<StormSessionViewModel>(
        viewResult.ViewData.Model);
    Assert.Equal("Test One", model.Name);
    Assert.Equal(2, model.DateCreated.Day);
    Assert.Equal(testSessionId, model.Id);
}
```

Moving to the Ideas controller, the app exposes functionality as a web API on the `api/ideas` route:

- A list of ideas (`IdeaDTO`) associated with a brainstorming session is returned by the `ForSession` method.
- The `Create` method adds new ideas to a session.

```
[HttpGet("forsession/{sessionId}")]
public async Task<IActionResult> ForSession(int sessionId)
{
    var session = await _sessionRepository.GetByIdAsync(sessionId);
    if (session == null)
    {
        return NotFound(sessionId);
    }

    var result = session.Ideas.Select(idea => new IdeaDTO()
    {
        Id = idea.Id,
        Name = idea.Name,
        Description = idea.Description,
        DateCreated = idea.DateCreated
    }).ToList();

    return Ok(result);
}

[HttpPost("create")]
public async Task<IActionResult> Create([FromBody]NewIdeaModel model)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }

    var session = await _sessionRepository.GetByIdAsync(model.SessionId);
    if (session == null)
    {
        return NotFound(model.SessionId);
    }

    var idea = new Idea()
    {
        DateCreated = DateTimeOffset.Now,
        Description = model.Description,
        Name = model.Name
    };
    session.AddIdea(idea);

    await _sessionRepository.UpdateAsync(session);

    return Ok(session);
}
```

Avoid returning business domain entities directly via API calls. Domain entities:

- Often include more data than the client requires.
- Unnecessarily couple the app's internal domain model with the publicly exposed API.

Mapping between domain entities and the types returned to the client can be performed:

- Manually with a LINQ `Select`, as the sample app uses. For more information, see LINQ (Language Integrated Query).
- Automatically with a library, such as AutoMapper.

Next, the sample app demonstrates unit tests for the `Create` and `ForSession` API methods of the Ideas controller.

The sample app contains two `ForSession` tests. The first test determines if `ForSession` returns a NotFoundObjectResult (HTTP Not Found) for an invalid session:

```
[Fact]
public async Task ForSession_ReturnsHttpNotFound_ForInvalidSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSession(testSessionId);

    // Assert
    var notFoundObjectResult = Assert.IsType<NotFoundObjectResult>(result);
    Assert.Equal(testSessionId, notFoundObjectResult.Value);
}
```

The second `ForSession` test determines if `ForSession` returns a list of session ideas (`<List<IdeaDTO>>`) for a valid session. The checks also examine the first idea to confirm its `Name` property is correct:

```
[Fact]
public async Task ForSession_ReturnsIdeasForSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSession());
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSession(testSessionId);

    // Assert
    var okResult = Assert.IsType<OkObjectResult>(result);
    var returnValue = Assert.IsType<List<IdeaDTO>>(okResult.Value);
    var idea = returnValue.FirstOrDefault();
    Assert.Equal("One", idea.Name);
}
```

To test the behavior of the `Create` method when the `ModelState` is invalid, the sample app adds a model error to the controller as part of the test. Don't try to test model validation or model binding in unit tests—just test the action method's behavior when confronted with an invalid `ModelState` :

```
[Fact]
public async Task Create_ReturnsBadRequest_GivenInvalidModel()
{
    // Arrange & Act
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    controller.ModelState.AddModelError("error", "some error");

    // Act
    var result = await controller.Create(model: null);

    // Assert
    Assert.IsType<BadRequestObjectResult>(result);
}
```

The second test of `Create` depends on the repository returning `null` , so the mock repository is configured to

return `null`. There's no need to create a test database (in memory or otherwise) and construct a query that returns this result. The test can be accomplished in a single statement, as the sample code illustrates:

```
[Fact]
public async Task Create_ReturnsHttpNotFound_ForInvalidSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.Create(new NewIdeaModel());

    // Assert
    Assert.IsType<NotFoundObjectResult>(result);
}
```

The third `Create` test, `Create_ReturnsNewlyCreatedIdeaForSession`, verifies that the repository's `UpdateAsync` method is called. The mock is called with `Verifiable`, and the mocked repository's `Verify` method is called to confirm the verifiable method is executed. It's not the unit test's responsibility to ensure that the `UpdateAsync` method saved the data—that can be performed with an integration test.

```
[Fact]
public async Task Create_ReturnsNewlyCreatedIdeaForSession()
{
    // Arrange
    int testSessionId = 123;
    string testName = "test name";
    string testDescription = "test description";
    var testSession = GetTestSession();
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(testSession);
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = testSessionId
    };
    mockRepo.Setup(repo => repo.UpdateAsync(testSession))
        .Returns(Task.CompletedTask)
        .Verifiable();

    // Act
    var result = await controller.Create(newIdea);

    // Assert
    var okResult = Assert.IsType<OkObjectResult>(result);
    var returnSession = Assert.IsType<BrainstormSession>(okResult.Value);
    mockRepo.Verify();
    Assert.Equal(2, returnSession.Ideas.Count());
    Assert.Equal(testName, returnSession.Ideas.LastOrDefault().Name);
    Assert.Equal(testDescription, returnSession.Ideas.LastOrDefault().Description);
}
```

Test ActionResult<T>

In ASP.NET Core 2.1 or later, ActionResult<T> (ActionResult<TValue>) enables you to return a type deriving from `ActionResult` or return a specific type.

The sample app includes a method that returns a `List<IdeaDTO>` for a given session `id`. If the session `id` doesn't exist, the controller returns NotFound:

```
[HttpGet("forsessionactionresult/{sessionId}")]
[ProducesResponseType(200)]
[ProducesResponseType(404)]
public async Task<ActionResult<List<IdeaDTO>>> ForSessionActionResult(int sessionId)
{
    var session = await _sessionRepository.GetByIdAsync(sessionId);

    if (session == null)
    {
        return NotFound(sessionId);
    }

    var result = session.Ideas.Select(idea => new IdeaDTO()
    {
        Id = idea.Id,
        Name = idea.Name,
        Description = idea.Description,
        DateCreated = idea.DateCreated
    }).ToList();

    return result;
}
```

Two tests of the `ForSessionActionResult` controller are included in the `ApiIdeasControllerTests`.

The first test confirms that the controller returns an `ActionResult` but not a nonexistent list of ideas for a nonexistent session `id`:

- The `ActionResult` type is `ActionResult<List<IdeaDTO>>`.
- The Result is a NotFoundObjectResult.

```
[Fact]
public async Task ForSessionActionResult_ReturnsNotFoundObjectResultForNonexistentSession()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    var nonExistentSessionId = 999;

    // Act
    var result = await controller.ForSessionActionResult(nonExistentSessionId);

    // Assert
    var actionResult = Assert.IsType<ActionResult<List<IdeaDTO>>>(result);
    Assert.IsType<NotFoundObjectResult>(actionResult.Result);
}
```

For a valid session `id`, the second test confirms that the method returns:

- An `ActionResult` with a `List<IdeaDTO>` type.
- The ActionResult<T>.Value is a `List<IdeaDTO>` type.
- The first item in the list is a valid idea matching the idea stored in the mock session (obtained by calling `GetTestSession`).

```
[Fact]
public async Task ForSessionActionResult_ReturnsIdeasForSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSession());
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSessionActionResult(testSessionId);

    // Assert
    var actionResult = Assert.IsType<ActionResult<List<IdeaDTO>>>(result);
    var returnValue = Assert.IsType<List<IdeaDTO>>(actionResult.Value);
    var idea = returnValue.FirstOrDefault();
    Assert.Equal("One", idea.Name);
}
```

The sample app also includes a method to create a new `Idea` for a given session. The controller returns:

- BadRequest for an invalid model.
- NotFound if the session doesn't exist.
- CreatedAtAction when the session is updated with the new idea.

```
[HttpPost("createactionresult")]
[ProducesResponseType(201)]
[ProducesResponseType(400)]
[ProducesResponseType(404)]
public async Task<ActionResult<BrainstormSession>> CreateActionResult([FromBody]NewIdeaModel model)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }

    var session = await _sessionRepository.GetByIdAsync(model.SessionId);

    if (session == null)
    {
        return NotFound(model.SessionId);
    }

    var idea = new Idea()
    {
        DateCreated = DateTimeOffset.Now,
        Description = model.Description,
        Name = model.Name
    };
    session.AddIdea(idea);

    await _sessionRepository.UpdateAsync(session);

    return CreatedAtAction(nameof(CreateActionResult), new { id = session.Id }, session);
}
```

Three tests of `CreateActionResult` are included in the `ApiIdeasControllerTests`.

The first text confirms that a BadRequest is returned for an invalid model.

```
[Fact]
public async Task CreateActionResult_ReturnsBadRequest_GivenInvalidModel()
{
    // Arrange & Act
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    controller.ModelState.AddModelError("error", "some error");

    // Act
    var result = await controller.CreateActionResult(model: null);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>(result);
    Assert.IsType<BadRequestObjectResult>(actionResult.Result);
}
```

The second test checks that a NotFound is returned if the session doesn't exist.

```
[Fact]
public async Task CreateActionResult_ReturnsNotFoundObjectResultForNonexistentSession()
{
    // Arrange
    var nonExistentSessionId = 999;
    string testName = "test name";
    string testDescription = "test description";
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = nonExistentSessionId
    };

    // Act
    var result = await controller.CreateActionResult(newIdea);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>(result);
    Assert.IsType<NotFoundObjectResult>(actionResult.Result);
}
```

For a valid session `id`, the final test confirms that:

- The method returns an `ActionResult` with a `BrainstormSession` type.
- The ActionResult<T>.Result is a CreatedAtActionResult. `CreatedAtActionResult` is analogous to a *201 Created* response with a `Location` header.
- The ActionResult<T>.Value is a `BrainstormSession` type.
- The mock call to update the session, `UpdateAsync(testSession)`, was invoked. The `Verifiable` method call is checked by executing `mockRepo.Verify()` in the assertions.
- Two `Idea` objects are returned for the session.
- The last item (the `Idea` added by the mock call to `UpdateAsync`) matches the `newIdea` added to the session in the test.

```
[Fact]
public async Task CreateActionResult_ReturnsNewlyCreatedIdeaForSession()
{
    // Arrange
    int testSessionId = 123;
    string testName = "test name";
    string testDescription = "test description";
    var testSession = GetTestSession();
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(testSession);
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = testSessionId
    };
    mockRepo.Setup(repo => repo.UpdateAsync(testSession))
        .Returns(Task.CompletedTask)
        .Verifiable();

    // Act
    var result = await controller.CreateActionResult(newIdea);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>(result);
    var createdAtActionResult = Assert.IsType<CreatedAtActionResult>(actionResult.Result);
    var returnValue = Assert.IsType<BrainstormSession>(createdAtActionResult.Value);
    mockRepo.Verify();
    Assert.Equal(2, returnValue.Ideas.Count());
    Assert.Equal(testName, returnValue.Ideas.LastOrDefault().Name);
    Assert.Equal(testDescription, returnValue.Ideas.LastOrDefault().Description);
}
```

Controllers play a central role in any ASP.NET Core MVC app. As such, you should have confidence that controllers behave as intended. Automated tests can detect errors before the app is deployed to a production environment.

View or download sample code (how to download)

Unit tests of controller logic

Unit tests involve testing a part of an app in isolation from its infrastructure and dependencies. When unit testing controller logic, only the contents of a single action are tested, not the behavior of its dependencies or of the framework itself.

Set up unit tests of controller actions to focus on the controller's behavior. A controller unit test avoids scenarios such as filters, routing, and model binding. Tests that cover the interactions among components that collectively respond to a request are handled by *integration tests*. For more information on integration tests, see Integration tests in ASP.NET Core.

If you're writing custom filters and routes, unit test them in isolation, not as part of tests on a particular controller action.

To demonstrate controller unit tests, review the following controller in the sample app. The Home controller displays a list of brainstorming sessions and allows the creation of new brainstorming sessions with a POST request:

```
public class HomeController : Controller
{
    private readonly IBrainstormSessionRepository _sessionRepository;

    public HomeController(IBrainstormSessionRepository sessionRepository)
    {
        _sessionRepository = sessionRepository;
    }

    public async Task<IActionResult> Index()
    {
        var sessionList = await _sessionRepository.ListAsync();

        var model = sessionList.Select(session => new StormSessionViewModel()
        {
            Id = session.Id,
            DateCreated = session.DateCreated,
            Name = session.Name,
            IdeaCount = session.Ideas.Count
        });

        return View(model);
    }

    public class NewSessionModel
    {
        [Required]
        public string SessionName { get; set; }
    }

    [HttpPost]
    public async Task<IActionResult> Index(NewSessionModel model)
    {
        if (!ModelState.IsValid)
        {
            return BadRequest(ModelState);
        }
        else
        {
            await _sessionRepository.AddAsync(new BrainstormSession()
            {
                DateCreated = DateTimeOffset.Now,
                Name = model.SessionName
            });
        }

        return RedirectToAction(actionName: nameof(Index));
    }
}
```

The preceding controller:

- Follows the Explicit Dependencies Principle.
- Expects dependency injection (DI) to provide an instance of `IBrainstormSessionRepository`.
- Can be tested with a mocked `IBrainstormSessionRepository` service using a mock object framework, such as Moq. A *mocked object* is a fabricated object with a predetermined set of property and method behaviors used for testing. For more information, see Introduction to integration tests.

The `HTTP GET Index` method has no looping or branching and only calls one method. The unit test for this action:

- Mocks the `IBrainstormSessionRepository` service using the `GetTestSessions` method. `GetTestSessions` creates two mock brainstorm sessions with dates and session names.
- Executes the `Index` method.

- Makes assertions on the result returned by the method:
  - A ViewResult is returned.
  - The ViewDataDictionary.Model is a `StormSessionViewModel`.
  - There are two brainstorming sessions stored in the `ViewDataDictionary.Model`.

```
[Fact]
public async Task Index_ReturnsAViewResult_WithAListOfBrainstormSessions()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.ListAsync())
        .ReturnsAsync(GetTestSessions());
    var controller = new HomeController(mockRepo.Object);

    // Act
    var result = await controller.Index();

    // Assert
    var viewResult = Assert.IsType<ViewResult>(result);
    var model = Assert.IsAssignableFrom<IEnumerable<StormSessionViewModel>>(
        viewResult.ViewData.Model);
    Assert.Equal(2, model.Count());
}
```

```
private List<BrainstormSession> GetTestSessions()
{
    var sessions = new List<BrainstormSession>();
    sessions.Add(new BrainstormSession()
    {
        DateCreated = new DateTime(2016, 7, 2),
        Id = 1,
        Name = "Test One"
    });
    sessions.Add(new BrainstormSession()
    {
        DateCreated = new DateTime(2016, 7, 1),
        Id = 2,
        Name = "Test Two"
    });
    return sessions;
}
```

The Home controller's `HTTP POST Index` method tests verifies that:

- When ModelState.IsValid is `false`, the action method returns a *400 Bad Request* ViewResult with the appropriate data.
- When `ModelState.IsValid` is `true`:
  - The `Add` method on the repository is called.
  - A RedirectToActionResult is returned with the correct arguments.

An invalid model state is tested by adding errors using AddModelError as shown in the first test below:

```
[Fact]
public async Task IndexPost_ReturnsBadRequestResult_WhenModelStateIsInvalid()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.ListAsync())
        .ReturnsAsync(GetTestSessions());
    var controller = new HomeController(mockRepo.Object);
    controller.ModelState.AddModelError("SessionName", "Required");
    var newSession = new HomeController.NewSessionModel();

    // Act
    var result = await controller.Index(newSession);

    // Assert
    var badRequestResult = Assert.IsType<BadRequestObjectResult>(result);
    Assert.IsType<SerializableError>(badRequestResult.Value);
}

[Fact]
public async Task IndexPost_ReturnsARedirectAndAddsSession_WhenModelStateIsValid()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.AddAsync(It.IsAny<BrainstormSession>()))
        .Returns(Task.CompletedTask)
        .Verifiable();
    var controller = new HomeController(mockRepo.Object);
    var newSession = new HomeController.NewSessionModel()
    {
        SessionName = "Test Name"
    };

    // Act
    var result = await controller.Index(newSession);

    // Assert
    var redirectToActionResult = Assert.IsType<RedirectToActionResult>(result);
    Assert.Null(redirectToActionResult.ControllerName);
    Assert.Equal("Index", redirectToActionResult.ActionName);
    mockRepo.Verify();
}
```

When ModelState isn't valid, the same `ViewResult` is returned as for a GET request. The test doesn't attempt to pass in an invalid model. Passing an invalid model isn't a valid approach, since model binding isn't running (although an integration test does use model binding). In this case, model binding isn't tested. These unit tests are only testing the code in the action method.

The second test verifies that when the `ModelState` is valid:

- A new `BrainstormSession` is added (via the repository).
- The method returns a `RedirectToActionResult` with the expected properties.

Mocked calls that aren't called are normally ignored, but calling `Verifiable` at the end of the setup call allows mock validation in the test. This is performed with the call to `mockRepo.Verify`, which fails the test if the expected method wasn't called.

> **NOTE**
>
> The Moq library used in this sample makes it possible to mix verifiable, or "strict", mocks with non-verifiable mocks (also called "loose" mocks or stubs). Learn more about customizing Mock behavior with Moq.

SessionController in the sample app displays information related to a particular brainstorming session. The controller includes logic to deal with invalid `id` values (there are two `return` scenarios in the following example to cover these scenarios). The final `return` statement returns a new `StormSessionViewModel` to the view (*Controllers/SessionController.cs*):

```
public class SessionController : Controller
{
    private readonly IBrainstormSessionRepository _sessionRepository;

    public SessionController(IBrainstormSessionRepository sessionRepository)
    {
        _sessionRepository = sessionRepository;
    }

    public async Task<IActionResult> Index(int? id)
    {
        if (!id.HasValue)
        {
            return RedirectToAction(actionName: nameof(Index),
                controllerName: "Home");
        }

        var session = await _sessionRepository.GetByIdAsync(id.Value);
        if (session == null)
        {
            return Content("Session not found.");
        }

        var viewModel = new StormSessionViewModel()
        {
            DateCreated = session.DateCreated,
            Name = session.Name,
            Id = session.Id
        };

        return View(viewModel);
    }
}
```

The unit tests include one test for each `return` scenario in the Session controller `Index` action:

```
[Fact]
public async Task IndexReturnsARedirectToIndexHomeWhenIdIsNull()
{
    // Arrange
    var controller = new SessionController(sessionRepository: null);

    // Act
    var result = await controller.Index(id: null);

    // Assert
    var redirectToActionResult =
        Assert.IsType<RedirectToActionResult>(result);
    Assert.Equal("Home", redirectToActionResult.ControllerName);
    Assert.Equal("Index", redirectToActionResult.ActionName);
}

[Fact]
public async Task IndexReturnsContentWithSessionNotFoundWhenSessionNotFound()
{
    // Arrange
    int testSessionId = 1;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new SessionController(mockRepo.Object);

    // Act
    var result = await controller.Index(testSessionId);

    // Assert
    var contentResult = Assert.IsType<ContentResult>(result);
    Assert.Equal("Session not found.", contentResult.Content);
}

[Fact]
public async Task IndexReturnsViewResultWithStormSessionViewModel()
{
    // Arrange
    int testSessionId = 1;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSessions().FirstOrDefault(
            s => s.Id == testSessionId));
    var controller = new SessionController(mockRepo.Object);

    // Act
    var result = await controller.Index(testSessionId);

    // Assert
    var viewResult = Assert.IsType<ViewResult>(result);
    var model = Assert.IsType<StormSessionViewModel>(
        viewResult.ViewData.Model);
    Assert.Equal("Test One", model.Name);
    Assert.Equal(2, model.DateCreated.Day);
    Assert.Equal(testSessionId, model.Id);
}
```

Moving to the Ideas controller, the app exposes functionality as a web API on the `api/ideas` route:

- A list of ideas (`IdeaDTO`) associated with a brainstorming session is returned by the `ForSession` method.
- The `Create` method adds new ideas to a session.

```
[HttpGet("forsession/{sessionId}")]
public async Task<IActionResult> ForSession(int sessionId)
{
    var session = await _sessionRepository.GetByIdAsync(sessionId);
    if (session == null)
    {
        return NotFound(sessionId);
    }

    var result = session.Ideas.Select(idea => new IdeaDTO()
    {
        Id = idea.Id,
        Name = idea.Name,
        Description = idea.Description,
        DateCreated = idea.DateCreated
    }).ToList();

    return Ok(result);
}

[HttpPost("create")]
public async Task<IActionResult> Create([FromBody]NewIdeaModel model)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }

    var session = await _sessionRepository.GetByIdAsync(model.SessionId);
    if (session == null)
    {
        return NotFound(model.SessionId);
    }

    var idea = new Idea()
    {
        DateCreated = DateTimeOffset.Now,
        Description = model.Description,
        Name = model.Name
    };
    session.AddIdea(idea);

    await _sessionRepository.UpdateAsync(session);

    return Ok(session);
}
```

Avoid returning business domain entities directly via API calls. Domain entities:

- Often include more data than the client requires.
- Unnecessarily couple the app's internal domain model with the publicly exposed API.

Mapping between domain entities and the types returned to the client can be performed:

- Manually with a LINQ `Select`, as the sample app uses. For more information, see LINQ (Language Integrated Query).
- Automatically with a library, such as AutoMapper.

Next, the sample app demonstrates unit tests for the `Create` and `ForSession` API methods of the Ideas controller.

The sample app contains two `ForSession` tests. The first test determines if `ForSession` returns a NotFoundObjectResult (HTTP Not Found) for an invalid session:

```
[Fact]
public async Task ForSession_ReturnsHttpNotFound_ForInvalidSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSession(testSessionId);

    // Assert
    var notFoundObjectResult = Assert.IsType<NotFoundObjectResult>(result);
    Assert.Equal(testSessionId, notFoundObjectResult.Value);
}
```

The second `ForSession` test determines if `ForSession` returns a list of session ideas (`<List<IdeaDTO>>`) for a valid session. The checks also examine the first idea to confirm its `Name` property is correct:

```
[Fact]
public async Task ForSession_ReturnsIdeasForSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSession());
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSession(testSessionId);

    // Assert
    var okResult = Assert.IsType<OkObjectResult>(result);
    var returnValue = Assert.IsType<List<IdeaDTO>>(okResult.Value);
    var idea = returnValue.FirstOrDefault();
    Assert.Equal("One", idea.Name);
}
```

To test the behavior of the `Create` method when the `ModelState` is invalid, the sample app adds a model error to the controller as part of the test. Don't try to test model validation or model binding in unit tests—just test the action method's behavior when confronted with an invalid `ModelState` :

```
[Fact]
public async Task Create_ReturnsBadRequest_GivenInvalidModel()
{
    // Arrange & Act
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    controller.ModelState.AddModelError("error", "some error");

    // Act
    var result = await controller.Create(model: null);

    // Assert
    Assert.IsType<BadRequestObjectResult>(result);
}
```

The second test of `Create` depends on the repository returning `null` , so the mock repository is configured to

return `null`. There's no need to create a test database (in memory or otherwise) and construct a query that returns this result. The test can be accomplished in a single statement, as the sample code illustrates:

```
[Fact]
public async Task Create_ReturnsHttpNotFound_ForInvalidSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.Create(new NewIdeaModel());

    // Assert
    Assert.IsType<NotFoundObjectResult>(result);
}
```

The third `Create` test, `Create_ReturnsNewlyCreatedIdeaForSession`, verifies that the repository's `UpdateAsync` method is called. The mock is called with `Verifiable`, and the mocked repository's `Verify` method is called to confirm the verifiable method is executed. It's not the unit test's responsibility to ensure that the `UpdateAsync` method saved the data—that can be performed with an integration test.

```
[Fact]
public async Task Create_ReturnsNewlyCreatedIdeaForSession()
{
    // Arrange
    int testSessionId = 123;
    string testName = "test name";
    string testDescription = "test description";
    var testSession = GetTestSession();
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(testSession);
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = testSessionId
    };
    mockRepo.Setup(repo => repo.UpdateAsync(testSession))
        .Returns(Task.CompletedTask)
        .Verifiable();

    // Act
    var result = await controller.Create(newIdea);

    // Assert
    var okResult = Assert.IsType<OkObjectResult>(result);
    var returnSession = Assert.IsType<BrainstormSession>(okResult.Value);
    mockRepo.Verify();
    Assert.Equal(2, returnSession.Ideas.Count());
    Assert.Equal(testName, returnSession.Ideas.LastOrDefault().Name);
    Assert.Equal(testDescription, returnSession.Ideas.LastOrDefault().Description);
}
```

Test ActionResult<T>

In ASP.NET Core 2.1 or later, ActionResult<T> (ActionResult<TValue>) enables you to return a type deriving from `ActionResult` or return a specific type.

The sample app includes a method that returns a `List<IdeaDTO>` for a given session `id`. If the session `id` doesn't exist, the controller returns NotFound:

```
[HttpGet("forsessionactionresult/{sessionId}")]
[ProducesResponseType(200)]
[ProducesResponseType(404)]
public async Task<ActionResult<List<IdeaDTO>>> ForSessionActionResult(int sessionId)
{
    var session = await _sessionRepository.GetByIdAsync(sessionId);

    if (session == null)
    {
        return NotFound(sessionId);
    }

    var result = session.Ideas.Select(idea => new IdeaDTO()
    {
        Id = idea.Id,
        Name = idea.Name,
        Description = idea.Description,
        DateCreated = idea.DateCreated
    }).ToList();

    return result;
}
```

Two tests of the `ForSessionActionResult` controller are included in the `ApiIdeasControllerTests`.

The first test confirms that the controller returns an `ActionResult` but not a nonexistent list of ideas for a nonexistent session `id`:

- The `ActionResult` type is `ActionResult<List<IdeaDTO>>`.
- The Result is a NotFoundObjectResult.

```
[Fact]
public async Task ForSessionActionResult_ReturnsNotFoundObjectResultForNonexistentSession()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    var nonExistentSessionId = 999;

    // Act
    var result = await controller.ForSessionActionResult(nonExistentSessionId);

    // Assert
    var actionResult = Assert.IsType<ActionResult<List<IdeaDTO>>>(result);
    Assert.IsType<NotFoundObjectResult>(actionResult.Result);
}
```

For a valid session `id`, the second test confirms that the method returns:

- An `ActionResult` with a `List<IdeaDTO>` type.
- The ActionResult<T>.Value is a `List<IdeaDTO>` type.
- The first item in the list is a valid idea matching the idea stored in the mock session (obtained by calling `GetTestSession`).

```
[Fact]
public async Task ForSessionActionResult_ReturnsIdeasForSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSession());
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSessionActionResult(testSessionId);

    // Assert
    var actionResult = Assert.IsType<ActionResult<List<IdeaDTO>>>(result);
    var returnValue = Assert.IsType<List<IdeaDTO>>(actionResult.Value);
    var idea = returnValue.FirstOrDefault();
    Assert.Equal("One", idea.Name);
}
```

The sample app also includes a method to create a new `Idea` for a given session. The controller returns:

- BadRequest for an invalid model.
- NotFound if the session doesn't exist.
- CreatedAtAction when the session is updated with the new idea.

```
[HttpPost("createactionresult")]
[ProducesResponseType(201)]
[ProducesResponseType(400)]
[ProducesResponseType(404)]
public async Task<ActionResult<BrainstormSession>> CreateActionResult([FromBody]NewIdeaModel model)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }

    var session = await _sessionRepository.GetByIdAsync(model.SessionId);

    if (session == null)
    {
        return NotFound(model.SessionId);
    }

    var idea = new Idea()
    {
        DateCreated = DateTimeOffset.Now,
        Description = model.Description,
        Name = model.Name
    };
    session.AddIdea(idea);

    await _sessionRepository.UpdateAsync(session);

    return CreatedAtAction(nameof(CreateActionResult), new { id = session.Id }, session);
}
```

Three tests of `CreateActionResult` are included in the `ApiIdeasControllerTests`.

The first text confirms that a BadRequest is returned for an invalid model.

```
[Fact]
public async Task CreateActionResult_ReturnsBadRequest_GivenInvalidModel()
{
    // Arrange & Act
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    controller.ModelState.AddModelError("error", "some error");

    // Act
    var result = await controller.CreateActionResult(model: null);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>(result);
    Assert.IsType<BadRequestObjectResult>(actionResult.Result);
}
```

The second test checks that a NotFound is returned if the session doesn't exist.

```
[Fact]
public async Task CreateActionResult_ReturnsNotFoundObjectResultForNonexistentSession()
{
    // Arrange
    var nonExistentSessionId = 999;
    string testName = "test name";
    string testDescription = "test description";
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = nonExistentSessionId
    };

    // Act
    var result = await controller.CreateActionResult(newIdea);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>(result);
    Assert.IsType<NotFoundObjectResult>(actionResult.Result);
}
```

For a valid session `id`, the final test confirms that:

- The method returns an `ActionResult` with a `BrainstormSession` type.
- The ActionResult<T>.Result is a CreatedAtActionResult. `CreatedAtActionResult` is analogous to a *201 Created* response with a `Location` header.
- The ActionResult<T>.Value is a `BrainstormSession` type.
- The mock call to update the session, `UpdateAsync(testSession)`, was invoked. The `Verifiable` method call is checked by executing `mockRepo.Verify()` in the assertions.
- Two `Idea` objects are returned for the session.
- The last item (the `Idea` added by the mock call to `UpdateAsync`) matches the `newIdea` added to the session in the test.

```
[Fact]
public async Task CreateActionResult_ReturnsNewlyCreatedIdeaForSession()
{
    // Arrange
    int testSessionId = 123;
    string testName = "test name";
    string testDescription = "test description";
    var testSession = GetTestSession();
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(testSession);
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = testSessionId
    };
    mockRepo.Setup(repo => repo.UpdateAsync(testSession))
        .Returns(Task.CompletedTask)
        .Verifiable();

    // Act
    var result = await controller.CreateActionResult(newIdea);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>(result);
    var createdAtActionResult = Assert.IsType<CreatedAtActionResult>(actionResult.Result);
    var returnValue = Assert.IsType<BrainstormSession>(createdAtActionResult.Value);
    mockRepo.Verify();
    Assert.Equal(2, returnValue.Ideas.Count());
    Assert.Equal(testName, returnValue.Ideas.LastOrDefault().Name);
    Assert.Equal(testDescription, returnValue.Ideas.LastOrDefault().Description);
}
```

Test ASP.NET Core middleware

9/22/2020 • 3 minutes to read • Edit Online

By Chris Ross

Middleware can be tested in isolation with TestServer. It allows you to:

- Instantiate an app pipeline containing only the components that you need to test.
- Send custom requests to verify middleware behavior.

Advantages:

- Requests are sent in-memory rather than being serialized over the network.
- This avoids additional concerns, such as port management and HTTPS certificates.
- Exceptions in the middleware can flow directly back to the calling test.
- It's possible to customize server data structures, such as HttpContext, directly in the test.

Set up the TestServer

In the test project, create a test:

- Build and start a host that uses TestServer.
- Add any required services that the middleware uses.
- Add the Microsoft.AspNetCore.TestHost NuGet package to the project:

```
<ItemGroup>
  <PackageReference Include="Microsoft.AspNetCore.TestHost" Version="3.1.*" />
</ItemGroup>
```

- Configure the processing pipeline to use the middleware for the test.

```
[Fact]
public async Task MiddlewareTest_ReturnsNotFoundForRequest()
{
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();

    ...
}
```

Send requests with HttpClient

Send a request using HttpClient:

```
[Fact]
public async Task MiddlewareTest_ReturnsNotFoundForRequest()
{
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();

    var response = await host.GetTestClient().GetAsync("/");

    ...
}
```

Assert the result. First, make an assertion the opposite of the result that you expect. An initial run with a false positive assertion confirms that the test fails when the middleware is performing correctly. Run the test and confirm that the test fails.

In the following example, the middleware should return a 404 status code (*Not Found*) when the root endpoint is requested. Make the first test run with `Assert.NotEqual( ... );`, which should fail:

```
[Fact]
public async Task MiddlewareTest_ReturnsNotFoundForRequest()
{
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();

    var response = await host.GetTestClient().GetAsync("/");

    Assert.NotEqual(HttpStatusCode.NotFound, response.StatusCode);
}
```

Change the assertion to test the middleware under normal operating conditions. The final test uses `Assert.Equal( ... );`. Run the test again to confirm that it passes.

```
[Fact]
public async Task MiddlewareTest_ReturnsNotFoundForRequest()
{
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();

    var response = await host.GetTestClient().GetAsync("/");

    Assert.Equal(HttpStatusCode.NotFound, response.StatusCode);
}
```

Send requests with HttpContext

A test app can also send a request using SendAsync(Action<HttpContext>, CancellationToken). In the following example, several checks are made when `https://example.com/A/Path/?and=query` is processed by the middleware:

```
[Fact]
public async Task TestMiddleware_ExpectedResponse()
{
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();

    var server = host.GetTestServer();
    server.BaseAddress = new Uri("https://example.com/A/Path/");

    var context = await server.SendAsync(c =>
    {
        c.Request.Method = HttpMethods.Post;
        c.Request.Path = "/and/file.txt";
        c.Request.QueryString = new QueryString("?and=query");
    });

    Assert.True(context.RequestAborted.CanBeCanceled);
    Assert.Equal(HttpProtocol.Http11, context.Request.Protocol);
    Assert.Equal("POST", context.Request.Method);
    Assert.Equal("https", context.Request.Scheme);
    Assert.Equal("example.com", context.Request.Host.Value);
    Assert.Equal("/A/Path", context.Request.PathBase.Value);
    Assert.Equal("/and/file.txt", context.Request.Path.Value);
    Assert.Equal("?and=query", context.Request.QueryString.Value);
    Assert.NotNull(context.Request.Body);
    Assert.NotNull(context.Request.Headers);
    Assert.NotNull(context.Response.Headers);
    Assert.NotNull(context.Response.Body);
    Assert.Equal(404, context.Response.StatusCode);
    Assert.Null(context.Features.Get<IHttpResponseFeature>().ReasonPhrase);
}
```

SendAsync permits direct configuration of an HttpContext object rather than using the HttpClient abstractions. Use SendAsync to manipulate structures only available on the server, such as HttpContext.Items or HttpContext.Features.

As with the earlier example that tested for a *404 - Not Found* response, check the opposite for each `Assert` statement in the preceding test. The check confirms that the test fails correctly when the middleware is operating normally. After you've confirmed that the false positive test works, set the final `Assert` statements for the expected conditions and values of the test. Run it again to confirm that the test passes.

TestServer limitations

TestServer:

- Was created to replicate server behaviors to test middleware.
- Does ***not*** try to replicate all HttpClient behaviors.
- Attempts to give the client access to as much control over the server as possible, and with as much visibility into what's happening on the server as possible. For example it may throw exceptions not normally thrown by

`HttpClient` in order to directly communicate server state.

- Doesn't set some transport specific headers by default as those are not usually relevant to middleware. For more information, see the next section.

Content-Length and Transfer-Encoding headers

TestServer does ***not*** set transport related request or response headers such as Content-Length or Transfer-Encoding. Applications should avoid depending on these headers because their usage varies by client, scenario, and protocol. If `Content-Length` and `Transfer-Encoding` are necessary to test a specific scenario, they can be specified in the test when composing the HttpRequestMessage or HttpContext. Integration tests in ASP.NET Core

9/22/2020 • 38 minutes to read • Edit Online

By Javier Calvarro Nelson, Steve Smith, and Jos van der Til

Integration tests ensure that an app's components function correctly at a level that includes the app's supporting infrastructure, such as the database, file system, and network. ASP.NET Core supports integration tests using a unit test framework with a test web host and an in-memory test server.

This topic assumes a basic understanding of unit tests. If unfamiliar with test concepts, see the Unit Testing in .NET Core and .NET Standard topic and its linked content.

View or download sample code (how to download)

The sample app is a Razor Pages app and assumes a basic understanding of Razor Pages. If unfamiliar with Razor Pages, see the following topics:

- Introduction to Razor Pages
- Get started with Razor Pages
- Razor Pages unit tests

> **NOTE**
> For testing SPAs, we recommended a tool such as Selenium, which can automate a browser.

Introduction to integration tests

Integration tests evaluate an app's components on a broader level than unit tests. Unit tests are used to test isolated software components, such as individual class methods. Integration tests confirm that two or more app components work together to produce an expected result, possibly including every component required to fully process a request.

These broader tests are used to test the app's infrastructure and whole framework, often including the following components:

- Database
- File system
- Network appliances
- Request-response pipeline

Unit tests use fabricated components, known as *fakes* or *mock objects*, in place of infrastructure components.

In contrast to unit tests, integration tests:

- Use the actual components that the app uses in production.
- Require more code and data processing.
- Take longer to run.

Therefore, limit the use of integration tests to the most important infrastructure scenarios. If a behavior can be tested using either a unit test or an integration test, choose the unit test.

TIP

Don't write integration tests for every possible permutation of data and file access with databases and file systems. Regardless of how many places across an app interact with databases and file systems, a focused set of read, write, update, and delete integration tests are usually capable of adequately testing database and file system components. Use unit tests for routine tests of method logic that interact with these components. In unit tests, the use of infrastructure fakes/mocks result in faster test execution.

NOTE

In discussions of integration tests, the tested project is frequently called the *System Under Test*, or "SUT" for short.

"SUT" is used throughout this topic to refer to the tested ASP.NET Core app.

ASP.NET Core integration tests

Integration tests in ASP.NET Core require the following:

- A test project is used to contain and execute the tests. The test project has a reference to the SUT.
- The test project creates a test web host for the SUT and uses a test server client to handle requests and responses with the SUT.
- A test runner is used to execute the tests and report the test results.

Integration tests follow a sequence of events that include the usual *Arrange*, *Act*, and *Assert* test steps:

1. The SUT's web host is configured.
2. A test server client is created to submit requests to the app.
3. The *Arrange* test step is executed: The test app prepares a request.
4. The *Act* test step is executed: The client submits the request and receives the response.
5. The *Assert* test step is executed: The *actual* response is validated as a *pass* or *fail* based on an *expected* response.
6. The process continues until all of the tests are executed.
7. The test results are reported.

Usually, the test web host is configured differently than the app's normal web host for the test runs. For example, a different database or different app settings might be used for the tests.

Infrastructure components, such as the test web host and in-memory test server (TestServer), are provided or managed by the Microsoft.AspNetCore.Mvc.Testing package. Use of this package streamlines test creation and execution.

The `Microsoft.AspNetCore.Mvc.Testing` package handles the following tasks:

- Copies the dependencies file (*.deps*) from the SUT into the test project's *bin* directory.
- Sets the content root to the SUT's project root so that static files and pages/views are found when the tests are executed.
- Provides the WebApplicationFactory class to streamline bootstrapping the SUT with `TestServer`.

The unit tests documentation describes how to set up a test project and test runner, along with detailed instructions on how to run tests and recommendations for how to name tests and test classes.

> **NOTE**
>
> When creating a test project for an app, separate the unit tests from the integration tests into different projects. This helps ensure that infrastructure testing components aren't accidentally included in the unit tests. Separation of unit and integration tests also allows control over which set of tests are run.

There's virtually no difference between the configuration for tests of Razor Pages apps and MVC apps. The only difference is in how the tests are named. In a Razor Pages app, tests of page endpoints are usually named after the page model class (for example, `IndexPageTests` to test component integration for the Index page). In an MVC app, tests are usually organized by controller classes and named after the controllers they test (for example, `HomeControllerTests` to test component integration for the Home controller).

Test app prerequisites

The test project must:

- Reference the Microsoft.AspNetCore.Mvc.Testing package.
- Specify the Web SDK in the project file (`<Project Sdk="Microsoft.NET.Sdk.Web">`).

These prerequisites can be seen in the sample app. Inspect the *tests/RazorPagesProject.Tests/RazorPagesProject.Tests.csproj* file. The sample app uses the xUnit test framework and the AngleSharp parser library, so the sample app also references:

- xunit
- xunit.runner.visualstudio
- AngleSharp

Entity Framework Core is also used in the tests. The app references:

- Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore
- Microsoft.AspNetCore.Identity.EntityFrameworkCore
- Microsoft.EntityFrameworkCore
- Microsoft.EntityFrameworkCore.InMemory
- Microsoft.EntityFrameworkCore.Tools

SUT environment

If the SUT's environment isn't set, the environment defaults to Development.

Basic tests with the default WebApplicationFactory

WebApplicationFactory<TEntryPoint> is used to create a TestServer for the integration tests. `TEntryPoint` is the entry point class of the SUT, usually the `Startup` class.

Test classes implement a *class fixture* interface (IClassFixture) to indicate the class contains tests and provide shared object instances across the tests in the class.

The following test class, `BasicTests`, uses the `WebApplicationFactory` to bootstrap the SUT and provide an HttpClient to a test method, `Get_EndpointsReturnSuccessAndCorrectContentType`. The method checks if the response status code is successful (status codes in the range 200-299) and the `Content-Type` header is `text/html; charset=utf-8` for several app pages.

CreateClient creates an instance of `HttpClient` that automatically follows redirects and handles cookies.

```
public class BasicTests
    : IClassFixture<WebApplicationFactory<RazorPagesProject.Startup>>
{
    private readonly WebApplicationFactory<RazorPagesProject.Startup> _factory;

    public BasicTests(WebApplicationFactory<RazorPagesProject.Startup> factory)
    {
        _factory = factory;
    }

    [Theory]
    [InlineData("/")]
    [InlineData("/Index")]
    [InlineData("/About")]
    [InlineData("/Privacy")]
    [InlineData("/Contact")]
    public async Task Get_EndpointsReturnSuccessAndCorrectContentType(string url)
    {
        // Arrange
        var client = _factory.CreateClient();

        // Act
        var response = await client.GetAsync(url);

        // Assert
        response.EnsureSuccessStatusCode(); // Status Code 200-299
        Assert.Equal("text/html; charset=utf-8",
            response.Content.Headers.ContentType.ToString());
    }
}
```

By default, non-essential cookies aren't preserved across requests when the GDPR consent policy is enabled. To preserve non-essential cookies, such as those used by the TempData provider, mark them as essential in your tests. For instructions on marking a cookie as essential, see Essential cookies.

Customize WebApplicationFactory

Web host configuration can be created independently of the test classes by inheriting from `WebApplicationFactory` to create one or more custom factories:

1. Inherit from `WebApplicationFactory` and override ConfigureWebHost. The IWebHostBuilder allows the configuration of the service collection with ConfigureServices:

```
public class CustomWebApplicationFactory<TStartup>
    : WebApplicationFactory<TStartup> where TStartup: class
{
    protected override void ConfigureWebHost(IWebHostBuilder builder)
    {
        builder.ConfigureServices(services =>
        {
            var descriptor = services.SingleOrDefault(
                d => d.ServiceType ==
                    typeof(DbContextOptions<ApplicationDbContext>));

            services.Remove(descriptor);

            services.AddDbContext<ApplicationDbContext>(options =>
            {
                options.UseInMemoryDatabase("InMemoryDbForTesting");
            });

            var sp = services.BuildServiceProvider();

            using (var scope = sp.CreateScope())
            {
                var scopedServices = scope.ServiceProvider;
                var db = scopedServices.GetRequiredService<ApplicationDbContext>();
                var logger = scopedServices
                    .GetRequiredService<ILogger<CustomWebApplicationFactory<TStartup>>>();

                db.Database.EnsureCreated();

                try
                {
                    Utilities.InitializeDbForTests(db);
                }
                catch (Exception ex)
                {
                    logger.LogError(ex, "An error occurred seeding the " +
                        "database with test messages. Error: {Message}", ex.Message);
                }
            }
        });
    }
}
```

Database seeding in the sample app is performed by the `InitializeDbForTests` method. The method is described in the Integration tests sample: Test app organization section.

The SUT's database context is registered in its `Startup.ConfigureServices` method. The test app's `builder.ConfigureServices` callback is executed *after* the app's `Startup.ConfigureServices` code is executed. The execution order is a breaking change for the Generic Host with the release of ASP.NET Core 3.0. To use a different database for the tests than the app's database, the app's database context must be replaced in `builder.ConfigureServices`.

For SUTs that still use the Web Host, the test app's `builder.ConfigureServices` callback is executed *before* the SUT's `Startup.ConfigureServices` code. The test app's `builder.ConfigureTestServices` callback is executed *after*.

The sample app finds the service descriptor for the database context and uses the descriptor to remove the service registration. Next, the factory adds a new `ApplicationDbContext` that uses an in-memory database for the tests.

To connect to a different database than the in-memory database, change the `UseInMemoryDatabase` call to connect the context to a different database. To use a SQL Server test database:

- Reference the Microsoft.EntityFrameworkCore.SqlServer NuGet package in the project file.
- Call `UseSqlServer` with a connection string to the database.

```
services.AddDbContext<ApplicationDbContext>((options, context) =>
{
    context.UseSqlServer(
        Configuration.GetConnectionString("TestingDbConnectionString"));
});
```

2. Use the custom `CustomWebApplicationFactory` in test classes. The following example uses the factory in the `IndexPageTests` class:

```
public class IndexPageTests :
    IClassFixture<CustomWebApplicationFactory<RazorPagesProject.Startup>>
{
    private readonly HttpClient _client;
    private readonly CustomWebApplicationFactory<RazorPagesProject.Startup>
        _factory;

    public IndexPageTests(
        CustomWebApplicationFactory<RazorPagesProject.Startup> factory)
    {
        _factory = factory;
        _client = factory.CreateClient(new WebApplicationFactoryClientOptions
            {
                AllowAutoRedirect = false
            });
    }
```

   The sample app's client is configured to prevent the `HttpClient` from following redirects. As explained later in the Mock authentication section, this permits tests to check the result of the app's first response. The first response is a redirect in many of these tests with a `Location` header.

3. A typical test uses the `HttpClient` and helper methods to process the request and the response:

```
[Fact]
public async Task Post_DeleteAllMessagesHandler_ReturnsRedirectToRoot()
{
    // Arrange
    var defaultPage = await _client.GetAsync("/");
    var content = await HtmlHelpers.GetDocumentAsync(defaultPage);

    //Act
    var response = await _client.SendAsync(
        (IHtmlFormElement)content.QuerySelector("form[id='messages']"),
        (IHtmlButtonElement)content.QuerySelector("button[id='deleteAllBtn']"));

    // Assert
    Assert.Equal(HttpStatusCode.OK, defaultPage.StatusCode);
    Assert.Equal(HttpStatusCode.Redirect, response.StatusCode);
    Assert.Equal("/", response.Headers.Location.OriginalString);
}
```

Any POST request to the SUT must satisfy the antiforgery check that's automatically made by the app's data protection antiforgery system. In order to arrange for a test's POST request, the test app must:

1. Make a request for the page.
2. Parse the antiforgery cookie and request validation token from the response.
3. Make the POST request with the antiforgery cookie and request validation token in place.

The `SendAsync` helper extension methods (*Helpers/HttpClientExtensions.cs*) and the `GetDocumentAsync` helper method (*Helpers/HtmlHelpers.cs*) in the sample app use the AngleSharp parser to handle the antiforgery check with the following methods:

- `GetDocumentAsync`: Receives the HttpResponseMessage and returns an `IHtmlDocument`. `GetDocumentAsync` uses a factory that prepares a *virtual response* based on the original `HttpResponseMessage`. For more information, see the AngleSharp documentation.
- `SendAsync` extension methods for the `HttpClient` compose an HttpRequestMessage and call SendAsync(HttpRequestMessage) to submit requests to the SUT. Overloads for `SendAsync` accept the HTML form (`IHtmlFormElement`) and the following:
  - Submit button of the form (`IHtmlElement`)
  - Form values collection (`IEnumerable<KeyValuePair<string, string>>`)
  - Submit button (`IHtmlElement`) and form values (`IEnumerable<KeyValuePair<string, string>>`)

> **NOTE**
>
> AngleSharp is a third-party parsing library used for demonstration purposes in this topic and the sample app. AngleSharp isn't supported or required for integration testing of ASP.NET Core apps. Other parsers can be used, such as the Html Agility Pack (HAP). Another approach is to write code to handle the antiforgery system's request verification token and antiforgery cookie directly.

Customize the client with WithWebHostBuilder

When additional configuration is required within a test method, WithWebHostBuilder creates a new `WebApplicationFactory` with an IWebHostBuilder that is further customized by configuration.

The `Post_DeleteMessageHandler_ReturnsRedirectToRoot` test method of the sample app demonstrates the use of `WithWebHostBuilder`. This test performs a record delete in the database by triggering a form submission in the SUT.

Because another test in the `IndexPageTests` class performs an operation that deletes all of the records in the database and may run before the `Post_DeleteMessageHandler_ReturnsRedirectToRoot` method, the database is reseeded in this test method to ensure that a record is present for the SUT to delete. Selecting the first delete button of the `messages` form in the SUT is simulated in the request to the SUT:

```
[Fact]
public async Task Post_DeleteMessageHandler_ReturnsRedirectToRoot()
{
    // Arrange
    var client = _factory.WithWebHostBuilder(builder =>
        {
            builder.ConfigureServices(services =>
            {
                var serviceProvider = services.BuildServiceProvider();

                using (var scope = serviceProvider.CreateScope())
                {
                    var scopedServices = scope.ServiceProvider;
                    var db = scopedServices
                        .GetRequiredService<ApplicationDbContext>();
                    var logger = scopedServices
                        .GetRequiredService<ILogger<IndexPageTests>>();

                    try
                    {
                        Utilities.ReinitializeDbForTests(db);
                    }
                    catch (Exception ex)
                    {
                        logger.LogError(ex, "An error occurred seeding " +
                            "the database with test messages. Error: {Message}",
                            ex.Message);
                    }
                }
            });
        })
        .CreateClient(new WebApplicationFactoryClientOptions
        {
            AllowAutoRedirect = false
        });
    var defaultPage = await client.GetAsync("/");
    var content = await HtmlHelpers.GetDocumentAsync(defaultPage);

    //Act
    var response = await client.SendAsync(
        (IHtmlFormElement)content.QuerySelector("form[id='messages']"),
        (IHtmlButtonElement)content.QuerySelector("form[id='messages']")
            .QuerySelector("div[class='panel-body']")
            .QuerySelector("button"));

    // Assert
    Assert.Equal(HttpStatusCode.OK, defaultPage.StatusCode);
    Assert.Equal(HttpStatusCode.Redirect, response.StatusCode);
    Assert.Equal("/", response.Headers.Location.OriginalString);
}
```

Client options

The following table shows the default WebApplicationFactoryClientOptions available when creating `HttpClient` instances.

OPTION	DESCRIPTION	DEFAULT
AllowAutoRedirect	Gets or sets whether or not `HttpClient` instances should automatically follow redirect responses.	`true`

OPTION	DESCRIPTION	DEFAULT
BaseAddress	Gets or sets the base address of `HttpClient` instances.	`http://localhost`
HandleCookies	Gets or sets whether `HttpClient` instances should handle cookies.	`true`
MaxAutomaticRedirections	Gets or sets the maximum number of redirect responses that `HttpClient` instances should follow.	7

Create the `WebApplicationFactoryClientOptions` class and pass it to the CreateClient method (default values are shown in the code example):

```
// Default client option values are shown
var clientOptions = new WebApplicationFactoryClientOptions();
clientOptions.AllowAutoRedirect = true;
clientOptions.BaseAddress = new Uri("http://localhost");
clientOptions.HandleCookies = true;
clientOptions.MaxAutomaticRedirections = 7;

_client = _factory.CreateClient(clientOptions);
```

Inject mock services

Services can be overridden in a test with a call to ConfigureTestServices on the host builder. **To inject mock services, the SUT must have a `Startup` class with a `Startup.ConfigureServices` method.**

The sample SUT includes a scoped service that returns a quote. The quote is embedded in a hidden field on the Index page when the Index page is requested.

Services/IQuoteService.cs:

```
public interface IQuoteService
{
    Task<string> GenerateQuote();
}
```

Services/QuoteService.cs:

```
// Quote ©1975 BBC: The Doctor (Tom Baker); Dr. Who: Planet of Evil
// https://www.bbc.co.uk/programmes/p00pyrx6
public class QuoteService : IQuoteService
{
    public Task<string> GenerateQuote()
    {
        return Task.FromResult<string>(
            "Come on, Sarah. We've an appointment in London, " +
            "and we're already 30,000 years late.");
    }
}
```

Startup.cs:

```
services.AddScoped<IQuoteService, QuoteService>();
```

Pages/Index.cshtml.cs:

```
public class IndexModel : PageModel
{
    private readonly ApplicationDbContext _db;
    private readonly IQuoteService _quoteService;

    public IndexModel(ApplicationDbContext db, IQuoteService quoteService)
    {
        _db = db;
        _quoteService = quoteService;
    }

    [BindProperty]
    public Message Message { get; set; }

    public IList<Message> Messages { get; private set; }

    [TempData]
    public string MessageAnalysisResult { get; set; }

    public string Quote { get; private set; }

    public async Task OnGetAsync()
    {
        Messages = await _db.GetMessagesAsync();

        Quote = await _quoteService.GenerateQuote();
    }
```

Pages/Index.cs:

```
<input id="quote" type="hidden" value="@Model.Quote">
```

The following markup is generated when the SUT app is run:

```
<input id="quote" type="hidden" value="Come on, Sarah. We&#x27;ve an appointment in
    London, and we&#x27;re already 30,000 years late.">
```

To test the service and quote injection in an integration test, a mock service is injected into the SUT by the test. The mock service replaces the app's `QuoteService` with a service provided by the test app, called `TestQuoteService`:

IntegrationTests.IndexPageTests.cs:

```
// Quote ©1975 BBC: The Doctor (Tom Baker); Pyramids of Mars
// https://www.bbc.co.uk/programmes/p00pys55
public class TestQuoteService : IQuoteService
{
    public Task<string> GenerateQuote()
    {
        return Task.FromResult<string>(
            "Something's interfering with time, Mr. Scarman, " +
            "and time is my business.");
    }
}
```

`ConfigureTestServices` is called, and the scoped service is registered:

```
[Fact]
public async Task Get_QuoteService_ProvidesQuoteInPage()
{
    // Arrange
    var client = _factory.WithWebHostBuilder(builder =>
        {
            builder.ConfigureTestServices(services =>
            {
                services.AddScoped<IQuoteService, TestQuoteService>();
            });
        })
        .CreateClient();

    //Act
    var defaultPage = await client.GetAsync("/");
    var content = await HtmlHelpers.GetDocumentAsync(defaultPage);
    var quoteElement = content.QuerySelector("#quote");

    // Assert
    Assert.Equal("Something's interfering with time, Mr. Scarman, " +
        "and time is my business.", quoteElement.Attributes["value"].Value);
}
```

The markup produced during the test's execution reflects the quote text supplied by `TestQuoteService`, thus the assertion passes:

```
<input id="quote" type="hidden" value="Something&#x27;s interfering with time,
    Mr. Scarman, and time is my business.">
```

Mock authentication

Tests in the `AuthTests` class check that a secure endpoint:

- Redirects an unauthenticated user to the app's Login page.
- Returns content for an authenticated user.

In the SUT, the `/SecurePage` page uses an AuthorizePage convention to apply an AuthorizeFilter to the page. For more information, see Razor Pages authorization conventions.

```
services.AddRazorPages(options =>
{
    options.Conventions.AuthorizePage("/SecurePage");
});
```

In the `Get_SecurePageRedirectsAnUnauthenticatedUser` test, a WebApplicationFactoryClientOptions is set to disallow redirects by setting AllowAutoRedirect to `false`:

```
[Fact]
public async Task Get_SecurePageRedirectsAnUnauthenticatedUser()
{
    // Arrange
    var client = _factory.CreateClient(
        new WebApplicationFactoryClientOptions
        {
            AllowAutoRedirect = false
        });

    // Act
    var response = await client.GetAsync("/SecurePage");

    // Assert
    Assert.Equal(HttpStatusCode.Redirect, response.StatusCode);
    Assert.StartsWith("http://localhost/Identity/Account/Login",
        response.Headers.Location.OriginalString);
}
```

By disallowing the client to follow the redirect, the following checks can be made:

- The status code returned by the SUT can be checked against the expected HttpStatusCode.Redirect result, not the final status code after the redirect to the Login page, which would be HttpStatusCode.OK.
- The `Location` header value in the response headers is checked to confirm that it starts with `http://localhost/Identity/Account/Login`, not the final Login page response, where the `Location` header wouldn't be present.

The test app can mock an AuthenticationHandler<TOptions> in ConfigureTestServices in order to test aspects of authentication and authorization. A minimal scenario returns an AuthenticateResult.Success:

```
public class TestAuthHandler : AuthenticationHandler<AuthenticationSchemeOptions>
{
    public TestAuthHandler(IOptionsMonitor<AuthenticationSchemeOptions> options,
        ILoggerFactory logger, UrlEncoder encoder, ISystemClock clock)
        : base(options, logger, encoder, clock)
    {
    }

    protected override Task<AuthenticateResult> HandleAuthenticateAsync()
    {
        var claims = new[] { new Claim(ClaimTypes.Name, "Test user") };
        var identity = new ClaimsIdentity(claims, "Test");
        var principal = new ClaimsPrincipal(identity);
        var ticket = new AuthenticationTicket(principal, "Test");

        var result = AuthenticateResult.Success(ticket);

        return Task.FromResult(result);
    }
}
```

The `TestAuthHandler` is called to authenticate a user when the authentication scheme is set to `Test` where `AddAuthentication` is registered for `ConfigureTestServices`. It's important for the `Test` scheme to match the scheme your app expects. Otherwise, authentication won't work.

```
[Fact]
public async Task Get_SecurePageIsReturnedForAnAuthenticatedUser()
{
    // Arrange
    var client = _factory.WithWebHostBuilder(builder =>
        {
            builder.ConfigureTestServices(services =>
            {
                services.AddAuthentication("Test")
                    .AddScheme<AuthenticationSchemeOptions, TestAuthHandler>(
                        "Test", options => {});
            });
        })
        .CreateClient(new WebApplicationFactoryClientOptions
        {
            AllowAutoRedirect = false,
        });

    client.DefaultRequestHeaders.Authorization =
        new AuthenticationHeaderValue("Test");

    //Act
    var response = await client.GetAsync("/SecurePage");

    // Assert
    Assert.Equal(HttpStatusCode.OK, response.StatusCode);
}
```

For more information on `WebApplicationFactoryClientOptions`, see the Client options section.

Set the environment

By default, the SUT's host and app environment is configured to use the Development environment. To override the SUT's environment when using `IHostBuilder`:

- Set the `ASPNETCORE_ENVIRONMENT` environment variable (for example, `Staging`, `Production`, or other custom value, such as `Testing`).
- Override `CreateHostBuilder` in the test app to read environment variables prefixed with `ASPNETCORE`.

```
protected override IHostBuilder CreateHostBuilder() =>
    base.CreateHostBuilder()
        .ConfigureHostConfiguration(
            config => config.AddEnvironmentVariables("ASPNETCORE"));
```

If the SUT uses the Web Host (`IWebHostBuilder`), override `CreateWebHostBuilder`:

```
protected override IWebHostBuilder CreateWebHostBuilder() =>
    base.CreateWebHostBuilder().UseEnvironment("Testing");
```

How the test infrastructure infers the app content root path

The `WebApplicationFactory` constructor infers the app content root path by searching for a WebApplicationFactoryContentRootAttribute on the assembly containing the integration tests with a key equal to the `TEntryPoint` assembly `System.Reflection.Assembly.FullName`. In case an attribute with the correct key isn't found, `WebApplicationFactory` falls back to searching for a solution file (*.sln*) and appends the `TEntryPoint` assembly name to the solution directory. The app root directory (the content root path) is used to discover views and content files.

Disable shadow copying

Shadow copying causes the tests to execute in a different directory than the output directory. For tests to work properly, shadow copying must be disabled. The sample app uses xUnit and disables shadow copying for xUnit by including an *xunit.runner.json* file with the correct configuration setting. For more information, see Configuring xUnit with JSON.

Add the *xunit.runner.json* file to root of the test project with the following content:

```
{
  "shadowCopy": false
}
```

Disposal of objects

After the tests of the `IClassFixture` implementation are executed, TestServer and HttpClient are disposed when xUnit disposes of the WebApplicationFactory. If objects instantiated by the developer require disposal, dispose of them in the `IClassFixture` implementation. For more information, see Implementing a Dispose method.

Integration tests sample

The sample app is composed of two apps:

APP	PROJECT DIRECTORY	DESCRIPTION
Message app (the SUT)	*src/RazorPagesProject*	Allows a user to add, delete one, delete all, and analyze messages.
Test app	*tests/RazorPagesProject.Tests*	Used to integration test the SUT.

The tests can be run using the built-in test features of an IDE, such as Visual Studio. If using Visual Studio Code or the command line, execute the following command at a command prompt in the *tests/RazorPagesProject.Tests* directory:

```
dotnet test
```

Message app (SUT) organization

The SUT is a Razor Pages message system with the following characteristics:

- The Index page of the app (*Pages/Index.cshtml* and *Pages/Index.cshtml.cs*) provides a UI and page model methods to control the addition, deletion, and analysis of messages (average words per message).
- A message is described by the `Message` class (*Data/Message.cs*) with two properties: `Id` (key) and `Text` (message). The `Text` property is required and limited to 200 characters.
- Messages are stored using Entity Framework's in-memory database†.
- The app contains a data access layer (DAL) in its database context class, `AppDbContext` (*Data/AppDbContext.cs*).
- If the database is empty on app startup, the message store is initialized with three messages.
- The app includes a `/SecurePage` that can only be accessed by an authenticated user.

†The EF topic, Test with InMemory, explains how to use an in-memory database for tests with MSTest. This topic uses the xUnit test framework. Test concepts and test implementations across different test frameworks are similar but not identical.

Although the app doesn't use the repository pattern and isn't an effective example of the Unit of Work (UoW) pattern, Razor Pages supports these patterns of development. For more information, see Designing the infrastructure persistence layer and Test controller logic (the sample implements the repository pattern).

Test app organization

The test app is a console app inside the *tests/RazorPagesProject.Tests* directory.

TEST APP DIRECTORY	DESCRIPTION
AuthTests	Contains test methods for: • Accessing a secure page by an unauthenticated user. • Accessing a secure page by an authenticated user with a mock AuthenticationHandler<TOptions>. • Obtaining a GitHub user profile and checking the profile's user login.
BasicTests	Contains a test method for routing and content type.
IntegrationTests	Contains the integration tests for the Index page using custom `WebApplicationFactory` class.
Helpers/Utilities	• *Utilities.cs* contains the `InitializeDbForTests` method used to seed the database with test data. • *HtmlHelpers.cs* provides a method to return an AngleSharp `IHtmlDocument` for use by the test methods. • *HttpClientExtensions.cs* provide overloads for `SendAsync` to submit requests to the SUT.

The test framework is xUnit. Integration tests are conducted using the Microsoft.AspNetCore.TestHost, which includes the TestServer. Because the Microsoft.AspNetCore.Mvc.Testing package is used to configure the test host and test server, the `TestHost` and `TestServer` packages don't require direct package references in the test app's project file or developer configuration in the test app.

Seeding the database for testing

Integration tests usually require a small dataset in the database prior to the test execution. For example, a delete test calls for a database record deletion, so the database must have at least one record for the delete request to succeed.

The sample app seeds the database with three messages in *Utilities.cs* that tests can use when they execute:

```
public static void InitializeDbForTests(ApplicationDbContext db)
{
    db.Messages.AddRange(GetSeedingMessages());
    db.SaveChanges();
}

public static void ReinitializeDbForTests(ApplicationDbContext db)
{
    db.Messages.RemoveRange(db.Messages);
    InitializeDbForTests(db);
}

public static List<Message> GetSeedingMessages()
{
    return new List<Message>()
    {
        new Message(){ Text = "TEST RECORD: You're standing on my scarf." },
        new Message(){ Text = "TEST RECORD: Would you like a jelly baby?" },
        new Message(){ Text = "TEST RECORD: To the rational mind, " +
            "nothing is inexplicable; only unexplained." }
    };
}
```

The SUT's database context is registered in its `Startup.ConfigureServices` method. The test app's `builder.ConfigureServices` callback is executed *after* the app's `Startup.ConfigureServices` code is executed. To use a different database for the tests, the app's database context must be replaced in `builder.ConfigureServices`. For more information, see the Customize WebApplicationFactory section.

For SUTs that still use the Web Host, the test app's `builder.ConfigureServices` callback is executed *before* the SUT's `Startup.ConfigureServices` code. The test app's `builder.ConfigureTestServices` callback is executed *after*.

Integration tests ensure that an app's components function correctly at a level that includes the app's supporting infrastructure, such as the database, file system, and network. ASP.NET Core supports integration tests using a unit test framework with a test web host and an in-memory test server.

This topic assumes a basic understanding of unit tests. If unfamiliar with test concepts, see the Unit Testing in .NET Core and .NET Standard topic and its linked content.

View or download sample code (how to download)

The sample app is a Razor Pages app and assumes a basic understanding of Razor Pages. If unfamiliar with Razor Pages, see the following topics:

- Introduction to Razor Pages
- Get started with Razor Pages
- Razor Pages unit tests

> **NOTE**
>
> For testing SPAs, we recommended a tool such as Selenium, which can automate a browser.

Introduction to integration tests

Integration tests evaluate an app's components on a broader level than unit tests. Unit tests are used to test isolated software components, such as individual class methods. Integration tests confirm that two or more app components work together to produce an expected result, possibly including every component required to fully process a request.

These broader tests are used to test the app's infrastructure and whole framework, often including the following components:

- Database
- File system
- Network appliances
- Request-response pipeline

Unit tests use fabricated components, known as *fakes* or *mock objects*, in place of infrastructure components.

In contrast to unit tests, integration tests:

- Use the actual components that the app uses in production.
- Require more code and data processing.
- Take longer to run.

Therefore, limit the use of integration tests to the most important infrastructure scenarios. If a behavior can be tested using either a unit test or an integration test, choose the unit test.

> **TIP**
> Don't write integration tests for every possible permutation of data and file access with databases and file systems. Regardless of how many places across an app interact with databases and file systems, a focused set of read, write, update, and delete integration tests are usually capable of adequately testing database and file system components. Use unit tests for routine tests of method logic that interact with these components. In unit tests, the use of infrastructure fakes/mocks result in faster test execution.

> **NOTE**
> In discussions of integration tests, the tested project is frequently called the *System Under Test*, or "SUT" for short.
>
> *"SUT" is used throughout this topic to refer to the tested ASP.NET Core app.*

ASP.NET Core integration tests

Integration tests in ASP.NET Core require the following:

- A test project is used to contain and execute the tests. The test project has a reference to the SUT.
- The test project creates a test web host for the SUT and uses a test server client to handle requests and responses with the SUT.
- A test runner is used to execute the tests and report the test results.

Integration tests follow a sequence of events that include the usual *Arrange*, *Act*, and *Assert* test steps:

1. The SUT's web host is configured.
2. A test server client is created to submit requests to the app.
3. The *Arrange* test step is executed: The test app prepares a request.
4. The *Act* test step is executed: The client submits the request and receives the response.
5. The *Assert* test step is executed: The *actual* response is validated as a *pass* or *fail* based on an *expected* response.
6. The process continues until all of the tests are executed.
7. The test results are reported.

Usually, the test web host is configured differently than the app's normal web host for the test runs. For

example, a different database or different app settings might be used for the tests.

Infrastructure components, such as the test web host and in-memory test server (TestServer), are provided or managed by the Microsoft.AspNetCore.Mvc.Testing package. Use of this package streamlines test creation and execution.

The `Microsoft.AspNetCore.Mvc.Testing` package handles the following tasks:

- Copies the dependencies file (*.deps*) from the SUT into the test project's *bin* directory.
- Sets the content root to the SUT's project root so that static files and pages/views are found when the tests are executed.
- Provides the WebApplicationFactory class to streamline bootstrapping the SUT with `TestServer`.

The unit tests documentation describes how to set up a test project and test runner, along with detailed instructions on how to run tests and recommendations for how to name tests and test classes.

> **NOTE**
> When creating a test project for an app, separate the unit tests from the integration tests into different projects. This helps ensure that infrastructure testing components aren't accidentally included in the unit tests. Separation of unit and integration tests also allows control over which set of tests are run.

There's virtually no difference between the configuration for tests of Razor Pages apps and MVC apps. The only difference is in how the tests are named. In a Razor Pages app, tests of page endpoints are usually named after the page model class (for example, `IndexPageTests` to test component integration for the Index page). In an MVC app, tests are usually organized by controller classes and named after the controllers they test (for example, `HomeControllerTests` to test component integration for the Home controller).

Test app prerequisites

The test project must:

- Reference the following packages:
  - Microsoft.AspNetCore.App
  - Microsoft.AspNetCore.Mvc.Testing
- Specify the Web SDK in the project file (`<Project Sdk="Microsoft.NET.Sdk.Web">`). The Web SDK is required when referencing the Microsoft.AspNetCore.App metapackage.

These prerequisites can be seen in the sample app. Inspect the *tests/RazorPagesProject.Tests/RazorPagesProject.Tests.csproj* file. The sample app uses the xUnit test framework and the AngleSharp parser library, so the sample app also references:

- xunit
- xunit.runner.visualstudio
- AngleSharp

SUT environment

If the SUT's environment isn't set, the environment defaults to Development.

Basic tests with the default WebApplicationFactory

WebApplicationFactory<TEntryPoint> is used to create a TestServer for the integration tests. `TEntryPoint` is the entry point class of the SUT, usually the `Startup` class.

Test classes implement a *class fixture* interface (IClassFixture) to indicate the class contains tests and provide shared object instances across the tests in the class.

The following test class, `BasicTests`, uses the `WebApplicationFactory` to bootstrap the SUT and provide an HttpClient to a test method, `Get_EndpointsReturnSuccessAndCorrectContentType`. The method checks if the response status code is successful (status codes in the range 200-299) and the `Content-Type` header is `text/html; charset=utf-8` for several app pages.

CreateClient creates an instance of `HttpClient` that automatically follows redirects and handles cookies.

```
public class BasicTests
    : IClassFixture<WebApplicationFactory<RazorPagesProject.Startup>>
{
    private readonly WebApplicationFactory<RazorPagesProject.Startup> _factory;

    public BasicTests(WebApplicationFactory<RazorPagesProject.Startup> factory)
    {
        _factory = factory;
    }

    [Theory]
    [InlineData("/")]
    [InlineData("/Index")]
    [InlineData("/About")]
    [InlineData("/Privacy")]
    [InlineData("/Contact")]
    public async Task Get_EndpointsReturnSuccessAndCorrectContentType(string url)
    {
        // Arrange
        var client = _factory.CreateClient();

        // Act
        var response = await client.GetAsync(url);

        // Assert
        response.EnsureSuccessStatusCode(); // Status Code 200-299
        Assert.Equal("text/html; charset=utf-8",
            response.Content.Headers.ContentType.ToString());
    }
}
```

By default, non-essential cookies aren't preserved across requests when the GDPR consent policy is enabled. To preserve non-essential cookies, such as those used by the TempData provider, mark them as essential in your tests. For instructions on marking a cookie as essential, see Essential cookies.

Customize WebApplicationFactory

Web host configuration can be created independently of the test classes by inheriting from `WebApplicationFactory` to create one or more custom factories:

1. Inherit from `WebApplicationFactory` and override ConfigureWebHost. The IWebHostBuilder allows the configuration of the service collection with ConfigureServices, which is executed before the app's `Startup.ConfigureServices`. The IWebHostBuilder allows overriding and modifying registered services in the service collection with ConfigureTestServices:

```
public class CustomWebApplicationFactory<TStartup>
    : WebApplicationFactory<TStartup> where TStartup: class
{
    protected override void ConfigureWebHost(IWebHostBuilder builder)
    {
        builder.ConfigureServices(services =>
        {
            // Create a new service provider.
            var serviceProvider = new ServiceCollection()
                .AddEntityFrameworkInMemoryDatabase()
                .BuildServiceProvider();

            // Add a database context (ApplicationDbContext) using an in-memory
            // database for testing.
            services.AddDbContext<ApplicationDbContext>(options =>
            {
                options.UseInMemoryDatabase("InMemoryDbForTesting");
                options.UseInternalServiceProvider(serviceProvider);
            });

            // Build the service provider.
            var sp = services.BuildServiceProvider();

            // Create a scope to obtain a reference to the database
            // context (ApplicationDbContext).
            using (var scope = sp.CreateScope())
            {
                var scopedServices = scope.ServiceProvider;
                var db = scopedServices.GetRequiredService<ApplicationDbContext>();
                var logger = scopedServices
                    .GetRequiredService<ILogger<CustomWebApplicationFactory<TStartup>>>();

                // Ensure the database is created.
                db.Database.EnsureCreated();

                try
                {
                    // Seed the database with test data.
                    Utilities.InitializeDbForTests(db);
                }
                catch (Exception ex)
                {
                    logger.LogError(ex, "An error occurred seeding the database. Error: {Message}",
ex.Message);
                }
            }
        });
    }
}
```

Database seeding in the sample app is performed by the `InitializeDbForTests` method. The method is described in the Integration tests sample: Test app organization section.

2. Use the custom `CustomWebApplicationFactory` in test classes. The following example uses the factory in the `IndexPageTests` class:

```
public class IndexPageTests :
    IClassFixture<CustomWebApplicationFactory<RazorPagesProject.Startup>>
{
    private readonly HttpClient _client;
    private readonly CustomWebApplicationFactory<RazorPagesProject.Startup>
        _factory;

    public IndexPageTests(
        CustomWebApplicationFactory<RazorPagesProject.Startup> factory)
    {
        _factory = factory;
        _client = factory.CreateClient(new WebApplicationFactoryClientOptions
            {
                AllowAutoRedirect = false
            });
    }
```

The sample app's client is configured to prevent the `HttpClient` from following redirects. As explained later in the Mock authentication section, this permits tests to check the result of the app's first response. The first response is a redirect in many of these tests with a `Location` header.

3. A typical test uses the `HttpClient` and helper methods to process the request and the response:

```
[Fact]
public async Task Post_DeleteAllMessagesHandler_ReturnsRedirectToRoot()
{
    // Arrange
    var defaultPage = await _client.GetAsync("/");
    var content = await HtmlHelpers.GetDocumentAsync(defaultPage);

    //Act
    var response = await _client.SendAsync(
        (IHtmlFormElement)content.QuerySelector("form[id='messages']"),
        (IHtmlButtonElement)content.QuerySelector("button[id='deleteAllBtn']"));

    // Assert
    Assert.Equal(HttpStatusCode.OK, defaultPage.StatusCode);
    Assert.Equal(HttpStatusCode.Redirect, response.StatusCode);
    Assert.Equal("/", response.Headers.Location.OriginalString);
}
```

Any POST request to the SUT must satisfy the antiforgery check that's automatically made by the app's data protection antiforgery system. In order to arrange for a test's POST request, the test app must:

1. Make a request for the page.
2. Parse the antiforgery cookie and request validation token from the response.
3. Make the POST request with the antiforgery cookie and request validation token in place.

The `SendAsync` helper extension methods (*Helpers/HttpClientExtensions.cs*) and the `GetDocumentAsync` helper method (*Helpers/HtmlHelpers.cs*) in the sample app use the AngleSharp parser to handle the antiforgery check with the following methods:

- `GetDocumentAsync`: Receives the HttpResponseMessage and returns an `IHtmlDocument`. `GetDocumentAsync` uses a factory that prepares a *virtual response* based on the original `HttpResponseMessage`. For more information, see the AngleSharp documentation.
- `SendAsync` extension methods for the `HttpClient` compose an HttpRequestMessage and call SendAsync(HttpRequestMessage) to submit requests to the SUT. Overloads for `SendAsync` accept the HTML form (`IHtmlFormElement`) and the following:
  - Submit button of the form (`IHtmlElement`)

- Form values collection (`IEnumerable<KeyValuePair<string, string>>`)
- Submit button (`IHtmlElement`) and form values (`IEnumerable<KeyValuePair<string, string>>`)

> **NOTE**
>
> AngleSharp is a third-party parsing library used for demonstration purposes in this topic and the sample app. AngleSharp isn't supported or required for integration testing of ASP.NET Core apps. Other parsers can be used, such as the Html Agility Pack (HAP). Another approach is to write code to handle the antiforgery system's request verification token and antiforgery cookie directly.

Customize the client with WithWebHostBuilder

When additional configuration is required within a test method, WithWebHostBuilder creates a new `WebApplicationFactory` with an IWebHostBuilder that is further customized by configuration.

The `Post_DeleteMessageHandler_ReturnsRedirectToRoot` test method of the sample app demonstrates the use of `WithWebHostBuilder`. This test performs a record delete in the database by triggering a form submission in the SUT.

Because another test in the `IndexPageTests` class performs an operation that deletes all of the records in the database and may run before the `Post_DeleteMessageHandler_ReturnsRedirectToRoot` method, the database is reseeded in this test method to ensure that a record is present for the SUT to delete. Selecting the first delete button of the `messages` form in the SUT is simulated in the request to the SUT:

```
[Fact]
public async Task Post_DeleteMessageHandler_ReturnsRedirectToRoot()
{
    // Arrange
    var client = _factory.WithWebHostBuilder(builder =>
        {
            builder.ConfigureServices(services =>
            {
                var serviceProvider = services.BuildServiceProvider();

                using (var scope = serviceProvider.CreateScope())
                {
                    var scopedServices = scope.ServiceProvider;
                    var db = scopedServices
                        .GetRequiredService<ApplicationDbContext>();
                    var logger = scopedServices
                        .GetRequiredService<ILogger<IndexPageTests>>();

                    try
                    {
                        Utilities.ReinitializeDbForTests(db);
                    }
                    catch (Exception ex)
                    {
                        logger.LogError(ex, "An error occurred seeding " +
                            "the database with test messages. Error: {Message}" +
                            ex.Message);
                    }
                }
            });
        })
        .CreateClient(new WebApplicationFactoryClientOptions
        {
            AllowAutoRedirect = false
        });
    var defaultPage = await client.GetAsync("/");
    var content = await HtmlHelpers.GetDocumentAsync(defaultPage);

    //Act
    var response = await client.SendAsync(
        (IHtmlFormElement)content.QuerySelector("form[id='messages']"),
        (IHtmlButtonElement)content.QuerySelector("form[id='messages']")
            .QuerySelector("div[class='panel-body']")
            .QuerySelector("button"));

    // Assert
    Assert.Equal(HttpStatusCode.OK, defaultPage.StatusCode);
    Assert.Equal(HttpStatusCode.Redirect, response.StatusCode);
    Assert.Equal("/", response.Headers.Location.OriginalString);
}
```

Client options

The following table shows the default WebApplicationFactoryClientOptions available when creating `HttpClient` instances.

OPTION	DESCRIPTION	DEFAULT
AllowAutoRedirect	Gets or sets whether or not `HttpClient` instances should automatically follow redirect responses.	`true`

OPTION	DESCRIPTION	DEFAULT
BaseAddress	Gets or sets the base address of `HttpClient` instances.	`http://localhost`
HandleCookies	Gets or sets whether `HttpClient` instances should handle cookies.	`true`
MaxAutomaticRedirections	Gets or sets the maximum number of redirect responses that `HttpClient` instances should follow.	7

Create the `WebApplicationFactoryClientOptions` class and pass it to the CreateClient method (default values are shown in the code example):

```
// Default client option values are shown
var clientOptions = new WebApplicationFactoryClientOptions();
clientOptions.AllowAutoRedirect = true;
clientOptions.BaseAddress = new Uri("http://localhost");
clientOptions.HandleCookies = true;
clientOptions.MaxAutomaticRedirections = 7;

_client = _factory.CreateClient(clientOptions);
```

Inject mock services

Services can be overridden in a test with a call to ConfigureTestServices on the host builder. **To inject mock services, the SUT must have a `Startup` class with a `Startup.ConfigureServices` method.**

The sample SUT includes a scoped service that returns a quote. The quote is embedded in a hidden field on the Index page when the Index page is requested.

Services/IQuoteService.cs:

```
public interface IQuoteService
{
    Task<string> GenerateQuote();
}
```

Services/QuoteService.cs:

```
// Quote ©1975 BBC: The Doctor (Tom Baker); Dr. Who: Planet of Evil
// https://www.bbc.co.uk/programmes/p00pyrx6
public class QuoteService : IQuoteService
{
    public Task<string> GenerateQuote()
    {
        return Task.FromResult<string>(
            "Come on, Sarah. We've an appointment in London, " +
            "and we're already 30,000 years late.");
    }
}
```

Startup.cs:

```
services.AddScoped<IQuoteService, QuoteService>();
```

Pages/Index.cshtml.cs:

```
public class IndexModel : PageModel
{
    private readonly ApplicationDbContext _db;
    private readonly IQuoteService _quoteService;

    public IndexModel(ApplicationDbContext db, IQuoteService quoteService)
    {
        _db = db;
        _quoteService = quoteService;
    }

    [BindProperty]
    public Message Message { get; set; }

    public IList<Message> Messages { get; private set; }

    [TempData]
    public string MessageAnalysisResult { get; set; }

    public string Quote { get; private set; }

    public async Task OnGetAsync()
    {
        Messages = await _db.GetMessagesAsync();

        Quote = await _quoteService.GenerateQuote();
    }
```

Pages/Index.cs:

```
<input id="quote" type="hidden" value="@Model.Quote">
```

The following markup is generated when the SUT app is run:

```
<input id="quote" type="hidden" value="Come on, Sarah. We&#x27;ve an appointment in
    London, and we&#x27;re already 30,000 years late.">
```

To test the service and quote injection in an integration test, a mock service is injected into the SUT by the test. The mock service replaces the app's `QuoteService` with a service provided by the test app, called `TestQuoteService`:

IntegrationTests.IndexPageTests.cs:

```
// Quote ©1975 BBC: The Doctor (Tom Baker); Pyramids of Mars
// https://www.bbc.co.uk/programmes/p00pys55
public class TestQuoteService : IQuoteService
{
    public Task<string> GenerateQuote()
    {
        return Task.FromResult<string>(
            "Something's interfering with time, Mr. Scarman, " +
            "and time is my business.");
    }
}
```

`ConfigureTestServices` is called, and the scoped service is registered:

```
[Fact]
public async Task Get_QuoteService_ProvidesQuoteInPage()
{
    // Arrange
    var client = _factory.WithWebHostBuilder(builder =>
        {
            builder.ConfigureTestServices(services =>
            {
                services.AddScoped<IQuoteService, TestQuoteService>();
            });
        })
        .CreateClient();

    //Act
    var defaultPage = await client.GetAsync("/");
    var content = await HtmlHelpers.GetDocumentAsync(defaultPage);
    var quoteElement = content.QuerySelector("#quote");

    // Assert
    Assert.Equal("Something's interfering with time, Mr. Scarman, " +
        "and time is my business.", quoteElement.Attributes["value"].Value);
}
```

The markup produced during the test's execution reflects the quote text supplied by `TestQuoteService`, thus the assertion passes:

```
<input id="quote" type="hidden" value="Something&#x27;s interfering with time,
    Mr. Scarman, and time is my business.">
```

Mock authentication

Tests in the `AuthTests` class check that a secure endpoint:

- Redirects an unauthenticated user to the app's Login page.
- Returns content for an authenticated user.

In the SUT, the `/SecurePage` page uses an AuthorizePage convention to apply an AuthorizeFilter to the page. For more information, see Razor Pages authorization conventions.

```
services.AddMvc()
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2)
    .AddRazorPagesOptions(options =>
    {
        options.Conventions.AuthorizePage("/SecurePage");
    });
```

In the `Get_SecurePageRedirectsAnUnauthenticatedUser` test, a WebApplicationFactoryClientOptions is set to disallow redirects by setting AllowAutoRedirect to `false`:

```
[Fact]
public async Task Get_SecurePageRedirectsAnUnauthenticatedUser()
{
    // Arrange
    var client = _factory.CreateClient(
        new WebApplicationFactoryClientOptions
        {
            AllowAutoRedirect = false
        });

    // Act
    var response = await client.GetAsync("/SecurePage");

    // Assert
    Assert.Equal(HttpStatusCode.Redirect, response.StatusCode);
    Assert.StartsWith("http://localhost/Identity/Account/Login",
        response.Headers.Location.OriginalString);
}
```

By disallowing the client to follow the redirect, the following checks can be made:

- The status code returned by the SUT can be checked against the expected HttpStatusCode.Redirect result, not the final status code after the redirect to the Login page, which would be HttpStatusCode.OK.
- The `Location` header value in the response headers is checked to confirm that it starts with `http://localhost/Identity/Account/Login`, not the final Login page response, where the `Location` header wouldn't be present.

The test app can mock an AuthenticationHandler<TOptions> in ConfigureTestServices in order to test aspects of authentication and authorization. A minimal scenario returns an AuthenticateResult.Success:

```
public class TestAuthHandler : AuthenticationHandler<AuthenticationSchemeOptions>
{
    public TestAuthHandler(IOptionsMonitor<AuthenticationSchemeOptions> options,
        ILoggerFactory logger, UrlEncoder encoder, ISystemClock clock)
        : base(options, logger, encoder, clock)
    {
    }

    protected override Task<AuthenticateResult> HandleAuthenticateAsync()
    {
        var claims = new[] { new Claim(ClaimTypes.Name, "Test user") };
        var identity = new ClaimsIdentity(claims, "Test");
        var principal = new ClaimsPrincipal(identity);
        var ticket = new AuthenticationTicket(principal, "Test");

        var result = AuthenticateResult.Success(ticket);

        return Task.FromResult(result);
    }
}
```

The `TestAuthHandler` is called to authenticate a user when the authentication scheme is set to `Test` where `AddAuthentication` is registered for `ConfigureTestServices`:

```
[Fact]
public async Task Get_SecurePageIsReturnedForAnAuthenticatedUser()
{
    // Arrange
    var client = _factory.WithWebHostBuilder(builder =>
        {
            builder.ConfigureTestServices(services =>
            {
                services.AddAuthentication("Test")
                    .AddScheme<AuthenticationSchemeOptions, TestAuthHandler>(
                        "Test", options => {});
            });
        })
        .CreateClient(new WebApplicationFactoryClientOptions
        {
            AllowAutoRedirect = false,
        });

    client.DefaultRequestHeaders.Authorization =
        new AuthenticationHeaderValue("Test");

    //Act
    var response = await client.GetAsync("/SecurePage");

    // Assert
    Assert.Equal(HttpStatusCode.OK, response.StatusCode);
}
```

For more information on `WebApplicationFactoryClientOptions`, see the Client options section.

Set the environment

By default, the SUT's host and app environment is configured to use the Development environment. To override the SUT's environment:

- Set the `ASPNETCORE_ENVIRONMENT` environment variable (for example, `Staging`, `Production`, or other custom value, such as `Testing`).
- Override `CreateWebHostBuilder` in the test app to read the `ASPNETCORE_ENVIRONMENT` environment variable.

```
public class CustomWebApplicationFactory<TStartup>
    : WebApplicationFactory<TStartup> where TStartup: class
{
    protected override IWebHostBuilder CreateWebHostBuilder()
    {
        return base.CreateWebHostBuilder()
            .UseEnvironment(
                Environment.GetEnvironmentVariable("ASPNETCORE_ENVIRONMENT"));
    }

    ...
}
```

The environment can also be set directly on the host builder in a custom WebApplicationFactory<TEntryPoint>:

```
public class CustomWebApplicationFactory<TStartup>
    : WebApplicationFactory<TStartup> where TStartup: class
{
    protected override void ConfigureWebHost(IWebHostBuilder builder)
    {
        builder.UseEnvironment(
            Environment.GetEnvironmentVariable("ASPNETCORE_ENVIRONMENT"));

        ...
    }

    ...
```

How the test infrastructure infers the app content root path

The `WebApplicationFactory` constructor infers the app content root path by searching for a WebApplicationFactoryContentRootAttribute on the assembly containing the integration tests with a key equal to the `TEntryPoint` assembly `System.Reflection.Assembly.FullName`. In case an attribute with the correct key isn't found, `WebApplicationFactory` falls back to searching for a solution file (*.sln*) and appends the `TEntryPoint` assembly name to the solution directory. The app root directory (the content root path) is used to discover views and content files.

Disable shadow copying

Shadow copying causes the tests to execute in a different directory than the output directory. For tests to work properly, shadow copying must be disabled. The sample app uses xUnit and disables shadow copying for xUnit by including an *xunit.runner.json* file with the correct configuration setting. For more information, see Configuring xUnit with JSON.

Add the *xunit.runner.json* file to root of the test project with the following content:

```
{
  "shadowCopy": false
}
```

If using Visual Studio, set the file's **Copy to Output Directory** property to **Copy always**. If not using Visual Studio, add a `Content` target to the test app's project file:

```
<ItemGroup>
  <Content Update="xunit.runner.json">
    <CopyToOutputDirectory>Always</CopyToOutputDirectory>
  </Content>
</ItemGroup>
```

Disposal of objects

After the tests of the `IClassFixture` implementation are executed, TestServer and HttpClient are disposed when xUnit disposes of the WebApplicationFactory. If objects instantiated by the developer require disposal, dispose of them in the `IClassFixture` implementation. For more information, see Implementing a Dispose method.

Integration tests sample

The sample app is composed of two apps:

APP	PROJECT DIRECTORY	DESCRIPTION
Message app (the SUT)	*src/RazorPagesProject*	Allows a user to add, delete one, delete all, and analyze messages.
Test app	*tests/RazorPagesProject.Tests*	Used to integration test the SUT.

The tests can be run using the built-in test features of an IDE, such as Visual Studio. If using Visual Studio Code or the command line, execute the following command at a command prompt in the *tests/RazorPagesProject.Tests* directory:

```
dotnet test
```

Message app (SUT) organization

The SUT is a Razor Pages message system with the following characteristics:

- The Index page of the app (*Pages/Index.cshtml* and *Pages/Index.cshtml.cs*) provides a UI and page model methods to control the addition, deletion, and analysis of messages (average words per message).
- A message is described by the `Message` class (*Data/Message.cs*) with two properties: `Id` (key) and `Text` (message). The `Text` property is required and limited to 200 characters.
- Messages are stored using Entity Framework's in-memory database†.
- The app contains a data access layer (DAL) in its database context class, `AppDbContext` (*Data/AppDbContext.cs*).
- If the database is empty on app startup, the message store is initialized with three messages.
- The app includes a `/SecurePage` that can only be accessed by an authenticated user.

†The EF topic, Test with InMemory, explains how to use an in-memory database for tests with MSTest. This topic uses the xUnit test framework. Test concepts and test implementations across different test frameworks are similar but not identical.

Although the app doesn't use the repository pattern and isn't an effective example of the Unit of Work (UoW) pattern, Razor Pages supports these patterns of development. For more information, see Designing the infrastructure persistence layer and Test controller logic (the sample implements the repository pattern).

Test app organization

The test app is a console app inside the *tests/RazorPagesProject.Tests* directory.

TEST APP DIRECTORY	DESCRIPTION
AuthTests	Contains test methods for: • Accessing a secure page by an unauthenticated user. • Accessing a secure page by an authenticated user with a mock AuthenticationHandler<TOptions>. • Obtaining a GitHub user profile and checking the profile's user login.
BasicTests	Contains a test method for routing and content type.
IntegrationTests	Contains the integration tests for the Index page using custom `WebApplicationFactory` class.

TEST APP DIRECTORY	DESCRIPTION
Helpers/Utilities	• *Utilities.cs* contains the `InitializeDbForTests` method used to seed the database with test data. • *HtmlHelpers.cs* provides a method to return an AngleSharp `IHtmlDocument` for use by the test methods. • *HttpClientExtensions.cs* provide overloads for `SendAsync` to submit requests to the SUT.

The test framework is xUnit. Integration tests are conducted using the Microsoft.AspNetCore.TestHost, which includes the TestServer. Because the Microsoft.AspNetCore.Mvc.Testing package is used to configure the test host and test server, the `TestHost` and `TestServer` packages don't require direct package references in the test app's project file or developer configuration in the test app.

Seeding the database for testing

Integration tests usually require a small dataset in the database prior to the test execution. For example, a delete test calls for a database record deletion, so the database must have at least one record for the delete request to succeed.

The sample app seeds the database with three messages in *Utilities.cs* that tests can use when they execute:

```
public static void InitializeDbForTests(ApplicationDbContext db)
{
    db.Messages.AddRange(GetSeedingMessages());
    db.SaveChanges();
}

public static void ReinitializeDbForTests(ApplicationDbContext db)
{
    db.Messages.RemoveRange(db.Messages);
    InitializeDbForTests(db);
}

public static List<Message> GetSeedingMessages()
{
    return new List<Message>()
    {
        new Message(){ Text = "TEST RECORD: You're standing on my scarf." },
        new Message(){ Text = "TEST RECORD: Would you like a jelly baby?" },
        new Message(){ Text = "TEST RECORD: To the rational mind, " +
            "nothing is inexplicable; only unexplained." }
    };
}
```

ASP.NET Core load/stress testing

9/22/2020 • 2 minutes to read • Edit Online

Load testing and stress testing are important to ensure a web app is performant and scalable. Their goals are different even though they often share similar tests.

Load tests: Test whether the app can handle a specified load of users for a certain scenario while still satisfying the response goal. The app is run under normal conditions.

Stress tests: Test app stability when running under extreme conditions, often for a long period of time. The tests place high user load, either spikes or gradually increasing load, on the app, or they limit the app's computing resources.

Stress tests determine if an app under stress can recover from failure and gracefully return to expected behavior. Under stress, the app isn't run under normal conditions.

Visual Studio 2019 announced plans to deprecate the load testing. The corresponding Azure DevOps cloud-based load testing service has been closed.

Third-party tools

The following list contains third-party web performance tools with various feature sets:

- Apache JMeter
- ApacheBench (ab)
- Gatling
- k6
- Locust
- West Wind WebSurge
- Netling
- Vegeta

Troubleshoot and debug ASP.NET Core projects

9/22/2020 • 4 minutes to read • Edit Online

By Rick Anderson

.NET Core SDK warnings

Both the 32-bit and 64-bit versions of the .NET Core SDK are installed

In the **New Project** dialog for ASP.NET Core, you may see the following warning:

> Both 32-bit and 64-bit versions of the .NET Core SDK are installed. Only templates from the 64-bit versions installed at 'C:\Program Files\dotnet\sdk\' are displayed.

This warning appears when both 32-bit (x86) and 64-bit (x64) versions of the .NET Core SDK are installed. Common reasons both versions may be installed include:

- You originally downloaded the .NET Core SDK installer using a 32-bit machine but then copied it across and installed it on a 64-bit machine.
- The 32-bit .NET Core SDK was installed by another application.
- The wrong version was downloaded and installed.

Uninstall the 32-bit .NET Core SDK to prevent this warning. Uninstall from **Control Panel** > **Programs and Features** > **Uninstall or change a program**. If you understand why the warning occurs and its implications, you can ignore the warning.

The .NET Core SDK is installed in multiple locations

In the **New Project** dialog for ASP.NET Core, you may see the following warning:

> The .NET Core SDK is installed in multiple locations. Only templates from the SDKs installed at 'C:\Program Files\dotnet\sdk\' are displayed.

You see this message when you have at least one installation of the .NET Core SDK in a directory outside of *C:\Program Files\dotnet\sdk*. Usually this happens when the .NET Core SDK has been deployed on a machine using copy/paste instead of the MSI installer.

Uninstall all 32-bit .NET Core SDKs and runtimes to prevent this warning. Uninstall from **Control Panel** > **Programs and Features** > **Uninstall or change a program**. If you understand why the warning occurs and its implications, you can ignore the warning.

No .NET Core SDKs were detected

- In the Visual Studio **New Project** dialog for ASP.NET Core, you may see the following warning:

  > No .NET Core SDKs were detected, ensure they are included in the environment variable `PATH`.

- When executing a `dotnet` command, the warning appears as:

> It was not possible to find any installed dotnet SDKs.

These warnings appear when the environment variable `PATH` doesn't point to any .NET Core SDKs on the machine. To resolve this problem:

- Install the .NET Core SDK. Obtain the latest installer from .NET Downloads.
- Verify that the `PATH` environment variable points to the location where the SDK is installed (`C:\Program Files\dotnet\` for 64-bit/x64 or `C:\Program Files (x86)\dotnet\` for 32-bit/x86). The SDK installer normally sets the `PATH`. Always install the same bitness SDKs and runtimes on the same machine.

Missing SDK after installing the .NET Core Hosting Bundle

Installing the .NET Core Hosting Bundle modifies the `PATH` when it installs the .NET Core runtime to point to the 32-bit (x86) version of .NET Core (`C:\Program Files (x86)\dotnet\`). This can result in missing SDKs when the 32-bit (x86) .NET Core `dotnet` command is used (No .NET Core SDKs were detected). To resolve this problem, move `C:\Program Files\dotnet\` to a position before `C:\Program Files (x86)\dotnet\` on the `PATH`.

Obtain data from an app

If an app is capable of responding to requests, you can obtain the following data from the app using middleware:

- Request: Method, scheme, host, pathbase, path, query string, headers
- Connection: Remote IP address, remote port, local IP address, local port, client certificate
- Identity: Name, display name
- Configuration settings
- Environment variables

Place the following middleware code at the beginning of the `Startup.Configure` method's request processing pipeline. The environment is checked before the middleware is run to ensure that the code is only executed in the Development environment.

To obtain the environment, use either of the following approaches:

- Inject the `IHostingEnvironment` into the `Startup.Configure` method and check the environment with the local variable. The following sample code demonstrates this approach.
- Assign the environment to a property in the `Startup` class. Check the environment using the property (for example, `if (Environment.IsDevelopment())`).

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env,
    IConfiguration config)
{
    if (env.IsDevelopment())
    {
        app.Run(async (context) =>
        {
            var sb = new StringBuilder();
            var nl = System.Environment.NewLine;
            var rule = string.Concat(nl, new string('-', 40), nl);
            var authSchemeProvider = app.ApplicationServices
                .GetRequiredService<IAuthenticationSchemeProvider>();

            sb.Append($"Request{rule}");
            sb.Append($"{DateTimeOffset.Now}{nl}");
            sb.Append($"{context.Request.Method} {context.Request.Path}{nl}");
            sb.Append($"Scheme: {context.Request.Scheme}{nl}");
```

```
            sb.Append($"Host: {context.Request.Headers["Host"]}{nl}");
            sb.Append($"PathBase: {context.Request.PathBase.Value}{nl}");
            sb.Append($"Path: {context.Request.Path.Value}{nl}");
            sb.Append($"Query: {context.Request.QueryString.Value}{nl}{nl}");

            sb.Append($"Connection{rule}");
            sb.Append($"RemoteIp: {context.Connection.RemoteIpAddress}{nl}");
            sb.Append($"RemotePort: {context.Connection.RemotePort}{nl}");
            sb.Append($"LocalIp: {context.Connection.LocalIpAddress}{nl}");
            sb.Append($"LocalPort: {context.Connection.LocalPort}{nl}");
            sb.Append($"ClientCert: {context.Connection.ClientCertificate}{nl}{nl}");

            sb.Append($"Identity{rule}");
            sb.Append($"User: {context.User.Identity.Name}{nl}");
            var scheme = await authSchemeProvider
                .GetSchemeAsync(IISDefaults.AuthenticationScheme);
            sb.Append($"DisplayName: {scheme?.DisplayName}{nl}{nl}");

            sb.Append($"Headers{rule}");
            foreach (var header in context.Request.Headers)
            {
                sb.Append($"{header.Key}: {header.Value}{nl}");
            }
            sb.Append(nl);

            sb.Append($"Websockets{rule}");
            if (context.Features.Get<IHttpUpgradeFeature>() != null)
            {
                sb.Append($"Status: Enabled{nl}{nl}");
            }
            else
            {
                sb.Append($"Status: Disabled{nl}{nl}");
            }

            sb.Append($"Configuration{rule}");
            foreach (var pair in config.AsEnumerable())
            {
                sb.Append($"{pair.Path}: {pair.Value}{nl}");
            }
            sb.Append(nl);

            sb.Append($"Environment Variables{rule}");
            var vars = System.Environment.GetEnvironmentVariables();
            foreach (var key in vars.Keys.Cast<string>().OrderBy(key => key,
                StringComparer.OrdinalIgnoreCase))
            {
                var value = vars[key];
                sb.Append($"{key}: {value}{nl}");
            }

            context.Response.ContentType = "text/plain";
            await context.Response.WriteAsync(sb.ToString());
        });
    }
}
```

Debug ASP.NET Core apps

Logging in .NET Core and ASP.NET Core

9/22/2020 • 57 minutes to read • Edit Online

By Kirk Larkin, Juergen Gutsch and Rick Anderson

.NET Core supports a logging API that works with a variety of built-in and third-party logging providers. This article shows how to use the logging API with built-in providers.

Most of the code examples shown in this article are from ASP.NET Core apps. The logging-specific parts of these code snippets apply to any .NET Core app that uses the Generic Host. The ASP.NET Core web app templates use the Generic Host.

View or download sample code (how to download)

Logging providers

Logging providers store logs, except for the `Console` provider which displays logs. For example, the Azure Application Insights provider stores logs in Azure Application Insights. Multiple providers can be enabled.

The default ASP.NET Core web app templates:

- Use the Generic Host.
- Call CreateDefaultBuilder, which adds the following logging providers:
  - Console
  - Debug
  - EventSource
  - EventLog: Windows only

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The preceding code shows the `Program` class created with the ASP.NET Core web app templates. The next several sections provide samples based on the ASP.NET Core web app templates, which use the Generic Host. Non-host console apps are discussed later in this document.

To override the default set of logging providers added by `Host.CreateDefaultBuilder`, call `ClearProviders` and add the required logging providers. For example, the following code:

- Calls ClearProviders to remove all the ILoggerProvider instances from the builder.
- Adds the Console logging provider.

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureLogging(logging =>
        {
            logging.ClearProviders();
            logging.AddConsole();
        })
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

For additional providers, see:

- Built-in logging providers
- Third-party logging providers.

Create logs

To create logs, use an ILogger<TCategoryName> object from dependency injection (DI).

The following example:

- Creates a logger, `ILogger<AboutModel>`, which uses a log *category* of the fully qualified name of the type `AboutModel`. The log category is a string that is associated with each log.
- Calls LogInformation to log at the `Information` level. The Log *level* indicates the severity of the logged event.

```
public class AboutModel : PageModel
{
    private readonly ILogger _logger;

    public AboutModel(ILogger<AboutModel> logger)
    {
        _logger = logger;
    }
    public string Message { get; set; }

    public void OnGet()
    {
        Message = $"About page visited at {DateTime.UtcNow.ToLongTimeString()}";
        _logger.LogInformation(Message);
    }
}
```

Levels and categories are explained in more detail later in this document.

For information on Blazor, see Create logs in Blazor and Blazor WebAssembly in this document.

Create logs in Main and Startup shows how to create logs in `Main` and `Startup`.

Configure logging

Logging configuration is commonly provided by the `Logging` section of *appsettings*.`{Environment}` *.json* files. The following *appsettings.Development.json* file is generated by the ASP.NET Core web app templates:

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  }
}
```

In the preceding JSON:

- The `"Default"`, `"Microsoft"`, and `"Microsoft.Hosting.Lifetime"` categories are specified.
- The `"Microsoft"` category applies to all categories that start with `"Microsoft"`. For example, this setting applies to the `"Microsoft.AspNetCore.Routing.EndpointMiddleware"` category.
- The `"Microsoft"` category logs at log level `Warning` and higher.
- The `"Microsoft.Hosting.Lifetime"` category is more specific than the `"Microsoft"` category, so the `"Microsoft.Hosting.Lifetime"` category logs at log level "Information" and higher.
- A specific log provider is not specified, so `LogLevel` applies to all the enabled logging providers except for the Windows EventLog.

The `Logging` property can have LogLevel and log provider properties. The `LogLevel` specifies the minimum level to log for selected categories. In the preceding JSON, `Information` and `Warning` log levels are specified. `LogLevel` indicates the severity of the log and ranges from 0 to 6:

`Trace` = 0, `Debug` = 1, `Information` = 2, `Warning` = 3, `Error` = 4, `Critical` = 5, and `None` = 6.

When a `LogLevel` is specified, logging is enabled for messages at the specified level and higher. In the preceding JSON, the `Default` category is logged for `Information` and higher. For example, `Information`, `Warning`, `Error`, and `Critical` messages are logged. If no `LogLevel` is specified, logging defaults to the `Information` level. For more information, see Log levels.

A provider property can specify a `LogLevel` property. `LogLevel` under a provider specifies levels to log for that provider, and overrides the non-provider log settings. Consider the following *appsettings.json* file:

```
{
  "Logging": {
    "LogLevel": { // All providers, LogLevel applies to all the enabled providers.
      "Default": "Error", // Default logging, Error and higher.
      "Microsoft": "Warning" // All Microsoft* categories, Warning and higher.
    },
    "Debug": { // Debug provider.
      "LogLevel": {
        "Default": "Information", // Overrides preceding LogLevel:Default setting.
        "Microsoft.Hosting": "Trace" // Debug:Microsoft.Hosting category.
      }
    },
    "EventSource": { // EventSource provider
      "LogLevel": {
        "Default": "Warning" // All categories of EventSource provider.
      }
    }
  }
}
```

Settings in `Logging.{providername}.LogLevel` override settings in `Logging.LogLevel`. In the preceding JSON, the `Debug` provider's default log level is set to `Information`:

`Logging:Debug:LogLevel:Default:Information`

The preceding setting specifies the `Information` log level for every `Logging:Debug:` category except `Microsoft.Hosting`. When a specific category is listed, the specific category overrides the default category. In the preceding JSON, the `Logging:Debug:LogLevel` categories `"Microsoft.Hosting"` and `"Default"` override the settings in `Logging:LogLevel`

The minimum log level can be specified for any of:

- Specific providers: For example, `Logging:EventSource:LogLevel:Default:Information`
- Specific categories: For example, `Logging:LogLevel:Microsoft:Warning`
- All providers and all categories: `Logging:LogLevel:Default:Warning`

Any logs below the minimum level are ***not***:

- Passed to the provider.
- Logged or displayed.

To suppress all logs, specify LogLevel.None. `LogLevel.None` has a value of 6, which is higher than `LogLevel.Critical` (5).

If a provider supports log scopes, `IncludeScopes` indicates whether they're enabled. For more information, see log scopes

The following *appsettings.json* file contains all the providers enabled by default:

```
{
  "Logging": {
    "LogLevel": { // No provider, LogLevel applies to all the enabled providers.
      "Default": "Error",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Warning"
    },
    "Debug": { // Debug provider.
      "LogLevel": {
        "Default": "Information" // Overrides preceding LogLevel:Default setting.
      }
    },
    "Console": {
      "IncludeScopes": true,
      "LogLevel": {
        "Microsoft.AspNetCore.Mvc.Razor.Internal": "Warning",
        "Microsoft.AspNetCore.Mvc.Razor.Razor": "Debug",
        "Microsoft.AspNetCore.Mvc.Razor": "Error",
        "Default": "Information"
      }
    },
    "EventSource": {
      "LogLevel": {
        "Microsoft": "Information"
      }
    },
    "EventLog": {
      "LogLevel": {
        "Microsoft": "Information"
      }
    },
    "AzureAppServicesFile": {
      "IncludeScopes": true,
      "LogLevel": {
        "Default": "Warning"
      }
    },
    "AzureAppServicesBlob": {
      "IncludeScopes": true,
      "LogLevel": {
        "Microsoft": "Information"
      }
    },
    "ApplicationInsights": {
      "LogLevel": {
        "Default": "Information"
      }
    }
  }
}
```

In the preceding sample:

- The categories and levels are not suggested values. The sample is provided to show all the default providers.
- Settings in `Logging.{providername}.LogLevel` override settings in `Logging.LogLevel`. For example, the level in `Debug.LogLevel.Default` overrides the level in `LogLevel.Default`.
- Each default provider *alias* is used. Each provider defines an *alias* that can be used in configuration in place of the fully qualified type name. The built-in providers aliases are:
  - Console
  - Debug
  - EventSource

- EventLog
- AzureAppServicesFile
- AzureAppServicesBlob
- ApplicationInsights

Set log level by command line, environment variables, and other configuration

Log level can be set by any of the configuration providers.

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. `__`, the double underscore, is:

- Supported by all platforms. For example, the `:` separator is not supported by Bash, but `__` is.
- Automatically replaced by a `:`

The following commands:

- Set the environment key `Logging:LogLevel:Microsoft` to a value of `Information` on Windows.
- Test the settings when using an app created with the ASP.NET Core web application templates. The `dotnet run` command must be run in the project directory after using `set`.

```
set Logging__LogLevel__Microsoft=Information
dotnet run
```

The preceding environment setting:

- Is only set in processes launched from the command window they were set in.
- Isn't read by browsers launched with Visual Studio.

The following setx command also sets the environment key and value on Windows. Unlike `set`, `setx` settings are persisted. The `/M` switch sets the variable in the system environment. If `/M` isn't used, a user environment variable is set.

```
setx Logging__LogLevel__Microsoft=Information /M
```

On Azure App Service, select **New application setting** on the **Settings** > **Configuration** page. Azure App Service application settings are:

- Encrypted at rest and transmitted over an encrypted channel.
- Exposed as environment variables.

For more information, see Azure Apps: Override app configuration using the Azure Portal.

For more information on setting ASP.NET Core configuration values using environment variables, see environment variables. For information on using other configuration sources, including the command line, Azure Key Vault, Azure App Configuration, other file formats, and more, see Configuration in ASP.NET Core.

How filtering rules are applied

When an ILogger<TCategoryName> object is created, the ILoggerFactory object selects a single rule per provider to apply to that logger. All messages written by an `ILogger` instance are filtered based on the selected rules. The most specific rule for each provider and category pair is selected from the

available rules.

The following algorithm is used for each provider when an `ILogger` is created for a given category:

- Select all rules that match the provider or its alias. If no match is found, select all rules with an empty provider.
- From the result of the preceding step, select rules with longest matching category prefix. If no match is found, select all rules that don't specify a category.
- If multiple rules are selected, take the **last** one.
- If no rules are selected, use `MinimumLevel`.

Logging output from dotnet run and Visual Studio

Logs created with the default logging providers are displayed:

- In Visual Studio
  - In the Debug output window when debugging.
  - In the ASP.NET Core Web Server window.
- In the console window when the app is run with `dotnet run`.

Logs that begin with "Microsoft" categories are from ASP.NET Core framework code. ASP.NET Core and application code use the same logging API and providers.

Log category

When an `ILogger` object is created, a *category* is specified. That category is included with each log message created by that instance of `ILogger`. The category string is arbitrary, but the convention is to use the class name. For example, in a controller the name might be `"TodoApi.Controllers.TodoController"`. The ASP.NET Core web apps use `ILogger<T>` to automatically get an `ILogger` instance that uses the fully qualified type name of `T` as the category:

```
public class PrivacyModel : PageModel
{
    private readonly ILogger<PrivacyModel> _logger;

    public PrivacyModel(ILogger<PrivacyModel> logger)
    {
        _logger = logger;
    }

    public void OnGet()
    {
        _logger.LogInformation("GET Pages.PrivacyModel called.");
    }
}
```

To explicitly specify the category, call `ILoggerFactory.CreateLogger`:

```
public class ContactModel : PageModel
{
    private readonly ILogger _logger;

    public ContactModel(ILoggerFactory logger)
    {
        _logger = logger.CreateLogger("MyCategory");
    }

    public void OnGet()
    {
        _logger.LogInformation("GET Pages.ContactModel called.");
    }
```

Calling `CreateLogger` with a fixed name can be useful when used in multiple methods so the events can be organized by category.

`ILogger<T>` is equivalent to calling `CreateLogger` with the fully qualified type name of `T`.

Log level

The following table lists the LogLevel values, the convenience `Log{LogLevel}` extension method, and the suggested usage:

LOGLEVEL	VALUE	METHOD	DESCRIPTION
Trace	0	LogTrace	Contain the most detailed messages. These messages may contain sensitive app data. These messages are disabled by default and should ***not*** be enabled in production.
Debug	1	LogDebug	For debugging and development. Use with caution in production due to the high volume.
Information	2	LogInformation	Tracks the general flow of the app. May have long-term value.
Warning	3	LogWarning	For abnormal or unexpected events. Typically includes errors or conditions that don't cause the app to fail.
Error	4	LogError	For errors and exceptions that cannot be handled. These messages indicate a failure in the current operation or request, not an app-wide failure.

LOGLEVEL	VALUE	METHOD	DESCRIPTION
Critical	5	LogCritical	For failures that require immediate attention. Examples: data loss scenarios, out of disk space.
None	6		Specifies that a logging category should not write any messages.

In the previous table, the `LogLevel` is listed from lowest to highest severity.

The Log method's first parameter, LogLevel, indicates the severity of the log. Rather than calling `Log(LogLevel, ...)`, most developers call the Log{LogLevel} extension methods. The `Log{LogLevel}` extension methods call the Log method and specify the LogLevel. For example, the following two logging calls are functionally equivalent and produce the same log:

```
[HttpGet]
public IActionResult Test1(int id)
{
    var routeInfo = ControllerContext.ToCtxString(id);

    _logger.Log(LogLevel.Information, MyLogEvents.TestItem, routeInfo);
    _logger.LogInformation(MyLogEvents.TestItem, routeInfo);

    return ControllerContext.MyDisplayRouteInfo();
}
```

`MyLogEvents.TestItem` is the event ID. `MyLogEvents` is part of the sample app and is displayed in the Log event ID section.

MyDisplayRouteInfo and ToCtxString are provided by the Rick.Docs.Samples.RouteInfo NuGet package. The methods display `Controller` route information.

The following code creates `Information` and `Warning` logs:

```
[HttpGet("{id}")]
public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
{
    _logger.LogInformation(MyLogEvents.GetItem, "Getting item {Id}", id);

    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        _logger.LogWarning(MyLogEvents.GetItemNotFound, "Get({Id}) NOT FOUND", id);
        return NotFound();
    }

    return ItemToDTO(todoItem);
}
```

In the preceding code, the first `Log{LogLevel}` parameter, `MyLogEvents.GetItem`, is the Log event ID. The second parameter is a message template with placeholders for argument values provided by the remaining method parameters. The method parameters are explained in the message template section later in this document.

Call the appropriate `Log{LogLevel}` method to control how much log output is written to a particular storage medium. For example:

- In production:
  - Logging at the `Trace` or `Information` levels produces a high-volume of detailed log messages. To control costs and not exceed data storage limits, log `Trace` and `Information` level messages to a high-volume, low-cost data store. Consider limiting `Trace` and `Information` to specific categories.
  - Logging at `Warning` through `Critical` levels should produce few log messages.
    - Costs and storage limits usually aren't a concern.
    - Few logs allow more flexibility in data store choices.
- In development:
  - Set to `Warning`.
  - Add `Trace` or `Information` messages when troubleshooting. To limit output, set `Trace` or `Information` only for the categories under investigation.

ASP.NET Core writes logs for framework events. For example, consider the log output for:

- A Razor Pages app created with the ASP.NET Core templates.
- Logging set to `Logging:Console:LogLevel:Microsoft:Information`
- Navigation to the Privacy page:

```
info: Microsoft.AspNetCore.Hosting.Diagnostics[1]
      Request starting HTTP/2 GET https://localhost:5001/Privacy
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[0]
      Executing endpoint '/Privacy'
info: Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[3]
      Route matched with {page = "/Privacy"}. Executing page /Privacy
info: Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[101]
      Executing handler method DefaultRP.Pages.PrivacyModel.OnGet - ModelState is Valid
info: Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[102]
      Executed handler method OnGet, returned result .
info: Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[103]
      Executing an implicit handler method - ModelState is Valid
info: Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[104]
      Executed an implicit handler method, returned result
Microsoft.AspNetCore.Mvc.RazorPages.PageResult.
info: Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[4]
      Executed page /Privacy in 74.5188ms
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[1]
      Executed endpoint '/Privacy'
info: Microsoft.AspNetCore.Hosting.Diagnostics[2]
      Request finished in 149.3023ms 200 text/html; charset=utf-8
```

The following JSON sets `Logging:Console:LogLevel:Microsoft:Information`:

```
{
  "Logging": {      // Default, all providers.
    "LogLevel": {
      "Microsoft": "Warning"
    },
    "Console": { // Console provider.
      "LogLevel": {
        "Microsoft": "Information"
      }
    }
  }
}
```

Log event ID

Each log can specify an *event ID*. The sample app uses the `MyLogEvents` class to define event IDs:

```
public class MyLogEvents
{
    public const int GenerateItems = 1000;
    public const int ListItems     = 1001;
    public const int GetItem       = 1002;
    public const int InsertItem    = 1003;
    public const int UpdateItem    = 1004;
    public const int DeleteItem    = 1005;

    public const int TestItem      = 3000;

    public const int GetItemNotFound    = 4000;
    public const int UpdateItemNotFound = 4001;
}
```

```
[HttpGet("{id}")]
public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
{
    _logger.LogInformation(MyLogEvents.GetItem, "Getting item {Id}", id);

    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        _logger.LogWarning(MyLogEvents.GetItemNotFound, "Get({Id}) NOT FOUND", id);
        return NotFound();
    }

    return ItemToDTO(todoItem);
}
```

An event ID associates a set of events. For example, all logs related to displaying a list of items on a page might be 1001.

The logging provider may store the event ID in an ID field, in the logging message, or not at all. The Debug provider doesn't show event IDs. The console provider shows event IDs in brackets after the category:

```
info: TodoApi.Controllers.TodoItemsController[1002]
      Getting item 1
warn: TodoApi.Controllers.TodoItemsController[4000]
      Get(1) NOT FOUND
```

Some logging providers store the event ID in a field, which allows for filtering on the ID.

Log message template

Each log API uses a message template. The message template can contain placeholders for which arguments are provided. Use names for the placeholders, not numbers.

```
[HttpGet("{id}")]
public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
{
    _logger.LogInformation(MyLogEvents.GetItem, "Getting item {Id}", id);

    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        _logger.LogWarning(MyLogEvents.GetItemNotFound, "Get({Id}) NOT FOUND", id);
        return NotFound();
    }

    return ItemToDTO(todoItem);
}
```

The order of placeholders, not their names, determines which parameters are used to provide their values. In the following code, the parameter names are out of sequence in the message template:

```
string p1 = "param1";
string p2 = "param2";
_logger.LogInformation("Parameter values: {p2}, {p1}", p1, p2);
```

The preceding code creates a log message with the parameter values in sequence:

```
Parameter values: param1, param2
```

This approach allows logging providers to implement semantic or structured logging. The arguments themselves are passed to the logging system, not just the formatted message template. This enables logging providers to store the parameter values as fields. For example, consider the following logger method:

```
_logger.LogInformation("Getting item {Id} at {RequestTime}", id, DateTime.Now);
```

For example, when logging to Azure Table Storage:

- Each Azure Table entity can have `ID` and `RequestTime` properties.
- Tables with properties simplify queries on logged data. For example, a query can find all logs within a particular `RequestTime` range without having to parse the time out of the text message.

Log exceptions

The logger methods have overloads that take an exception parameter:

```
[HttpGet("{id}")]
public IActionResult TestExp(int id)
{
    var routeInfo = ControllerContext.ToCtxString(id);
    _logger.LogInformation(MyLogEvents.TestItem, routeInfo);

    try
    {
        if (id == 3)
        {
            throw new Exception("Test exception");
        }
    }
    catch (Exception ex)
    {
        _logger.LogWarning(MyLogEvents.GetItemNotFound, ex, "TestExp({Id})", id);
        return NotFound();
    }

    return ControllerContext.MyDisplayRouteInfo();
}
```

MyDisplayRouteInfo and ToCtxString are provided by the Rick.Docs.Samples.RouteInfo NuGet package. The methods display `Controller` route information.

Exception logging is provider-specific.

Default log level

If the default log level is not set, the default log level value is `Information`.

For example, consider the following web app:

- Created with the ASP.NET web app templates.
- *appsettings.json* and *appsettings.Development.json* deleted or renamed.

With the preceding setup, navigating to the privacy or home page produces many `Trace`, `Debug`, and `Information` messages with `Microsoft` in the category name.

The following code sets the default log level when the default log level is not set in configuration:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureLogging(logging => logging.SetMinimumLevel(LogLevel.Warning))
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

Generally, log levels should be specified in configuration and not code.

Filter function

A filter function is invoked for all providers and categories that don't have rules assigned to them by configuration or code:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureLogging(logging =>
            {
                logging.AddFilter((provider, category, logLevel) =>
                {
                    if (provider.Contains("ConsoleLoggerProvider")
                        && category.Contains("Controller")
                        && logLevel >= LogLevel.Information)
                    {
                        return true;
                    }
                    else if (provider.Contains("ConsoleLoggerProvider")
                        && category.Contains("Microsoft")
                        && logLevel >= LogLevel.Information)
                    {
                        return true;
                    }
                    else
                    {
                        return false;
                    }
                });
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The preceding code displays console logs when the category contains `Controller` or `Microsoft` and the log level is `Information` or higher.

Generally, log levels should be specified in configuration and not code.

ASP.NET Core and EF Core categories

The following table contains some categories used by ASP.NET Core and Entity Framework Core, with notes about the logs:

CATEGORY	NOTES
Microsoft.AspNetCore	General ASP.NET Core diagnostics.
Microsoft.AspNetCore.DataProtection	Which keys were considered, found, and used.
Microsoft.AspNetCore.HostFiltering	Hosts allowed.
Microsoft.AspNetCore.Hosting	How long HTTP requests took to complete and what time they started. Which hosting startup assemblies were loaded.

CATEGORY	NOTES
Microsoft.AspNetCore.Mvc	MVC and Razor diagnostics. Model binding, filter execution, view compilation, action selection.
Microsoft.AspNetCore.Routing	Route matching information.
Microsoft.AspNetCore.Server	Connection start, stop, and keep alive responses. HTTPS certificate information.
Microsoft.AspNetCore.StaticFiles	Files served.
Microsoft.EntityFrameworkCore	General Entity Framework Core diagnostics. Database activity and configuration, change detection, migrations.

To view more categories in the console window, set **appsettings.Development.json** to the following:

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Trace",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  }
}
```

Log scopes

A *scope* can group a set of logical operations. This grouping can be used to attach the same data to each log that's created as part of a set. For example, every log created as part of processing a transaction can include the transaction ID.

A scope:

- Is an IDisposable type that's returned by the BeginScope method.
- Lasts until it's disposed.

The following providers support scopes:

- `Console`
- AzureAppServicesFile and AzureAppServicesBlob

Use a scope by wrapping logger calls in a `using` block:

```
[HttpGet("{id}")]
public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
{
    TodoItem todoItem;

    using (_logger.BeginScope("using block message"))
    {
        _logger.LogInformation(MyLogEvents.GetItem, "Getting item {Id}", id);

        todoItem = await _context.TodoItems.FindAsync(id);

        if (todoItem == null)
        {
            _logger.LogWarning(MyLogEvents.GetItemNotFound,
                "Get({Id}) NOT FOUND", id);
            return NotFound();
        }
    }

    return ItemToDTO(todoItem);
}
```

The following JSON enables scopes for the console provider:

```
{
  "Logging": {
    "Debug": {
      "LogLevel": {
        "Default": "Information"
      }
    },
    "Console": {
      "IncludeScopes": true, // Required to use Scopes.
      "LogLevel": {
        "Microsoft": "Warning",
        "Default": "Information"
      }
    },
    "LogLevel": {
      "Default": "Debug"
    }
  }
}
```

The following code enables scopes for the console provider:

```
public class Scopes
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureLogging((hostingContext, logging) =>
            {
                logging.ClearProviders();
                logging.AddConsole(options => options.IncludeScopes = true);
                logging.AddDebug();
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

Generally, logging should be specified in configuration and not code.

Built-in logging providers

ASP.NET Core includes the following logging providers as part of the shared framework:

- Console
- Debug
- EventSource
- EventLog

The following logging providers are shipped by Microsoft, but not as part of the shared framework. They must be installed as additional nuget.

- AzureAppServicesFile and AzureAppServicesBlob
- ApplicationInsights

For information on `stdout` and debug logging with the ASP.NET Core Module, see Troubleshoot ASP.NET Core on Azure App Service and IIS and ASP.NET Core Module.

Console

The `Console` provider logs output to the console. For more information on viewing `Console` logs in development, see Logging output from dotnet run and Visual Studio.

Debug

The `Debug` provider writes log output by using the System.Diagnostics.Debug class. Calls to `System.Diagnostics.Debug.WriteLine` write to the `Debug` provider.

On Linux, the `Debug` provider log location is distribution-dependent and may be one of the following:

- */var/log/message*
- */var/log/syslog*

Event Source

The `EventSource` provider writes to a cross-platform event source with the name `Microsoft-Extensions-Logging`. On Windows, the provider uses ETW.

dotnet trace tooling

The dotnet-trace tool is a cross-platform CLI global tool that enables the collection of .NET Core traces of a running process. The tool collects Microsoft.Extensions.Logging.EventSource provider data using a LoggingEventSource.

See dotnet-trace for installation instructions.

Use the dotnet trace tooling to collect a trace from an app:

1. Run the app with the `dotnet run` command.
2. Determine the process identifier (PID) of the .NET Core app:
   - On Windows, use one of the following approaches:
     - Task Manager (Ctrl+Alt+Del)
     - tasklist command
     - Get-Process Powershell command
   - On Linux, use the pidof command.

   Find the PID for the process that has the same name as the app's assembly.
3. Execute the `dotnet trace` command.

   General command syntax:

   ```
   dotnet trace collect -p {PID}
       --providers Microsoft-Extensions-Logging:{Keyword}:{Provider Level}
           :FilterSpecs=\"
               {Logger Category 1}:{Category Level 1};
               {Logger Category 2}:{Category Level 2};
               ...
               {Logger Category N}:{Category Level N}\"
   ```

   When using a PowerShell command shell, enclose the `--providers` value in single quotes (`'`):

   ```
   dotnet trace collect -p {PID}
       --providers 'Microsoft-Extensions-Logging:{Keyword}:{Provider Level}
           :FilterSpecs=\"
               {Logger Category 1}:{Category Level 1};
               {Logger Category 2}:{Category Level 2};
               ...
               {Logger Category N}:{Category Level N}\"'
   ```

   On non-Windows platforms, add the `-f speedscope` option to change the format of the output trace file to `speedscope`.

   The following table defines the Keyword:

KEYWORD	DESCRIPTION
1	Log meta events about the `LoggingEventSource`. Doesn't log events from `ILogger`.
2	Turns on the `Message` event when `ILogger.Log()` is called. Provides information in a programmatic (not formatted) way.

KEYWORD	DESCRIPTION
4	Turns on the `FormatMessage` event when `ILogger.Log()` is called. Provides the formatted string version of the information.
8	Turns on the `MessageJson` event when `ILogger.Log()` is called. Provides a JSON representation of the arguments.

The following table lists the provider levels:

PROVIDER LEVEL	DESCRIPTION
0	`LogAlways`
1	`Critical`
2	`Error`
3	`Warning`
4	`Informational`
5	`Verbose`

The parsing for a category level can be either a string or a number:

CATEGORY NAMED VALUE	NUMERIC VALUE
`Trace`	0
`Debug`	1
`Information`	2
`Warning`	3
`Error`	4
`Critical`	5

The provider level and category level:

- Are in reverse order.
- The string constants aren't all identical.

If no `FilterSpecs` are specified then the `EventSourceLogger` implementation attempts to convert the provider level to a category level and applies it to all categories.

PROVIDER LEVEL	CATEGORY LEVEL
`Verbose` (5)	`Debug` (1)

PROVIDER LEVEL	CATEGORY LEVEL
`Informational` (4)	`Information` (2)
`Warning` (3)	`Warning` (3)
`Error` (2)	`Error` (4)
`Critical` (1)	`Critical` (5)

If `FilterSpecs` are provided, any category that is included in the list uses the category level encoded there, all other categories are filtered out.

The following examples assume:

- An app is running and calling `logger.LogDebug("12345")`.
- The process ID (PID) has been set via `set PID=12345`, where `12345` is the actual PID.

Consider the following command:

```
dotnet trace collect -p %PID% --providers Microsoft-Extensions-Logging:4:5
```

The preceding command:

- Captures debug messages.
- Doesn't apply a `FilterSpecs`.
- Specifies level 5 which maps category Debug.

Consider the following command:

```
dotnet trace collect -p %PID%  --providers Microsoft-Extensions-
Logging:4:5:\"FilterSpecs=*:5\"
```

The preceding command:

- Doesn't capture debug messages because the category level 5 is `Critical`.
- Provides a `FilterSpecs`.

The following command captures debug messages because category level 1 specifies `Debug`.

```
dotnet trace collect -p %PID%  --providers Microsoft-Extensions-
Logging:4:5:\"FilterSpecs=*:1\"
```

The following command captures debug messages because category specifies `Debug`.

```
dotnet trace collect -p %PID%  --providers Microsoft-Extensions-
Logging:4:5:\"FilterSpecs=*:Debug\"
```

`FilterSpecs` entries for `{Logger Category}` and `{Category Level}` represent additional log filtering conditions. Separate `FilterSpecs` entries with the `;` semicolon character.

Example using a Windows command shell:

```
dotnet trace collect -p %PID% --providers Microsoft-Extensions-
Logging:4:2:FilterSpecs=\"Microsoft.AspNetCore.Hosting*:4\"
```

The preceding command activates:

- The Event Source logger to produce formatted strings (`4`) for errors (`2`).
- `Microsoft.AspNetCore.Hosting` logging at the `Informational` logging level (`4`).

4. Stop the dotnet trace tooling by pressing the Enter key or Ctrl+C.

   The trace is saved with the name *trace.nettrace* in the folder where the `dotnet trace` command is executed.

5. Open the trace with Perfview. Open the *trace.nettrace* file and explore the trace events.

If the app doesn't build the host with `CreateDefaultBuilder`, add the Event Source provider to the app's logging configuration.

For more information, see:

- Trace for performance analysis utility (dotnet-trace) (.NET Core documentation)
- Trace for performance analysis utility (dotnet-trace) (dotnet/diagnostics GitHub repository documentation)
- LoggingEventSource Class (.NET API Browser)
- EventLevel
- LoggingEventSource reference source (3.0): To obtain reference source for a different version, change the branch to `release/{Version}`, where `{Version}` is the version of ASP.NET Core desired.
- Perfview: Useful for viewing Event Source traces.

Perfview

Use the PerfView utility to collect and view logs. There are other tools for viewing ETW logs, but PerfView provides the best experience for working with the ETW events emitted by ASP.NET Core.

To configure PerfView for collecting events logged by this provider, add the string `*Microsoft-Extensions-Logging` to the **Additional Providers** list. Don't miss the `*` at the start of the string.

Windows EventLog

The `EventLog` provider sends log output to the Windows Event Log. Unlike the other providers, the `EventLog` provider does ***not*** inherit the default non-provider settings. If `EventLog` log settings aren't specified, they default to LogLevel.Warning.

To log events lower than LogLevel.Warning, explicitly set the log level. The following example sets the Event Log default log level to LogLevel.Information:

```
"Logging": {
  "EventLog": {
    "LogLevel": {
      "Default": "Information"
    }
  }
}
```

AddEventLog overloads can pass in EventLogSettings. If `null` or not specified, the following default settings are used:

- `LogName`: "Application"

- `SourceName`: ".NET Runtime"
- `MachineName`: The local machine name is used.

The following code changes the `SourceName` from the default value of `".NET Runtime"` to `MyLogs`:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureLogging(logging =>
            {
                logging.AddEventLog(eventLogSettings =>
                {
                    eventLogSettings.SourceName = "MyLogs";
                });
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

Azure App Service

The Microsoft.Extensions.Logging.AzureAppServices provider package writes logs to text files in an Azure App Service app's file system and to blob storage in an Azure Storage account.

The provider package isn't included in the shared framework. To use the provider, add the provider package to the project.

To configure provider settings, use AzureFileLoggerOptions and AzureBlobLoggerOptions, as shown in the following example:

```
public class Scopes
{
    public class Program
    {
        public static void Main(string[] args)
        {
            CreateHostBuilder(args).Build().Run();
        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureLogging(logging => logging.AddAzureWebAppDiagnostics())
                .ConfigureServices(serviceCollection => serviceCollection
                    .Configure<AzureFileLoggerOptions>(options =>
                    {
                        options.FileName = "azure-diagnostics-";
                        options.FileSizeLimit = 50 * 1024;
                        options.RetainedFileCountLimit = 5;
                    })
                    .Configure<AzureBlobLoggerOptions>(options =>
                    {
                        options.BlobName = "log.txt";
                    }))
                .ConfigureWebHostDefaults(webBuilder =>
                {
                    webBuilder.UseStartup<Startup>();
                });
    }
}
```

When deployed to Azure App Service, the app uses the settings in the App Service logs section of the **App Service** page of the Azure portal. When the following settings are updated, the changes take effect immediately without requiring a restart or redeployment of the app.

- **Application Logging (Filesystem)**
- **Application Logging (Blob)**

The default location for log files is in the *D:\home\LogFiles\Application* folder, and the default file name is *diagnostics-yyyymmdd.txt*. The default file size limit is 10 MB, and the default maximum number of files retained is 2. The default blob name is *{app-name}{timestamp}/yyyy/mm/dd/hh/{guid}-applicationLog.txt*.

This provider only logs when the project runs in the Azure environment.

Azure log streaming

Azure log streaming supports viewing log activity in real time from:

- The app server
- The web server
- Failed request tracing

To configure Azure log streaming:

- Navigate to the **App Service logs** page from the app's portal page.
- Set **Application Logging (Filesystem)** to **On**.
- Choose the log **Level**. This setting only applies to Azure log streaming.

Navigate to the **Log Stream** page to view logs. The logged messages are logged with the `ILogger` interface.

Azure Application Insights

The Microsoft.Extensions.Logging.ApplicationInsights provider package writes logs to Azure Application Insights. Application Insights is a service that monitors a web app and provides tools for querying and analyzing the telemetry data. If you use this provider, you can query and analyze your logs by using the Application Insights tools.

The logging provider is included as a dependency of Microsoft.ApplicationInsights.AspNetCore, which is the package that provides all available telemetry for ASP.NET Core. If you use this package, you don't have to install the provider package.

The Microsoft.ApplicationInsights.Web package is for ASP.NET 4.x, not ASP.NET Core.

For more information, see the following resources:

- Application Insights overview
- Application Insights for ASP.NET Core applications - Start here if you want to implement the full range of Application Insights telemetry along with logging.
- ApplicationInsightsLoggerProvider for .NET Core ILogger logs - Start here if you want to implement the logging provider without the rest of Application Insights telemetry.
- Application Insights logging adapters.
- Install, configure, and initialize the Application Insights SDK - Interactive tutorial on the Microsoft Learn site.

Third-party logging providers

Third-party logging frameworks that work with ASP.NET Core:

- elmah.io (GitHub repo)
- Gelf (GitHub repo)
- JSNLog (GitHub repo)
- KissLog.net (GitHub repo)
- Log4Net (GitHub repo)
- Loggr (GitHub repo)
- NLog (GitHub repo)
- PLogger (GitHub repo)
- Sentry (GitHub repo)
- Serilog (GitHub repo)
- Stackdriver (Github repo)

Some third-party frameworks can perform semantic logging, also known as structured logging.

Using a third-party framework is similar to using one of the built-in providers:

1. Add a NuGet package to your project.
2. Call an `ILoggerFactory` extension method provided by the logging framework.

For more information, see each provider's documentation. Third-party logging providers aren't supported by Microsoft.

Non-host console app

For an example of how to use the Generic Host in a non-web console app, see the *Program.cs* file of the Background Tasks sample app (Background tasks with hosted services in ASP.NET Core).

Logging code for apps without Generic Host differs in the way providers are added and loggers are created.

Logging providers

In a non-host console app, call the provider's `Add{provider name}` extension method while creating a `LoggerFactory`:

```
class Program
{
    static void Main(string[] args)
    {
        using var loggerFactory = LoggerFactory.Create(builder =>
        {
            builder
                .AddFilter("Microsoft", LogLevel.Warning)
                .AddFilter("System", LogLevel.Warning)
                .AddFilter("LoggingConsoleApp.Program", LogLevel.Debug)
                .AddConsole()
                .AddEventLog();
        });
        ILogger logger = loggerFactory.CreateLogger<Program>();
        logger.LogInformation("Example log message");
    }
}
```

Create logs

To create logs, use an ILogger<TCategoryName> object. Use the `LoggerFactory` to create an `ILogger`.

The following example creates a logger with `LoggingConsoleApp.Program` as the category.

```
class Program
{
    static void Main(string[] args)
    {
        using var loggerFactory = LoggerFactory.Create(builder =>
        {
            builder
                .AddFilter("Microsoft", LogLevel.Warning)
                .AddFilter("System", LogLevel.Warning)
                .AddFilter("LoggingConsoleApp.Program", LogLevel.Debug)
                .AddConsole()
                .AddEventLog();
        });
        ILogger logger = loggerFactory.CreateLogger<Program>();
        logger.LogInformation("Example log message");
    }
}
```

In the following example, the logger is used to create logs with `Information` as the level. The Log *level* indicates the severity of the logged event.

```
class Program
{
    static void Main(string[] args)
    {
        using var loggerFactory = LoggerFactory.Create(builder =>
        {
            builder
                .AddFilter("Microsoft", LogLevel.Warning)
                .AddFilter("System", LogLevel.Warning)
                .AddFilter("LoggingConsoleApp.Program", LogLevel.Debug)
                .AddConsole()
                .AddEventLog();
        });
        ILogger logger = loggerFactory.CreateLogger<Program>();
        logger.LogInformation("Example log message");
    }
}
```

Levels and categories are explained in more detail in this document.

Log during host construction

Logging during host construction isn't directly supported. However, a separate logger can be used. In the following example, a Serilog logger is used to log in `CreateHostBuilder`. `AddSerilog` uses the static configuration specified in `Log.Logger`:

```
using System;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;

public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args)
    {
        var builtConfig = new ConfigurationBuilder()
            .AddJsonFile("appsettings.json")
            .AddCommandLine(args)
            .Build();

        Log.Logger = new LoggerConfiguration()
            .WriteTo.Console()
            .WriteTo.File(builtConfig["Logging:FilePath"])
            .CreateLogger();

        try
        {
            return Host.CreateDefaultBuilder(args)
                .ConfigureServices((context, services) =>
                {
                    services.AddRazorPages();
                })
                .ConfigureAppConfiguration((hostingContext, config) =>
                {
                    config.AddConfiguration(builtConfig);
                })
                .ConfigureLogging(logging =>
                {
                    logging.AddSerilog();
                })
                .ConfigureWebHostDefaults(webBuilder =>
                {
                    webBuilder.UseStartup<Startup>();
                });
        }
        catch (Exception ex)
        {
            Log.Fatal(ex, "Host builder error");

            throw;
        }
        finally
        {
            Log.CloseAndFlush();
        }
    }
}
```

Configure a service that depends on ILogger

Constructor injection of a logger into `Startup` works in earlier versions of ASP.NET Core because a separate DI container is created for the Web Host. For information about why only one container is created for the Generic Host, see the breaking change announcement.

To configure a service that depends on `ILogger<T>`, use constructor injection or provide a factory method. The factory method approach is recommended only if there is no other option. For example, consider a service that needs an `ILogger<T>` instance provided by DI:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllers();
    services.AddRazorPages();

    services.AddSingleton<IMyService>((container) =>
    {
        var logger = container.GetRequiredService<ILogger<MyService>>();
        return new MyService() { Logger = logger };
    });
}
```

The preceding highlighted code is a Func that runs the first time the DI container needs to construct an instance of `MyService`. You can access any of the registered services in this way.

Create logs in Main

The following code logs in `Main` by getting an `ILogger` instance from DI after building the host:

```
public static void Main(string[] args)
{
    var host = CreateHostBuilder(args).Build();

    var logger = host.Services.GetRequiredService<ILogger<Program>>();
    logger.LogInformation("Host created.");

    host.Run();
}

public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

Create logs in Startup

The following code writes logs in `Startup.Configure`:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env,
                      ILogger<Startup> logger)
{
    if (env.IsDevelopment())
    {
        logger.LogInformation("In Development.");
        app.UseDeveloperExceptionPage();
    }
    else
    {
        logger.LogInformation("Not Development.");
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
        endpoints.MapRazorPages();
    });
}
```

Writing logs before completion of the DI container setup in the `Startup.ConfigureServices` method is not supported:

- Logger injection into the `Startup` constructor is not supported.
- Logger injection into the `Startup.ConfigureServices` method signature is not supported

The reason for this restriction is that logging depends on DI and on configuration, which in turns depends on DI. The DI container isn't set up until `ConfigureServices` finishes.

For information on configuring a service that depends on `ILogger<T>` or why constructor injection of a logger into `Startup` worked in earlier versions, see Configure a service that depends on ILogger

No asynchronous logger methods

Logging should be so fast that it isn't worth the performance cost of asynchronous code. If a logging data store is slow, don't write to it directly. Consider writing the log messages to a fast store initially, then moving them to the slow store later. For example, when logging to SQL Server, don't do so directly in a `Log` method, since the `Log` methods are synchronous. Instead, synchronously add log messages to an in-memory queue and have a background worker pull the messages out of the queue to do the asynchronous work of pushing data to SQL Server. For more information, see this GitHub issue.

Change log levels in a running app

The Logging API doesn't include a scenario to change log levels while an app is running. However, some configuration providers are capable of reloading configuration, which takes immediate effect on logging configuration. For example, the File Configuration Provider, reloads logging configuration by default. If configuration is changed in code while an app is running, the app can call IConfigurationRoot.Reload to update the app's logging configuration.

ILogger and ILoggerFactory

The ILogger<TCategoryName> and ILoggerFactory interfaces and implementations are included in the .NET Core SDK. They are also available in the following NuGet packages:

- The interfaces are in Microsoft.Extensions.Logging.Abstractions.
- The default implementations are in Microsoft.Extensions.Logging.

Apply log filter rules in code

The preferred approach for setting log filter rules is by using Configuration.

The following example shows how to register filter rules in code:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureLogging(logging =>
               logging.AddFilter("System", LogLevel.Debug)
                  .AddFilter<DebugLoggerProvider>("Microsoft", LogLevel.Information)
                  .AddFilter<ConsoleLoggerProvider>("Microsoft", LogLevel.Trace))
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

`logging.AddFilter("System", LogLevel.Debug)` specifies the `System` category and log level `Debug`. The filter is applied to all providers because a specific provider was not configured.

`AddFilter<DebugLoggerProvider>("Microsoft", LogLevel.Information)` specifies:

- The `Debug` logging provider.
- Log level `Information` and higher.
- All categories starting with `"Microsoft"`.

Create a custom logger

To add a custom logger, add an ILoggerProvider with ILoggerFactory:

```
public void Configure(
    IApplicationBuilder app,
    IWebHostEnvironment env,
    ILoggerFactory loggerFactory)
{
    loggerFactory.AddProvider(new CustomLoggerProvider(new CustomLoggerConfiguration()));
```

The `ILoggerProvider` creates one or more `ILogger` instances. The `ILogger` instances are used by the framework to log the information.

Sample custom logger configuration

The sample:

- Is designed to be a very basic sample that sets the color of the log console by event ID and log level. Loggers generally don't change by event ID and are not specific to log level.
- Creates different color console entries per log level and event ID using the following configuration type:

```
public class ColorConsoleLoggerConfiguration
{
    public LogLevel LogLevel { get; set; } = LogLevel.Warning;
    public int EventId { get; set; } = 0;
    public ConsoleColor Color { get; set; } = ConsoleColor.Yellow;
}
```

The preceding code sets the default level to `Warning` and the color to `Yellow`. If the `EventId` is set to 0, we will log all events.

Create the custom logger

The `ILogger` implementation category name is typically the logging source. For example, the type where the logger is created:

```
public class ColorConsoleLogger : ILogger
{
    private readonly string _name;
    private readonly ColorConsoleLoggerConfiguration _config;

    public ColorConsoleLogger(string name, ColorConsoleLoggerConfiguration config)
    {
        _name = name;
        _config = config;
    }

    public IDisposable BeginScope<TState>(TState state)
    {
        return null;
    }

    public bool IsEnabled(LogLevel logLevel)
    {
        return logLevel == _config.LogLevel;
    }

    public void Log<TState>(LogLevel logLevel, EventId eventId, TState state,
                        Exception exception, Func<TState, Exception, string> formatter)
    {
        if (!IsEnabled(logLevel))
        {
            return;
        }

        if (_config.EventId == 0 || _config.EventId == eventId.Id)
        {
            var color = Console.ForegroundColor;
            Console.ForegroundColor = _config.Color;
            Console.WriteLine($"{logLevel} - {eventId.Id} " +
                              $"- {_name} - {formatter(state, exception)}");
            Console.ForegroundColor = color;
        }
    }
}
```

The preceding code:

- Creates a logger instance per category name.

- Checks `logLevel == _config.LogLevel` in `IsEnabled`, so each `logLevel` has a unique logger. Generally, loggers should also be enabled for all higher log levels:

```
public bool IsEnabled(LogLevel logLevel)
{
    return logLevel >= _config.LogLevel;
}
```

Create the custom LoggerProvider

The `LoggerProvider` is the class that creates the logger instances. Maybe it is not needed to create a logger instance per category, but this makes sense for some Loggers, like NLog or log4net. Doing this you are also able to choose different logging output targets per category if needed:

```
public class ColorConsoleLoggerProvider : ILoggerProvider
{
    private readonly ColorConsoleLoggerConfiguration _config;
    private readonly ConcurrentDictionary<string, ColorConsoleLogger> _loggers = new
ConcurrentDictionary<string, ColorConsoleLogger>();

    public ColorConsoleLoggerProvider(ColorConsoleLoggerConfiguration config)
    {
        _config = config;
    }

    public ILogger CreateLogger(string categoryName)
    {
        return _loggers.GetOrAdd(categoryName, name => new ColorConsoleLogger(name, _config));
    }

    public void Dispose()
    {
        _loggers.Clear();
    }
}
```

In the preceding code, CreateLogger creates a single instance of the `ColorConsoleLogger` per category name and stores it in the `ConcurrentDictionary<TKey,TValue>`;

Usage and registration of the custom logger

Register the logger in the `Startup.Configure`:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env,
                      ILoggerFactory loggerFactory)
{
    // Default registration.
    loggerFactory.AddProvider(new ColorConsoleLoggerProvider(
                              new ColorConsoleLoggerConfiguration
    {
        LogLevel = LogLevel.Error,
        Color = ConsoleColor.Red
    }));

    // Custom registration with default values.
    loggerFactory.AddColorConsoleLogger();

    // Custom registration with a new configuration instance.
    loggerFactory.AddColorConsoleLogger(new ColorConsoleLoggerConfiguration
    {
        LogLevel = LogLevel.Debug,
        Color = ConsoleColor.Gray
    });

    // Custom registration with a configuration object.
    loggerFactory.AddColorConsoleLogger(c =>
    {
        c.LogLevel = LogLevel.Information;
        c.Color = ConsoleColor.Blue;
    });

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }
    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllerRoute(
            name: "default",
            pattern: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

For the preceding code, provide at least one extension method for the `ILoggerFactory`:

```
public static class ColorConsoleLoggerExtensions
{
    public static ILoggerFactory AddColorConsoleLogger(
                                      this ILoggerFactory loggerFactory,
                                      ColorConsoleLoggerConfiguration config)
    {
        loggerFactory.AddProvider(new ColorConsoleLoggerProvider(config));
        return loggerFactory;
    }
    public static ILoggerFactory AddColorConsoleLogger(
                                      this ILoggerFactory loggerFactory)
    {
        var config = new ColorConsoleLoggerConfiguration();
        return loggerFactory.AddColorConsoleLogger(config);
    }
    public static ILoggerFactory AddColorConsoleLogger(
                                    this ILoggerFactory loggerFactory,
                                    Action<ColorConsoleLoggerConfiguration> configure)
    {
        var config = new ColorConsoleLoggerConfiguration();
        configure(config);
        return loggerFactory.AddColorConsoleLogger(config);
    }
}
```

By Tom Dykstra and Steve Smith

.NET Core supports a logging API that works with a variety of built-in and third-party logging providers. This article shows how to use the logging API with built-in providers.

View or download sample code (how to download)

Add providers

A logging provider displays or stores logs. For example, the Console provider displays logs on the console, and the Azure Application Insights provider stores them in Azure Application Insights. Logs can be sent to multiple destinations by adding multiple providers.

To add a provider, call the provider's `Add{provider name}` extension method in *Program.cs*:

```
public static void Main(string[] args)
{
    var webHost = new WebHostBuilder()
        .UseKestrel()
        .UseContentRoot(Directory.GetCurrentDirectory())
        .ConfigureAppConfiguration((hostingContext, config) =>
        {
            var env = hostingContext.HostingEnvironment;
            config.AddJsonFile("appsettings.json", optional: true, reloadOnChange: true)
                  .AddJsonFile($"appsettings.{env.EnvironmentName}.json",
                      optional: true, reloadOnChange: true);
            config.AddEnvironmentVariables();
        })
        .ConfigureLogging((hostingContext, logging) =>
        {
            // Requires `using Microsoft.Extensions.Logging;`
            logging.AddConfiguration(hostingContext.Configuration.GetSection("Logging"));
            logging.AddConsole();
            logging.AddDebug();
            logging.AddEventSourceLogger();
        })
        .UseStartup<Startup>()
        .Build();

    webHost.Run();
}
```

The preceding code requires references to `Microsoft.Extensions.Logging` and `Microsoft.Extensions.Configuration`.

The default project template calls CreateDefaultBuilder, which adds the following logging providers:

- Console
- Debug
- EventSource (starting in ASP.NET Core 2.2)

```
public static void Main(string[] args)
{
    CreateWebHostBuilder(args).Build().Run();
}

public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>();
```

If you use `CreateDefaultBuilder`, you can replace the default providers with your own choices. Call ClearProviders, and add the providers you want.

```
public static void Main(string[] args)
{
    var host = CreateWebHostBuilder(args).Build();

    var todoRepository = host.Services.GetRequiredService<ITodoRepository>();
    todoRepository.Add(new Core.Model.TodoItem() { Name = "Feed the dog" });
    todoRepository.Add(new Core.Model.TodoItem() { Name = "Walk the dog" });

    var logger = host.Services.GetRequiredService<ILogger<Program>>();
    logger.LogInformation("Seeded the database.");

    host.Run();
}

public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureLogging(logging =>
        {
            logging.ClearProviders();
            logging.AddConsole();
        });
```

Learn more about built-in logging providers and third-party logging providers later in the article.

Create logs

To create logs, use an ILogger<TCategoryName> object. In a web app or hosted service, get an `ILogger` from dependency injection (DI). In non-host console apps, use the `LoggerFactory` to create an `ILogger`.

The following ASP.NET Core example creates a logger with `TodoApiSample.Pages.AboutModel` as the category. The log *category* is a string that is associated with each log. The `ILogger<T>` instance provided by DI creates logs that have the fully qualified name of type `T` as the category.

```
public class AboutModel : PageModel
{
    private readonly ILogger _logger;

    public AboutModel(ILogger<AboutModel> logger)
    {
        _logger = logger;
    }
```

In the following ASP.NET Core and console app examples, the logger is used to create logs with `Information` as the level. The Log *level* indicates the severity of the logged event.

```
public void OnGet()
{
    Message = $"About page visited at {DateTime.UtcNow.ToLongTimeString()}";
    _logger.LogInformation("Message displayed: {Message}", Message);
}
```

Levels and categories are explained in more detail later in this article.

Create logs in Startup

To write logs in the `Startup` class, include an `ILogger` parameter in the constructor signature:

```
public class Startup
{
    private readonly ILogger _logger;

    public Startup(IConfiguration configuration, ILogger<Startup> logger)
    {
        Configuration = configuration;
        _logger = logger;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

        // Add our repository type
        services.AddSingleton<ITodoRepository, TodoRepository>();
        _logger.LogInformation("Added TodoRepository to services");
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            _logger.LogInformation("In Development environment");
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseCookiePolicy();

        app.UseMvc();
    }
}
```

Create logs in the Program class

To write logs in the `Program` class, get an `ILogger` instance from DI:

```
public static void Main(string[] args)
{
    var host = CreateWebHostBuilder(args).Build();

    var todoRepository = host.Services.GetRequiredService<ITodoRepository>();
    todoRepository.Add(new Core.Model.TodoItem() { Name = "Feed the dog" });
    todoRepository.Add(new Core.Model.TodoItem() { Name = "Walk the dog" });

    var logger = host.Services.GetRequiredService<ILogger<Program>>();
    logger.LogInformation("Seeded the database.");

    host.Run();
}

public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureLogging(logging =>
        {
            logging.ClearProviders();
            logging.AddConsole();
        });
```

Logging during host construction isn't directly supported. However, a separate logger can be used. In the following example, a Serilog logger is used to log in `CreateWebHostBuilder`. `AddSerilog` uses the static configuration specified in `Log.Logger`:

```
using System;
using Microsoft.AspNetCore;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.Logging;

public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args)
    {
        var builtConfig = new ConfigurationBuilder()
            .AddJsonFile("appsettings.json")
            .AddCommandLine(args)
            .Build();

        Log.Logger = new LoggerConfiguration()
            .WriteTo.Console()
            .WriteTo.File(builtConfig["Logging:FilePath"])
            .CreateLogger();

        try
        {
            return WebHost.CreateDefaultBuilder(args)
                .ConfigureServices((context, services) =>
                {
                    services.AddMvc();
                })
                .ConfigureAppConfiguration((hostingContext, config) =>
                {
                    config.AddConfiguration(builtConfig);
                })
                .ConfigureLogging(logging =>
                {
                    logging.AddSerilog();
                })
                .UseStartup<Startup>();
        }
        catch (Exception ex)
        {
            Log.Fatal(ex, "Host builder error");

            throw;
        }
        finally
        {
            Log.CloseAndFlush();
        }
    }
}
```

No asynchronous logger methods

Logging should be so fast that it isn't worth the performance cost of asynchronous code. If your logging data store is slow, don't write to it directly. Consider writing the log messages to a fast store initially, then move them to the slow store later. For example, if you're logging to SQL Server, you don't want to do that directly in a `Log` method, since the `Log` methods are synchronous. Instead, synchronously add log messages to an in-memory queue and have a background worker pull the messages out of the queue to do the asynchronous work of pushing data to SQL Server. For more information, see this GitHub issue.

Configuration

Logging provider configuration is provided by one or more configuration providers:

- File formats (INI, JSON, and XML).
- Command-line arguments.
- Environment variables.
- In-memory .NET objects.
- The unencrypted Secret Manager storage.
- An encrypted user store, such as Azure Key Vault.
- Custom providers (installed or created).

For example, logging configuration is commonly provided by the `Logging` section of app settings files. The following example shows the contents of a typical *appsettings.Development.json* file:

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Debug",
      "System": "Information",
      "Microsoft": "Information"
    },
    "Console":
    {
      "IncludeScopes": true
    }
  }
}
```

The `Logging` property can have `LogLevel` and log provider properties (Console is shown).

The `LogLevel` property under `Logging` specifies the minimum level to log for selected categories. In the example, `System` and `Microsoft` categories log at `Information` level, and all others log at `Debug` level.

Other properties under `Logging` specify logging providers. The example is for the Console provider. If a provider supports log scopes, `IncludeScopes` indicates whether they're enabled. A provider property (such as `Console` in the example) may also specify a `LogLevel` property. `LogLevel` under a provider specifies levels to log for that provider.

If levels are specified in `Logging.{providername}.LogLevel`, they override anything set in `Logging.LogLevel`. For example, consider the following JSON:

```
{
  "Logging": {      // Default, all providers.
    "LogLevel": {
      "Microsoft": "Warning"
    },
    "Console": { // Console provider.
      "LogLevel": {
        "Microsoft": "Information"
      }
    }
  }
}
```

In the preceding JSON, the `Console` provider settings overrides the preceding (default) log level.

The Logging API doesn't include a scenario to change log levels while an app is running. However, some configuration providers are capable of reloading configuration, which takes immediate effect on logging configuration. For example, the File Configuration Provider, which is added by `CreateDefaultBuilder` to read settings files, reloads logging configuration by default. If configuration is changed in code while an app is running, the app can call IConfigurationRoot.Reload to update the app's logging configuration.

For information on implementing configuration providers, see Configuration in ASP.NET Core.

Sample logging output

With the sample code shown in the preceding section, logs appear in the console when the app is run from the command line. Here's an example of console output:

```
info: Microsoft.AspNetCore.Hosting.Internal.WebHost[1]
      Request starting HTTP/1.1 GET http://localhost:5000/api/todo/0
info: Microsoft.AspNetCore.Mvc.Internal.ControllerActionInvoker[1]
      Executing action method TodoApi.Controllers.TodoController.GetById (TodoApi) with arguments
(0) - ModelState is Valid
info: TodoApi.Controllers.TodoController[1002]
      Getting item 0
warn: TodoApi.Controllers.TodoController[4000]
      GetById(0) NOT FOUND
info: Microsoft.AspNetCore.Mvc.StatusCodeResult[1]
      Executing HttpStatusCodeResult, setting HTTP status code 404
info: Microsoft.AspNetCore.Mvc.Internal.ControllerActionInvoker[2]
      Executed action TodoApi.Controllers.TodoController.GetById (TodoApi) in 42.9286ms
info: Microsoft.AspNetCore.Hosting.Internal.WebHost[2]
      Request finished in 148.889ms 404
```

The preceding logs were generated by making an HTTP Get request to the sample app at `http://localhost:5000/api/todo/0`.

Here's an example of the same logs as they appear in the Debug window when you run the sample app in Visual Studio:

```
Microsoft.AspNetCore.Hosting.Internal.WebHost:Information: Request starting HTTP/1.1 GET
http://localhost:53104/api/todo/0
Microsoft.AspNetCore.Mvc.Internal.ControllerActionInvoker:Information: Executing action method
TodoApi.Controllers.TodoController.GetById (TodoApi) with arguments (0) - ModelState is Valid
TodoApi.Controllers.TodoController:Information: Getting item 0
TodoApi.Controllers.TodoController:Warning: GetById(0) NOT FOUND
Microsoft.AspNetCore.Mvc.StatusCodeResult:Information: Executing HttpStatusCodeResult, setting
HTTP status code 404
Microsoft.AspNetCore.Mvc.Internal.ControllerActionInvoker:Information: Executed action
TodoApi.Controllers.TodoController.GetById (TodoApi) in 152.5657ms
Microsoft.AspNetCore.Hosting.Internal.WebHost:Information: Request finished in 316.3195ms 404
```

The logs that are created by the `ILogger` calls shown in the preceding section begin with "TodoApi". The logs that begin with "Microsoft" categories are from ASP.NET Core framework code. ASP.NET Core and application code are using the same logging API and providers.

The remainder of this article explains some details and options for logging.

NuGet packages

The `ILogger` and `ILoggerFactory` interfaces are in Microsoft.Extensions.Logging.Abstractions, and default implementations for them are in Microsoft.Extensions.Logging.

Log category

When an `ILogger` object is created, a *category* is specified for it. That category is included with each log message created by that instance of `ILogger`. The category may be any string, but the convention is to use the class name, such as "TodoApi.Controllers.TodoController".

Use `ILogger<T>` to get an `ILogger` instance that uses the fully qualified type name of `T` as the category:

```
public class TodoController : Controller
{
    private readonly ITodoRepository _todoRepository;
    private readonly ILogger _logger;

    public TodoController(ITodoRepository todoRepository,
        ILogger<TodoController> logger)
    {
        _todoRepository = todoRepository;
        _logger = logger;
    }
```

To explicitly specify the category, call `ILoggerFactory.CreateLogger`:

```
public class TodoController : Controller
{
    private readonly ITodoRepository _todoRepository;
    private readonly ILogger _logger;

    public TodoController(ITodoRepository todoRepository,
        ILoggerFactory logger)
    {
        _todoRepository = todoRepository;
        _logger = logger.CreateLogger("TodoApiSample.Controllers.TodoController");
    }
```

`ILogger<T>` is equivalent to calling `CreateLogger` with the fully qualified type name of `T`.

Log level

Every log specifies a LogLevel value. The log level indicates the severity or importance. For example, you might write an `Information` log when a method ends normally and a `Warning` log when a method returns a *404 Not Found* status code.

The following code creates `Information` and `Warning` logs:

```
public IActionResult GetById(string id)
{
    _logger.LogInformation(LoggingEvents.GetItem, "Getting item {Id}", id);
    var item = _todoRepository.Find(id);
    if (item == null)
    {
        _logger.LogWarning(LoggingEvents.GetItemNotFound, "GetById({Id}) NOT FOUND", id);
        return NotFound();
    }
    return new ObjectResult(item);
}
```

In the preceding code, the `MyLogEvents.GetItem` and `MyLogEvents.GetItemNotFound` parameters are the Log event ID. The second parameter is a message template with placeholders for argument values

provided by the remaining method parameters. The method parameters are explained in the Log message template section in this article.

Log methods that include the level in the method name (for example, `LogInformation` and `LogWarning`) are extension methods for ILogger. These methods call a `Log` method that takes a `LogLevel` parameter. You can call the `Log` method directly rather than one of these extension methods, but the syntax is relatively complicated. For more information, see ILogger and the logger extensions source code.

ASP.NET Core defines the following log levels, ordered here from lowest to highest severity.

- Trace = 0

  For information that's typically valuable only for debugging. These messages may contain sensitive application data and so shouldn't be enabled in a production environment. *Disabled by default.*

- Debug = 1

  For information that may be useful in development and debugging. Example: `Entering method Configure with flag set to true.` Enable `Debug` level logs in production only when troubleshooting, due to the high volume of logs.

- Information = 2

  For tracking the general flow of the app. These logs typically have some long-term value. Example: `Request received for path /api/todo`

- Warning = 3

  For abnormal or unexpected events in the app flow. These may include errors or other conditions that don't cause the app to stop but might need to be investigated. Handled exceptions are a common place to use the `Warning` log level. Example: `FileNotFoundException for file quotes.txt.`

- Error = 4

  For errors and exceptions that cannot be handled. These messages indicate a failure in the current activity or operation (such as the current HTTP request), not an app-wide failure. Example log message: `Cannot insert record due to duplicate key violation.`

- Critical = 5

  For failures that require immediate attention. Examples: data loss scenarios, out of disk space.

Use the log level to control how much log output is written to a particular storage medium or display window. For example:

- In production:
  - Logging at the `Trace` through `Information` levels produces a high-volume of detailed log messages. To control costs and not exceed data storage limits, log `Trace` through `Information` level messages to a high-volume, low-cost data store.
  - Logging at `Warning` through `Critical` levels typically produces fewer, smaller log messages. Therefore, costs and storage limits usually aren't a concern, which results in greater flexibility of data store choice.
- During development:
  - Log `Warning` through `Critical` messages to the console.
  - Add `Trace` through `Information` messages when troubleshooting.

The Log filtering section later in this article explains how to control which log levels a provider handles.

ASP.NET Core writes logs for framework events. The log examples earlier in this article excluded logs below `Information` level, so no `Debug` or `Trace` level logs were created. Here's an example of console logs produced by running the sample app configured to show `Debug` logs:

```
info: Microsoft.AspNetCore.Hosting.Internal.WebHost[1]
      Request starting HTTP/1.1 GET http://localhost:62555/api/todo/0
dbug: Microsoft.AspNetCore.Routing.Tree.TreeRouter[1]
      Request successfully matched the route with name 'GetTodo' and template 'api/Todo/{id}'.
dbug: Microsoft.AspNetCore.Mvc.Internal.ActionSelector[2]

info: Microsoft.AspNetCore.Mvc.Internal.ControllerActionInvoker[1]
      Executing action method TodoApi.Controllers.TodoController.GetById (TodoApi) with arguments
(0) - ModelState is Valid
info: TodoApi.Controllers.TodoController[1002]
      Getting item 0
warn: TodoApi.Controllers.TodoController[4000]
      GetById(0) NOT FOUND
dbug: Microsoft.AspNetCore.Mvc.Internal.ControllerActionInvoker[2]
      Executed action method TodoApi.Controllers.TodoController.GetById (TodoApi), returned result
Microsoft.AspNetCore.Mvc.NotFoundResult.
info: Microsoft.AspNetCore.Mvc.StatusCodeResult[1]
      Executing HttpStatusCodeResult, setting HTTP status code 404
info: Microsoft.AspNetCore.Mvc.Internal.ControllerActionInvoker[2]
      Executed action TodoApi.Controllers.TodoController.GetById (TodoApi) in 0.8788ms
dbug: Microsoft.AspNetCore.Server.Kestrel[9]
      Connection id "0HL6L7NEFF2QD" completed keep alive response.
info: Microsoft.AspNetCore.Hosting.Internal.WebHost[2]
      Request finished in 2.7286ms 404
```

Log event ID

Each log can specify an *event ID*. The sample app does this by using a locally defined `LoggingEvents` class:

```
public IActionResult GetById(string id)
{
    _logger.LogInformation(LoggingEvents.GetItem, "Getting item {Id}", id);
    var item = _todoRepository.Find(id);
    if (item == null)
    {
        _logger.LogWarning(LoggingEvents.GetItemNotFound, "GetById({Id}) NOT FOUND", id);
        return NotFound();
    }
    return new ObjectResult(item);
}
```

```
public class LoggingEvents
{
    public const int GenerateItems = 1000;
    public const int ListItems = 1001;
    public const int GetItem = 1002;
    public const int InsertItem = 1003;
    public const int UpdateItem = 1004;
    public const int DeleteItem = 1005;

    public const int GetItemNotFound = 4000;
    public const int UpdateItemNotFound = 4001;
}
```

An event ID associates a set of events. For example, all logs related to displaying a list of items on a page might be 1001.

The logging provider may store the event ID in an ID field, in the logging message, or not at all. The Debug provider doesn't show event IDs. The console provider shows event IDs in brackets after the category:

```
info: TodoApi.Controllers.TodoController[1002]
      Getting item invalidid
warn: TodoApi.Controllers.TodoController[4000]
      GetById(invalidid) NOT FOUND
```

Log message template

Each log specifies a message template. The message template can contain placeholders for which arguments are provided. Use names for the placeholders, not numbers.

```
public IActionResult GetById(string id)
{
    _logger.LogInformation(LoggingEvents.GetItem, "Getting item {Id}", id);
    var item = _todoRepository.Find(id);
    if (item == null)
    {
        _logger.LogWarning(LoggingEvents.GetItemNotFound, "GetById({Id}) NOT FOUND", id);
        return NotFound();
    }
    return new ObjectResult(item);
}
```

The order of placeholders, not their names, determines which parameters are used to provide their values. In the following code, notice that the parameter names are out of sequence in the message template:

```
string p1 = "parm1";
string p2 = "parm2";
_logger.LogInformation("Parameter values: {p2}, {p1}", p1, p2);
```

This code creates a log message with the parameter values in sequence:

```
Parameter values: parm1, parm2
```

The logging framework works this way so that logging providers can implement semantic logging, also known as structured logging. The arguments themselves are passed to the logging system, not

just the formatted message template. This information enables logging providers to store the parameter values as fields. For example, suppose logger method calls look like this:

```
_logger.LogInformation("Getting item {Id} at {RequestTime}", id, DateTime.Now);
```

If you're sending the logs to Azure Table Storage, each Azure Table entity can have `ID` and `RequestTime` properties, which simplifies queries on log data. A query can find all logs within a particular `RequestTime` range without parsing the time out of the text message.

Logging exceptions

The logger methods have overloads that let you pass in an exception, as in the following example:

```
catch (Exception ex)
{
    _logger.LogWarning(LoggingEvents.GetItemNotFound, ex, "GetById({Id}) NOT FOUND", id);
    return NotFound();
}
return new ObjectResult(item);
```

Different providers handle the exception information in different ways. Here's an example of Debug provider output from the code shown above.

```
TodoApiSample.Controllers.TodoController: Warning: GetById(55) NOT FOUND

System.Exception: Item not found exception.
   at TodoApiSample.Controllers.TodoController.GetById(String id) in
C:\TodoApiSample\Controllers\TodoController.cs:line 226
```

Log filtering

You can specify a minimum log level for a specific provider and category or for all providers or all categories. Any logs below the minimum level aren't passed to that provider, so they don't get displayed or stored.

To suppress all logs, specify `LogLevel.None` as the minimum log level. The integer value of `LogLevel.None` is 6, which is higher than `LogLevel.Critical` (5).

Create filter rules in configuration

The project template code calls `CreateDefaultBuilder` to set up logging for the Console, Debug, and EventSource (ASP.NET Core 2.2 or later) providers. The `CreateDefaultBuilder` method sets up logging to look for configuration in a `Logging` section, as explained earlier in this article.

The configuration data specifies minimum log levels by provider and category, as in the following example:

```
{
  "Logging": {
    "Debug": {
      "LogLevel": {
        "Default": "Information"
      }
    },
    "Console": {
      "IncludeScopes": false,
      "LogLevel": {
        "Microsoft.AspNetCore.Mvc.Razor.Internal": "Warning",
        "Microsoft.AspNetCore.Mvc.Razor.Razor": "Debug",
        "Microsoft.AspNetCore.Mvc.Razor": "Error",
        "Default": "Information"
      }
    },
    "LogLevel": {
      "Default": "Debug"
    }
  }
}
```

This JSON creates six filter rules: one for the Debug provider, four for the Console provider, and one for all providers. A single rule is chosen for each provider when an `ILogger` object is created.

Filter rules in code

The following example shows how to register filter rules in code:

```
WebHost.CreateDefaultBuilder(args)
    .UseStartup<Startup>()
    .ConfigureLogging(logging =>
        logging.AddFilter("System", LogLevel.Debug)
               .AddFilter<DebugLoggerProvider>("Microsoft", LogLevel.Trace));
```

The second `AddFilter` specifies the Debug provider by using its type name. The first `AddFilter` applies to all providers because it doesn't specify a provider type.

How filtering rules are applied

The configuration data and the `AddFilter` code shown in the preceding examples create the rules shown in the following table. The first six come from the configuration example and the last two come from the code example.

NUMBER	PROVIDER	CATEGORIES THAT BEGIN WITH ...	MINIMUM LOG LEVEL
1	Debug	All categories	Information
2	Console	Microsoft.AspNetCore.Mvc.Razor.Internal	Warning
3	Console	Microsoft.AspNetCore.Mvc.Razor.Razor	Debug
4	Console	Microsoft.AspNetCore.Mvc.Razor	Error
5	Console	All categories	Information

NUMBER	PROVIDER	CATEGORIES THAT BEGIN WITH ...	MINIMUM LOG LEVEL
6	All providers	All categories	Debug
7	All providers	System	Debug
8	Debug	Microsoft	Trace

When an `ILogger` object is created, the `ILoggerFactory` object selects a single rule per provider to apply to that logger. All messages written by an `ILogger` instance are filtered based on the selected rules. The most specific rule possible for each provider and category pair is selected from the available rules.

The following algorithm is used for each provider when an `ILogger` is created for a given category:

- Select all rules that match the provider or its alias. If no match is found, select all rules with an empty provider.
- From the result of the preceding step, select rules with longest matching category prefix. If no match is found, select all rules that don't specify a category.
- If multiple rules are selected, take the **last** one.
- If no rules are selected, use `MinimumLevel`.

With the preceding list of rules, suppose you create an `ILogger` object for category "Microsoft.AspNetCore.Mvc.Razor.RazorViewEngine":

- For the Debug provider, rules 1, 6, and 8 apply. Rule 8 is most specific, so that's the one selected.
- For the Console provider, rules 3, 4, 5, and 6 apply. Rule 3 is most specific.

The resulting `ILogger` instance sends logs of `Trace` level and above to the Debug provider. Logs of `Debug` level and above are sent to the Console provider.

Provider aliases

Each provider defines an *alias* that can be used in configuration in place of the fully qualified type name. For the built-in providers, use the following aliases:

- Console
- Debug
- EventSource
- EventLog
- TraceSource
- AzureAppServicesFile
- AzureAppServicesBlob
- ApplicationInsights

Default minimum level

There's a minimum level setting that takes effect only if no rules from configuration or code apply for a given provider and category. The following example shows how to set the minimum level:

```
WebHost.CreateDefaultBuilder(args)
    .UseStartup<Startup>()
    .ConfigureLogging(logging => logging.SetMinimumLevel(LogLevel.Warning));
```

If you don't explicitly set the minimum level, the default value is `Information`, which means that `Trace` and `Debug` logs are ignored.

Filter functions

A filter function is invoked for all providers and categories that don't have rules assigned to them by configuration or code. Code in the function has access to the provider type, category, and log level. For example:

```
WebHost.CreateDefaultBuilder(args)
    .UseStartup<Startup>()
    .ConfigureLogging(logBuilder =>
    {
        logBuilder.AddFilter((provider, category, logLevel) =>
        {
            if (provider == "Microsoft.Extensions.Logging.Console.ConsoleLoggerProvider" &&
                category == "TodoApiSample.Controllers.TodoController")
            {
                return false;
            }
            return true;
        });
    });
```

System categories and levels

Here are some categories used by ASP.NET Core and Entity Framework Core, with notes about what logs to expect from them:

CATEGORY	NOTES
Microsoft.AspNetCore	General ASP.NET Core diagnostics.
Microsoft.AspNetCore.DataProtection	Which keys were considered, found, and used.
Microsoft.AspNetCore.HostFiltering	Hosts allowed.
Microsoft.AspNetCore.Hosting	How long HTTP requests took to complete and what time they started. Which hosting startup assemblies were loaded.
Microsoft.AspNetCore.Mvc	MVC and Razor diagnostics. Model binding, filter execution, view compilation, action selection.
Microsoft.AspNetCore.Routing	Route matching information.
Microsoft.AspNetCore.Server	Connection start, stop, and keep alive responses. HTTPS certificate information.
Microsoft.AspNetCore.StaticFiles	Files served.
Microsoft.EntityFrameworkCore	General Entity Framework Core diagnostics. Database activity and configuration, change detection, migrations.

Log scopes

A *scope* can group a set of logical operations. This grouping can be used to attach the same data to each log that's created as part of a set. For example, every log created as part of processing a transaction can include the transaction ID.

A scope is an `IDisposable` type that's returned by the BeginScope method and lasts until it's disposed. Use a scope by wrapping logger calls in a `using` block:

```
public IActionResult GetById(string id)
{
    TodoItem item;
    using (_logger.BeginScope("Message attached to logs created in the using block"))
    {
        _logger.LogInformation(LoggingEvents.GetItem, "Getting item {Id}", id);
        item = _todoRepository.Find(id);
        if (item == null)
        {
            _logger.LogWarning(LoggingEvents.GetItemNotFound, "GetById({Id}) NOT FOUND", id);
            return NotFound();
        }
    }
    return new ObjectResult(item);
}
```

The following code enables scopes for the console provider:

Program.cs:

```
.ConfigureLogging((hostingContext, logging) =>
{
    logging.AddConfiguration(hostingContext.Configuration.GetSection("Logging"));
    logging.AddConsole(options => options.IncludeScopes = true);
    logging.AddDebug();
})
```

> **NOTE**
>
> Configuring the `IncludeScopes` console logger option is required to enable scope-based logging.
>
> For information on configuration, see the Configuration section.

Each log message includes the scoped information:

```
info: TodoApiSample.Controllers.TodoController[1002]
      => RequestId:0HKV9C49II9CK RequestPath:/api/todo/0 =>
TodoApiSample.Controllers.TodoController.GetById (TodoApi) => Message attached to logs created in
the using block
      Getting item 0
warn: TodoApiSample.Controllers.TodoController[4000]
      => RequestId:0HKV9C49II9CK RequestPath:/api/todo/0 =>
TodoApiSample.Controllers.TodoController.GetById (TodoApi) => Message attached to logs created in
the using block
      GetById(0) NOT FOUND
```

Built-in logging providers

ASP.NET Core ships the following providers:

- Console

- Debug
- EventSource
- EventLog
- TraceSource
- AzureAppServicesFile
- AzureAppServicesBlob
- ApplicationInsights

For information on stdout and debug logging with the ASP.NET Core Module, see Troubleshoot ASP.NET Core on Azure App Service and IIS and ASP.NET Core Module.

Console provider

The Microsoft.Extensions.Logging.Console provider package sends log output to the console.

```
logging.AddConsole();
```

To see console logging output, open a command prompt in the project folder and run the following command:

```
dotnet run
```

Debug provider

The Microsoft.Extensions.Logging.Debug provider package writes log output by using the System.Diagnostics.Debug class (`Debug.WriteLine` method calls).

On Linux, this provider writes logs to */var/log/message*.

```
logging.AddDebug();
```

Event Source provider

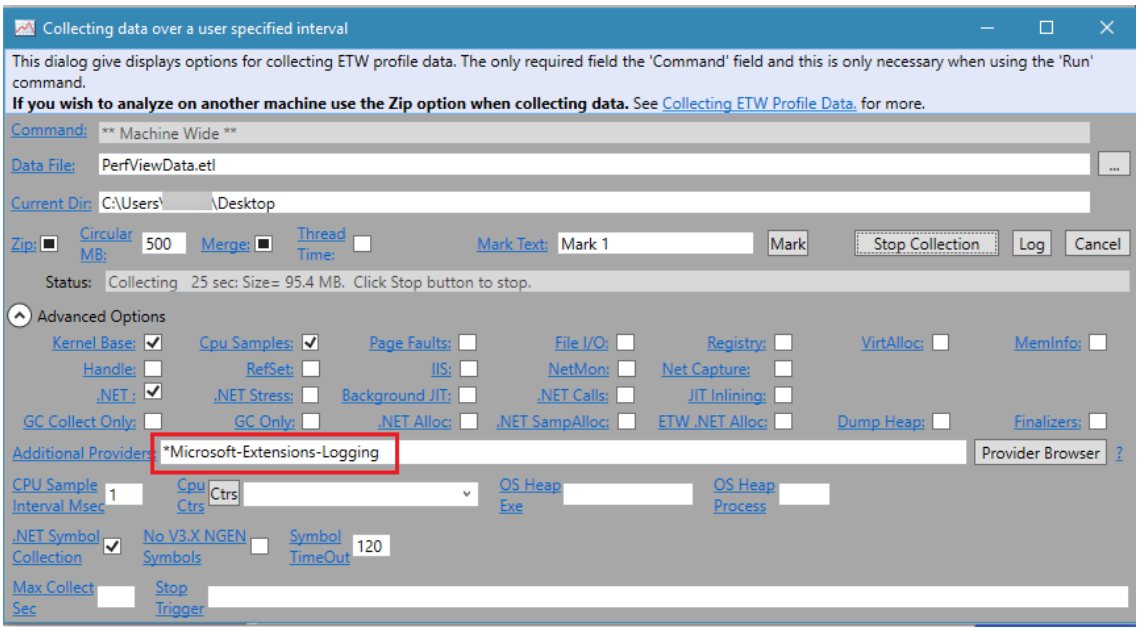
The Microsoft.Extensions.Logging.EventSource provider package writes to an Event Source cross-platform with the name `Microsoft-Extensions-Logging`. On Windows, the provider uses ETW.

```
logging.AddEventSourceLogger();
```

The Event Source provider is added automatically when `CreateDefaultBuilder` is called to build the host.

Use the PerfView utility to collect and view logs. There are other tools for viewing ETW logs, but PerfView provides the best experience for working with the ETW events emitted by ASP.NET Core.

To configure PerfView for collecting events logged by this provider, add the string `*Microsoft-Extensions-Logging` to the **Additional Providers** list. (Don't miss the asterisk at the start of the string.)



Windows EventLog provider

The Microsoft.Extensions.Logging.EventLog provider package sends log output to the Windows Event Log.

```
logging.AddEventLog();
```

AddEventLog overloads let you pass in EventLogSettings. If `null` or not specified, the following default settings are used:

- `LogName`: "Application"
- `SourceName`: ".NET Runtime"
- `MachineName`: The local machine name is used.

Events are logged for Warning level and higher. The following example sets the Event Log default log level to LogLevel.Information:

```
"Logging": {
  "EventLog": {
    "LogLevel": {
      "Default": "Information"
    }
  }
}
```

TraceSource provider

The Microsoft.Extensions.Logging.TraceSource provider package uses the TraceSource libraries and providers.

```
logging.AddTraceSource(sourceSwitchName);
```

AddTraceSource overloads let you pass in a source switch and a trace listener.

To use this provider, an app has to run on the .NET Framework (rather than .NET Core). The provider can route messages to a variety of listeners, such as the TextWriterTraceListener used in the sample app.

Azure App Service provider

The Microsoft.Extensions.Logging.AzureAppServices provider package writes logs to text files in an Azure App Service app's file system and to blob storage in an Azure Storage account.

```
logging.AddAzureWebAppDiagnostics();
```

The provider package isn't included in the Microsoft.AspNetCore.App metapackage. When targeting .NET Framework or referencing the `Microsoft.AspNetCore.App` metapackage, add the provider package to the project.

An AddAzureWebAppDiagnostics overload lets you pass in AzureAppServicesDiagnosticsSettings. The settings object can override default settings, such as the logging output template, blob name, and file size limit. (*Output template* is a message template that's applied to all logs in addition to what's provided with an `ILogger` method call.)

When you deploy to an App Service app, the application honors the settings in the App Service logs section of the **App Service** page of the Azure portal. When the following settings are updated, the changes take effect immediately without requiring a restart or redeployment of the app.

- **Application Logging (Filesystem)**
- **Application Logging (Blob)**

The default location for log files is in the *D:\home\LogFiles\Application* folder, and the default file name is *diagnostics-yyyymmdd.txt*. The default file size limit is 10 MB, and the default maximum number of files retained is 2. The default blob name is *{app-name}{timestamp}/yyyy/mm/dd/hh/{guid}-applicationLog.txt*.

The provider only works when the project runs in the Azure environment. It has no effect when the project is run locally—it doesn't write to local files or local development storage for blobs.

Azure log streaming

Azure log streaming lets you view log activity in real time from:

- The app server
- The web server
- Failed request tracing

To configure Azure log streaming:

- Navigate to the **App Service logs** page from your app's portal page.
- Set **Application Logging (Filesystem)** to **On**.
- Choose the log **Level**. This setting only applies to Azure log streaming, not other logging providers in the app.

Navigate to the **Log Stream** page to view app messages. They're logged by the app through the `ILogger` interface.

Azure Application Insights trace logging

The Microsoft.Extensions.Logging.ApplicationInsights provider package writes logs to Azure Application Insights. Application Insights is a service that monitors a web app and provides tools for querying and analyzing the telemetry data. If you use this provider, you can query and analyze your logs by using the Application Insights tools.

The provider package isn't included in the shared framework. To use the provider, add the provider package to the project. The logging provider is included as a dependency of Microsoft.ApplicationInsights.AspNetCore, which is the package that provides all available telemetry for ASP.NET Core. If you use this package, you don't have to install the provider package.

Don't use the Microsoft.ApplicationInsights.Web package—that's for ASP.NET 4.x.

For more information, see the following resources:

- Application Insights overview
- Application Insights for ASP.NET Core applications - Start here if you want to implement the full range of Application Insights telemetry along with logging.
- ApplicationInsightsLoggerProvider for .NET Core ILogger logs - Start here if you want to implement the logging provider without the rest of Application Insights telemetry.
- Application Insights logging adapters.
- Install, configure, and initialize the Application Insights SDK - Interactive tutorial on the Microsoft Learn site.

Third-party logging providers

Third-party logging frameworks that work with ASP.NET Core:

- elmah.io (GitHub repo)
- Gelf (GitHub repo)
- JSNLog (GitHub repo)
- KissLog.net (GitHub repo)
- Log4Net (GitHub repo)
- Loggr (GitHub repo)
- NLog (GitHub repo)
- Sentry (GitHub repo)
- Serilog (GitHub repo)
- Stackdriver (Github repo)

Some third-party frameworks can perform semantic logging, also known as structured logging.

Using a third-party framework is similar to using one of the built-in providers:

1. Add a NuGet package to your project.
2. Call an `ILoggerFactory` or `ILoggingBuilder` extension method provided by the logging framework.

For more information, see each provider's documentation. Third-party logging providers aren't supported by Microsoft.

Troubleshoot ASP.NET Core on Azure App Service and IIS

9/22/2020 • 59 minutes to read • Edit Online

By Justin Kotalik

This article provides information on common app startup errors and instructions on how to diagnose errors when an app is deployed to Azure App Service or IIS:

App startup errors
Explains common startup HTTP status code scenarios.

Troubleshoot on Azure App Service
Provides troubleshooting advice for apps deployed to Azure App Service.

Troubleshoot on IIS
Provides troubleshooting advice for apps deployed to IIS or running on IIS Express locally. The guidance applies to both Windows Server and Windows desktop deployments.

Clear package caches
Explains what to do when incoherent packages break an app when performing major upgrades or changing package versions.

Additional resources
Lists additional troubleshooting topics.

App startup errors

In Visual Studio, an ASP.NET Core project defaults to IIS Express hosting during debugging. A *502.5 - Process Failure* or a *500.30 - Start Failure* that occurs when debugging locally can be diagnosed using the advice in this topic.

403.14 Forbidden

The app fails to start. The following error is logged:

```
The Web server is configured to not list the contents of this directory.
```

The error is usually caused by a broken deployment on the hosting system, which includes any of the following scenarios:

- The app is deployed to the wrong folder on the hosting system.
- The deployment process failed to move all of the app's files and folders to the deployment folder on the hosting system.
- The *web.config* file is missing from the deployment, or the *web.config* file contents are malformed.

Perform the following steps:

1. Delete all of the files and folders from the deployment folder on the hosting system.
2. Redeploy the contents of the app's *publish* folder to the hosting system using your normal method of deployment, such as Visual Studio, PowerShell, or manual deployment:
   - Confirm that the *web.config* file is present in the deployment and that its contents are correct.
   - When hosting on Azure App Service, confirm that the app is deployed to the `D:\home\site\wwwroot` folder.

- When the app is hosted by IIS, confirm that the app is deployed to the IIS **Physical path** shown in **IIS Manager**'s **Basic Settings**.

3. Confirm that all of the app's files and folders are deployed by comparing the deployment on the hosting system to the contents of the project's *publish* folder.

For more information on the layout of a published ASP.NET Core app, see ASP.NET Core directory structure. For more information on the *web.config* file, see ASP.NET Core Module.

500 Internal Server Error

The app starts, but an error prevents the server from fulfilling the request.

This error occurs within the app's code during startup or while creating a response. The response may contain no content, or the response may appear as a *500 Internal Server Error* in the browser. The Application Event Log usually states that the app started normally. From the server's perspective, that's correct. The app did start, but it can't generate a valid response. Run the app at a command prompt on the server or enable the ASP.NET Core Module stdout log to troubleshoot the problem.

500.0 In-Process Handler Load Failure

The worker process fails. The app doesn't start.

An unknown error occurred loading ASP.NET Core Module components. Take one of the following actions:

- Contact Microsoft Support (select **Developer Tools** then **ASP.NET Core**).
- Ask a question on Stack Overflow.
- File an issue on our GitHub repository.

500.30 In-Process Startup Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the .NET Core CLR in-process, but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

Common failure conditions:

- The app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine.
- Using Azure Key Vault, lack of permissions to the Key Vault. Check the access policies in the targeted Key Vault to ensure that the correct permissions are granted.

500.31 ANCM Failed to Find Native Dependencies

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the .NET Core runtime in-process, but it fails to start. The most common cause of this startup failure is when the `Microsoft.NETCore.App` or `Microsoft.AspNetCore.App` runtime isn't installed. If the app is deployed to target ASP.NET Core 3.0 and that version doesn't exist on the machine, this error occurs. An example error message follows:

```
The specified framework 'Microsoft.NETCore.App', version '3.0.0' was not found.
  - The following frameworks were found:
      2.2.1 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview5-27626-15 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27713-13 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27714-15 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27723-08 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
```

The error message lists all the installed .NET Core versions and the version requested by the app. To fix this error,

either:

- Install the appropriate version of .NET Core on the machine.
- Change the app to target a version of .NET Core that's present on the machine.
- Publish the app as a self-contained deployment.

When running in development (the `ASPNETCORE_ENVIRONMENT` environment variable is set to `Development`), the specific error is written to the HTTP response. The cause of a process startup failure is also found in the Application Event Log.

500.32 ANCM Failed to Load dll

The worker process fails. The app doesn't start.

The most common cause for this error is that the app is published for an incompatible processor architecture. If the worker process is running as a 32-bit app and the app was published to target 64-bit, this error occurs.

To fix this error, either:

- Republish the app for the same processor architecture as the worker process.
- Publish the app as a framework-dependent deployment.

500.33 ANCM Request Handler Load Failure

The worker process fails. The app doesn't start.

The app didn't reference the `Microsoft.AspNetCore.App` framework. Only apps targeting the `Microsoft.AspNetCore.App` framework can be hosted by the ASP.NET Core Module.

To fix this error, confirm that the app is targeting the `Microsoft.AspNetCore.App` framework. Check the `.runtimeconfig.json` to verify the framework targeted by the app.

500.34 ANCM Mixed Hosting Models Not Supported

The worker process can't run both an in-process app and an out-of-process app in the same process.

To fix this error, run apps in separate IIS application pools.

500.35 ANCM Multiple In-Process Applications in same Process

The worker process can't run multiple in-process apps in the same process.

To fix this error, run apps in separate IIS application pools.

500.36 ANCM Out-Of-Process Handler Load Failure

The out-of-process request handler, *aspnetcorev2_outofprocess.dll*, isn't next to the *aspnetcorev2.dll* file. This indicates a corrupted installation of the ASP.NET Core Module.

To fix this error, repair the installation of the .NET Core Hosting Bundle (for IIS) or Visual Studio (for IIS Express).

500.37 ANCM Failed to Start Within Startup Time Limit

ANCM failed to start within the provided startup time limit. By default, the timeout is 120 seconds.

This error can occur when starting a large number of apps on the same machine. Check for CPU/Memory usage spikes on the server during startup. You may need to stagger the startup process of multiple apps.

500.38 ANCM Application DLL Not Found

ANCM failed to locate the application DLL, which should be next to the executable.

This error occurs when hosting an app packaged as a single-file executable using the in-process hosting model. The in-process model requires that the ANCM load the .NET Core app into the existing IIS process. This scenario isn't supported by the single-file deployment model. Use **one** of the following approaches in the app's project file to fix

this error:

1. Disable single-file publishing by setting the `PublishSingleFile` MSBuild property to `false`.
2. Switch to the out-of-process hosting model by setting the `AspNetCoreHostingModel` MSBuild property to `OutOfProcess`.

502.5 Process Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the worker process but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

A common failure condition is the app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and referenced by a metapackage such as `Microsoft.AspNetCore.App`. The metapackage reference can specify a minimum required version. For more information, see The shared framework.

The *502.5 Process Failure* error page is returned when a hosting or app misconfiguration causes the worker process to fail:

Failed to start application (ErrorCode '0x800700c1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/6/ROOT/', ErrorCode '0x800700c1'.
```

The app failed to start because the app's assembly (*.dll*) couldn't be loaded.

This error occurs when there's a bitness mismatch between the published app and the w3wp/iisexpress process.

Confirm that the app pool's 32-bit setting is correct:

1. Select the app pool in IIS Manager's **Application Pools**.
2. Select **Advanced Settings** under **Edit Application Pool** in the **Actions** panel.
3. Set **Enable 32-Bit Applications**:
   - If deploying a 32-bit (x86) app, set the value to `True`.
   - If deploying a 64-bit (x64) app, set the value to `False`.

Confirm that there isn't a conflict between a `<Platform>` MSBuild property in the project file and the published bitness of the app.

Connection reset

If an error occurs after the headers are sent, it's too late for the server to send a **500 Internal Server Error** when an error occurs. This often happens when an error occurs during the serialization of complex objects for a response. This type of error appears as a *connection reset* error on the client. Application logging can help troubleshoot these types of errors.

Default startup limits

The ASP.NET Core Module is configured with a default *startupTimeLimit* of 120 seconds. When left at the default value, an app may take up to two minutes to start before the module logs a process failure. For information on configuring the module, see Attributes of the aspNetCore element.

Troubleshoot on Azure App Service

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

Application Event Log (Azure App Service)

To access the Application Event Log, use the **Diagnose and solve problems** blade in the Azure portal:

1. In the Azure portal, open the app in **App Services**.
2. Select **Diagnose and solve problems**.
3. Select the **Diagnostic Tools** heading.
4. Under **Support Tools**, select the **Application Events** button.
5. Examine the latest error provided by the *IIS AspNetCoreModule* or *IIS AspNetCoreModule V2* entry in the **Source** column.

An alternative to using the **Diagnose and solve problems** blade is to examine the Application Event Log file directly using Kudu:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the **LogFiles** folder.
4. Select the pencil icon next to the *eventlog.xml* file.
5. Examine the log. Scroll to the bottom of the log to see the most recent events.

Run the app in the Kudu console

Many startup errors don't produce useful information in the Application Event Log. You can run the app in the Kudu Remote Execution Console to discover the error:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.

Test a 32-bit (x86) app

Current release

1. `cd d:\home\site\wwwroot`
2. Run the app:
   - If the app is a framework-dependent deployment:

     ```
     dotnet .\{ASSEMBLY NAME}.dll
     ```

   - If the app is a self-contained deployment:

     ```
     {ASSEMBLY NAME}.exe
     ```

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x86) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x32` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

Test a 64-bit (x64) app

Current release

- If the app is a 64-bit (x64) framework-dependent deployment:
  1. `cd D:\Program Files\dotnet`
  2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`
- If the app is a self-contained deployment:
  1. `cd D:\home\site\wwwroot`
  2. Run the app: `{ASSEMBLY NAME}.exe`

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x64) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x64` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

ASP.NET Core Module stdout log (Azure App Service)

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created. Only use stdout logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

The ASP.NET Core Module stdout log often records useful error messages not found in the Application Event Log. To enable and view stdout logs:

1. In the Azure Portal, navigate to the web app.
2. In the **App Service** blade, enter **kudu** in the search box.
3. Select **Advanced Tools** > **Go**.
4. Select **Debug console** > **CMD**.
5. Navigate to *site/wwwroot*
6. Select the pencil icon to edit the *web.config* file.
7. In the `<aspNetCore />` element, set `stdoutLogEnabled="true"` and select **Save**.

Disable stdout logging when troubleshooting is complete by setting `stdoutLogEnabled="false"`.

For more information, see ASP.NET Core Module.

ASP.NET Core Module debug log (Azure App Service)

The ASP.NET Core Module debug log provides additional, deeper logging from the ASP.NET Core Module. To enable and view stdout logs:

1. To enable the enhanced diagnostic log, perform either of the following:
   - Follow the instructions in Enhanced diagnostic logs to configure the app for an enhanced diagnostic

logging. Redeploy the app.

- Add the `<handlerSettings>` shown in Enhanced diagnostic logs to the live app's *web.config* file using the Kudu console:
  a. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
  b. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
  c. Open the folders to the path **site** > **wwwroot**. Edit the *web.config* file by selecting the pencil button. Add the `<handlerSettings>` section as shown in Enhanced diagnostic logs. Select the **Save** button.

2. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
3. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
4. Open the folders to the path **site** > **wwwroot**. If you didn't supply a path for the *aspnetcore-debug.log* file, the file appears in the list. If you supplied a path, navigate to the location of the log file.
5. Open the log file with the pencil button next to the file name.

Disable debug logging when troubleshooting is complete:

To disable the enhanced debug log, perform either of the following:

- Remove the `<handlerSettings>` from the *web.config* file locally and redeploy the app.
- Use the Kudu console to edit the *web.config* file and remove the `<handlerSettings>` section. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
> Failure to disable the debug log can lead to app or server failure. There's no limit on log file size. Only use debug logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Slow or hanging app (Azure App Service)

When an app responds slowly or hangs on a request, see the following articles:

- Troubleshoot slow web app performance issues in Azure App Service
- Use Crash Diagnoser Site Extension to Capture Dump for Intermittent Exception issues or performance issues on Azure Web App

Monitoring blades

Monitoring blades provide an alternative troubleshooting experience to the methods described earlier in the topic. These blades can be used to diagnose 500-series errors.

Confirm that the ASP.NET Core Extensions are installed. If the extensions aren't installed, install them manually:

1. In the **DEVELOPMENT TOOLS** blade section, select the **Extensions** blade.
2. The **ASP.NET Core Extensions** should appear in the list.
3. If the extensions aren't installed, select the **Add** button.
4. Choose the **ASP.NET Core Extensions** from the list.
5. Select **OK** to accept the legal terms.
6. Select **OK** on the **Add extension** blade.
7. An informational pop-up message indicates when the extensions are successfully installed.

If stdout logging isn't enabled, follow these steps:

1. In the Azure portal, select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the folders to the path **site** > **wwwroot** and scroll down to reveal the *web.config* file at the bottom of the list.
4. Click the pencil icon next to the *web.config* file.
5. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
6. Select **Save** to save the updated *web.config* file.

Proceed to activate diagnostic logging:

1. In the Azure portal, select the **Diagnostics logs** blade.
2. Select the **On** switch for **Application Logging (Filesystem)** and **Detailed error messages**. Select the **Save** button at the top of the blade.
3. To include failed request tracing, also known as Failed Request Event Buffering (FREB) logging, select the **On** switch for **Failed request tracing**.
4. Select the **Log stream** blade, which is listed immediately under the **Diagnostics logs** blade in the portal.
5. Make a request to the app.
6. Within the log stream data, the cause of the error is indicated.

Be sure to disable stdout logging when troubleshooting is complete.

To view the failed request tracing logs (FREB logs):

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Select **Failed Request Tracing Logs** from the **SUPPORT TOOLS** area of the sidebar.

See Failed request traces section of the Enable diagnostics logging for web apps in Azure App Service topic and the Application performance FAQs for Web Apps in Azure: How do I turn on failed request tracing? for more information.

For more information, see Enable diagnostics logging for web apps in Azure App Service.

> **WARNING**
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Troubleshoot on IIS

Application Event Log (IIS)

Access the Application Event Log:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.
2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app. Errors have a value of *IIS AspNetCore Module* or *IIS Express AspNetCore Module* in the *Source* column.

Run the app at a command prompt

Many startup errors don't produce useful information in the Application Event Log. You can find the cause of some errors by running the app at a command prompt on the hosting system.

Framework-dependent deployment

If the app is a framework-dependent deployment:

1. At a command prompt, navigate to the deployment folder and run the app by executing the app's assembly with *dotnet.exe*. In the following command, substitute the name of the app's assembly for <assembly_name>: `dotnet .\<assembly_name>.dll`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

Self-contained deployment

If the app is a self-contained deployment:

1. At a command prompt, navigate to the deployment folder and run the app's executable. In the following command, substitute the name of the app's assembly for <assembly_name>: `<assembly_name>.exe`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

ASP.NET Core Module stdout log (IIS)

To enable and view stdout logs:

1. Navigate to the site's deployment folder on the hosting system.
2. If the *logs* folder isn't present, create the folder. For instructions on how to enable MSBuild to create the *logs* folder in the deployment automatically, see the Directory structure topic.
3. Edit the *web.config* file. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to point to the *logs* folder (for example, `.\logs\stdout`). `stdout` in the path is the log file name prefix. A timestamp, process id, and file extension are added automatically when the log is created. Using `stdout` as the file name prefix, a typical log file is named *stdout_20180205184032_5412.log*.
4. Ensure your application pool's identity has write permissions to the *logs* folder.
5. Save the updated *web.config* file.
6. Make a request to the app.
7. Navigate to the *logs* folder. Find and open the most recent stdout log.
8. Study the log for errors.

Disable stdout logging when troubleshooting is complete:

1. Edit the *web.config* file.
2. Set **stdoutLogEnabled** to `false`.
3. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

ASP.NET Core Module debug log (IIS)

Add the following handler settings to the app's *web.config* file to enable ASP.NET Core Module debug log:

```
<aspNetCore ...>
  <handlerSettings>
    <handlerSetting name="debugLevel" value="file" />
    <handlerSetting name="debugFile" value="c:\temp\ancm.log" />
  </handlerSettings>
</aspNetCore>
```

Confirm that the path specified for the log exists and that the app pool's identity has write permissions to the location.

For more information, see ASP.NET Core Module.

Enable the Developer Exception Page

The `ASPNETCORE_ENVIRONMENT` environment variable can be added to web.config to run the app in the Development environment. As long as the environment isn't overridden in app startup by `UseEnvironment` on the host builder, setting the environment variable allows the Developer Exception Page to appear when the app is run.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout"
      hostingModel="InProcess">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
  </environmentVariables>
</aspNetCore>
```

Setting the environment variable for `ASPNETCORE_ENVIRONMENT` is only recommended for use on staging and testing servers that aren't exposed to the Internet. Remove the environment variable from the *web.config* file after troubleshooting. For information on setting environment variables in *web.config*, see environmentVariables child element of aspNetCore.

Obtain data from an app

If an app is capable of responding to requests, obtain request, connection, and additional data from the app using terminal inline middleware. For more information and sample code, see Troubleshoot and debug ASP.NET Core projects.

Slow or hanging app (IIS)

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`. The app pool must have write access to the folder.

2. Run the EnableDumps PowerShell script:

   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\EnableDumps w3wp.exe c:\dumps
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\EnableDumps dotnet.exe c:\dumps
     ```

3. Run the app under the conditions that cause the crash to occur.

4. After the crash has occurred, run the DisableDumps PowerShell script:

   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\DisableDumps w3wp.exe
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\DisableDumps dotnet.exe
     ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> **WARNING**
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App hangs, fails during startup, or runs normally

When an app *hangs* (stops responding but doesn't crash), fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.

2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.

3. Restore and rebuild the project.

4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

This article provides information on common app startup errors and instructions on how to diagnose errors when an app is deployed to Azure App Service or IIS:

App startup errors
Explains common startup HTTP status code scenarios.

Troubleshoot on Azure App Service
Provides troubleshooting advice for apps deployed to Azure App Service.

Troubleshoot on IIS
Provides troubleshooting advice for apps deployed to IIS or running on IIS Express locally. The guidance applies to both Windows Server and Windows desktop deployments.

Clear package caches
Explains what to do when incoherent packages break an app when performing major upgrades or changing package versions.

Additional resources
Lists additional troubleshooting topics.

App startup errors

In Visual Studio, an ASP.NET Core project defaults to IIS Express hosting during debugging. A *502.5 - Process Failure* or a *500.30 - Start Failure* that occurs when debugging locally can be diagnosed using the advice in this topic.

403.14 Forbidden

The app fails to start. The following error is logged:

```
The Web server is configured to not list the contents of this directory.
```

The error is usually caused by a broken deployment on the hosting system, which includes any of the following scenarios:

- The app is deployed to the wrong folder on the hosting system.
- The deployment process failed to move all of the app's files and folders to the deployment folder on the hosting system.
- The *web.config* file is missing from the deployment, or the *web.config* file contents are malformed.

Perform the following steps:

1. Delete all of the files and folders from the deployment folder on the hosting system.
2. Redeploy the contents of the app's *publish* folder to the hosting system using your normal method of deployment, such as Visual Studio, PowerShell, or manual deployment:
   - Confirm that the *web.config* file is present in the deployment and that its contents are correct.
   - When hosting on Azure App Service, confirm that the app is deployed to the `D:\home\site\wwwroot` folder.
   - When the app is hosted by IIS, confirm that the app is deployed to the IIS **Physical path** shown in **IIS Manager**'s **Basic Settings**.
3. Confirm that all of the app's files and folders are deployed by comparing the deployment on the hosting system to the contents of the project's *publish* folder.

For more information on the layout of a published ASP.NET Core app, see ASP.NET Core directory structure. For more information on the *web.config* file, see ASP.NET Core Module.

500 Internal Server Error

The app starts, but an error prevents the server from fulfilling the request.

This error occurs within the app's code during startup or while creating a response. The response may contain no content, or the response may appear as a *500 Internal Server Error* in the browser. The Application Event Log usually states that the app started normally. From the server's perspective, that's correct. The app did start, but it can't generate a valid response. Run the app at a command prompt on the server or enable the ASP.NET Core Module stdout log to troubleshoot the problem.

500.0 In-Process Handler Load Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module fails to find the .NET Core CLR and find the in-process request handler (*aspnetcorev2_inprocess.dll*). Check that:

- The app targets either the Microsoft.AspNetCore.Server.IIS NuGet package or the Microsoft.AspNetCore.App metapackage.
- The version of the ASP.NET Core shared framework that the app targets is installed on the target machine.

500.0 Out-Of-Process Handler Load Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module fails to find the out-of-process hosting request handler. Make sure the *aspnetcorev2_outofprocess.dll* is present in a subfolder next to *aspnetcorev2.dll*.

502.5 Process Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the worker process but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout

log.

A common failure condition is the app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and referenced by a metapackage such as `Microsoft.AspNetCore.App`. The metapackage reference can specify a minimum required version. For more information, see The shared framework.

The *502.5 Process Failure* error page is returned when a hosting or app misconfiguration causes the worker process to fail:

Failed to start application (ErrorCode '0x800700c1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/6/ROOT/', ErrorCode '0x800700c1'.
```

The app failed to start because the app's assembly (*.dll*) couldn't be loaded.

This error occurs when there's a bitness mismatch between the published app and the w3wp/iisexpress process.

Confirm that the app pool's 32-bit setting is correct:

1. Select the app pool in IIS Manager's **Application Pools**.
2. Select **Advanced Settings** under **Edit Application Pool** in the **Actions** panel.
3. Set **Enable 32-Bit Applications**:
   - If deploying a 32-bit (x86) app, set the value to `True`.
   - If deploying a 64-bit (x64) app, set the value to `False`.

Confirm that there isn't a conflict between a `<Platform>` MSBuild property in the project file and the published bitness of the app.

Connection reset

If an error occurs after the headers are sent, it's too late for the server to send a **500 Internal Server Error** when an error occurs. This often happens when an error occurs during the serialization of complex objects for a response. This type of error appears as a *connection reset* error on the client. Application logging can help troubleshoot these types of errors.

Default startup limits

The ASP.NET Core Module is configured with a default *startupTimeLimit* of 120 seconds. When left at the default value, an app may take up to two minutes to start before the module logs a process failure. For information on configuring the module, see Attributes of the aspNetCore element.

Troubleshoot on Azure App Service

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

Application Event Log (Azure App Service)

To access the Application Event Log, use the **Diagnose and solve problems** blade in the Azure portal:

1. In the Azure portal, open the app in **App Services**.

2. Select **Diagnose and solve problems**.
3. Select the **Diagnostic Tools** heading.
4. Under **Support Tools**, select the **Application Events** button.
5. Examine the latest error provided by the *IIS AspNetCoreModule* or *IIS AspNetCoreModule V2* entry in the **Source** column.

An alternative to using the **Diagnose and solve problems** blade is to examine the Application Event Log file directly using Kudu:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the **LogFiles** folder.
4. Select the pencil icon next to the *eventlog.xml* file.
5. Examine the log. Scroll to the bottom of the log to see the most recent events.

Run the app in the Kudu console

Many startup errors don't produce useful information in the Application Event Log. You can run the app in the Kudu Remote Execution Console to discover the error:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.

Test a 32-bit (x86) app

Current release

1. `cd d:\home\site\wwwroot`
2. Run the app:
   - If the app is a framework-dependent deployment:

     ```
     dotnet .\{ASSEMBLY NAME}.dll
     ```

   - If the app is a self-contained deployment:

     ```
     {ASSEMBLY NAME}.exe
     ```

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x86) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x32` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

Test a 64-bit (x64) app

Current release

- If the app is a 64-bit (x64) framework-dependent deployment:
  1. `cd D:\Program Files\dotnet`
  2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

- If the app is a self-contained deployment:
  1. `cd D:\home\site\wwwroot`
  2. Run the app: `{ASSEMBLY NAME}.exe`

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x64) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x64` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

ASP.NET Core Module stdout log (Azure App Service)

The ASP.NET Core Module stdout log often records useful error messages not found in the Application Event Log. To enable and view stdout logs:

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Under **SELECT PROBLEM CATEGORY**, select the **Web App Down** button.
3. Under **Suggested Solutions** > **Enable Stdout Log Redirection**, select the button to **Open Kudu Console to edit Web.Config**.
4. In the Kudu **Diagnostic Console**, open the folders to the path **site** > **wwwroot**. Scroll down to reveal the *web.config* file at the bottom of the list.
5. Click the pencil icon next to the *web.config* file.
6. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
7. Select **Save** to save the updated *web.config* file.
8. Make a request to the app.
9. Return to the Azure portal. Select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
10. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
11. Select the **LogFiles** folder.
12. Inspect the **Modified** column and select the pencil icon to edit the stdout log with the latest modification date.
13. When the log file opens, the error is displayed.

Disable stdout logging when troubleshooting is complete:

1. In the Kudu **Diagnostic Console**, return to the path **site** > **wwwroot** to reveal the *web.config* file. Open the **web.config** file again by selecting the pencil icon.
2. Set **stdoutLogEnabled** to `false`.
3. Select **Save** to save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created. Only use stdout logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

ASP.NET Core Module debug log (Azure App Service)

The ASP.NET Core Module debug log provides additional, deeper logging from the ASP.NET Core Module. To enable and view stdout logs:

1. To enable the enhanced diagnostic log, perform either of the following:
   - Follow the instructions in Enhanced diagnostic logs to configure the app for an enhanced diagnostic logging. Redeploy the app.
   - Add the `<handlerSettings>` shown in Enhanced diagnostic logs to the live app's *web.config* file using the Kudu console:
     a. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
     b. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
     c. Open the folders to the path **site** > **wwwroot**. Edit the *web.config* file by selecting the pencil button. Add the `<handlerSettings>` section as shown in Enhanced diagnostic logs. Select the **Save** button.
2. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
3. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
4. Open the folders to the path **site** > **wwwroot**. If you didn't supply a path for the *aspnetcore-debug.log* file, the file appears in the list. If you supplied a path, navigate to the location of the log file.
5. Open the log file with the pencil button next to the file name.

Disable debug logging when troubleshooting is complete:

To disable the enhanced debug log, perform either of the following:

- Remove the `<handlerSettings>` from the *web.config* file locally and redeploy the app.
- Use the Kudu console to edit the *web.config* file and remove the `<handlerSettings>` section. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
> Failure to disable the debug log can lead to app or server failure. There's no limit on log file size. Only use debug logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Slow or hanging app (Azure App Service)

When an app responds slowly or hangs on a request, see the following articles:

- Troubleshoot slow web app performance issues in Azure App Service
- Use Crash Diagnoser Site Extension to Capture Dump for Intermittent Exception issues or performance issues on Azure Web App

Monitoring blades

Monitoring blades provide an alternative troubleshooting experience to the methods described earlier in the topic. These blades can be used to diagnose 500-series errors.

Confirm that the ASP.NET Core Extensions are installed. If the extensions aren't installed, install them manually:

1. In the **DEVELOPMENT TOOLS** blade section, select the **Extensions** blade.
2. The **ASP.NET Core Extensions** should appear in the list.
3. If the extensions aren't installed, select the **Add** button.

4. Choose the **ASP.NET Core Extensions** from the list.
5. Select **OK** to accept the legal terms.
6. Select **OK** on the **Add extension** blade.
7. An informational pop-up message indicates when the extensions are successfully installed.

If stdout logging isn't enabled, follow these steps:

1. In the Azure portal, select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the folders to the path **site** > **wwwroot** and scroll down to reveal the *web.config* file at the bottom of the list.
4. Click the pencil icon next to the *web.config* file.
5. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
6. Select **Save** to save the updated *web.config* file.

Proceed to activate diagnostic logging:

1. In the Azure portal, select the **Diagnostics logs** blade.
2. Select the **On** switch for **Application Logging (Filesystem)** and **Detailed error messages**. Select the **Save** button at the top of the blade.
3. To include failed request tracing, also known as Failed Request Event Buffering (FREB) logging, select the **On** switch for **Failed request tracing**.
4. Select the **Log stream** blade, which is listed immediately under the **Diagnostics logs** blade in the portal.
5. Make a request to the app.
6. Within the log stream data, the cause of the error is indicated.

Be sure to disable stdout logging when troubleshooting is complete.

To view the failed request tracing logs (FREB logs):

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Select **Failed Request Tracing Logs** from the **SUPPORT TOOLS** area of the sidebar.

See Failed request traces section of the Enable diagnostics logging for web apps in Azure App Service topic and the Application performance FAQs for Web Apps in Azure: How do I turn on failed request tracing? for more information.

For more information, see Enable diagnostics logging for web apps in Azure App Service.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Troubleshoot on IIS

Application Event Log (IIS)

Access the Application Event Log:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.

2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app. Errors have a value of *IIS AspNetCore Module* or *IIS Express AspNetCore Module* in the *Source* column.

Run the app at a command prompt

Many startup errors don't produce useful information in the Application Event Log. You can find the cause of some errors by running the app at a command prompt on the hosting system.

Framework-dependent deployment

If the app is a framework-dependent deployment:

1. At a command prompt, navigate to the deployment folder and run the app by executing the app's assembly with *dotnet.exe*. In the following command, substitute the name of the app's assembly for <assembly_name>: `dotnet .\<assembly_name>.dll`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

Self-contained deployment

If the app is a self-contained deployment:

1. At a command prompt, navigate to the deployment folder and run the app's executable. In the following command, substitute the name of the app's assembly for <assembly_name>: `<assembly_name>.exe`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

ASP.NET Core Module stdout log (IIS)

To enable and view stdout logs:

1. Navigate to the site's deployment folder on the hosting system.
2. If the *logs* folder isn't present, create the folder. For instructions on how to enable MSBuild to create the *logs* folder in the deployment automatically, see the Directory structure topic.
3. Edit the *web.config* file. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to point to the *logs* folder (for example, `.\logs\stdout`). `stdout` in the path is the log file name prefix. A timestamp, process id, and file extension are added automatically when the log is created. Using `stdout` as the file name prefix, a typical log file is named *stdout_20180205184032_5412.log*.
4. Ensure your application pool's identity has write permissions to the *logs* folder.
5. Save the updated *web.config* file.
6. Make a request to the app.
7. Navigate to the *logs* folder. Find and open the most recent stdout log.
8. Study the log for errors.

Disable stdout logging when troubleshooting is complete:

1. Edit the *web.config* file.
2. Set **stdoutLogEnabled** to `false`.
3. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

ASP.NET Core Module debug log (IIS)

Add the following handler settings to the app's *web.config* file to enable ASP.NET Core Module debug log:

```
<aspNetCore ...>
  <handlerSettings>
    <handlerSetting name="debugLevel" value="file" />
    <handlerSetting name="debugFile" value="c:\temp\ancm.log" />
  </handlerSettings>
</aspNetCore>
```

Confirm that the path specified for the log exists and that the app pool's identity has write permissions to the location.

For more information, see ASP.NET Core Module.

Enable the Developer Exception Page

The `ASPNETCORE_ENVIRONMENT` environment variable can be added to web.config to run the app in the Development environment. As long as the environment isn't overridden in app startup by `UseEnvironment` on the host builder, setting the environment variable allows the Developer Exception Page to appear when the app is run.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout"
      hostingModel="InProcess">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
  </environmentVariables>
</aspNetCore>
```

Setting the environment variable for `ASPNETCORE_ENVIRONMENT` is only recommended for use on staging and testing servers that aren't exposed to the Internet. Remove the environment variable from the *web.config* file after troubleshooting. For information on setting environment variables in *web.config*, see environmentVariables child element of aspNetCore.

Obtain data from an app

If an app is capable of responding to requests, obtain request, connection, and additional data from the app using terminal inline middleware. For more information and sample code, see Troubleshoot and debug ASP.NET Core projects.

Slow or hanging app (IIS)

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`. The app pool must have write access to the folder.
2. Run the EnableDumps PowerShell script:
   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\EnableDumps w3wp.exe c:\dumps
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\EnableDumps dotnet.exe c:\dumps
     ```

3. Run the app under the conditions that cause the crash to occur.
4. After the crash has occurred, run the DisableDumps PowerShell script:
   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\DisableDumps w3wp.exe
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\DisableDumps dotnet.exe
     ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> **WARNING**
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App hangs, fails during startup, or runs normally

When an app *hangs* (stops responding but doesn't crash), fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.
2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

This article provides information on common app startup errors and instructions on how to diagnose errors when an app is deployed to Azure App Service or IIS:

App startup errors
Explains common startup HTTP status code scenarios.

Troubleshoot on Azure App Service
Provides troubleshooting advice for apps deployed to Azure App Service.

Troubleshoot on IIS
Provides troubleshooting advice for apps deployed to IIS or running on IIS Express locally. The guidance applies to both Windows Server and Windows desktop deployments.

Clear package caches
Explains what to do when incoherent packages break an app when performing major upgrades or changing package versions.

Additional resources
Lists additional troubleshooting topics.

App startup errors

In Visual Studio, an ASP.NET Core project defaults to IIS Express hosting during debugging. A *502.5 Process Failure* that occurs when debugging locally can be diagnosed using the advice in this topic.

403.14 Forbidden

The app fails to start. The following error is logged:

```
The Web server is configured to not list the contents of this directory.
```

The error is usually caused by a broken deployment on the hosting system, which includes any of the following scenarios:

- The app is deployed to the wrong folder on the hosting system.
- The deployment process failed to move all of the app's files and folders to the deployment folder on the hosting system.
- The *web.config* file is missing from the deployment, or the *web.config* file contents are malformed.

Perform the following steps:

1. Delete all of the files and folders from the deployment folder on the hosting system.
2. Redeploy the contents of the app's *publish* folder to the hosting system using your normal method of deployment, such as Visual Studio, PowerShell, or manual deployment:
   - Confirm that the *web.config* file is present in the deployment and that its contents are correct.
   - When hosting on Azure App Service, confirm that the app is deployed to the `D:\home\site\wwwroot` folder.
   - When the app is hosted by IIS, confirm that the app is deployed to the IIS **Physical path** shown in **IIS Manager**'s **Basic Settings**.
3. Confirm that all of the app's files and folders are deployed by comparing the deployment on the hosting system to the contents of the project's *publish* folder.

For more information on the layout of a published ASP.NET Core app, see ASP.NET Core directory structure. For more information on the *web.config* file, see ASP.NET Core Module.

500 Internal Server Error

The app starts, but an error prevents the server from fulfilling the request.

This error occurs within the app's code during startup or while creating a response. The response may contain no content, or the response may appear as a *500 Internal Server Error* in the browser. The Application Event Log usually states that the app started normally. From the server's perspective, that's correct. The app did start, but it can't generate a valid response. Run the app at a command prompt on the server or enable the ASP.NET Core Module stdout log to troubleshoot the problem.

502.5 Process Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the worker process but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

A common failure condition is the app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and referenced by a metapackage such as `Microsoft.AspNetCore.App`. The metapackage reference can specify a minimum required version. For more information, see The shared framework.

The *502.5 Process Failure* error page is returned when a hosting or app misconfiguration causes the worker process to fail:

Failed to start application (ErrorCode '0x800700c1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/6/ROOT/', ErrorCode '0x800700c1'.
```

The app failed to start because the app's assembly (*.dll*) couldn't be loaded.

This error occurs when there's a bitness mismatch between the published app and the w3wp/iisexpress process.

Confirm that the app pool's 32-bit setting is correct:

1. Select the app pool in IIS Manager's **Application Pools**.
2. Select **Advanced Settings** under **Edit Application Pool** in the **Actions** panel.
3. Set **Enable 32-Bit Applications**:
   - If deploying a 32-bit (x86) app, set the value to `True`.
   - If deploying a 64-bit (x64) app, set the value to `False`.

Confirm that there isn't a conflict between a `<Platform>` MSBuild property in the project file and the published bitness of the app.

Connection reset

If an error occurs after the headers are sent, it's too late for the server to send a **500 Internal Server Error** when an error occurs. This often happens when an error occurs during the serialization of complex objects for a response. This type of error appears as a *connection reset* error on the client. Application logging can help troubleshoot these types of errors.

Default startup limits

The ASP.NET Core Module is configured with a default *startupTimeLimit* of 120 seconds. When left at the default value, an app may take up to two minutes to start before the module logs a process failure. For information on configuring the module, see Attributes of the aspNetCore element.

Troubleshoot on Azure App Service

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

Application Event Log (Azure App Service)

To access the Application Event Log, use the **Diagnose and solve problems** blade in the Azure portal:

1. In the Azure portal, open the app in **App Services**.
2. Select **Diagnose and solve problems**.
3. Select the **Diagnostic Tools** heading.
4. Under **Support Tools**, select the **Application Events** button.
5. Examine the latest error provided by the *IIS AspNetCoreModule* or *IIS AspNetCoreModule V2* entry in the **Source** column.

An alternative to using the **Diagnose and solve problems** blade is to examine the Application Event Log file directly using Kudu:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.

2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the **LogFiles** folder.
4. Select the pencil icon next to the *eventlog.xml* file.
5. Examine the log. Scroll to the bottom of the log to see the most recent events.

Run the app in the Kudu console

Many startup errors don't produce useful information in the Application Event Log. You can run the app in the Kudu Remote Execution Console to discover the error:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.

Test a 32-bit (x86) app

Current release

1. `cd d:\home\site\wwwroot`
2. Run the app:
   - If the app is a framework-dependent deployment:

     ```
     dotnet .\{ASSEMBLY NAME}.dll
     ```

   - If the app is a self-contained deployment:

     ```
     {ASSEMBLY NAME}.exe
     ```

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x86) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x32` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

Test a 64-bit (x64) app

Current release

- If the app is a 64-bit (x64) framework-dependent deployment:
  1. `cd D:\Program Files\dotnet`
  2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`
- If the app is a self-contained deployment:
  1. `cd D:\home\site\wwwroot`
  2. Run the app: `{ASSEMBLY NAME}.exe`

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x64) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x64` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

ASP.NET Core Module stdout log (Azure App Service)

The ASP.NET Core Module stdout log often records useful error messages not found in the Application Event Log. To enable and view stdout logs:

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Under **SELECT PROBLEM CATEGORY**, select the **Web App Down** button.
3. Under **Suggested Solutions** > **Enable Stdout Log Redirection**, select the button to **Open Kudu Console to edit Web.Config**.
4. In the Kudu **Diagnostic Console**, open the folders to the path **site** > **wwwroot**. Scroll down to reveal the *web.config* file at the bottom of the list.
5. Click the pencil icon next to the *web.config* file.
6. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
7. Select **Save** to save the updated *web.config* file.
8. Make a request to the app.
9. Return to the Azure portal. Select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
10. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
11. Select the **LogFiles** folder.
12. Inspect the **Modified** column and select the pencil icon to edit the stdout log with the latest modification date.
13. When the log file opens, the error is displayed.

Disable stdout logging when troubleshooting is complete:

1. In the Kudu **Diagnostic Console**, return to the path **site** > **wwwroot** to reveal the *web.config* file. Open the **web.config** file again by selecting the pencil icon.
2. Set **stdoutLogEnabled** to `false`.
3. Select **Save** to save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created. Only use stdout logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Slow or hanging app (Azure App Service)

When an app responds slowly or hangs on a request, see the following articles:

- Troubleshoot slow web app performance issues in Azure App Service
- Use Crash Diagnoser Site Extension to Capture Dump for Intermittent Exception issues or performance issues on Azure Web App

Monitoring blades

Monitoring blades provide an alternative troubleshooting experience to the methods described earlier in the topic. These blades can be used to diagnose 500-series errors.

Confirm that the ASP.NET Core Extensions are installed. If the extensions aren't installed, install them manually:

1. In the **DEVELOPMENT TOOLS** blade section, select the **Extensions** blade.

2. The **ASP.NET Core Extensions** should appear in the list.
3. If the extensions aren't installed, select the **Add** button.
4. Choose the **ASP.NET Core Extensions** from the list.
5. Select **OK** to accept the legal terms.
6. Select **OK** on the **Add extension** blade.
7. An informational pop-up message indicates when the extensions are successfully installed.

If stdout logging isn't enabled, follow these steps:

1. In the Azure portal, select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the folders to the path **site** > **wwwroot** and scroll down to reveal the *web.config* file at the bottom of the list.
4. Click the pencil icon next to the *web.config* file.
5. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
6. Select **Save** to save the updated *web.config* file.

Proceed to activate diagnostic logging:

1. In the Azure portal, select the **Diagnostics logs** blade.
2. Select the **On** switch for **Application Logging (Filesystem)** and **Detailed error messages**. Select the **Save** button at the top of the blade.
3. To include failed request tracing, also known as Failed Request Event Buffering (FREB) logging, select the **On** switch for **Failed request tracing**.
4. Select the **Log stream** blade, which is listed immediately under the **Diagnostics logs** blade in the portal.
5. Make a request to the app.
6. Within the log stream data, the cause of the error is indicated.

Be sure to disable stdout logging when troubleshooting is complete.

To view the failed request tracing logs (FREB logs):

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Select **Failed Request Tracing Logs** from the **SUPPORT TOOLS** area of the sidebar.

See Failed request traces section of the Enable diagnostics logging for web apps in Azure App Service topic and the Application performance FAQs for Web Apps in Azure: How do I turn on failed request tracing? for more information.

For more information, see Enable diagnostics logging for web apps in Azure App Service.

> **WARNING**
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Troubleshoot on IIS

Application Event Log (IIS)

Access the Application Event Log:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.
2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app. Errors have a value of *IIS AspNetCore Module* or *IIS Express AspNetCore Module* in the *Source* column.

Run the app at a command prompt

Many startup errors don't produce useful information in the Application Event Log. You can find the cause of some errors by running the app at a command prompt on the hosting system.

Framework-dependent deployment

If the app is a framework-dependent deployment:

1. At a command prompt, navigate to the deployment folder and run the app by executing the app's assembly with *dotnet.exe*. In the following command, substitute the name of the app's assembly for <assembly_name>: `dotnet .\<assembly_name>.dll`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

Self-contained deployment

If the app is a self-contained deployment:

1. At a command prompt, navigate to the deployment folder and run the app's executable. In the following command, substitute the name of the app's assembly for <assembly_name>: `<assembly_name>.exe`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

ASP.NET Core Module stdout log (IIS)

To enable and view stdout logs:

1. Navigate to the site's deployment folder on the hosting system.
2. If the *logs* folder isn't present, create the folder. For instructions on how to enable MSBuild to create the *logs* folder in the deployment automatically, see the Directory structure topic.
3. Edit the *web.config* file. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to point to the *logs* folder (for example, `.\logs\stdout`). `stdout` in the path is the log file name prefix. A timestamp, process id, and file extension are added automatically when the log is created. Using `stdout` as the file name prefix, a typical log file is named *stdout_20180205184032_5412.log*.
4. Ensure your application pool's identity has write permissions to the *logs* folder.
5. Save the updated *web.config* file.
6. Make a request to the app.
7. Navigate to the *logs* folder. Find and open the most recent stdout log.
8. Study the log for errors.

Disable stdout logging when troubleshooting is complete:

1. Edit the *web.config* file.
2. Set **stdoutLogEnabled** to `false`.

3. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Enable the Developer Exception Page

The `ASPNETCORE_ENVIRONMENT` environment variable can be added to web.config to run the app in the Development environment. As long as the environment isn't overridden in app startup by `UseEnvironment` on the host builder, setting the environment variable allows the Developer Exception Page to appear when the app is run.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
  </environmentVariables>
</aspNetCore>
```

Setting the environment variable for `ASPNETCORE_ENVIRONMENT` is only recommended for use on staging and testing servers that aren't exposed to the Internet. Remove the environment variable from the *web.config* file after troubleshooting. For information on setting environment variables in *web.config*, see environmentVariables child element of aspNetCore.

Obtain data from an app

If an app is capable of responding to requests, obtain request, connection, and additional data from the app using terminal inline middleware. For more information and sample code, see Troubleshoot and debug ASP.NET Core projects.

Slow or hanging app (IIS)

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`. The app pool must have write access to the folder.
2. Run the EnableDumps PowerShell script:
   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\EnableDumps w3wp.exe c:\dumps
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\EnableDumps dotnet.exe c:\dumps
     ```

3. Run the app under the conditions that cause the crash to occur.
4. After the crash has occurred, run the DisableDumps PowerShell script:
   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\DisableDumps w3wp.exe
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\DisableDumps dotnet.exe
     ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> **WARNING**
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App hangs, fails during startup, or runs normally

When an app *hangs* (stops responding but doesn't crash), fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.
2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

Common errors reference for Azure App Service and IIS with ASP.NET Core

9/22/2020 • 22 minutes to read • Edit Online

This topic describes common errors and provides troubleshooting advice for specific errors when hosting ASP.NET Core apps on Azure Apps Service and IIS.

For general troubleshooting guidance, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

Collect the following information:

- Browser behavior (status code and error message)
- Application Event Log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS
    1. Select **Start** on the **Windows** menu, type *Event Viewer*, and press **Enter**.
    2. After the **Event Viewer** opens, expand **Windows Logs** > **Application** in the sidebar.
- ASP.NET Core Module stdout and debug log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS: Follow the instructions in the Log creation and redirection and Enhanced diagnostic logs sections of the ASP.NET Core Module topic.

Compare error information to the following common errors. If a match is found, follow the troubleshooting advice.

The list of errors in this topic isn't exhaustive. If you encounter an error not listed here, open a new issue using the **Content feedback** button at the bottom of this topic with detailed instructions on how to reproduce the error.

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

OS upgrade removed the 32-bit ASP.NET Core Module

Application Log: The Module DLL **C:\WINDOWS\system32\inetsrv\aspnetcore.dll** failed to load. The data is the error.

Troubleshooting:

Non-OS files in the **C:\Windows\SysWOW64\inetsrv** directory aren't preserved during an OS upgrade. If the ASP.NET Core Module is installed prior to an OS upgrade and then any app pool is run in 32-bit mode after an OS upgrade, this issue is encountered. After an OS upgrade, repair the ASP.NET Core Module. See Install the .NET Core Hosting bundle. Select **Repair** when the installer is run.

Missing site extension, 32-bit (x86) and 64-bit (x64) site extensions installed, or wrong process bitness set

Applies to apps hosted by Azure App Services.

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found. Failed to start application '/LM/W3SVC/1416782824/ROOT', ErrorCode '0x8000ffff'.
- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.
- **ASP.NET Core Module Debug Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Failed HRESULT returned: 0x8000ffff. Could not find inprocess request handler. It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.

Troubleshooting:

- If running the app on a preview runtime, install either the 32-bit (x86) **or** 64-bit (x64) site extension that matches the bitness of the app and the app's runtime version. **Don't install both extensions or multiple runtime versions of the extension.**
  - ASP.NET Core {RUNTIME VERSION} (x86) Runtime
  - ASP.NET Core {RUNTIME VERSION} (x64) Runtime

  Restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and both the 32-bit (x86) and 64-bit (x64) site extensions are installed, uninstall the site extension that doesn't match the bitness of the app. After removing the site extension, restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and the site extension's bitness matches that of the app, confirm that the preview site extension's *runtime version* matches the app's runtime version.
- Confirm that the app's **Platform** in **Application Settings** matches the bitness of the app.

For more information, see Deploy ASP.NET Core apps to Azure App Service.

An x86 app is deployed but the app pool isn't enabled for 32-bit apps

- **Browser:** HTTP Error 500.30 - ANCM In-Process Start Failure
- **Application Log:** Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' hit unexpected managed exception, exception code = '0xe0434352'. Please check the stderr logs for more information. Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' failed to load clr and managed application. CLR worker thread exited prematurely
- **ASP.NET Core Module stdout Log:** The log file is created but empty.
- **ASP.NET Core Module Debug Log:** Failed HRESULT returned: 0x8007023e

This scenario is trapped by the SDK when publishing a self-contained app. The SDK produces an error if the RID doesn't match the platform target (for example, `win10-x64` RID with `<PlatformTarget>x86</PlatformTarget>` in the project file).

Troubleshooting:

For an x86 framework-dependent deployment (`<PlatformTarget>x86</PlatformTarget>`), enable the IIS app pool for 32-bit apps. In IIS Manager, open the app pool's **Advanced Settings** and set **Enable 32-Bit Applications** to **True**.

Platform conflicts with RID

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"C:{PATH}{ASSEMBLY}.{exe|dll}" ', ErrorCode = '0x80004005 : ff.
- **ASP.NET Core Module stdout Log:** Unhandled Exception: System.BadImageFormatException: Could not load file or assembly '{ASSEMBLY}.dll'. An attempt was made to load a program with an incorrect format.

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- If this exception occurs for an Azure Apps deployment when upgrading an app and deploying newer assemblies, manually delete all files from the prior deployment. Lingering incompatible assemblies can result in a `System.BadImageFormatException` exception when deploying an upgraded app.

URI endpoint wrong or stopped website

- **Browser:** ERR_CONNECTION_REFUSED --**OR**-- Unable to connect
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

- Confirm the correct URI endpoint for the app is in use. Check the bindings.
- Confirm that the IIS website isn't in the *Stopped* state.

CoreWebEngine or W3SVC server features disabled

OS Exception: The IIS 7.0 CoreWebEngine and W3SVC features must be installed to use the ASP.NET Core Module.

Troubleshooting:

Confirm that the proper role and features are enabled. See IIS Configuration.

Incorrect website physical path or app missing

- **Browser:** 403 Forbidden - Access is denied --**OR**-- 403.14 Forbidden - The Web server is configured to not list the contents of this directory.
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

Check the IIS website **Basic Settings** and the physical app folder. Confirm that the app is in the folder at the IIS

website **Physical path**.

Incorrect role, ASP.NET Core Module not installed, or incorrect permissions

- **Browser:** 500.19 Internal Server Error - The requested page cannot be accessed because the related configuration data for the page is invalid. **--OR--** This page can't be displayed
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

- Confirm that the proper role is enabled. See IIS Configuration.
- Open **Programs & Features** or **Apps & features** and confirm that **Windows Server Hosting** is installed. If **Windows Server Hosting** isn't present in the list of installed programs, download and install the .NET Core Hosting Bundle.

  Current .NET Core Hosting Bundle installer (direct download)

  For more information, see Install the .NET Core Hosting Bundle.
- Make sure that the **Application Pool** > **Process Model** > **Identity** is set to **ApplicationPoolIdentity** or the custom identity has the correct permissions to access the app's deployment folder.
- If you uninstalled the ASP.NET Core Hosting Bundle and installed an earlier version of the hosting bundle, the *applicationHost.config* file doesn't include a section for the ASP.NET Core Module. Open *applicationHost.config* at *%windir%/System32/inetsrv/config* and find the `<configuration><configSections><sectionGroup name="system.webServer">` section group. If the section for the ASP.NET Core Module is missing from the section group, add the section element:

  ```
  <section name="aspNetCore" overrideModeDefault="Allow" />
  ```

  Alternatively, install the latest version of the ASP.NET Core Hosting Bundle. The latest version is backwards-compatible with supported ASP.NET Core apps.

Incorrect processPath, missing PATH variable, Hosting Bundle not installed, system/IIS not restarted, VC++ Redistributable not installed, or dotnet.exe access violation

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"{...}" ', ErrorCode = '0x80070002 : 0. Application '{PATH}' wasn't able to start. Executable was not found at '{PATH}'. Failed to start application '/LM/W3SVC/2/ROOT', ErrorCode '0x8007023e'.
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** Event Log: 'Application '{PATH}' wasn't able to start. Executable was not found at '{PATH}'. Failed HRESULT returned: 0x8007023e

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Check the *processPath* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's `dotnet` for a framework-dependent deployment (FDD) or `.\{ASSEMBLY}.exe` for a self-contained deployment (SCD).
- For an FDD, *dotnet.exe* might not be accessible via the PATH settings. Confirm that *C:\Program Files\dotnet* exists in the System PATH settings.
- For an FDD, *dotnet.exe* might not be accessible for the user identity of the app pool. Confirm that the app pool user identity has access to the *C:\Program Files\dotnet* directory. Confirm that there are no deny rules configured for the app pool user identity on the *C:\Program Files\dotnet* and app directories.
- An FDD may have been deployed and .NET Core installed without restarting IIS. Either restart the server or restart IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.
- An FDD may have been deployed without installing the .NET Core runtime on the hosting system. If the .NET Core runtime hasn't been installed, run the **.NET Core Hosting Bundle installer** on the system.

  Current .NET Core Hosting Bundle installer (direct download)

  For more information, see Install the .NET Core Hosting Bundle.

  If a specific runtime is required, download the runtime from the .NET Download Archives and install it on the system. Complete the installation by restarting the system or restarting IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.

Incorrect arguments of <aspNetCore> element

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Could not find inprocess request handler. Captured output from invoking hostfxr: Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409 Failed to start application '/LM/W3SVC/3/ROOT', ErrorCode '0x8000ffff'.
- **ASP.NET Core Module stdout Log:** Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409
- **ASP.NET Core Module Debug Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Failed HRESULT returned: 0x8000ffff Could not find inprocess request handler. Captured output from invoking hostfxr: Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409 Failed HRESULT returned: 0x8000ffff

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Examine the *arguments* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's either (a) `.\{ASSEMBLY}.dll` for a framework-dependent deployment (FDD); or (b) not present, an empty string (`arguments=""`), or a list of the app's arguments (`arguments="{ARGUMENT_1}, {ARGUMENT_2}, ... {ARGUMENT_X}"`) for a self-contained deployment (SCD).

Missing .NET Core shared framework

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}' was not found.

Failed to start application '/LM/W3SVC/5/ROOT', ErrorCode '0x8000ffff'.

- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}' was not found.
- **ASP.NET Core Module Debug Log:** Failed HRESULT returned: 0x8000ffff

Troubleshooting:

For a framework-dependent deployment (FDD), confirm that the correct runtime installed on the system.

Stopped Application Pool

- **Browser:** 503 Service Unavailable
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

Confirm that the Application Pool isn't in the *Stopped* state.

Sub-application includes a <handlers> section

- **Browser:** HTTP Error 500.19 - Internal Server Error
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.
- **ASP.NET Core Module Debug Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.

Troubleshooting:

Confirm that the sub-app's *web.config* file doesn't include a `<handlers>` section or that the sub-app doesn't inherit the parent app's handlers.

The parent app's `<system.webServer>` section of *web.config* is placed inside of a `<location>` element. The InheritInChildApplications property is set to `false` to indicate that the settings specified within the <location> element aren't inherited by apps that reside in a subdirectory of the parent app. For more information, see ASP.NET Core Module.

stdout log path incorrect

- **Browser:** The app responds normally.
- **Application Log:** Could not start stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070005 returned at {PATH}\aspnetcoremodulev2\commonlib\fileoutputmanager.cpp:84. Could not stop stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070002 returned at {PATH}. Could not start stdout redirection in {PATH}\aspnetcorev2_inprocess.dll.
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module debug Log:** Could not start stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070005 returned at {PATH}\aspnetcoremodulev2\commonlib\fileoutputmanager.cpp:84. Could not stop stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070002 returned at {PATH}. Could not start stdout redirection in {PATH}\aspnetcorev2_inprocess.dll.

Troubleshooting:

- The `stdoutLogFile` path specified in the `<aspNetCore>` element of *web.config* doesn't exist. For more information, see ASP.NET Core Module: Log creation and redirection.
- The app pool user doesn't have write access to the stdout log path.

Application configuration general issue

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure --**OR**-- HTTP Error 500.30 - ANCM In-Process Start Failure
- **Application Log:** Variable
- **ASP.NET Core Module stdout Log:** The log file is created but empty or created with normal entries until the point of the app failing.
- **ASP.NET Core Module Debug Log:** Variable

Troubleshooting:

The process failed to start, most likely due to an app configuration or programming issue.

For more information, see the following topics:

- Troubleshoot ASP.NET Core on Azure App Service and IIS
- Troubleshoot and debug ASP.NET Core projects

This topic describes common errors and provides troubleshooting advice for specific errors when hosting ASP.NET Core apps on Azure Apps Service and IIS.

For general troubleshooting guidance, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

Collect the following information:

- Browser behavior (status code and error message)
- Application Event Log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS
    1. Select **Start** on the **Windows** menu, type *Event Viewer*, and press **Enter**.
    2. After the **Event Viewer** opens, expand **Windows Logs** > **Application** in the sidebar.
- ASP.NET Core Module stdout and debug log entries

- Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
- IIS: Follow the instructions in the Log creation and redirection and Enhanced diagnostic logs sections of the ASP.NET Core Module topic.

Compare error information to the following common errors. If a match is found, follow the troubleshooting advice.

The list of errors in this topic isn't exhaustive. If you encounter an error not listed here, open a new issue using the **Content feedback** button at the bottom of this topic with detailed instructions on how to reproduce the error.

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

OS upgrade removed the 32-bit ASP.NET Core Module

Application Log: The Module DLL **C:\WINDOWS\system32\inetsrv\aspnetcore.dll** failed to load. The data is the error.

Troubleshooting:

Non-OS files in the **C:\Windows\SysWOW64\inetsrv** directory aren't preserved during an OS upgrade. If the ASP.NET Core Module is installed prior to an OS upgrade and then any app pool is run in 32-bit mode after an OS upgrade, this issue is encountered. After an OS upgrade, repair the ASP.NET Core Module. See Install the .NET Core Hosting bundle. Select **Repair** when the installer is run.

Missing site extension, 32-bit (x86) and 64-bit (x64) site extensions installed, or wrong process bitness set

Applies to apps hosted by Azure App Services.

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found. Failed to start application '/LM/W3SVC/1416782824/ROOT', ErrorCode '0x8000ffff'.
- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.

Troubleshooting:

- If running the app on a preview runtime, install either the 32-bit (x86) **or** 64-bit (x64) site extension that matches the bitness of the app and the app's runtime version. **Don't install both extensions or multiple runtime versions of the extension.**
  - ASP.NET Core {RUNTIME VERSION} (x86) Runtime
  - ASP.NET Core {RUNTIME VERSION} (x64) Runtime

  Restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and both the 32-bit (x86) and 64-bit (x64) site extensions are installed, uninstall the site extension that doesn't match the bitness of the app. After removing the site

extension, restart the app. Wait several seconds for the app to restart.

- If running the app on a preview runtime and the site extension's bitness matches that of the app, confirm that the preview site extension's *runtime version* matches the app's runtime version.
- Confirm that the app's **Platform** in **Application Settings** matches the bitness of the app.

For more information, see Deploy ASP.NET Core apps to Azure App Service.

An x86 app is deployed but the app pool isn't enabled for 32-bit apps

- **Browser:** HTTP Error 500.30 - ANCM In-Process Start Failure
- **Application Log:** Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' hit unexpected managed exception, exception code = '0xe0434352'. Please check the stderr logs for more information. Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' failed to load clr and managed application. CLR worker thread exited prematurely
- **ASP.NET Core Module stdout Log:** The log file is created but empty.

This scenario is trapped by the SDK when publishing a self-contained app. The SDK produces an error if the RID doesn't match the platform target (for example, `win10-x64` RID with `<PlatformTarget>x86</PlatformTarget>` in the project file).

Troubleshooting:

For an x86 framework-dependent deployment (`<PlatformTarget>x86</PlatformTarget>`), enable the IIS app pool for 32-bit apps. In IIS Manager, open the app pool's **Advanced Settings** and set **Enable 32-Bit Applications** to **True**.

Platform conflicts with RID

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"C:{PATH}{ASSEMBLY}.{exe|dll}" ', ErrorCode = '0x80004005 : ff.
- **ASP.NET Core Module stdout Log:** Unhandled Exception: System.BadImageFormatException: Could not load file or assembly '{ASSEMBLY}.dll'. An attempt was made to load a program with an incorrect format.

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- If this exception occurs for an Azure Apps deployment when upgrading an app and deploying newer assemblies, manually delete all files from the prior deployment. Lingering incompatible assemblies can result in a `System.BadImageFormatException` exception when deploying an upgraded app.

URI endpoint wrong or stopped website

- **Browser:** ERR_CONNECTION_REFUSED --**OR**-- Unable to connect
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

- Confirm the correct URI endpoint for the app is in use. Check the bindings.

- Confirm that the IIS website isn't in the *Stopped* state.

CoreWebEngine or W3SVC server features disabled

OS Exception: The IIS 7.0 CoreWebEngine and W3SVC features must be installed to use the ASP.NET Core Module.

Troubleshooting:

Confirm that the proper role and features are enabled. See IIS Configuration.

Incorrect website physical path or app missing

- **Browser:** 403 Forbidden - Access is denied --**OR**-- 403.14 Forbidden - The Web server is configured to not list the contents of this directory.
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

Check the IIS website **Basic Settings** and the physical app folder. Confirm that the app is in the folder at the IIS website **Physical path**.

Incorrect role, ASP.NET Core Module not installed, or incorrect permissions

- **Browser:** 500.19 Internal Server Error - The requested page cannot be accessed because the related configuration data for the page is invalid. --**OR**-- This page can't be displayed
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

- Confirm that the proper role is enabled. See IIS Configuration.
- Open **Programs & Features** or **Apps & features** and confirm that **Windows Server Hosting** is installed. If **Windows Server Hosting** isn't present in the list of installed programs, download and install the .NET Core Hosting Bundle.

  Current .NET Core Hosting Bundle installer (direct download)

  For more information, see Install the .NET Core Hosting Bundle.
- Make sure that the **Application Pool** > **Process Model** > **Identity** is set to **ApplicationPoolIdentity** or the custom identity has the correct permissions to access the app's deployment folder.
- If you uninstalled the ASP.NET Core Hosting Bundle and installed an earlier version of the hosting bundle, the *applicationHost.config* file doesn't include a section for the ASP.NET Core Module. Open *applicationHost.config* at *%windir%/System32/inetsrv/config* and find the `<configuration><configSections><sectionGroup name="system.webServer">` section group. If the section for the ASP.NET Core Module is missing from the section group, add the section element:

  ```
  <section name="aspNetCore" overrideModeDefault="Allow" />
  ```

  Alternatively, install the latest version of the ASP.NET Core Hosting Bundle. The latest version is backwards-

compatible with supported ASP.NET Core apps.

Incorrect processPath, missing PATH variable, Hosting Bundle not installed, system/IIS not restarted, VC++ Redistributable not installed, or dotnet.exe access violation

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"{...}" ', ErrorCode = '0x80070002 : 0.
- **ASP.NET Core Module stdout Log:** The log file is created but empty.

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Check the *processPath* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's `dotnet` for a framework-dependent deployment (FDD) or `.\{ASSEMBLY}.exe` for a self-contained deployment (SCD).
- For an FDD, *dotnet.exe* might not be accessible via the PATH settings. Confirm that *C:\Program Files\dotnet* exists in the System PATH settings.
- For an FDD, *dotnet.exe* might not be accessible for the user identity of the app pool. Confirm that the app pool user identity has access to the *C:\Program Files\dotnet* directory. Confirm that there are no deny rules configured for the app pool user identity on the *C:\Program Files\dotnet* and app directories.
- An FDD may have been deployed and .NET Core installed without restarting IIS. Either restart the server or restart IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.
- An FDD may have been deployed without installing the .NET Core runtime on the hosting system. If the .NET Core runtime hasn't been installed, run the **.NET Core Hosting Bundle installer** on the system.

  Current .NET Core Hosting Bundle installer (direct download)

  For more information, see Install the .NET Core Hosting Bundle.

  If a specific runtime is required, download the runtime from the .NET Download Archives and install it on the system. Complete the installation by restarting the system or restarting IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.

Incorrect arguments of <aspNetCore> element

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"dotnet" .{ASSEMBLY}.dll', ErrorCode = '0x80004005 : 80008081.
- **ASP.NET Core Module stdout Log:** The application to execute does not exist: 'PATH{ASSEMBLY}.dll'

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Examine the *arguments* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's either (a) `.\{ASSEMBLY}.dll` for a framework-dependent deployment (FDD); or (b) not present, an empty string (`arguments=""`), or a list of the app's arguments (`arguments="{ARGUMENT_1}, {ARGUMENT_2}, ... {ARGUMENT_X}"`)

for a self-contained deployment (SCD).

Troubleshooting:

For a framework-dependent deployment (FDD), confirm that the correct runtime installed on the system.

Stopped Application Pool

- **Browser:** 503 Service Unavailable
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

Confirm that the Application Pool isn't in the *Stopped* state.

Sub-application includes a <handlers> section

- **Browser:** HTTP Error 500.19 - Internal Server Error
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.

Troubleshooting:

Confirm that the sub-app's *web.config* file doesn't include a `<handlers>` section.

stdout log path incorrect

- **Browser:** The app responds normally.
- **Application Log:** Warning: Could not create stdoutLogFile \?{PATH}\path_doesnt_exist\stdout_{PROCESS ID}_{TIMESTAMP}.log, ErrorCode = -2147024893.
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

- The `stdoutLogFile` path specified in the `<aspNetCore>` element of *web.config* doesn't exist. For more information, see ASP.NET Core Module: Log creation and redirection.
- The app pool user doesn't have write access to the stdout log path.

Application configuration general issue

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' created process with commandline '"C:{PATH}{ASSEMBLY}.{exe|dll}" ' but either crashed or did not respond or did not listen on the given port '{PORT}', ErrorCode = '{ERROR CODE}'
- **ASP.NET Core Module stdout Log:** The log file is created but empty.

Troubleshooting:

The process failed to start, most likely due to an app configuration or programming issue.

Razor Pages with Entity Framework Core in ASP.NET Core - Tutorial 1 of 8

9/22/2020 • 50 minutes to read • Edit Online

By Tom Dykstra and Rick Anderson

This is the first in a series of tutorials that show how to use Entity Framework (EF) Core in an ASP.NET Core Razor Pages app. The tutorials build a web site for a fictional Contoso University. The site includes functionality such as student admission, course creation, and instructor assignments. The tutorial uses the code first approach. For information on following this tutorial using the database first approach, see this Github issue.

Download or view the completed app. Download instructions.

Prerequisites

- If you're new to Razor Pages, go through the Get started with Razor Pages tutorial series before starting this one.
- Visual Studio
- Visual Studio Code
- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core 3.0 SDK or later

Database engines

The Visual Studio instructions use SQL Server LocalDB, a version of SQL Server Express that runs only on Windows.

The Visual Studio Code instructions use SQLite, a cross-platform database engine.

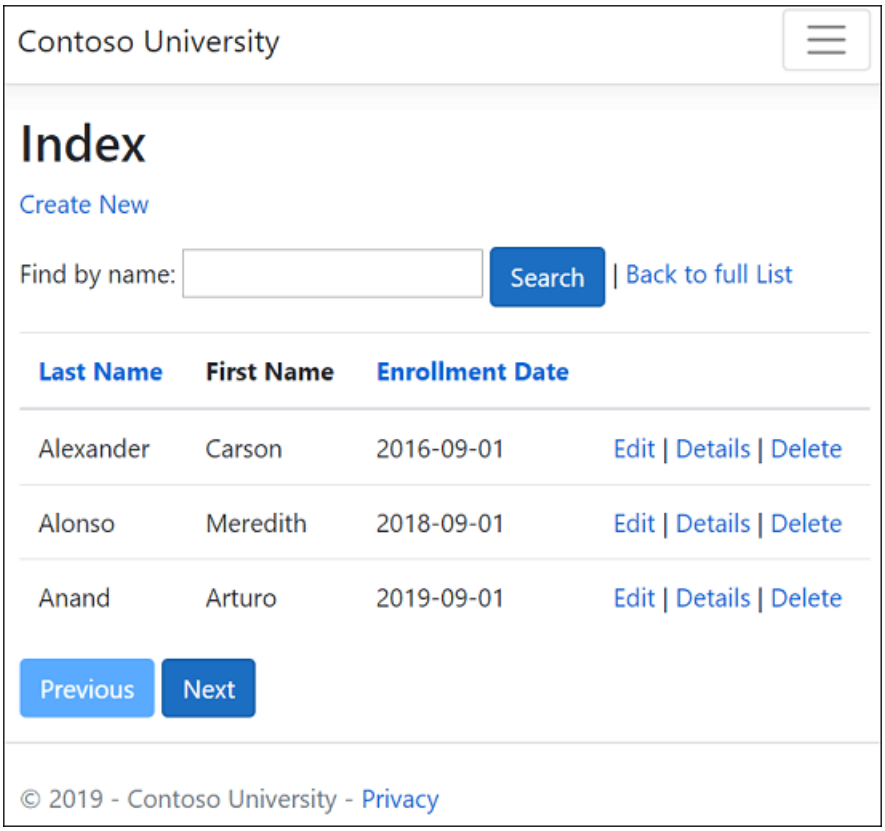
If you choose to use SQLite, download and install a third-party tool for managing and viewing a SQLite database, such as DB Browser for SQLite.

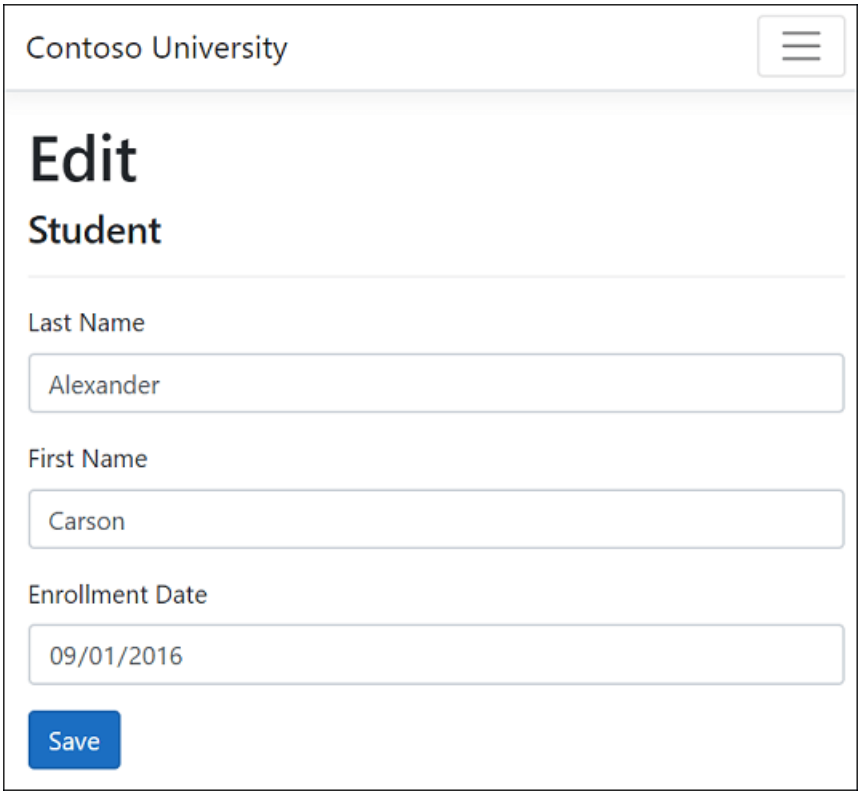
Troubleshooting

If you run into a problem you can't resolve, compare your code to the completed project. A good way to get help is by posting a question to StackOverflow.com, using the ASP.NET Core tag or the EF Core tag.

The sample app

The app built in these tutorials is a basic university web site. Users can view and update student, course, and instructor information. Here are a few of the screens created in the tutorial.





The UI style of this site is based on the built-in project templates. The tutorial's focus is on how to use EF Core, not how to customize the UI.

Follow the link at the top of the page to get the source code for the completed project. The *cu30* folder has the code for the ASP.NET Core 3.0 version of the tutorial. Files that reflect the state of the code for tutorials 1-7 can be found in the *cu30snapshots* folder.

- Visual Studio
- Visual Studio Code

To run the app after downloading the completed project:

- Build the project.
- In Package Manager Console (PMC) run the following command:

```
Update-Database
```

- Run the project to seed the database.

Create the web app project

- Visual Studio
- Visual Studio Code

- From the Visual Studio **File** menu, select **New** > **Project**.
- Select **ASP.NET Core Web Application**.
- Name the project *ContosoUniversity*. It's important to use this exact name including capitalization, so the namespaces match when code is copied and pasted.
- Select **.NET Core** and **ASP.NET Core 3.0** in the dropdowns, and then select **Web Application**.

Set up the site style

Set up the site header, footer, and menu by updating *Pages/Shared/_Layout.cshtml*:

- Change each occurrence of "ContosoUniversity" to "Contoso University". There are three occurrences.
- Delete the **Home** and **Privacy** menu entries, and add entries for **About**, **Students**, **Courses**, **Instructors**, and **Departments**.

The changes are highlighted.

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Contoso University</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-light bg-white border-bottom
box-shadow mb-3">
            <div class="container">
                <a class="navbar-brand" asp-area="" asp-page="/Index">Contoso University</a>
                <button class="navbar-toggler" type="button" data-toggle="collapse" data-
target=".navbar-collapse" aria-controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle navigation">
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex flex-sm-row-reverse">
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-page="/About">About</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Students/Index">Students</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Courses/Index">Courses</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Instructors/Index">Instructors</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Departments/Index">Departments</a>
                        </li>
                    </ul>
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2019 - Contoso University - <a asp-area="" asp-page="/Privacy">Privacy</a>
        </div>
    </footer>

    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>

    @RenderSection("Scripts", required: false)
</body>
</html>
```

In *Pages/Index.cshtml*, replace the contents of the file with the following code to replace the text about ASP.NET Core with text about this app:

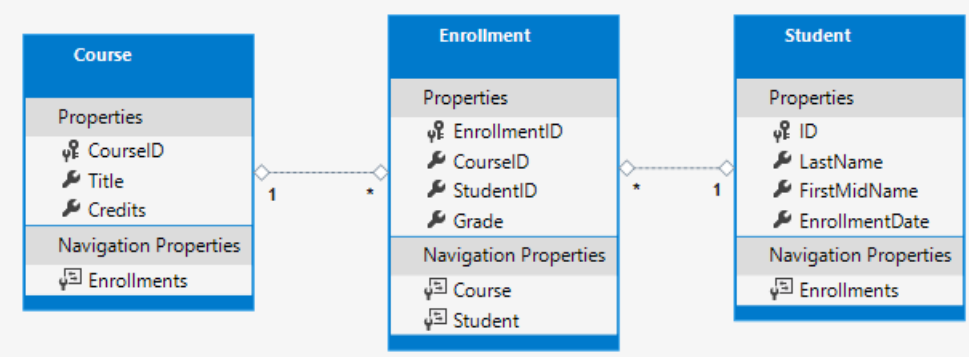
```
@page
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

<div class="row mb-auto">
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 mb-4 ">
                <p class="card-text">
                    Contoso University is a sample application that
                    demonstrates how to use Entity Framework Core in an
                    ASP.NET Core Razor Pages web app.
                </p>
            </div>
        </div>
    </div>
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 d-flex flex-column position-static">
                <p class="card-text mb-auto">
                    You can build the application by following the steps in a series of tutorials.
                </p>
                <p>
                    <a href="https://docs.microsoft.com/aspnet/core/data/ef-rp/intro" class="stretched-
link">See the tutorial</a>
                </p>
            </div>
        </div>
    </div>
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 d-flex flex-column">
                <p class="card-text mb-auto">
                    You can download the completed project from GitHub.
                </p>
                <p>
                    <a href="https://github.com/dotnet/AspNetCore.Docs/tree/master/aspnetcore/data/ef-
rp/intro/samples" class="stretched-link">See project source code</a>
                </p>
            </div>
        </div>
    </div>
</div>
```

Run the app to verify that the home page appears.

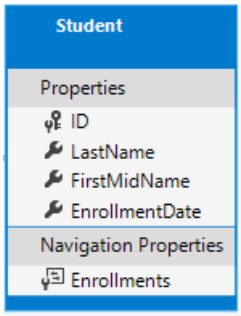
The data model

The following sections create a data model:



A student can enroll in any number of courses, and a course can have any number of students enrolled in it.

The Student entity



- Create a *Models* folder in the project folder.
- Create *Models/Student.cs* with the following code:

```
using System;
using System.Collections.Generic;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

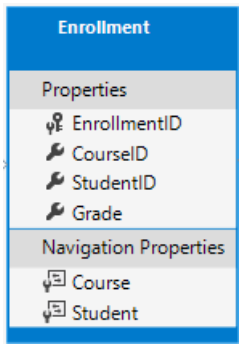
The `ID` property becomes the primary key column of the database table that corresponds to this class. By default, EF Core interprets a property that's named `ID` or `classnameID` as the primary key. So the alternative automatically recognized name for the `Student` class primary key is `StudentID`. For more information, see EF Core - Keys.

The `Enrollments` property is a navigation property. Navigation properties hold other entities that are related to this entity. In this case, the `Enrollments` property of a `Student` entity holds all of the `Enrollment` entities that are related to that Student. For example, if a Student row in the database has two related Enrollment rows, the `Enrollments` navigation property contains those two Enrollment entities.

In the database, an Enrollment row is related to a Student row if its StudentID column contains the student's ID value. For example, suppose a Student row has ID=1. Related Enrollment rows will have StudentID = 1. StudentID is a *foreign key* in the Enrollment table.

The `Enrollments` property is defined as `ICollection<Enrollment>` because there may be multiple related Enrollment entities. You can use other collection types, such as `List<Enrollment>` or `HashSet<Enrollment>`. When `ICollection<Enrollment>` is used, EF Core creates a `HashSet<Enrollment>` collection by default.

The Enrollment entity



Create *Models/Enrollment.cs* with the following code:

```
namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

The `EnrollmentID` property is the primary key; this entity uses the `classnameID` pattern instead of `ID` by itself. For a production data model, choose one pattern and use it consistently. This tutorial uses both just to illustrate that both work. Using `ID` without `classname` makes it easier to implement some kinds of data model changes.

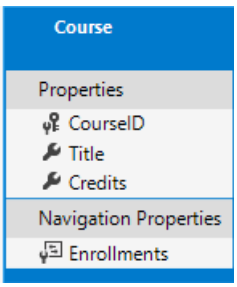
The `Grade` property is an `enum`. The question mark after the `Grade` type declaration indicates that the `Grade` property is nullable. A grade that's null is different from a zero grade—null means a grade isn't known or hasn't been assigned yet.

The `StudentID` property is a foreign key, and the corresponding navigation property is `Student`. An `Enrollment` entity is associated with one `Student` entity, so the property contains a single `Student` entity.

The `CourseID` property is a foreign key, and the corresponding navigation property is `Course`. An `Enrollment` entity is associated with one `Course` entity.

EF Core interprets a property as a foreign key if it's named `<navigation property name><primary key property name>`. For example, `StudentID` is the foreign key for the `Student` navigation property, since the `Student` entity's primary key is `ID`. Foreign key properties can also be named `<primary key property name>`. For example, `CourseID` since the `Course` entity's primary key is `CourseID`.

The Course entity



Create *Models/Course.cs* with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        public int CourseID { get; set; }
        public string Title { get; set; }
        public int Credits { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `Enrollments` property is a navigation property. A `Course` entity can be related to any number of `Enrollment` entities.

The `DatabaseGenerated` attribute allows the app to specify the primary key rather than having the database generate it.

Build the project to validate that there are no compiler errors.

Scaffold Student pages

In this section, you use the ASP.NET Core scaffolding tool to generate:

- An EF Core *context* class. The context is the main class that coordinates Entity Framework functionality for a given data model. It derives from the `Microsoft.EntityFrameworkCore.DbContext` class.
- Razor pages that handle Create, Read, Update, and Delete (CRUD) operations for the `Student` entity.

- Visual Studio
- Visual Studio Code

- Create a *Students* folder in the *Pages* folder.
- In **Solution Explorer**, right-click the *Pages/Students* folder and select **Add** > **New Scaffolded Item**.
- In the **Add Scaffold** dialog, select **Razor Pages using Entity Framework (CRUD)** > **ADD**.
- In the **Add Razor Pages using Entity Framework (CRUD)** dialog:
  - In the **Model class** drop-down, select **Student (ContosoUniversity.Models)**.
  - In the **Data context class** row, select the **+** (plus) sign.
  - Change the data context name from *ContosoUniversity.Models.ContosoUniversityContext* to *ContosoUniversity.Data.SchoolContext*.
  - Select **Add**.

The following packages are automatically installed:

- `Microsoft.VisualStudio.Web.CodeGeneration.Design`
- `Microsoft.EntityFrameworkCore.SqlServer`
- `Microsoft.Extensions.Logging.Debug`
- `Microsoft.EntityFrameworkCore.Tools`

If you have a problem with the preceding step, build the project and retry the scaffold step.

The scaffolding process:

- Creates Razor pages in the *Pages/Students* folder:
  - *Create.cshtml* and *Create.cshtml.cs*
  - *Delete.cshtml* and *Delete.cshtml.cs*
  - *Details.cshtml* and *Details.cshtml.cs*
  - *Edit.cshtml* and *Edit.cshtml.cs*
  - *Index.cshtml* and *Index.cshtml.cs*
- Creates *Data/SchoolContext.cs*.
- Adds the context to dependency injection in *Startup.cs*.
- Adds a database connection string to *appsettings.json*.

Database connection string

- Visual Studio
- Visual Studio Code

The connection string specifies SQL Server LocalDB.

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "SchoolContext": "Server=
(localdb)\\mssqllocaldb;Database=SchoolContext6;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

LocalDB is a lightweight version of the SQL Server Express Database Engine and is intended for app development, not production use. By default, LocalDB creates *.mdf* files in the `C:/Users/<user>` directory.

Update the database context class

The main class that coordinates EF Core functionality for a given data model is the database context class. The context is derived from Microsoft.EntityFrameworkCore.DbContext. The context specifies which entities are included in the data model. In this project, the class is named `SchoolContext`.

Update *SchoolContext.cs* with the following code:

```
using Microsoft.EntityFrameworkCore;
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext (DbContextOptions<SchoolContext> options)
            : base(options)
        {
        }

        public DbSet<Student> Students { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Course> Courses { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
        }
    }
}
```

The highlighted code creates a DbSet<TEntity> property for each entity set. In EF Core terminology:

- An entity set typically corresponds to a database table.
- An entity corresponds to a row in the table.

Since an entity set contains multiple entities, the DBSet properties should be plural names. Since the scaffolding tool created a `Student` DBSet, this step changes it to plural `Students`.

To make the Razor Pages code match the new DBSet name, make a global change across the whole project of `_context.Student` to `_context.Students`. There are 8 occurrences.

Build the project to verify there are no compiler errors.

Startup.cs

ASP.NET Core is built with dependency injection. Services (such as the EF Core database context) are registered with dependency injection during application startup. Components that require these services (such as Razor Pages) are provided these services via constructor parameters. The constructor code that gets a database context instance is shown later in the tutorial.

The scaffolding tool automatically registered the context class with the dependency injection container.

- Visual Studio
- Visual Studio Code

- In `ConfigureServices`, the highlighted lines were added by the scaffolder:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();

    services.AddDbContext<SchoolContext>(options =>
            options.UseSqlServer(Configuration.GetConnectionString("SchoolContext")));
}
```

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Create the database

Update *Program.cs* to create the database if it doesn't exist:

```
using ContosoUniversity.Data;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
using System;

namespace ContosoUniversity
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateHostBuilder(args).Build();

            CreateDbIfNotExists(host);

            host.Run();
        }

        private static void CreateDbIfNotExists(IHost host)
        {
            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    var context = services.GetRequiredService<SchoolContext>();
                    context.Database.EnsureCreated();
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred creating the DB.");
                }
            }
        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureWebHostDefaults(webBuilder =>
                {
                    webBuilder.UseStartup<Startup>();
                });
    }
}
```

The EnsureCreated method takes no action if a database for the context exists. If no database exists, it creates the database and schema. `EnsureCreated` enables the following workflow for handling data model changes:

- Delete the database. Any existing data is lost.
- Change the data model. For example, add an `EmailAddress` field.
- Run the app.

- `EnsureCreated` creates a database with the new schema.

This workflow works well early in development when the schema is rapidly evolving, as long as you don't need to preserve data. The situation is different when data that has been entered into the database needs to be preserved. When that is the case, use migrations.

Later in the tutorial series, you delete the database that was created by `EnsureCreated` and use migrations instead. A database that is created by `EnsureCreated` can't be updated by using migrations.

Test the app

- Run the app.
- Select the **Students** link and then **Create New**.
- Test the Edit, Details, and Delete links.

Seed the database

The `EnsureCreated` method creates an empty database. This section adds code that populates the database with test data.

Create *Data/DbInitializer.cs* with the following code:

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using System;
using System.Linq;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            context.Database.EnsureCreated();

            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
                new
Student{FirstMidName="Carson",LastName="Alexander",EnrollmentDate=DateTime.Parse("2019-09-01")},
                new
Student{FirstMidName="Meredith",LastName="Alonso",EnrollmentDate=DateTime.Parse("2017-09-01")},
                new Student{FirstMidName="Arturo",LastName="Anand",EnrollmentDate=DateTime.Parse("2018-
09-01")},
                new
Student{FirstMidName="Gytis",LastName="Barzdukas",EnrollmentDate=DateTime.Parse("2017-09-01")},
                new Student{FirstMidName="Yan",LastName="Li",EnrollmentDate=DateTime.Parse("2017-09-
01")},
                new
Student{FirstMidName="Peggy",LastName="Justice",EnrollmentDate=DateTime.Parse("2016-09-01")},
                new Student{FirstMidName="Laura",LastName="Norman",EnrollmentDate=DateTime.Parse("2018-
09-01")},
                new
Student{FirstMidName="Nino",LastName="Olivetto",EnrollmentDate=DateTime.Parse("2019-09-01")}
            };

            context.Students.AddRange(students);
            context.SaveChanges();

            var courses = new Course[]
```

```
            var courses = new Course[]
            {
                new Course{CourseID=1050,Title="Chemistry",Credits=3},
                new Course{CourseID=4022,Title="Microeconomics",Credits=3},
                new Course{CourseID=4041,Title="Macroeconomics",Credits=3},
                new Course{CourseID=1045,Title="Calculus",Credits=4},
                new Course{CourseID=3141,Title="Trigonometry",Credits=4},
                new Course{CourseID=2021,Title="Composition",Credits=3},
                new Course{CourseID=2042,Title="Literature",Credits=4}
            };

            context.Courses.AddRange(courses);
            context.SaveChanges();

            var enrollments = new Enrollment[]
            {
                new Enrollment{StudentID=1,CourseID=1050,Grade=Grade.A},
                new Enrollment{StudentID=1,CourseID=4022,Grade=Grade.C},
                new Enrollment{StudentID=1,CourseID=4041,Grade=Grade.B},
                new Enrollment{StudentID=2,CourseID=1045,Grade=Grade.B},
                new Enrollment{StudentID=2,CourseID=3141,Grade=Grade.F},
                new Enrollment{StudentID=2,CourseID=2021,Grade=Grade.F},
                new Enrollment{StudentID=3,CourseID=1050},
                new Enrollment{StudentID=4,CourseID=1050},
                new Enrollment{StudentID=4,CourseID=4022,Grade=Grade.F},
                new Enrollment{StudentID=5,CourseID=4041,Grade=Grade.C},
                new Enrollment{StudentID=6,CourseID=1045},
                new Enrollment{StudentID=7,CourseID=3141,Grade=Grade.A},
            };

            context.Enrollments.AddRange(enrollments);
            context.SaveChanges();
        }
    }
}
```

The code checks if there are any students in the database. If there are no students, it adds test data to the database. It creates the test data in arrays rather than `List<T>` collections to optimize performance.

- In *Program.cs*, replace the `EnsureCreated` call with a `DbInitializer.Initialize` call:

  ```
  // context.Database.EnsureCreated();
  DbInitializer.Initialize(context);
  ```

- Visual Studio
- Visual Studio Code

Stop the app if it's running, and run the following command in the **Package Manager Console** (PMC):

```
Drop-Database
```

- Restart the app.
- Select the Students page to see the seeded data.

View the database

- Visual Studio
- Visual Studio Code

- Open **SQL Server Object Explorer** (SSOX) from the **View** menu in Visual Studio.

- In SSOX, select **(localdb)\MSSQLLocalDB > Databases > SchoolContext-{GUID}**. The database name is generated from the context name you provided earlier plus a dash and a GUID.
- Expand the **Tables** node.
- Right-click the **Student** table and click **View Data** to see the columns created and the rows inserted into the table.
- Right-click the **Student** table and click **View Code** to see how the `Student` model maps to the `Student` table schema.

Asynchronous code

Asynchronous programming is the default mode for ASP.NET Core and EF Core.

A web server has a limited number of threads available, and in high load situations all of the available threads might be in use. When that happens, the server can't process new requests until the threads are freed up. With synchronous code, many threads may be tied up while they aren't actually doing any work because they're waiting for I/O to complete. With asynchronous code, when a process is waiting for I/O to complete, its thread is freed up for the server to use for processing other requests. As a result, asynchronous code enables server resources to be used more efficiently, and the server can handle more traffic without delays.

Asynchronous code does introduce a small amount of overhead at run time. For low traffic situations, the performance hit is negligible, while for high traffic situations, the potential performance improvement is substantial.

In the following code, the async keyword, `Task<T>` return value, `await` keyword, and `ToListAsync` method make the code execute asynchronously.

```
public async Task OnGetAsync()
{
    Students = await _context.Students.ToListAsync();
}
```

- The `async` keyword tells the compiler to:
  - Generate callbacks for parts of the method body.
  - Create the Task object that's returned.
- The `Task<T>` return type represents ongoing work.
- The `await` keyword causes the compiler to split the method into two parts. The first part ends with the operation that's started asynchronously. The second part is put into a callback method that's called when the operation completes.
- `ToListAsync` is the asynchronous version of the `ToList` extension method.

Some things to be aware of when writing asynchronous code that uses EF Core:

- Only statements that cause queries or commands to be sent to the database are executed asynchronously. That includes `ToListAsync`, `SingleOrDefaultAsync`, `FirstOrDefaultAsync`, and `SaveChangesAsync`. It doesn't include statements that just change an `IQueryable`, such as `var students = context.Students.Where(s => s.LastName == "Davolio")`.
- An EF Core context isn't thread safe: don't try to do multiple operations in parallel.
- To take advantage of the performance benefits of async code, verify that library packages (such as for paging) use async if they call EF Core methods that send queries to the database.

For more information about asynchronous programming in .NET, see Async Overview and Asynchronous programming with async and await.

Next steps

NEXT TUTORIAL

This is the first in a series of tutorials that show how to use Entity Framework (EF) Core in an ASP.NET Core Razor Pages app. The tutorials build a web site for a fictional Contoso University. The site includes functionality such as student admission, course creation, and instructor assignments. The tutorial uses the code first approach. For information on following this tutorial using the database first approach, see this Github issue.

Download or view the completed app. Download instructions.

Prerequisites

- If you're new to Razor Pages, go through the Get started with Razor Pages tutorial series before starting this one.
- Visual Studio
- Visual Studio Code
- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core 3.0 SDK or later

Database engines

The Visual Studio instructions use SQL Server LocalDB, a version of SQL Server Express that runs only on Windows.

The Visual Studio Code instructions use SQLite, a cross-platform database engine.

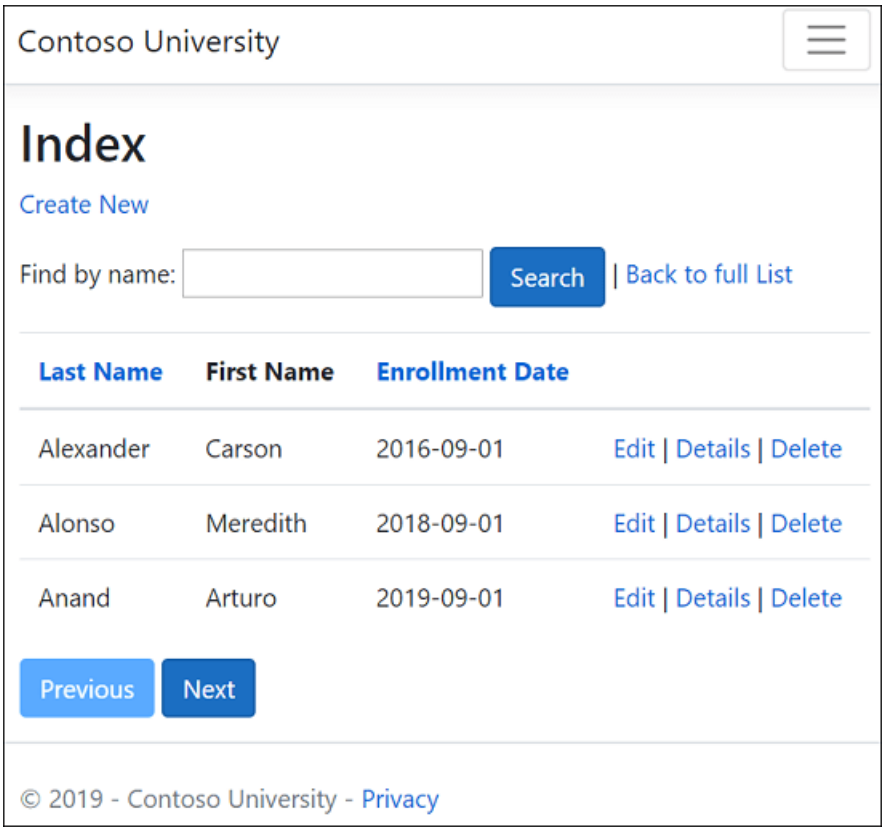
If you choose to use SQLite, download and install a third-party tool for managing and viewing a SQLite database, such as DB Browser for SQLite.

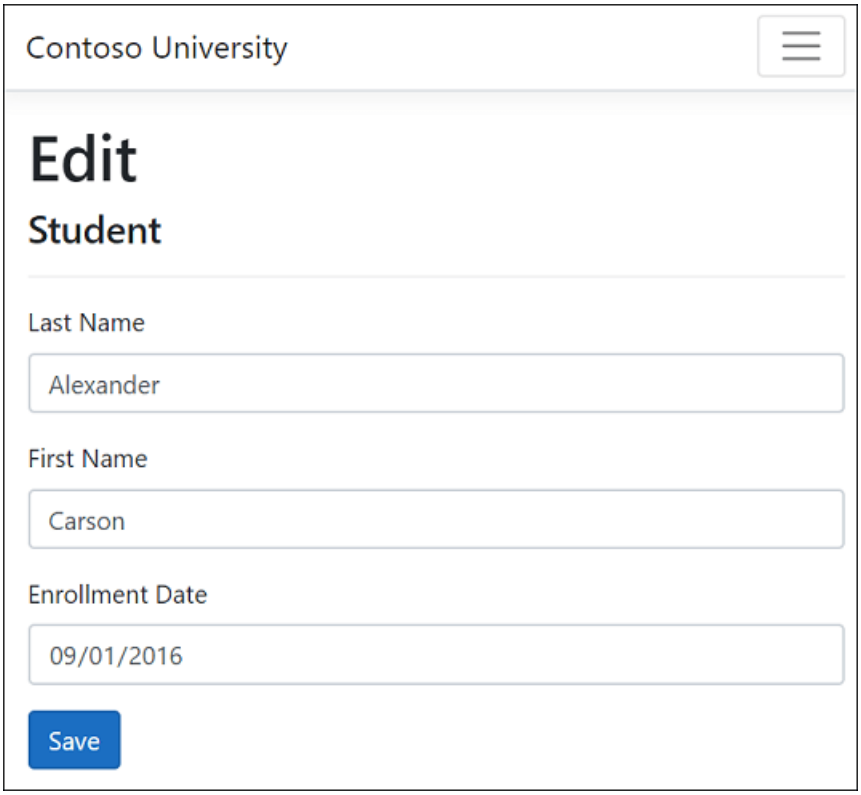
Troubleshooting

If you run into a problem you can't resolve, compare your code to the completed project. A good way to get help is by posting a question to StackOverflow.com, using the ASP.NET Core tag or the EF Core tag.

The sample app

The app built in these tutorials is a basic university web site. Users can view and update student, course, and instructor information. Here are a few of the screens created in the tutorial.





The UI style of this site is based on the built-in project templates. The tutorial's focus is on how to use EF Core, not how to customize the UI.

Follow the link at the top of the page to get the source code for the completed project. The *cu30* folder has the code for the ASP.NET Core 3.0 version of the tutorial. Files that reflect the state of the code for tutorials 1-7 can be found in the *cu30snapshots* folder.

- Visual Studio
- Visual Studio Code

To run the app after downloading the completed project:

- Build the project.
- In Package Manager Console (PMC) run the following command:

```
Update-Database
```

- Run the project to seed the database.

Create the web app project

- Visual Studio
- Visual Studio Code

- From the Visual Studio **File** menu, select **New** > **Project**.
- Select **ASP.NET Core Web Application**.
- Name the project *ContosoUniversity*. It's important to use this exact name including capitalization, so the namespaces match when code is copied and pasted.
- Select **.NET Core** and **ASP.NET Core 3.0** in the dropdowns, and then select **Web Application**.

Set up the site style

Set up the site header, footer, and menu by updating *Pages/Shared/_Layout.cshtml*:

- Change each occurrence of "ContosoUniversity" to "Contoso University". There are three occurrences.
- Delete the **Home** and **Privacy** menu entries, and add entries for **About**, **Students**, **Courses**, **Instructors**, and **Departments**.

The changes are highlighted.

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Contoso University</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-light bg-white border-bottom
box-shadow mb-3">
            <div class="container">
                <a class="navbar-brand" asp-area="" asp-page="/Index">Contoso University</a>
                <button class="navbar-toggler" type="button" data-toggle="collapse" data-
target=".navbar-collapse" aria-controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle navigation">
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex flex-sm-row-reverse">
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-page="/About">About</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Students/Index">Students</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Courses/Index">Courses</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Instructors/Index">Instructors</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Departments/Index">Departments</a>
                        </li>
                    </ul>
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2019 - Contoso University - <a asp-area="" asp-page="/Privacy">Privacy</a>
        </div>
    </footer>

    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>

    @RenderSection("Scripts", required: false)
</body>
</html>
```

In *Pages/Index.cshtml*, replace the contents of the file with the following code to replace the text about ASP.NET Core with text about this app:

```
@page
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

<div class="row mb-auto">
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 mb-4 ">
                <p class="card-text">
                    Contoso University is a sample application that
                    demonstrates how to use Entity Framework Core in an
                    ASP.NET Core Razor Pages web app.
                </p>
            </div>
        </div>
    </div>
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 d-flex flex-column position-static">
                <p class="card-text mb-auto">
                    You can build the application by following the steps in a series of tutorials.
                </p>
                <p>
                    <a href="https://docs.microsoft.com/aspnet/core/data/ef-rp/intro" class="stretched-
link">See the tutorial</a>
                </p>
            </div>
        </div>
    </div>
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 d-flex flex-column">
                <p class="card-text mb-auto">
                    You can download the completed project from GitHub.
                </p>
                <p>
                    <a href="https://github.com/dotnet/AspNetCore.Docs/tree/master/aspnetcore/data/ef-
rp/intro/samples" class="stretched-link">See project source code</a>
                </p>
            </div>
        </div>
    </div>
</div>
```

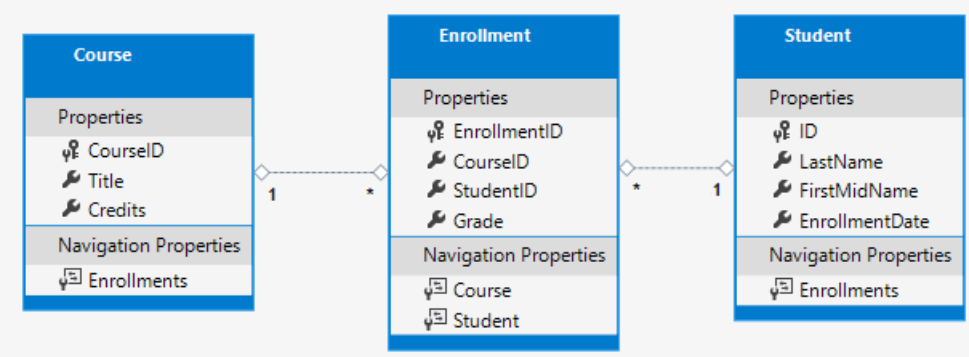
Run the app to verify that the home page appears.

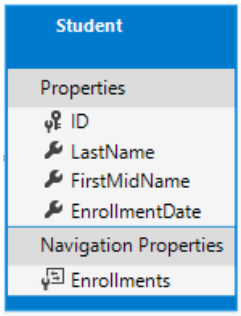
The data model

The following sections create a data model:



A student can enroll in any number of courses, and a course can have any number of students enrolled in it.

The Student entity



- Create a *Models* folder in the project folder.
- Create *Models/Student.cs* with the following code:

```
using System;
using System.Collections.Generic;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

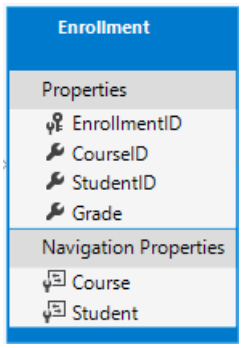
The `ID` property becomes the primary key column of the database table that corresponds to this class. By default, EF Core interprets a property that's named `ID` or `classnameID` as the primary key. So the alternative automatically recognized name for the `Student` class primary key is `StudentID`. For more information, see EF Core - Keys.

The `Enrollments` property is a navigation property. Navigation properties hold other entities that are related to this entity. In this case, the `Enrollments` property of a `Student` entity holds all of the `Enrollment` entities that are related to that Student. For example, if a Student row in the database has two related Enrollment rows, the `Enrollments` navigation property contains those two Enrollment entities.

In the database, an Enrollment row is related to a Student row if its StudentID column contains the student's ID value. For example, suppose a Student row has ID=1. Related Enrollment rows will have StudentID = 1. StudentID is a *foreign key* in the Enrollment table.

The `Enrollments` property is defined as `ICollection<Enrollment>` because there may be multiple related Enrollment entities. You can use other collection types, such as `List<Enrollment>` or `HashSet<Enrollment>`. When `ICollection<Enrollment>` is used, EF Core creates a `HashSet<Enrollment>` collection by default.

The Enrollment entity



Create *Models/Enrollment.cs* with the following code:

```
namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

The `EnrollmentID` property is the primary key; this entity uses the `classnameID` pattern instead of `ID` by itself. For a production data model, choose one pattern and use it consistently. This tutorial uses both just to illustrate that both work. Using `ID` without `classname` makes it easier to implement some kinds of data model changes.

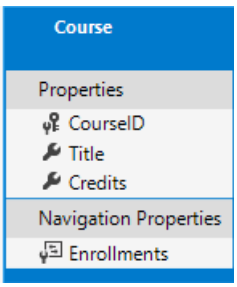
The `Grade` property is an `enum`. The question mark after the `Grade` type declaration indicates that the `Grade` property is nullable. A grade that's null is different from a zero grade—null means a grade isn't known or hasn't been assigned yet.

The `StudentID` property is a foreign key, and the corresponding navigation property is `Student`. An `Enrollment` entity is associated with one `Student` entity, so the property contains a single `Student` entity.

The `CourseID` property is a foreign key, and the corresponding navigation property is `Course`. An `Enrollment` entity is associated with one `Course` entity.

EF Core interprets a property as a foreign key if it's named `<navigation property name><primary key property name>`. For example, `StudentID` is the foreign key for the `Student` navigation property, since the `Student` entity's primary key is `ID`. Foreign key properties can also be named `<primary key property name>`. For example, `CourseID` since the `Course` entity's primary key is `CourseID`.

The Course entity



Create *Models/Course.cs* with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        public int CourseID { get; set; }
        public string Title { get; set; }
        public int Credits { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `Enrollments` property is a navigation property. A `Course` entity can be related to any number of `Enrollment` entities.

The `DatabaseGenerated` attribute allows the app to specify the primary key rather than having the database generate it.

Build the project to validate that there are no compiler errors.

Scaffold Student pages

In this section, you use the ASP.NET Core scaffolding tool to generate:

- An EF Core *context* class. The context is the main class that coordinates Entity Framework functionality for a given data model. It derives from the `Microsoft.EntityFrameworkCore.DbContext` class.
- Razor pages that handle Create, Read, Update, and Delete (CRUD) operations for the `Student` entity.

- Visual Studio
- Visual Studio Code

- Create a *Students* folder in the *Pages* folder.
- In **Solution Explorer**, right-click the *Pages/Students* folder and select **Add** > **New Scaffolded Item**.
- In the **Add Scaffold** dialog, select **Razor Pages using Entity Framework (CRUD)** > **ADD**.
- In the **Add Razor Pages using Entity Framework (CRUD)** dialog:
  - In the **Model class** drop-down, select **Student (ContosoUniversity.Models)**.
  - In the **Data context class** row, select the **+** (plus) sign.
  - Change the data context name from *ContosoUniversity.Models.ContosoUniversityContext* to *ContosoUniversity.Data.SchoolContext*.
  - Select **Add**.

The following packages are automatically installed:

- `Microsoft.VisualStudio.Web.CodeGeneration.Design`
- `Microsoft.EntityFrameworkCore.SqlServer`
- `Microsoft.Extensions.Logging.Debug`
- `Microsoft.EntityFrameworkCore.Tools`

If you have a problem with the preceding step, build the project and retry the scaffold step.

The scaffolding process:

- Creates Razor pages in the *Pages/Students* folder:
  - *Create.cshtml* and *Create.cshtml.cs*
  - *Delete.cshtml* and *Delete.cshtml.cs*
  - *Details.cshtml* and *Details.cshtml.cs*
  - *Edit.cshtml* and *Edit.cshtml.cs*
  - *Index.cshtml* and *Index.cshtml.cs*
- Creates *Data/SchoolContext.cs*.
- Adds the context to dependency injection in *Startup.cs*.
- Adds a database connection string to *appsettings.json*.

Database connection string

- Visual Studio
- Visual Studio Code

The connection string specifies SQL Server LocalDB.

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "SchoolContext": "Server=
(localdb)\\mssqllocaldb;Database=SchoolContext6;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

LocalDB is a lightweight version of the SQL Server Express Database Engine and is intended for app development, not production use. By default, LocalDB creates *.mdf* files in the `C:/Users/<user>` directory.

Update the database context class

The main class that coordinates EF Core functionality for a given data model is the database context class. The context is derived from Microsoft.EntityFrameworkCore.DbContext. The context specifies which entities are included in the data model. In this project, the class is named `SchoolContext`.

Update *SchoolContext.cs* with the following code:

```
using Microsoft.EntityFrameworkCore;
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext (DbContextOptions<SchoolContext> options)
            : base(options)
        {
        }

        public DbSet<Student> Students { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Course> Courses { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
        }
    }
}
```

The highlighted code creates a DbSet<TEntity> property for each entity set. In EF Core terminology:

- An entity set typically corresponds to a database table.
- An entity corresponds to a row in the table.

Since an entity set contains multiple entities, the DBSet properties should be plural names. Since the scaffolding tool created a `Student` DBSet, this step changes it to plural `Students`.

To make the Razor Pages code match the new DBSet name, make a global change across the whole project of `_context.Student` to `_context.Students`. There are 8 occurrences.

Build the project to verify there are no compiler errors.

Startup.cs

ASP.NET Core is built with dependency injection. Services (such as the EF Core database context) are registered with dependency injection during application startup. Components that require these services (such as Razor Pages) are provided these services via constructor parameters. The constructor code that gets a database context instance is shown later in the tutorial.

The scaffolding tool automatically registered the context class with the dependency injection container.

- Visual Studio
- Visual Studio Code

- In `ConfigureServices`, the highlighted lines were added by the scaffolder:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();

    services.AddDbContext<SchoolContext>(options =>
            options.UseSqlServer(Configuration.GetConnectionString("SchoolContext")));
}
```

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Create the database

Update *Program.cs* to create the database if it doesn't exist:

```
using ContosoUniversity.Data;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
using System;

namespace ContosoUniversity
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateHostBuilder(args).Build();

            CreateDbIfNotExists(host);

            host.Run();
        }

        private static void CreateDbIfNotExists(IHost host)
        {
            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    var context = services.GetRequiredService<SchoolContext>();
                    context.Database.EnsureCreated();
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred creating the DB.");
                }
            }
        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureWebHostDefaults(webBuilder =>
                {
                    webBuilder.UseStartup<Startup>();
                });
    }
}
```

The EnsureCreated method takes no action if a database for the context exists. If no database exists, it creates the database and schema. `EnsureCreated` enables the following workflow for handling data model changes:

- Delete the database. Any existing data is lost.
- Change the data model. For example, add an `EmailAddress` field.
- Run the app.

- `EnsureCreated` creates a database with the new schema.

This workflow works well early in development when the schema is rapidly evolving, as long as you don't need to preserve data. The situation is different when data that has been entered into the database needs to be preserved. When that is the case, use migrations.

Later in the tutorial series, you delete the database that was created by `EnsureCreated` and use migrations instead. A database that is created by `EnsureCreated` can't be updated by using migrations.

Test the app

- Run the app.
- Select the **Students** link and then **Create New**.
- Test the Edit, Details, and Delete links.

Seed the database

The `EnsureCreated` method creates an empty database. This section adds code that populates the database with test data.

Create *Data/DbInitializer.cs* with the following code:

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using System;
using System.Linq;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            context.Database.EnsureCreated();

            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
                new
Student{FirstMidName="Carson",LastName="Alexander",EnrollmentDate=DateTime.Parse("2019-09-01")},
                new
Student{FirstMidName="Meredith",LastName="Alonso",EnrollmentDate=DateTime.Parse("2017-09-01")},
                new Student{FirstMidName="Arturo",LastName="Anand",EnrollmentDate=DateTime.Parse("2018-
09-01")},
                new
Student{FirstMidName="Gytis",LastName="Barzdukas",EnrollmentDate=DateTime.Parse("2017-09-01")},
                new Student{FirstMidName="Yan",LastName="Li",EnrollmentDate=DateTime.Parse("2017-09-
01")},
                new
Student{FirstMidName="Peggy",LastName="Justice",EnrollmentDate=DateTime.Parse("2016-09-01")},
                new Student{FirstMidName="Laura",LastName="Norman",EnrollmentDate=DateTime.Parse("2018-
09-01")},
                new
Student{FirstMidName="Nino",LastName="Olivetto",EnrollmentDate=DateTime.Parse("2019-09-01")}
            };

            context.Students.AddRange(students);
            context.SaveChanges();

            var courses = new Course[]
```

```
            var courses = new Course[]
            {
                new Course{CourseID=1050,Title="Chemistry",Credits=3},
                new Course{CourseID=4022,Title="Microeconomics",Credits=3},
                new Course{CourseID=4041,Title="Macroeconomics",Credits=3},
                new Course{CourseID=1045,Title="Calculus",Credits=4},
                new Course{CourseID=3141,Title="Trigonometry",Credits=4},
                new Course{CourseID=2021,Title="Composition",Credits=3},
                new Course{CourseID=2042,Title="Literature",Credits=4}
            };

            context.Courses.AddRange(courses);
            context.SaveChanges();

            var enrollments = new Enrollment[]
            {
                new Enrollment{StudentID=1,CourseID=1050,Grade=Grade.A},
                new Enrollment{StudentID=1,CourseID=4022,Grade=Grade.C},
                new Enrollment{StudentID=1,CourseID=4041,Grade=Grade.B},
                new Enrollment{StudentID=2,CourseID=1045,Grade=Grade.B},
                new Enrollment{StudentID=2,CourseID=3141,Grade=Grade.F},
                new Enrollment{StudentID=2,CourseID=2021,Grade=Grade.F},
                new Enrollment{StudentID=3,CourseID=1050},
                new Enrollment{StudentID=4,CourseID=1050},
                new Enrollment{StudentID=4,CourseID=4022,Grade=Grade.F},
                new Enrollment{StudentID=5,CourseID=4041,Grade=Grade.C},
                new Enrollment{StudentID=6,CourseID=1045},
                new Enrollment{StudentID=7,CourseID=3141,Grade=Grade.A},
            };

            context.Enrollments.AddRange(enrollments);
            context.SaveChanges();
        }
    }
}
```

The code checks if there are any students in the database. If there are no students, it adds test data to the database. It creates the test data in arrays rather than `List<T>` collections to optimize performance.

- In *Program.cs*, replace the `EnsureCreated` call with a `DbInitializer.Initialize` call:

  ```
  // context.Database.EnsureCreated();
  DbInitializer.Initialize(context);
  ```

- Visual Studio
- Visual Studio Code

Stop the app if it's running, and run the following command in the **Package Manager Console** (PMC):

```
Drop-Database
```

- Restart the app.
- Select the Students page to see the seeded data.

View the database

- Visual Studio
- Visual Studio Code

- Open **SQL Server Object Explorer** (SSOX) from the **View** menu in Visual Studio.

- In SSOX, select **(localdb)\MSSQLLocalDB > Databases > SchoolContext-{GUID}**. The database name is generated from the context name you provided earlier plus a dash and a GUID.
- Expand the **Tables** node.
- Right-click the **Student** table and click **View Data** to see the columns created and the rows inserted into the table.
- Right-click the **Student** table and click **View Code** to see how the `Student` model maps to the `Student` table schema.

Asynchronous code

Asynchronous programming is the default mode for ASP.NET Core and EF Core.

A web server has a limited number of threads available, and in high load situations all of the available threads might be in use. When that happens, the server can't process new requests until the threads are freed up. With synchronous code, many threads may be tied up while they aren't actually doing any work because they're waiting for I/O to complete. With asynchronous code, when a process is waiting for I/O to complete, its thread is freed up for the server to use for processing other requests. As a result, asynchronous code enables server resources to be used more efficiently, and the server can handle more traffic without delays.

Asynchronous code does introduce a small amount of overhead at run time. For low traffic situations, the performance hit is negligible, while for high traffic situations, the potential performance improvement is substantial.

In the following code, the async keyword, `Task<T>` return value, `await` keyword, and `ToListAsync` method make the code execute asynchronously.

```
public async Task OnGetAsync()
{
    Students = await _context.Students.ToListAsync();
}
```

- The `async` keyword tells the compiler to:
  - Generate callbacks for parts of the method body.
  - Create the Task object that's returned.
- The `Task<T>` return type represents ongoing work.
- The `await` keyword causes the compiler to split the method into two parts. The first part ends with the operation that's started asynchronously. The second part is put into a callback method that's called when the operation completes.
- `ToListAsync` is the asynchronous version of the `ToList` extension method.

Some things to be aware of when writing asynchronous code that uses EF Core:

- Only statements that cause queries or commands to be sent to the database are executed asynchronously. That includes `ToListAsync`, `SingleOrDefaultAsync`, `FirstOrDefaultAsync`, and `SaveChangesAsync`. It doesn't include statements that just change an `IQueryable`, such as `var students = context.Students.Where(s => s.LastName == "Davolio")`.
- An EF Core context isn't thread safe: don't try to do multiple operations in parallel.
- To take advantage of the performance benefits of async code, verify that library packages (such as for paging) use async if they call EF Core methods that send queries to the database.

For more information about asynchronous programming in .NET, see Async Overview and Asynchronous programming with async and await.

Next steps

NEXT TUTORIAL

The Contoso University sample web app demonstrates how to create an ASP.NET Core Razor Pages app using Entity Framework (EF) Core.

The sample app is a web site for a fictional Contoso University. It includes functionality such as student admission, course creation, and instructor assignments. This page is the first in a series of tutorials that explain how to build the Contoso University sample app.

Download or view the completed app. Download instructions.

Prerequisites

- Visual Studio
- Visual Studio Code

Visual Studio 2019 with the following workloads:

- **ASP.NET and web development**
- **.NET Core cross-platform development**

.NET Core 2.1 SDK or later

Familiarity with Razor Pages. New programmers should complete Get started with Razor Pages before starting this series.

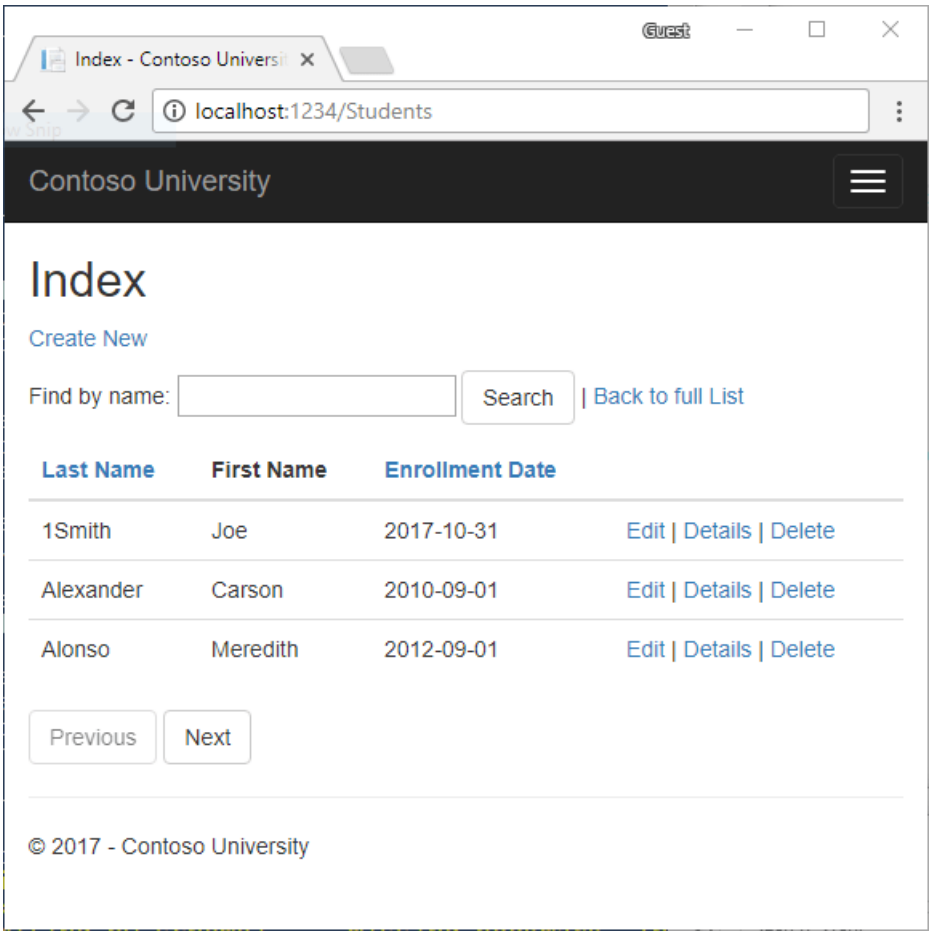
Troubleshooting

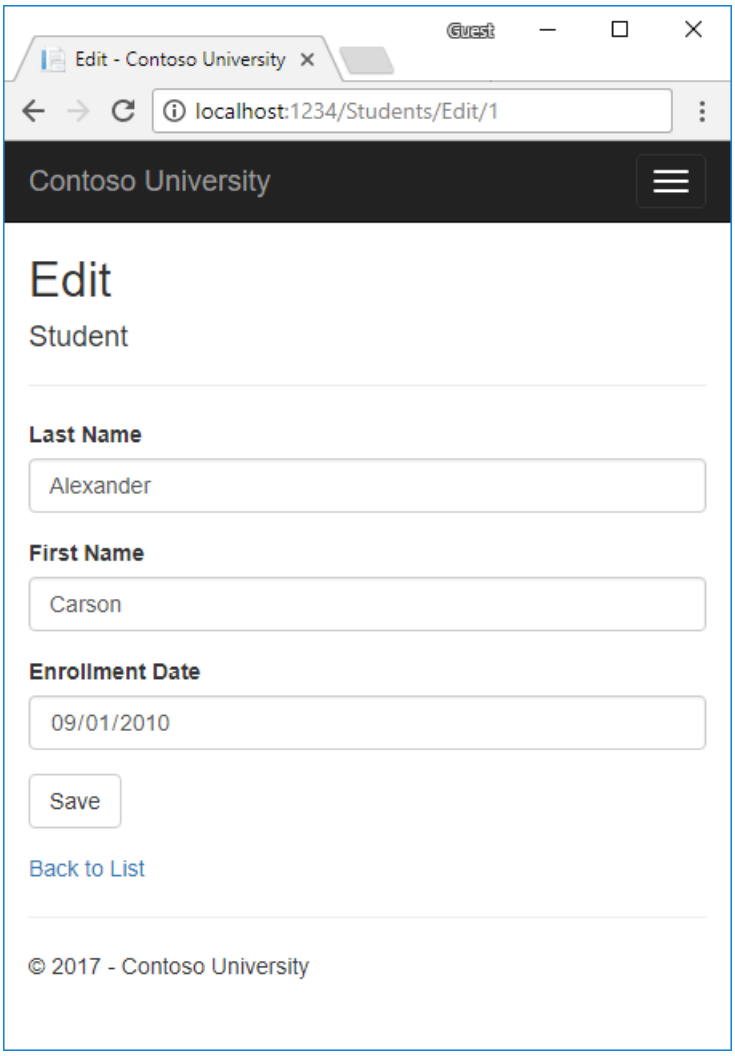
If you run into a problem you can't resolve, you can generally find the solution by comparing your code to the completed project. A good way to get help is by posting a question to StackOverflow.com for ASP.NET Core or EF Core.

The Contoso University web app

The app built in these tutorials is a basic university web site.

Users can view and update student, course, and instructor information. Here are a few of the screens created in the tutorial.





The UI style of this site is close to what's generated by the built-in templates. The tutorial focus is on EF Core

with Razor Pages, not the UI.

Create the ContosoUniversity Razor Pages web app

- Visual Studio
- Visual Studio Code

- From the Visual Studio **File** menu, select **New** > **Project**.
- Create a new ASP.NET Core Web Application. Name the project **ContosoUniversity**. It's important to name the project *ContosoUniversity* so the namespaces match when code is copy/pasted.
- Select **ASP.NET Core 2.1** in the dropdown, and then select **Web Application**.

For images of the preceding steps, see Create a Razor web app. Run the app.

Set up the site style

A few changes set up the site menu, layout, and home page. Update *Pages/Shared/_Layout.cshtml* with the following changes:

- Change each occurrence of "ContosoUniversity" to "Contoso University". There are three occurrences.
- Add menu entries for **Students**, **Courses**, **Instructors**, and **Departments**, and delete the **Contact** menu entry.

The changes are highlighted. (All the markup is *not* displayed.)

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] : Contoso University</title>

    <environment include="Development">
        <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
        <link rel="stylesheet" href="~/css/site.css" />
    </environment>
    <environment exclude="Development">
        <link rel="stylesheet"
href="https://ajax.aspnetcdn.com/ajax/bootstrap/3.3.7/css/bootstrap.min.css"
              asp-fallback-href="~/lib/bootstrap/dist/css/bootstrap.min.css"
              asp-fallback-test-class="sr-only" asp-fallback-test-property="position" asp-fallback-
test-value="absolute" />
        <link rel="stylesheet" href="~/css/site.min.css" asp-append-version="true" />
    </environment>
</head>
<body>
    <nav class="navbar navbar-inverse navbar-fixed-top">
        <div class="container">
            <div class="navbar-header">
                <button type="button" class="navbar-toggle" data-toggle="collapse" data-
target=".navbar-collapse">
                    <span class="sr-only">Toggle navigation</span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                </button>
                <a asp-page="/Index" class="navbar-brand">Contoso University</a>
            </div>
            <div class="navbar-collapse collapse">
                <ul class="nav navbar-nav">
                    <li><a asp-page="/Index">Home</a></li>
                    <li><a asp-page="/About">About</a></li>
                    <li><a asp-page="/Students/Index">Students</a></li>
                    <li><a asp-page="/Courses/Index">Courses</a></li>
                    <li><a asp-page="/Instructors/Index">Instructors</a></li>
                    <li><a asp-page="/Departments/Index">Departments</a></li>
                </ul>
            </div>
        </div>
    </nav>

    <partial name="_CookieConsentPartial" />

    <div class="container body-content">
        @RenderBody()
        <hr />
        <footer>
            <p>&copy; 2018 : Contoso University</p>
        </footer>
    </div>

    @*Remaining markup not shown for brevity.*@
```

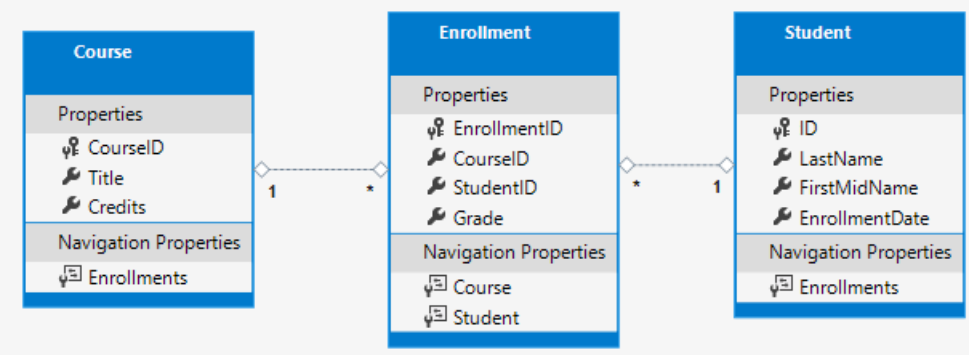
In *Pages/Index.cshtml*, replace the contents of the file with the following code to replace the text about ASP.NET and MVC with text about this app:

```
@page
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

<div class="jumbotron">
    <h1>Contoso University</h1>
</div>
<div class="row">
    <div class="col-md-4">
        <h2>Welcome to Contoso University</h2>
        <p>
            Contoso University is a sample application that
            demonstrates how to use Entity Framework Core in an
            ASP.NET Core Razor Pages web app.
        </p>
    </div>
    <div class="col-md-4">
        <h2>Build it from scratch</h2>
        <p>You can build the application by following the steps in a series of tutorials.</p>
        <p>
            <a class="btn btn-default"
               href="https://docs.microsoft.com/aspnet/core/data/ef-rp/intro">
                See the tutorial &raquo;
            </a>
        </p>
    </div>
    <div class="col-md-4">
        <h2>Download it</h2>
        <p>You can download the completed project from GitHub.</p>
        <p>
            <a class="btn btn-default"
               href="https://github.com/dotnet/AspNetCore.Docs/tree/master/aspnetcore/data/ef-
rp/intro/samples/">
                See project source code &raquo;
            </a>
        </p>
    </div>
</div>
```

Create the data model

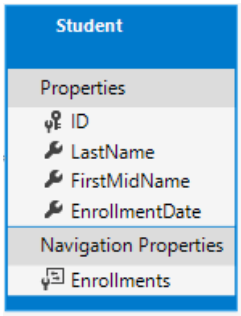
Create entity classes for the Contoso University app. Start with the following three entities:



There's a one-to-many relationship between `Student` and `Enrollment` entities. There's a one-to-many relationship between `Course` and `Enrollment` entities. A student can enroll in any number of courses. A course can have any number of students enrolled in it.

In the following sections, a class for each one of these entities is created.

The Student entity



Create a *Models* folder. In the *Models* folder, create a class file named *Student.cs* with the following code:

```
using System;
using System.Collections.Generic;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }

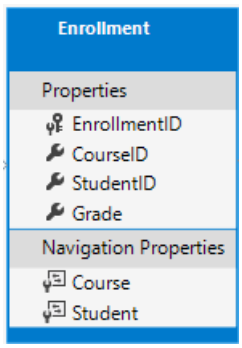
        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `ID` property becomes the primary key column of the database (DB) table that corresponds to this class. By default, EF Core interprets a property that's named `ID` or `classnameID` as the primary key. In `classnameID`, `classname` is the name of the class. The alternative automatically recognized primary key is `StudentID` in the preceding example.

The `Enrollments` property is a navigation property. Navigation properties link to other entities that are related to this entity. In this case, the `Enrollments` property of a `Student entity` holds all of the `Enrollment` entities that are related to that `Student`. For example, if a Student row in the DB has two related Enrollment rows, the `Enrollments` navigation property contains those two `Enrollment` entities. A related `Enrollment` row is a row that contains that student's primary key value in the `StudentID` column. For example, suppose the student with ID=1 has two rows in the `Enrollment` table. The `Enrollment` table has two rows with `StudentID` = 1. `StudentID` is a foreign key in the `Enrollment` table that specifies the student in the `Student` table.

If a navigation property can hold multiple entities, the navigation property must be a list type, such as `ICollection<T>`. `ICollection<T>` can be specified, or a type such as `List<T>` or `HashSet<T>`. When `ICollection<T>` is used, EF Core creates a `HashSet<T>` collection by default. Navigation properties that hold multiple entities come from many-to-many and one-to-many relationships.

The Enrollment entity



In the *Models* folder, create *Enrollment.cs* with the following code:

```
namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

The `EnrollmentID` property is the primary key. This entity uses the `classnameID` pattern instead of `ID` like the `Student` entity. Typically developers choose one pattern and use it throughout the data model. In a later tutorial, using ID without classname is shown to make it easier to implement inheritance in the data model.

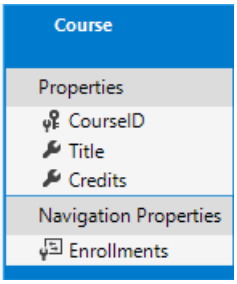
The `Grade` property is an `enum`. The question mark after the `Grade` type declaration indicates that the `Grade` property is nullable. A grade that's null is different from a zero grade -- null means a grade isn't known or hasn't been assigned yet.

The `StudentID` property is a foreign key, and the corresponding navigation property is `Student`. An `Enrollment` entity is associated with one `Student` entity, so the property contains a single `Student` entity. The `Student` entity differs from the `Student.Enrollments` navigation property, which contains multiple `Enrollment` entities.

The `CourseID` property is a foreign key, and the corresponding navigation property is `Course`. An `Enrollment` entity is associated with one `Course` entity.

EF Core interprets a property as a foreign key if it's named `<navigation property name><primary key property name>`. For example, `StudentID` for the `Student` navigation property, since the `Student` entity's primary key is `ID`. Foreign key properties can also be named `<primary key property name>`. For example, `CourseID` since the `Course` entity's primary key is `CourseID`.

The Course entity



In the *Models* folder, create *Course.cs* with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        public int CourseID { get; set; }
        public string Title { get; set; }
        public int Credits { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `Enrollments` property is a navigation property. A `Course` entity can be related to any number of `Enrollment` entities.

The `DatabaseGenerated` attribute allows the app to specify the primary key rather than having the DB generate it.

Scaffold the student model

In this section, the student model is scaffolded. That is, the scaffolding tool produces pages for Create, Read, Update, and Delete (CRUD) operations for the student model.

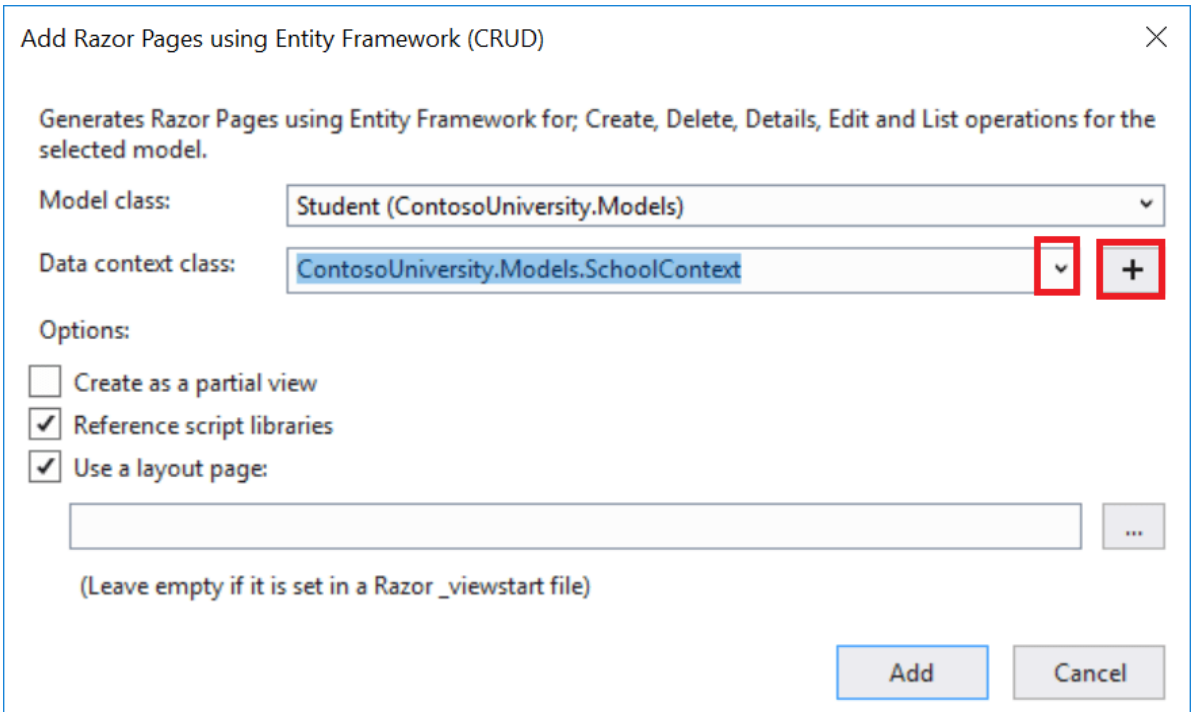
- Build the project.
- Create the *Pages/Students* folder.

- Visual Studio
- Visual Studio Code

- In **Solution Explorer**, right click on the *Pages/Students* folder > **Add** > **New Scaffolded Item**.
- In the **Add Scaffold** dialog, select **Razor Pages using Entity Framework (CRUD)** > **ADD**.

Complete the **Add Razor Pages using Entity Framework (CRUD)** dialog:

- In the **Model class** drop-down, select **Student (ContosoUniversity.Models)**.
- In the **Data context class** row, select the **+** (plus) sign and change the generated name to **ContosoUniversity.Models.SchoolContext**.
- In the **Data context class** drop-down, select **ContosoUniversity.Models.SchoolContext**
- Select **Add**.



See Scaffold the movie model if you have a problem with the preceding step.

The scaffold process created and changed the following files:

Files created

- *Pages/Students* Create, Delete, Details, Edit, Index.
- *Data/SchoolContext.cs*

File updates

- *Startup.cs* : Changes to this file are detailed in the next section.
- *appsettings.json* : The connection string used to connect to a local database is added.

Examine the context registered with dependency injection

ASP.NET Core is built with dependency injection. Services (such as the EF Core DB context) are registered with dependency injection during application startup. Components that require these services (such as Razor Pages) are provided these services via constructor parameters. The constructor code that gets a db context instance is shown later in the tutorial.

The scaffolding tool automatically created a DB Context and registered it with the dependency injection container.

Examine the `ConfigureServices` method in *Startup.cs*. The highlighted line was added by the scaffolder:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        // This lambda determines whether user consent for
        //non -essential cookies is needed for a given request.
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);

    services.AddDbContext<SchoolContext>(options =>
       options.UseSqlServer(Configuration.GetConnectionString("SchoolContext")));
}
```

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Update main

In *Program.cs*, modify the `Main` method to do the following:

- Get a DB context instance from the dependency injection container.
- Call the EnsureCreated.
- Dispose the context when the `EnsureCreated` method completes.

The following code shows the updated *Program.cs* file.

```
using ContosoUniversity.Models;                  // SchoolContext
using Microsoft.AspNetCore;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;   // CreateScope
using Microsoft.Extensions.Logging;
using System;

namespace ContosoUniversity
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateWebHostBuilder(args).Build();

            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    var context = services.GetRequiredService<SchoolContext>();
                    context.Database.EnsureCreated();
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred creating the DB.");
                }
            }

            host.Run();
        }

        public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>();
    }
}
```

`EnsureCreated` ensures that the database for the context exists. If it exists, no action is taken. If it does not exist, then the database and all its schema are created. `EnsureCreated` does not use migrations to create the database. A database that is created with `EnsureCreated` cannot be later updated using migrations.

`EnsureCreated` is called on app start, which allows the following work flow:

- Delete the DB.
- Change the DB schema (for example, add an `EmailAddress` field).
- Run the app.
- `EnsureCreated` creates a DB with the `EmailAddress` column.

`EnsureCreated` is convenient early in development when the schema is rapidly evolving. Later in the tutorial the DB is deleted and migrations are used.

Test the app

Run the app and accept the cookie policy. This app doesn't keep personal information. You can read about the cookie policy at EU General Data Protection Regulation (GDPR) support.

- Select the **Students** link and then **Create New**.
- Test the Edit, Details, and Delete links.

Examine the SchoolContext DB context

The main class that coordinates EF Core functionality for a given data model is the DB context class. The data context is derived from Microsoft.EntityFrameworkCore.DbContext. The data context specifies which entities are included in the data model. In this project, the class is named `SchoolContext`.

Update *SchoolContext.cs* with the following code:

```
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Models
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options)
            : base(options)
        {
        }

        public DbSet<Student> Student { get; set; }
        public DbSet<Enrollment> Enrollment { get; set; }
        public DbSet<Course> Course { get; set; }
    }
}
```

The highlighted code creates a DbSet<TEntity> property for each entity set. In EF Core terminology:

- An entity set typically corresponds to a DB table.
- An entity corresponds to a row in the table.

`DbSet<Enrollment>` and `DbSet<Course>` could be omitted. EF Core includes them implicitly because the `Student` entity references the `Enrollment` entity, and the `Enrollment` entity references the `Course` entity. For this tutorial, keep `DbSet<Enrollment>` and `DbSet<Course>` in the `SchoolContext`.

SQL Server Express LocalDB

The connection string specifies SQL Server LocalDB. LocalDB is a lightweight version of the SQL Server Express Database Engine and is intended for app development, not production use. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB creates *.mdf* DB files in the `C:/Users/<user>` directory.

Add code to initialize the DB with test data

EF Core creates an empty DB. In this section, an `Initialize` method is written to populate it with test data.

In the *Data* folder, create a new class file named *DbInitializer.cs* and add the following code:

```
using ContosoUniversity.Models;
using System;
using System.Linq;

namespace ContosoUniversity.Models
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            context.Database.EnsureCreated();

            // Look for any students.
            if (context.Student.Any())
            {
```

```
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
            new Student{FirstMidName="Carson",LastName="Alexander",EnrollmentDate=DateTime.Parse("2005-
09-01")},
            new Student{FirstMidName="Meredith",LastName="Alonso",EnrollmentDate=DateTime.Parse("2002-
09-01")},
            new Student{FirstMidName="Arturo",LastName="Anand",EnrollmentDate=DateTime.Parse("2003-09-
01")},
            new Student{FirstMidName="Gytis",LastName="Barzdukas",EnrollmentDate=DateTime.Parse("2002-
09-01")},
            new Student{FirstMidName="Yan",LastName="Li",EnrollmentDate=DateTime.Parse("2002-09-01")},
            new Student{FirstMidName="Peggy",LastName="Justice",EnrollmentDate=DateTime.Parse("2001-09-
01")},
            new Student{FirstMidName="Laura",LastName="Norman",EnrollmentDate=DateTime.Parse("2003-09-
01")},
            new Student{FirstMidName="Nino",LastName="Olivetto",EnrollmentDate=DateTime.Parse("2005-09-
01")}
            };
            foreach (Student s in students)
            {
                context.Student.Add(s);
            }
            context.SaveChanges();

            var courses = new Course[]
            {
            new Course{CourseID=1050,Title="Chemistry",Credits=3},
            new Course{CourseID=4022,Title="Microeconomics",Credits=3},
            new Course{CourseID=4041,Title="Macroeconomics",Credits=3},
            new Course{CourseID=1045,Title="Calculus",Credits=4},
            new Course{CourseID=3141,Title="Trigonometry",Credits=4},
            new Course{CourseID=2021,Title="Composition",Credits=3},
            new Course{CourseID=2042,Title="Literature",Credits=4}
            };
            foreach (Course c in courses)
            {
                context.Course.Add(c);
            }
            context.SaveChanges();

            var enrollments = new Enrollment[]
            {
            new Enrollment{StudentID=1,CourseID=1050,Grade=Grade.A},
            new Enrollment{StudentID=1,CourseID=4022,Grade=Grade.C},
            new Enrollment{StudentID=1,CourseID=4041,Grade=Grade.B},
            new Enrollment{StudentID=2,CourseID=1045,Grade=Grade.B},
            new Enrollment{StudentID=2,CourseID=3141,Grade=Grade.F},
            new Enrollment{StudentID=2,CourseID=2021,Grade=Grade.F},
            new Enrollment{StudentID=3,CourseID=1050},
            new Enrollment{StudentID=4,CourseID=1050},
            new Enrollment{StudentID=4,CourseID=4022,Grade=Grade.F},
            new Enrollment{StudentID=5,CourseID=4041,Grade=Grade.C},
            new Enrollment{StudentID=6,CourseID=1045},
            new Enrollment{StudentID=7,CourseID=3141,Grade=Grade.A},
            };
            foreach (Enrollment e in enrollments)
            {
                context.Enrollment.Add(e);
            }
            context.SaveChanges();
        }
    }
}
```

Note: The preceding code uses `Models` for the namespace (`namespace ContosoUniversity.Models`) rather than `Data` . `Models` is consistent with the scaffolder-generated code. For more information, see this GitHub scaffolding issue.

The code checks if there are any students in the DB. If there are no students in the DB, the DB is initialized with test data. It loads test data into arrays rather than `List<T>` collections to optimize performance.

The `EnsureCreated` method automatically creates the DB for the DB context. If the DB exists, `EnsureCreated` returns without modifying the DB.

In *Program.cs*, modify the `Main` method to call `Initialize` :

```
public class Program
{
    public static void Main(string[] args)
    {
        var host = CreateWebHostBuilder(args).Build();

        using (var scope = host.Services.CreateScope())
        {
            var services = scope.ServiceProvider;

            try
            {
                var context = services.GetRequiredService<SchoolContext>();
                // using ContosoUniversity.Data;
                DbInitializer.Initialize(context);
            }
            catch (Exception ex)
            {
                var logger = services.GetRequiredService<ILogger<Program>>();
                logger.LogError(ex, "An error occurred creating the DB.");
            }
        }

        host.Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

- Visual Studio
- Visual Studio Code

Stop the app if it's running, and run the following command in the **Package Manager Console** (PMC):

```
Drop-Database
```

View the DB

The database name is generated from the context name you provided earlier plus a dash and a GUID. Thus, the database name will be "SchoolContext-{GUID}". The GUID will be different for each user. Open **SQL Server Object Explorer** (SSOX) from the **View** menu in Visual Studio. In SSOX, click **(localdb)\MSSQLLocalDB > Databases > SchoolContext-{GUID}**.

Expand the **Tables** node.

Right-click the **Student** table and click **View Data** to see the columns created and the rows inserted into

the table.

Asynchronous code

Asynchronous programming is the default mode for ASP.NET Core and EF Core.

A web server has a limited number of threads available, and in high load situations all of the available threads might be in use. When that happens, the server can't process new requests until the threads are freed up. With synchronous code, many threads may be tied up while they aren't actually doing any work because they're waiting for I/O to complete. With asynchronous code, when a process is waiting for I/O to complete, its thread is freed up for the server to use for processing other requests. As a result, asynchronous code enables server resources to be used more efficiently, and the server is enabled to handle more traffic without delays.

Asynchronous code does introduce a small amount of overhead at run time. For low traffic situations, the performance hit is negligible, while for high traffic situations, the potential performance improvement is substantial.

In the following code, the async keyword, `Task<T>` return value, `await` keyword, and `ToListAsync` method make the code execute asynchronously.

```
public async Task OnGetAsync()
{
    Student = await _context.Student.ToListAsync();
}
```

- The `async` keyword tells the compiler to:
  - Generate callbacks for parts of the method body.
  - Automatically create the Task object that's returned. For more information, see Task Return Type.
- The implicit return type `Task` represents ongoing work.
- The `await` keyword causes the compiler to split the method into two parts. The first part ends with the operation that's started asynchronously. The second part is put into a callback method that's called when the operation completes.
- `ToListAsync` is the asynchronous version of the `ToList` extension method.

Some things to be aware of when writing asynchronous code that uses EF Core:

- Only statements that cause queries or commands to be sent to the DB are executed asynchronously. That includes, `ToListAsync`, `SingleOrDefaultAsync`, `FirstOrDefaultAsync`, and `SaveChangesAsync`. It doesn't include statements that just change an `IQueryable`, such as `var students = context.Students.Where(s => s.LastName == "Davolio")`.
- An EF Core context isn't thread safe: don't try to do multiple operations in parallel.
- To take advantage of the performance benefits of async code, verify that library packages (such as for paging) use async if they call EF Core methods that send queries to the DB.

For more information about asynchronous programming in .NET, see Async Overview and Asynchronous programming with async and await.

In the next tutorial, basic CRUD (create, read, update, delete) operations are examined.

Part 2, Razor Pages with EF Core in ASP.NET Core - CRUD

9/22/2020 • 22 minutes to read • Edit Online

By Tom Dykstra, Jon P Smith, and Rick Anderson

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

In this tutorial, the scaffolded CRUD (create, read, update, delete) code is reviewed and customized.

No repository

Some developers use a service layer or repository pattern to create an abstraction layer between the UI (Razor Pages) and the data access layer. This tutorial doesn't do that. To minimize complexity and keep the tutorial focused on EF Core, EF Core code is added directly to the page model classes.

Update the Details page

The scaffolded code for the Students pages doesn't include enrollment data. In this section, you add enrollments to the Details page.

Read enrollments

To display a student's enrollment data on the page, you need to read it. The scaffolded code in *Pages/Students/Details.cshtml.cs* reads only the Student data, without the Enrollment data:

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    Student = await _context.Students.FirstOrDefaultAsync(m => m.ID == id);

    if (Student == null)
    {
        return NotFound();
    }
    return Page();
}
```

Replace the `OnGetAsync` method with the following code to read enrollment data for the selected student. The changes are highlighted.

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    Student = await _context.Students
        .Include(s => s.Enrollments)
        .ThenInclude(e => e.Course)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);

    if (Student == null)
    {
        return NotFound();
    }
    return Page();
}
```

The Include and ThenInclude methods cause the context to load the `Student.Enrollments` navigation property, and within each enrollment the `Enrollment.Course` navigation property. These methods are examined in detail in the Reading related data tutorial.

The AsNoTracking method improves performance in scenarios where the entities returned are not updated in the current context. `AsNoTracking` is discussed later in this tutorial.

Display enrollments

Replace the code in *Pages/Students/Details.cshtml* with the following code to display a list of enrollments. The changes are highlighted.

```
@page
@model ContosoUniversity.Pages.Students.DetailsModel

@{
    ViewData["Title"] = "Details";
}

<h1>Details</h1>

<div>
    <h4>Student</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.LastName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.LastName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.FirstMidName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.FirstMidName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.EnrollmentDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.EnrollmentDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.Enrollments)
        </dt>
        <dd class="col-sm-10">
            <table class="table">
                <tr>
                    <th>Course Title</th>
                    <th>Grade</th>
                </tr>
                @foreach (var item in Model.Student.Enrollments)
                {
                    <tr>
                        <td>
                            @Html.DisplayFor(modelItem => item.Course.Title)
                        </td>
                        <td>
                            @Html.DisplayFor(modelItem => item.Grade)
                        </td>
                    </tr>
                }
            </table>
        </dd>
    </dl>
</div>
<div>
    <a asp-page="./Edit" asp-route-id="@Model.Student.ID">Edit</a> |
    <a asp-page="./Index">Back to List</a>
</div>
```

The preceding code loops through the entities in the `Enrollments` navigation property. For each enrollment, it displays the course title and the grade. The course title is retrieved from the Course entity that's stored in the `Course` navigation property of the Enrollments entity.

Run the app, select the **Students** tab, and click the **Details** link for a student. The list of courses and grades for

the selected student is displayed.

Ways to read one entity

The generated code uses FirstOrDefaultAsync to read one entity. This method returns null if nothing is found; otherwise, it returns the first row found that satisfies the query filter criteria. `FirstOrDefaultAsync` is generally a better choice than the following alternatives:

- SingleOrDefaultAsync - Throws an exception if there's more than one entity that satisfies the query filter. To determine if more than one row could be returned by the query, `SingleOrDefaultAsync` tries to fetch multiple rows. This extra work is unnecessary if the query can only return one entity, as when it searches on a unique key.
- FindAsync - Finds an entity with the primary key (PK). If an entity with the PK is being tracked by the context, it's returned without a request to the database. This method is optimized to look up a single entity, but you can't call `Include` with `FindAsync`. So if related data is needed, `FirstOrDefaultAsync` is the better choice.

Route data vs. query string

The URL for the Details page is `https://localhost:<port>/Students/Details?id=1`. The entity's primary key value is in the query string. Some developers prefer to pass the key value in route data: `https://localhost:<port>/Students/Details/1`. For more information, see Update the generated code.

Update the Create page

The scaffolded `OnPostAsync` code for the Create page is vulnerable to overposting. Replace the `OnPostAsync` method in *Pages/Students/Create.cshtml.cs* with the following code.

```
public async Task<IActionResult> OnPostAsync()
{
    var emptyStudent = new Student();

    if (await TryUpdateModelAsync<Student>(
        emptyStudent,
        "student",   // Prefix for form value.
        s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
    {
        _context.Students.Add(emptyStudent);
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }

    return Page();
}
```

TryUpdateModelAsync

The preceding code creates a Student object and then uses posted form fields to update the Student object's properties. The TryUpdateModelAsync method:

- Uses the posted form values from the PageContext property in the PageModel.
- Updates only the properties listed (`s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate`).
- Looks for form fields with a "student" prefix. For example, `Student.FirstMidName`. It's not case sensitive.
- Uses the model binding system to convert form values from strings to the types in the `Student` model. For example, `EnrollmentDate` has to be converted to DateTime.

Run the app, and create a student entity to test the Create page.

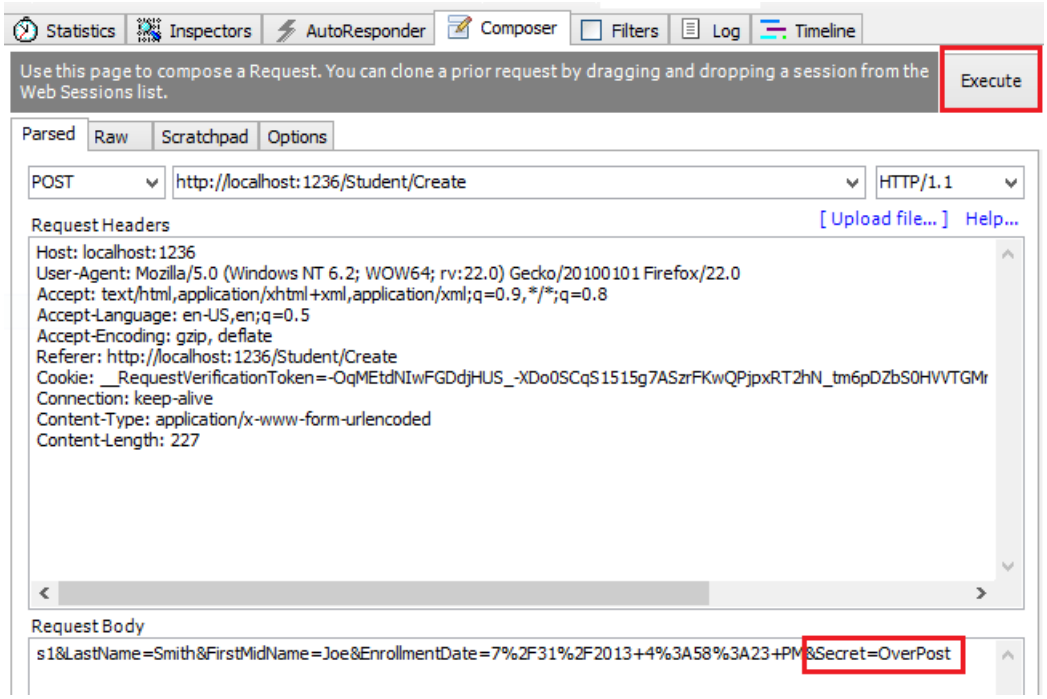
Overposting

Using `TryUpdateModel` to update fields with posted values is a security best practice because it prevents overposting. For example, suppose the Student entity includes a `Secret` property that this web page shouldn't update or add:

```
public class Student
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstMidName { get; set; }
    public DateTime EnrollmentDate { get; set; }
    public string Secret { get; set; }
}
```

Even if the app doesn't have a `Secret` field on the create or update Razor Page, a hacker could set the `Secret` value by overposting. A hacker could use a tool such as Fiddler, or write some JavaScript, to post a `Secret` form value. The original code doesn't limit the fields that the model binder uses when it creates a Student instance.

Whatever value the hacker specified for the `Secret` form field is updated in the database. The following image shows the Fiddler tool adding the `Secret` field (with the value "OverPost") to the posted form values.



The value "OverPost" is successfully added to the `Secret` property of the inserted row. That happens even though the app designer never intended the `Secret` property to be set with the Create page.

View model

View models provide an alternative way to prevent overposting.

The application model is often called the domain model. The domain model typically contains all the properties required by the corresponding entity in the database. The view model contains only the properties needed for the UI that it is used for (for example, the Create page).

In addition to the view model, some apps use a binding model or input model to pass data between the Razor Pages page model class and the browser.

Consider the following `Student` view model:

```
using System;

namespace ContosoUniversity.Models
{
    public class StudentVM
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }
    }
}
```

The following code uses the `StudentVM` view model to create a new student:

```
[BindProperty]
public StudentVM StudentVM { get; set; }

public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    var entry = _context.Add(new Student());
    entry.CurrentValues.SetValues(StudentVM);
    await _context.SaveChangesAsync();
    return RedirectToPage("./Index");
}
```

The SetValues method sets the values of this object by reading values from another PropertyValues object. `SetValues` uses property name matching. The view model type doesn't need to be related to the model type, it just needs to have properties that match.

Using `StudentVM` requires Create.cshtml be updated to use `StudentVM` rather than `Student`.

Update the Edit page

In *Pages/Students/Edit.cshtml.cs*, replace the `OnGetAsync` and `OnPostAsync` methods with the following code.

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    Student = await _context.Students.FindAsync(id);

    if (Student == null)
    {
        return NotFound();
    }
    return Page();
}

public async Task<IActionResult> OnPostAsync(int id)
{
    var studentToUpdate = await _context.Students.FindAsync(id);

    if (studentToUpdate == null)
    {
        return NotFound();
    }

    if (await TryUpdateModelAsync<Student>(
        studentToUpdate,
        "student",
        s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
    {
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }

    return Page();
}
```

The code changes are similar to the Create page with a few exceptions:

- `FirstOrDefaultAsync` has been replaced with FindAsync. When you don't have to include related data, `FindAsync` is more efficient.
- `OnPostAsync` has an `id` parameter.
- The current student is fetched from the database, rather than creating an empty student.

Run the app, and test it by creating and editing a student.

Entity States

The database context keeps track of whether entities in memory are in sync with their corresponding rows in the database. This tracking information determines what happens when SaveChangesAsync is called. For example, when a new entity is passed to the AddAsync method, that entity's state is set to Added. When `SaveChangesAsync` is called, the database context issues a SQL INSERT command.

An entity may be in one of the following states:

- `Added`: The entity doesn't yet exist in the database. The `SaveChanges` method issues an INSERT statement.
- `Unchanged`: No changes need to be saved with this entity. An entity has this status when it's read from the database.
- `Modified`: Some or all of the entity's property values have been modified. The `SaveChanges` method issues an UPDATE statement.

- `Deleted`: The entity has been marked for deletion. The `SaveChanges` method issues a DELETE statement.
- `Detached`: The entity isn't being tracked by the database context.

In a desktop app, state changes are typically set automatically. An entity is read, changes are made, and the entity state is automatically changed to `Modified`. Calling `SaveChanges` generates a SQL UPDATE statement that updates only the changed properties.

In a web app, the `DbContext` that reads an entity and displays the data is disposed after a page is rendered. When a page's `OnPostAsync` method is called, a new web request is made and with a new instance of the `DbContext`. Rereading the entity in that new context simulates desktop processing.

Update the Delete page

In this section, you implement a custom error message when the call to `SaveChanges` fails.

Replace the code in *Pages/Students/Delete.cshtml.cs* with the following code. The changes are highlighted (other than cleanup of `using` statements).

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Students
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Student Student { get; set; }
        public string ErrorMessage { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id, bool? saveChangesError = false)
        {
            if (id == null)
            {
                return NotFound();
            }

            Student = await _context.Students
                .AsNoTracking()
                .FirstOrDefaultAsync(m => m.ID == id);

            if (Student == null)
            {
                return NotFound();
            }

            if (saveChangesError.GetValueOrDefault())
            {
                ErrorMessage = "Delete failed. Try again";
            }

            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
```

```
        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            var student = await _context.Students.FindAsync(id);

            if (student == null)
            {
                return NotFound();
            }

            try
            {
                _context.Students.Remove(student);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }
            catch (DbUpdateException /* ex */)
            {
                //Log the error (uncomment ex variable name and write a log.)
                return RedirectToAction("./Delete",
                                        new { id, saveChangesError = true });
            }
        }
    }
}
```

The preceding code adds the optional parameter `saveChangesError` to the `OnGetAsync` method signature. `saveChangesError` indicates whether the method was called after a failure to delete the student object. The delete operation might fail because of transient network problems. Transient network errors are more likely when the database is in the cloud. The `saveChangesError` parameter is false when the Delete page `OnGetAsync` is called from the UI. When `OnGetAsync` is called by `OnPostAsync` (because the delete operation failed), the `saveChangesError` parameter is true.

The `OnPostAsync` method retrieves the selected entity, then calls the Remove method to set the entity's status to `Deleted`. When `SaveChanges` is called, a SQL DELETE command is generated. If `Remove` fails:

- The database exception is caught.
- The Delete pages `OnGetAsync` method is called with `saveChangesError=true`.

Add an error message to the Delete Razor Page (*Pages/Students/Delete.cshtml*):

```
@page
@model ContosoUniversity.Pages.Students.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h1>Delete</h1>

<p class="text-danger">@Model.ErrorMessage</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Student</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.LastName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.LastName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.FirstMidName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.FirstMidName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.EnrollmentDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.EnrollmentDate)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Student.ID" />
        <input type="submit" value="Delete" class="btn btn-danger" /> |
        <a asp-page="./Index">Back to List</a>
    </form>
</div>
```

Run the app and delete a student to test the Delete page.

Next steps

PREVIOUS TUTORIAL NEXT TUTORIAL

In this tutorial, the scaffolded CRUD (create, read, update, delete) code is reviewed and customized.

To minimize complexity and keep these tutorials focused on EF Core, EF Core code is used in the page models. Some developers use a service layer or repository pattern in to create an abstraction layer between the UI (Razor Pages) and the data access layer.

In this tutorial, the Create, Edit, Delete, and Details Razor Pages in the *Students* folder are examined.

The scaffolded code uses the following pattern for Create, Edit, and Delete pages:

- Get and display the requested data with the HTTP GET method `OnGetAsync`.

- Save changes to the data with the HTTP POST method `OnPostAsync`.

The Index and Details pages get and display the requested data with the HTTP GET method `OnGetAsync`

SingleOrDefaultAsync vs. FirstOrDefaultAsync

The generated code uses FirstOrDefaultAsync, which is generally preferred over SingleOrDefaultAsync.

`FirstOrDefaultAsync` is more efficient than `SingleOrDefaultAsync` at fetching one entity:

- Unless the code needs to verify that there's not more than one entity returned from the query.
- `SingleOrDefaultAsync` fetches more data and does unnecessary work.
- `SingleOrDefaultAsync` throws an exception if there's more than one entity that fits the filter part.
- `FirstOrDefaultAsync` doesn't throw if there's more than one entity that fits the filter part.

FindAsync

In much of the scaffolded code, FindAsync can be used in place of `FirstOrDefaultAsync`.

`FindAsync`:

- Finds an entity with the primary key (PK). If an entity with the PK is being tracked by the context, it's returned without a request to the DB.
- Is simple and concise.
- Is optimized to look up a single entity.
- Can have perf benefits in some situations, but that rarely happens for typical web apps.
- Implicitly uses FirstAsync instead of SingleAsync.

But if you want to `Include` other entities, then `FindAsync` is no longer appropriate. This means that you may need to abandon `FindAsync` and move to a query as your app progresses.

Customize the Details page

Browse to `Pages/Students` page. The **Edit**, **Details**, and **Delete** links are generated by the Anchor Tag Helper in the *Pages/Students/Index.cshtml* file.

```
<td>
    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
</td>
```

Run the app and select a **Details** link. The URL is of the form `http://localhost:5000/Students/Details?id=2`. The Student ID is passed using a query string (`?id=2`).

Update the Edit, Details, and Delete Razor Pages to use the `"{id:int}"` route template. Change the page directive for each of these pages from `@page` to `@page "{id:int}"`.

A request to the page with the "{id:int}" route template that does **not** include a integer route value returns an HTTP 404 (not found) error. For example, `http://localhost:5000/Students/Details` returns a 404 error. To make the ID optional, append `?` to the route constraint:

```
@page "{id:int?}"
```

Run the app, click on a Details link, and verify the URL is passing the ID as route data (

`http://localhost:5000/Students/Details/2`).

Don't globally change `@page` to `@page "{id:int}"`, doing so breaks the links to the Home and Create pages.

Add related data

The scaffolded code for the Students Index page doesn't include the `Enrollments` property. In this section, the contents of the `Enrollments` collection is displayed in the Details page.

The `OnGetAsync` method of *Pages/Students/Details.cshtml.cs* uses the `FirstOrDefaultAsync` method to retrieve a single `Student` entity. Add the following highlighted code:

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    Student = await _context.Student
                        .Include(s => s.Enrollments)
                            .ThenInclude(e => e.Course)
                        .AsNoTracking()
                        .FirstOrDefaultAsync(m => m.ID == id);

    if (Student == null)
    {
        return NotFound();
    }
    return Page();
}
```

The Include and ThenInclude methods cause the context to load the `Student.Enrollments` navigation property, and within each enrollment the `Enrollment.Course` navigation property. These methods are examined in detail in the reading-related data tutorial.

The AsNoTracking method improves performance in scenarios when the entities returned are not updated in the current context. `AsNoTracking` is discussed later in this tutorial.

Display related enrollments on the Details page

Open *Pages/Students/Details.cshtml*. Add the following highlighted code to display a list of enrollments:

```
@page "{id:int}"
@model ContosoUniversity.Pages.Students.DetailsModel

@{
    ViewData["Title"] = "Details";
}

<h2>Details</h2>

<div>
    <h4>Student</h4>
    <hr />
    <dl class="dl-horizontal">
        <dt>
            @Html.DisplayNameFor(model => model.Student.LastName)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Student.LastName)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Student.FirstMidName)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Student.FirstMidName)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Student.EnrollmentDate)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Student.EnrollmentDate)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Student.Enrollments)
        </dt>
        <dd>
            <table class="table">
                <tr>
                    <th>Course Title</th>
                    <th>Grade</th>
                </tr>
                @foreach (var item in Model.Student.Enrollments)
                {
                    <tr>
                        <td>
                            @Html.DisplayFor(modelItem => item.Course.Title)
                        </td>
                        <td>
                            @Html.DisplayFor(modelItem => item.Grade)
                        </td>
                    </tr>
                }
            </table>
        </dd>
    </dl>
</div>
<div>
    <a asp-page="./Edit" asp-route-id="@Model.Student.ID">Edit</a> |
    <a asp-page="./Index">Back to List</a>
</div>
```

If code indentation is wrong after the code is pasted, press CTRL-K-D to correct it.

The preceding code loops through the entities in the `Enrollments` navigation property. For each enrollment, it displays the course title and the grade. The course title is retrieved from the Course entity that's stored in the `Course` navigation property of the Enrollments entity.

Run the app, select the **Students** tab, and click the **Details** link for a student. The list of courses and grades for the selected student is displayed.

Update the Create page

Update the `OnPostAsync` method in *Pages/Students/Create.cshtml.cs* with the following code:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    var emptyStudent = new Student();

    if (await TryUpdateModelAsync<Student>(
        emptyStudent,
        "student",   // Prefix for form value.
        s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
    {
        _context.Student.Add(emptyStudent);
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }

    return null;
}
```

TryUpdateModelAsync

Examine the TryUpdateModelAsync code:

```
var emptyStudent = new Student();

if (await TryUpdateModelAsync<Student>(
    emptyStudent,
    "student",   // Prefix for form value.
    s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
{
```

In the preceding code, `TryUpdateModelAsync<Student>` tries to update the `emptyStudent` object using the posted form values from the PageContext property in the PageModel. `TryUpdateModelAsync` only updates the properties listed (`s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate`).

In the preceding sample:

- The second argument (`"student", // Prefix`) is the prefix uses to look up values. It's not case sensitive.
- The posted form values are converted to the types in the `Student` model using model binding.

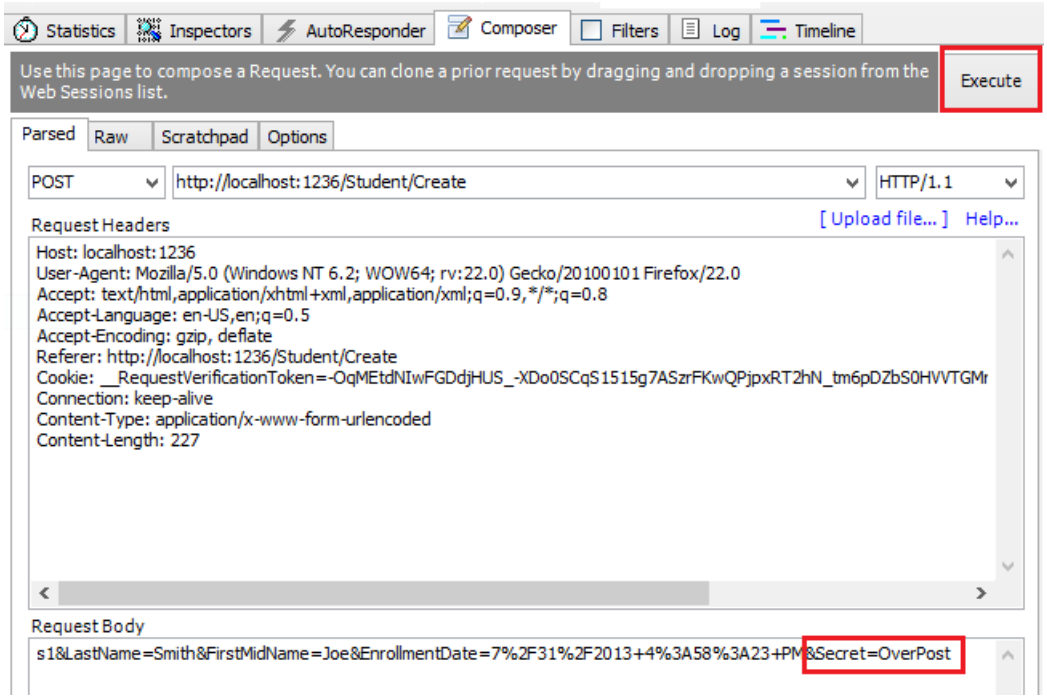
Overposting

Using `TryUpdateModel` to update fields with posted values is a security best practice because it prevents overposting. For example, suppose the Student entity includes a `Secret` property that this web page shouldn't update or add:

```
public class Student
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstMidName { get; set; }
    public DateTime EnrollmentDate { get; set; }
    public string Secret { get; set; }
}
```

Even if the app doesn't have a `Secret` field on the create/update Razor Page, a hacker could set the `Secret` value by overposting. A hacker could use a tool such as Fiddler, or write some JavaScript, to post a `Secret` form value. The original code doesn't limit the fields that the model binder uses when it creates a Student instance.

Whatever value the hacker specified for the `Secret` form field is updated in the DB. The following image shows the Fiddler tool adding the `Secret` field (with the value "OverPost") to the posted form values.



The value "OverPost" is successfully added to the `Secret` property of the inserted row. The app designer never intended the `Secret` property to be set with the Create page.

View model

A view model typically contains a subset of the properties included in the model used by the application. The application model is often called the domain model. The domain model typically contains all the properties required by the corresponding entity in the DB. The view model contains only the properties needed for the UI layer (for example, the Create page). In addition to the view model, some apps use a binding model or input model to pass data between the Razor Pages page model class and the browser. Consider the following `Student` view model:

```
using System;

namespace ContosoUniversity.Models
{
    public class StudentVM
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }
    }
}
```

View models provide an alternative way to prevent overposting. The view model contains only the properties to view (display) or update.

The following code uses the `StudentVM` view model to create a new student:

```
[BindProperty]
public StudentVM StudentVM { get; set; }

public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    var entry = _context.Add(new Student());
    entry.CurrentValues.SetValues(StudentVM);
    await _context.SaveChangesAsync();
    return RedirectToPage("./Index");
}
```

The SetValues method sets the values of this object by reading values from another PropertyValues object. `SetValues` uses property name matching. The view model type doesn't need to be related to the model type, it just needs to have properties that match.

Using `StudentVM` requires CreateVM.cshtml be updated to use `StudentVM` rather than `Student`.

In Razor Pages, the `PageModel` derived class is the view model.

Update the Edit page

Update the page model for the Edit page. The major changes are highlighted:

```
public class EditModel : PageModel
{
    private readonly SchoolContext _context;

    public EditModel(SchoolContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Student Student { get; set; }

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Student = await _context.Student.FindAsync(id);

        if (Student == null)
        {
            return NotFound();
        }
        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int? id)
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        var studentToUpdate = await _context.Student.FindAsync(id);

        if (await TryUpdateModelAsync<Student>(
            studentToUpdate,
            "student",
            s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
        {
            await _context.SaveChangesAsync();
            return RedirectToPage("./Index");
        }

        return Page();
    }
}
```

The code changes are similar to the Create page with a few exceptions:

- `OnPostAsync` has an optional `id` parameter.
- The current student is fetched from the DB, rather than creating an empty student.
- `FirstOrDefaultAsync` has been replaced with FindAsync. `FindAsync` is a good choice when selecting an entity from the primary key. See FindAsync for more information.

Test the Edit and Create pages

Create and edit a few student entities.

Entity States

The DB context keeps track of whether entities in memory are in sync with their corresponding rows in the DB.

The DB context sync information determines what happens when SaveChangesAsync is called. For example, when a new entity is passed to the AddAsync method, that entity's state is set to Added. When `SaveChangesAsync` is called, the DB context issues a SQL INSERT command.

An entity may be in one of the following states:

- `Added`: The entity doesn't yet exist in the DB. The `SaveChanges` method issues an INSERT statement.
- `Unchanged`: No changes need to be saved with this entity. An entity has this status when it's read from the DB.
- `Modified`: Some or all of the entity's property values have been modified. The `SaveChanges` method issues an UPDATE statement.
- `Deleted`: The entity has been marked for deletion. The `SaveChanges` method issues a DELETE statement.
- `Detached`: The entity isn't being tracked by the DB context.

In a desktop app, state changes are typically set automatically. An entity is read, changes are made, and the entity state to automatically be changed to `Modified`. Calling `SaveChanges` generates a SQL UPDATE statement that updates only the changed properties.

In a web app, the `DbContext` that reads an entity and displays the data is disposed after a page is rendered. When a page's `OnPostAsync` method is called, a new web request is made and with a new instance of the `DbContext`. Re-reading the entity in that new context simulates desktop processing.

Update the Delete page

In this section, code is added to implement a custom error message when the call to `SaveChanges` fails. Add a string to contain possible error messages:

```
public class DeleteModel : PageModel
{
    private readonly SchoolContext _context;

    public DeleteModel(SchoolContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Student Student { get; set; }
    public string ErrorMessage { get; set; }
```

Replace the `OnGetAsync` method with the following code:

```
public async Task<IActionResult> OnGetAsync(int? id, bool? saveChangesError = false)
{
    if (id == null)
    {
        return NotFound();
    }

    Student = await _context.Student
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);

    if (Student == null)
    {
        return NotFound();
    }

    if (saveChangesError.GetValueOrDefault())
    {
        ErrorMessage = "Delete failed. Try again";
    }

    return Page();
}
```

The preceding code contains the optional parameter `saveChangesError`. `saveChangesError` indicates whether the method was called after a failure to delete the student object. The delete operation might fail because of transient network problems. Transient network errors are more likely in the cloud. `saveChangesError` is false when the Delete page `OnGetAsync` is called from the UI. When `OnGetAsync` is called by `OnPostAsync` (because the delete operation failed), the `saveChangesError` parameter is true.

The Delete pages OnPostAsync method

Replace the `OnPostAsync` with the following code:

```
public async Task<IActionResult> OnPostAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var student = await _context.Student
                    .AsNoTracking()
                    .FirstOrDefaultAsync(m => m.ID == id);

    if (student == null)
    {
        return NotFound();
    }

    try
    {
        _context.Student.Remove(student);
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }
    catch (DbUpdateException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.)
        return RedirectToAction("./Delete",
                             new { id, saveChangesError = true });
    }
}
```

The preceding code retrieves the selected entity, then calls the Remove method to set the entity's status to `Deleted`. When `SaveChanges` is called, a SQL DELETE command is generated. If `Remove` fails:

- The DB exception is caught.
- The Delete pages `OnGetAsync` method is called with `saveChangesError=true`.

Update the Delete Razor Page

Add the following highlighted error message to the Delete Razor Page.

```
@page "{id:int}"
@model ContosoUniversity.Pages.Students.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

<p class="text-danger">@Model.ErrorMessage</p>

<h3>Are you sure you want to delete this?</h3>
<div>
```

Test Delete.

Common errors

Students/Index or other links don't work:

Verify the Razor Page contains the correct `@page` directive. For example, The Students/Index Razor Page should **not** contain a route template:

```
@page "{id:int}"
```

Each Razor Page must include the `@page` directive.

Part 3, Razor Pages with EF Core in ASP.NET Core - Sort, Filter, Paging

9/22/2020 • 29 minutes to read • Edit Online

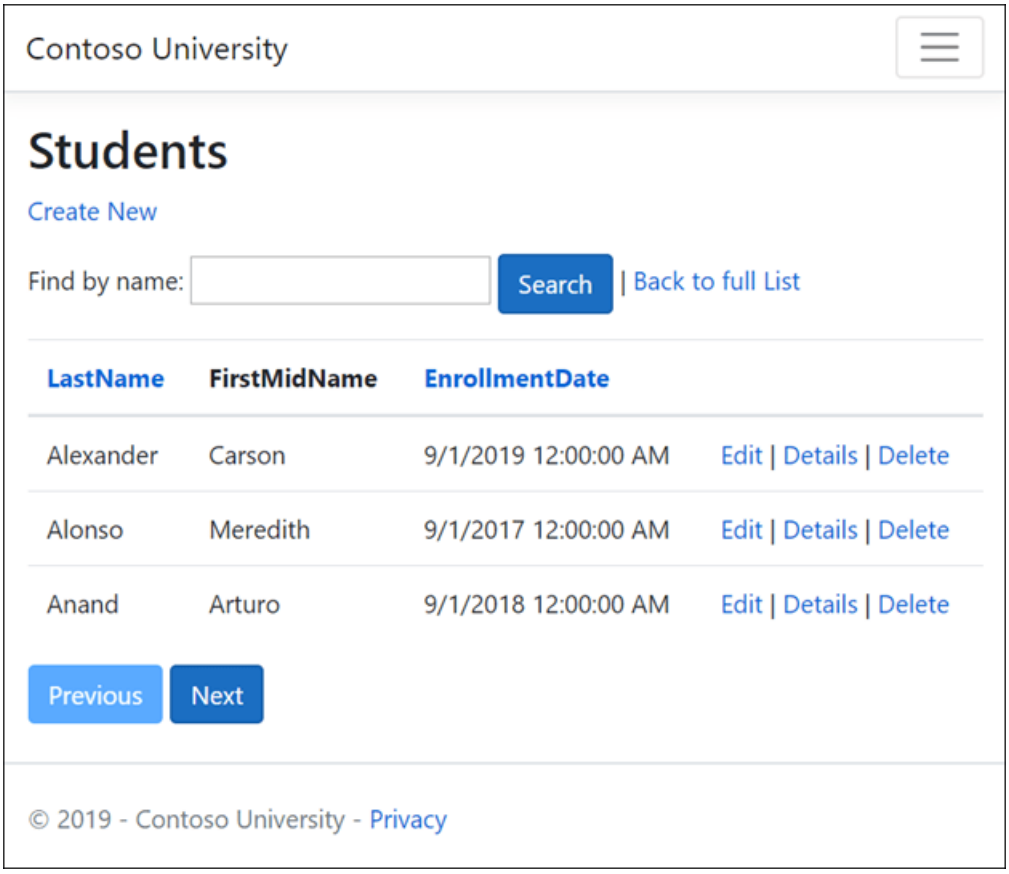
By Tom Dykstra, Rick Anderson, and Jon P Smith

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial adds sorting, filtering, and paging functionality to the Students pages.

The following illustration shows a completed page. The column headings are clickable links to sort the column. Click a column heading repeatedly to switch between ascending and descending sort order.



Add sorting

Replace the code in *Pages/Students/Index.cshtml.cs* with the following code to add sorting.

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Students
{
    public class IndexModel : PageModel
    {
        private readonly SchoolContext _context;

        public IndexModel(SchoolContext context)
        {
            _context = context;
        }

        public string NameSort { get; set; }
        public string DateSort { get; set; }
        public string CurrentFilter { get; set; }
        public string CurrentSort { get; set; }

        public IList<Student> Students { get; set; }

        public async Task OnGetAsync(string sortOrder)
        {
            NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
            DateSort = sortOrder == "Date" ? "date_desc" : "Date";

            IQueryable<Student> studentsIQ = from s in _context.Students
                                             select s;

            switch (sortOrder)
            {
                case "name_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s => s.LastName);
                    break;
                case "Date":
                    studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
                    break;
                case "date_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s => s.EnrollmentDate);
                    break;
                default:
                    studentsIQ = studentsIQ.OrderBy(s => s.LastName);
                    break;
            }

            Students = await studentsIQ.AsNoTracking().ToListAsync();
        }
    }
}
```

The preceding code:

- Adds properties to contain the sorting parameters.
- Changes the name of the `Student` property to `Students`.
- Replaces the code in the `OnGetAsync` method.

The `OnGetAsync` method receives a `sortOrder` parameter from the query string in the URL. The URL (including the query string) is generated by the Anchor Tag Helper.

The `sortOrder` parameter is either "Name" or "Date." The `sortOrder` parameter is optionally followed by "_desc" to specify descending order. The default sort order is ascending.

When the Index page is requested from the **Students** link, there's no query string. The students are displayed in ascending order by last name. Ascending order by last name is the default (fall-through case) in the `switch` statement. When the user clicks a column heading link, the appropriate `sortOrder` value is provided in the query string value.

`NameSort` and `DateSort` are used by the Razor Page to configure the column heading hyperlinks with the appropriate query string values:

```
NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
DateSort = sortOrder == "Date" ? "date_desc" : "Date";
```

The code uses the C# conditional operator ?:. The `?:` operator is a ternary operator (it takes three operands). The first line specifies that when `sortOrder` is null or empty, `NameSort` is set to "name_desc." If `sortOrder` is **not** null or empty, `NameSort` is set to an empty string.

These two statements enable the page to set the column heading hyperlinks as follows:

CURRENT SORT ORDER	LAST NAME HYPERLINK	DATE HYPERLINK
Last Name ascending	descending	ascending
Last Name descending	ascending	ascending
Date ascending	ascending	descending
Date descending	ascending	ascending

The method uses LINQ to Entities to specify the column to sort by. The code initializes an `IQueryable<Student>` before the switch statement, and modifies it in the switch statement:

```
IQueryable<Student> studentsIQ = from s in _context.Students
                                 select s;

switch (sortOrder)
{
    case "name_desc":
        studentsIQ = studentsIQ.OrderByDescending(s => s.LastName);
        break;
    case "Date":
        studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
        break;
    case "date_desc":
        studentsIQ = studentsIQ.OrderByDescending(s => s.EnrollmentDate);
        break;
    default:
        studentsIQ = studentsIQ.OrderBy(s => s.LastName);
        break;
}

Students = await studentsIQ.AsNoTracking().ToListAsync();
```

When an `IQueryable` is created or modified, no query is sent to the database. The query isn't executed until the `IQueryable` object is converted into a collection. `IQueryable` are converted to a collection by calling a method such as `ToListAsync`. Therefore, the `IQueryable` code results in a single query that's not executed until the

following statement:

```
Students = await studentsIQ.AsNoTracking().ToListAsync();
```

`OnGetAsync` could get verbose with a large number of sortable columns. For information about an alternative way to code this functionality, see Use dynamic LINQ to simplify code in the MVC version of this tutorial series.

Add column heading hyperlinks to the Student Index page

Replace the code in *Students/Index.cshtml*, with the following code. The changes are highlighted.

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Students";
}

<h2>Students</h2>
<p>
    <a asp-page="Create">Create New</a>
</p>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort">
                    @Html.DisplayNameFor(model => model.Students[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Students[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort">
                    @Html.DisplayNameFor(model => model.Students[0].EnrollmentDate)
                </a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Students)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

The preceding code:

- Adds hyperlinks to the `LastName` and `EnrollmentDate` column headings.
- Uses the information in `NameSort` and `DateSort` to set up hyperlinks with the current sort order values.
- Changes the page heading from Index to Students.
- Changes `Model.Student` to `Model.Students`.

To verify that sorting works:

- Run the app and select the **Students** tab.
- Click the column headings.

Add filtering

To add filtering to the Students Index page:

- A text box and a submit button is added to the Razor Page. The text box supplies a search string on the first or last name.
- The page model is updated to use the text box value.

Update the OnGetAsync method

Replace the code in *Students/Index.cshtml.cs* with the following code to add filtering:

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Students
{
    public class IndexModel : PageModel
    {
        private readonly SchoolContext _context;

        public IndexModel(SchoolContext context)
        {
            _context = context;
        }

        public string NameSort { get; set; }
        public string DateSort { get; set; }
        public string CurrentFilter { get; set; }
        public string CurrentSort { get; set; }

        public IList<Student> Students { get; set; }

        public async Task OnGetAsync(string sortOrder, string searchString)
        {
            NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
            DateSort = sortOrder == "Date" ? "date_desc" : "Date";

            CurrentFilter = searchString;

            IQueryable<Student> studentsIQ = from s in _context.Students
                                             select s;
            if (!String.IsNullOrEmpty(searchString))
            {
                studentsIQ = studentsIQ.Where(s => s.LastName.Contains(searchString)
                                       || s.FirstMidName.Contains(searchString));
            }

            switch (sortOrder)
            {
                case "name_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s => s.LastName);
                    break;
                case "Date":
                    studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
                    break;
                case "date_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s => s.EnrollmentDate);
                    break;
                default:
                    studentsIQ = studentsIQ.OrderBy(s => s.LastName);
                    break;
            }

            Students = await studentsIQ.AsNoTracking().ToListAsync();
        }
    }
}
```

The preceding code:

- Adds the `searchString` parameter to the `OnGetAsync` method, and saves the parameter value in the

`CurrentFilter` property. The search string value is received from a text box that's added in the next section.

- Adds to the LINQ statement a `Where` clause. The `Where` clause selects only students whose first name or last name contains the search string. The LINQ statement is executed only if there's a value to search for.

IQueryable vs. IEnumerable

The code calls the `Where` method on an `IQueryable` object, and the filter is processed on the server. In some scenarios, the app might be calling the `Where` method as an extension method on an in-memory collection. For example, suppose `_context.Students` changes from EF Core `DbSet` to a repository method that returns an `IEnumerable` collection. The result would normally be the same but in some cases may be different.

For example, the .NET Framework implementation of `Contains` performs a case-sensitive comparison by default. In SQL Server, `Contains` case-sensitivity is determined by the collation setting of the SQL Server instance. SQL Server defaults to case-insensitive. SQLite defaults to case-sensitive. `ToUpper` could be called to make the test explicitly case-insensitive:

```
Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())`
```

The preceding code would ensure that the filter is case-insensitive even if the `Where` method is called on an `IEnumerable` or runs on SQLite.

When `Contains` is called on an `IEnumerable` collection, the .NET Core implementation is used. When `Contains` is called on an `IQueryable` object, the database implementation is used.

Calling `Contains` on an `IQueryable` is usually preferable for performance reasons. With `IQueryable`, the filtering is done by the database server. If an `IEnumerable` is created first, all the rows have to be returned from the database server.

There's a performance penalty for calling `ToUpper`. The `ToUpper` code adds a function in the WHERE clause of the TSQL SELECT statement. The added function prevents the optimizer from using an index. Given that SQL is installed as case-insensitive, it's best to avoid the `ToUpper` call when it's not needed.

For more information, see How to use case-insensitive query with Sqlite provider.

Update the Razor page

Replace the code in *Pages/Students/Index.cshtml* to create a **Search** button and assorted chrome.

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Students";
}

<h2>Students</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form asp-page="./Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name:
            <input type="text" name="SearchString" value="@Model.CurrentFilter" />
            <input type="submit" value="Search" class="btn btn-primary" /> |
            <a asp-page="./Index">Back to full List</a>
        </p>
    </div>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort">
                    @Html.DisplayNameFor(model => model.Students[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Students[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort">
                    @Html.DisplayNameFor(model => model.Students[0].EnrollmentDate)
                </a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Students)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

The preceding code uses the `<form>` tag helper to add the search text box and button. By default, the `<form>` tag helper submits form data with a POST. With POST, the parameters are passed in the HTTP message body and not in the URL. When HTTP GET is used, the form data is passed in the URL as query strings. Passing the data with query strings enables users to bookmark the URL. The W3C guidelines recommend that GET should be used when the action doesn't result in an update.

Test the app:

- Select the **Students** tab and enter a search string. If you're using SQLite, the filter is case-insensitive only if you implemented the optional `ToUpper` code shown earlier.
- Select **Search**.

Notice that the URL contains the search string. For example:

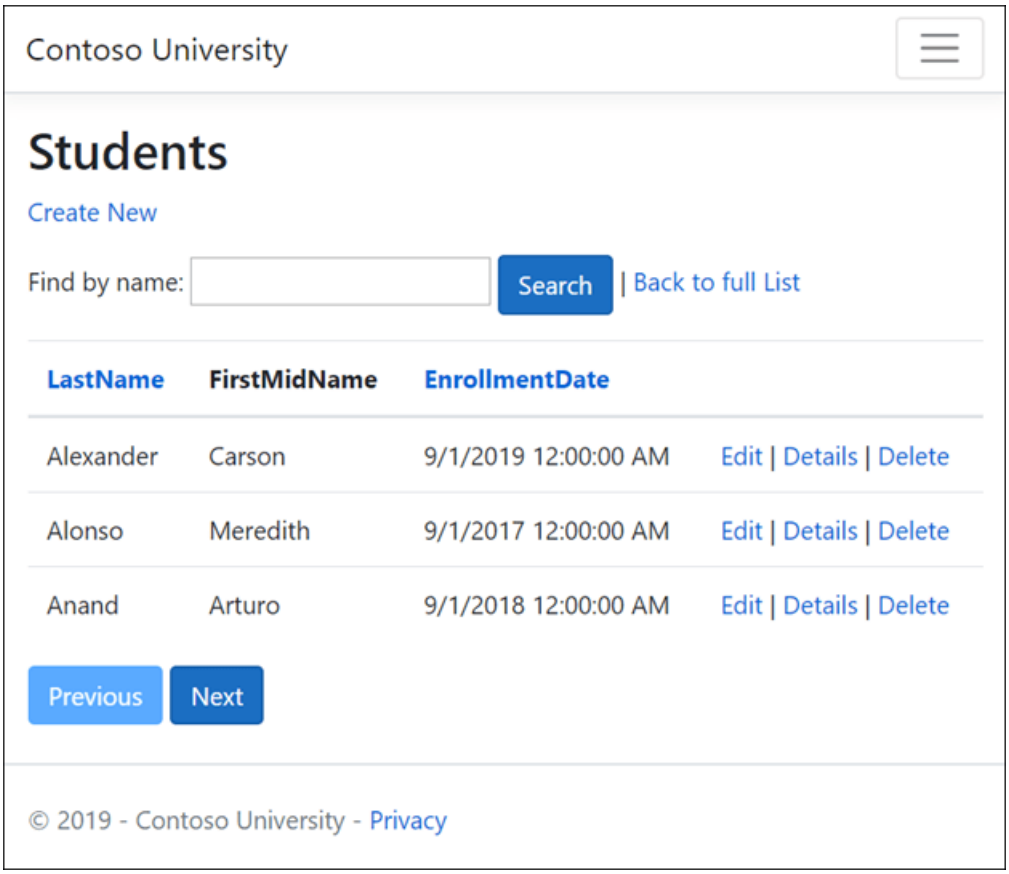
```
https://localhost:<port>/Students?SearchString=an
```

If the page is bookmarked, the bookmark contains the URL to the page and the `SearchString` query string. The `method="get"` in the `form` tag is what caused the query string to be generated.

Currently, when a column heading sort link is selected, the filter value from the **Search** box is lost. The lost filter value is fixed in the next section.

Add paging

In this section, a `PaginatedList` class is created to support paging. The `PaginatedList` class uses `Skip` and `Take` statements to filter data on the server instead of retrieving all rows of the table. The following illustration shows the paging buttons.



Create the PaginatedList class

In the project folder, create `PaginatedList.cs` with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity
{
    public class PaginatedList<T> : List<T>
    {
        public int PageIndex { get; private set; }
        public int TotalPages { get; private set; }

        public PaginatedList(List<T> items, int count, int pageIndex, int pageSize)
        {
            PageIndex = pageIndex;
            TotalPages = (int)Math.Ceiling(count / (double)pageSize);

            this.AddRange(items);
        }

        public bool HasPreviousPage
        {
            get
            {
                return (PageIndex > 1);
            }
        }

        public bool HasNextPage
        {
            get
            {
                return (PageIndex < TotalPages);
            }
        }

        public static async Task<PaginatedList<T>> CreateAsync(
            IQueryable<T> source, int pageIndex, int pageSize)
        {
            var count = await source.CountAsync();
            var items = await source.Skip(
                (pageIndex - 1) * pageSize)
                .Take(pageSize).ToListAsync();
            return new PaginatedList<T>(items, count, pageIndex, pageSize);
        }
    }
}
```

The `CreateAsync` method in the preceding code takes page size and page number and applies the appropriate `Skip` and `Take` statements to the `IQueryable`. When `ToListAsync` is called on the `IQueryable`, it returns a List containing only the requested page. The properties `HasPreviousPage` and `HasNextPage` are used to enable or disable **Previous** and **Next** paging buttons.

The `CreateAsync` method is used to create the `PaginatedList<T>`. A constructor can't create the `PaginatedList<T>` object; constructors can't run asynchronous code.

Add paging to the PageModel class

Replace the code in *Students/Index.cshtml.cs* to add paging.

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
```

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Students
{
    public class IndexModel : PageModel
    {
        private readonly SchoolContext _context;

        public IndexModel(SchoolContext context)
        {
            _context = context;
        }

        public string NameSort { get; set; }
        public string DateSort { get; set; }
        public string CurrentFilter { get; set; }
        public string CurrentSort { get; set; }

        public PaginatedList<Student> Students { get; set; }

        public async Task OnGetAsync(string sortOrder,
            string currentFilter, string searchString, int? pageIndex)
        {
            CurrentSort = sortOrder;
            NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
            DateSort = sortOrder == "Date" ? "date_desc" : "Date";
            if (searchString != null)
            {
                pageIndex = 1;
            }
            else
            {
                searchString = currentFilter;
            }

            CurrentFilter = searchString;

            IQueryable<Student> studentsIQ = from s in _context.Students
                                             select s;
            if (!String.IsNullOrEmpty(searchString))
            {
                studentsIQ = studentsIQ.Where(s => s.LastName.Contains(searchString)
                                       || s.FirstMidName.Contains(searchString));
            }
            switch (sortOrder)
            {
                case "name_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s => s.LastName);
                    break;
                case "Date":
                    studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
                    break;
                case "date_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s => s.EnrollmentDate);
                    break;
                default:
                    studentsIQ = studentsIQ.OrderBy(s => s.LastName);
                    break;
            }

            int pageSize = 3;
            Students = await PaginatedList<Student>.CreateAsync(
                studentsIQ.AsNoTracking(), pageIndex ?? 1, pageSize);
        }
    }
}
```

The preceding code:

- Changes the type of the `Students` property from `IList<Student>` to `PaginatedList<Student>`.
- Adds the page index, the current `sortOrder`, and the `currentFilter` to the `OnGetAsync` method signature.
- Saves the sort order in the CurrentSort property.
- Resets page index to 1 when there's a new search string.
- Uses the `PaginatedList` class to get Student entities.

All the parameters that `OnGetAsync` receives are null when:

- The page is called from the **Students** link.
- The user hasn't clicked a paging or sorting link.

When a paging link is clicked, the page index variable contains the page number to display.

The `CurrentSort` property provides the Razor Page with the current sort order. The current sort order must be included in the paging links to keep the sort order while paging.

The `CurrentFilter` property provides the Razor Page with the current filter string. The `CurrentFilter` value:

- Must be included in the paging links in order to maintain the filter settings during paging.
- Must be restored to the text box when the page is redisplayed.

If the search string is changed while paging, the page is reset to 1. The page has to be reset to 1 because the new filter can result in different data to display. When a search value is entered and **Submit** is selected:

- The search string is changed.
- The `searchString` parameter isn't null.

The `PaginatedList.CreateAsync` method converts the student query to a single page of students in a collection type that supports paging. That single page of students is passed to the Razor Page.

The two question marks after `pageIndex` in the `PaginatedList.CreateAsync` call represent the null-coalescing operator. The null-coalescing operator defines a default value for a nullable type. The expression `(pageIndex ?? 1)` means return the value of `pageIndex` if it has a value. If `pageIndex` doesn't have a value, return 1.

Add paging links to the Razor Page

Replace the code in *Students/Index.cshtml* with the following code. The changes are highlighted:

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Students";
}

<h2>Students</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form asp-page="./Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name:
            <input type="text" name="SearchString" value="@Model.CurrentFilter" />
```

```
            <input type="submit" value="Search" class="btn btn-primary" /> |
            <a asp-page="./Index">Back to full List</a>
        </p>
    </div>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort"
                   asp-route-currentFilter="@Model.CurrentFilter">
                    @Html.DisplayNameFor(model => model.Students[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Students[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort"
                   asp-route-currentFilter="@Model.CurrentFilter">
                    @Html.DisplayNameFor(model => model.Students[0].EnrollmentDate)
                </a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Students)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>

@{
    var prevDisabled = !Model.Students.HasPreviousPage ? "disabled" : "";
    var nextDisabled = !Model.Students.HasNextPage ? "disabled" : "";
}

<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex - 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @prevDisabled">
    Previous
</a>
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex + 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @nextDisabled">
    Next
</a>
```

The column header links use the query string to pass the current search string to the `OnGetAsync` method:

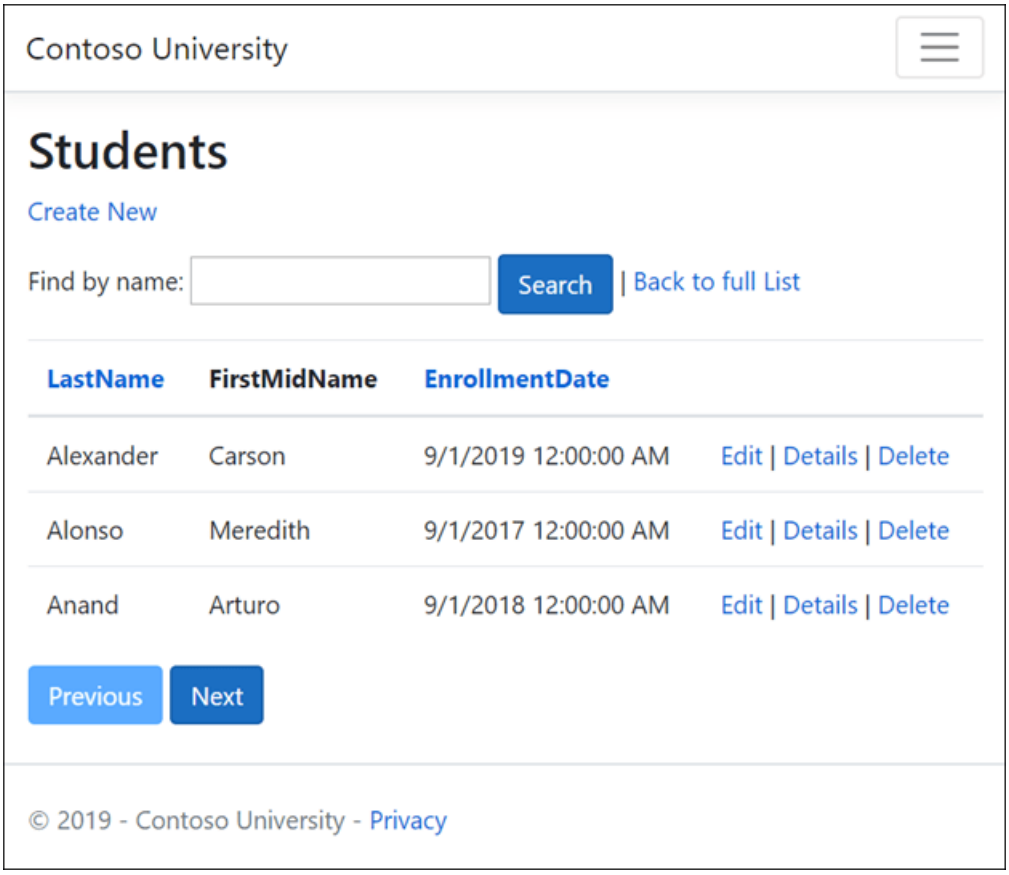
```
<a asp-page="./Index" asp-route-sortOrder="@Model.NameSort"
   asp-route-currentFilter="@Model.CurrentFilter">
    @Html.DisplayNameFor(model => model.Students[0].LastName)
</a>
```

The paging buttons are displayed by tag helpers:

```
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex - 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @prevDisabled">
    Previous
</a>
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex + 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @nextDisabled">
    Next
</a>
```

Run the app and navigate to the students page.

- To make sure paging works, click the paging links in different sort orders.
- To verify that paging works correctly with sorting and filtering, enter a search string and try paging.



Add grouping

This section creates an About page that displays how many students have enrolled for each enrollment date. The update uses grouping and includes the following steps:

- Create a view model for the data used by the **About** page.
- Update the About page to use the view model.

Create the view model

Create a *Models/SchoolViewModels* folder.

Create *SchoolViewModels/EnrollmentDateGroup.cs* with the following code:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class EnrollmentDateGroup
    {
        [DataType(DataType.Date)]
        public DateTime? EnrollmentDate { get; set; }

        public int StudentCount { get; set; }
    }
}
```

Create the Razor Page

Create a *Pages/About.cshtml* file with the following code:

```
@page
@model ContosoUniversity.Pages.AboutModel

@{
    ViewData["Title"] = "Student Body Statistics";
}

<h2>Student Body Statistics</h2>

<table>
    <tr>
        <th>
            Enrollment Date
        </th>
        <th>
            Students
        </th>
    </tr>

    @foreach (var item in Model.Students)
    {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                @item.StudentCount
            </td>
        </tr>
    }
</table>
```

Create the page model

Create a *Pages/About.cshtml.cs* file with the following code:

```
using ContosoUniversity.Models.SchoolViewModels;
using ContosoUniversity.Data;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using ContosoUniversity.Models;

namespace ContosoUniversity.Pages
{
    public class AboutModel : PageModel
    {
        private readonly SchoolContext _context;

        public AboutModel(SchoolContext context)
        {
            _context = context;
        }

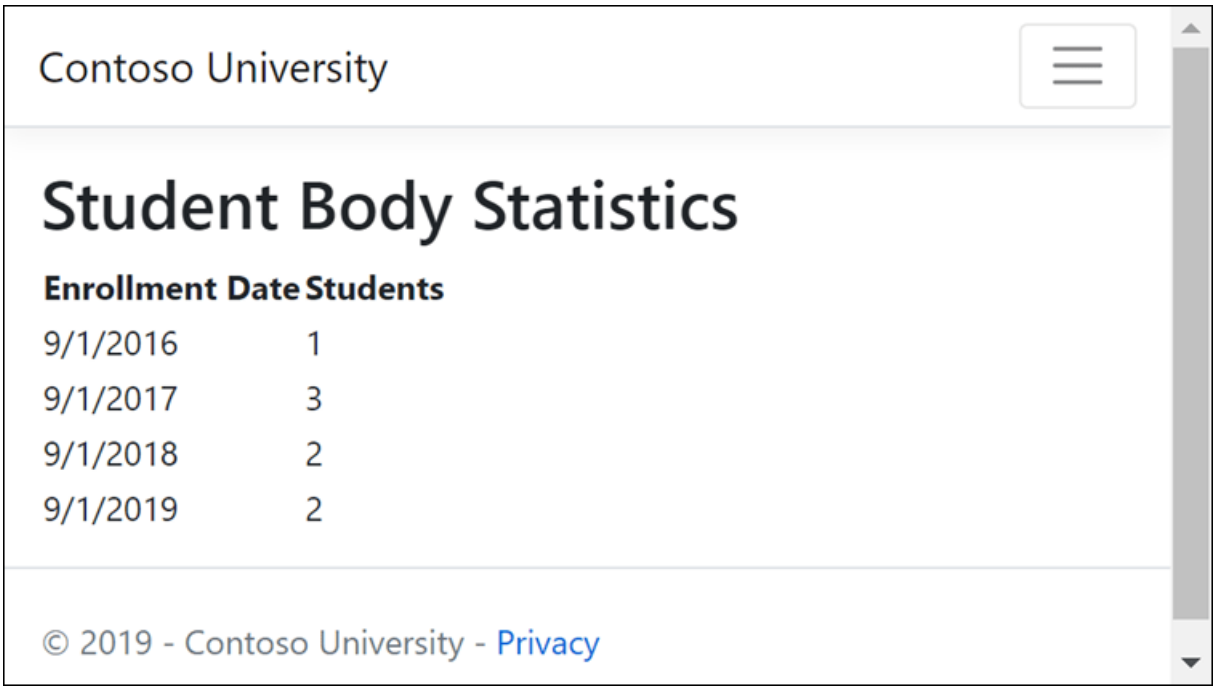
        public IList<EnrollmentDateGroup> Students { get; set; }

        public async Task OnGetAsync()
        {
            IQueryable<EnrollmentDateGroup> data =
                from student in _context.Students
                group student by student.EnrollmentDate into dateGroup
                select new EnrollmentDateGroup()
                {
                    EnrollmentDate = dateGroup.Key,
                    StudentCount = dateGroup.Count()
                };

            Students = await data.AsNoTracking().ToListAsync();
        }
    }
}
```

The LINQ statement groups the student entities by enrollment date, calculates the number of entities in each group, and stores the results in a collection of `EnrollmentDateGroup` view model objects.

Run the app and navigate to the About page. The count of students for each enrollment date is displayed in a table.



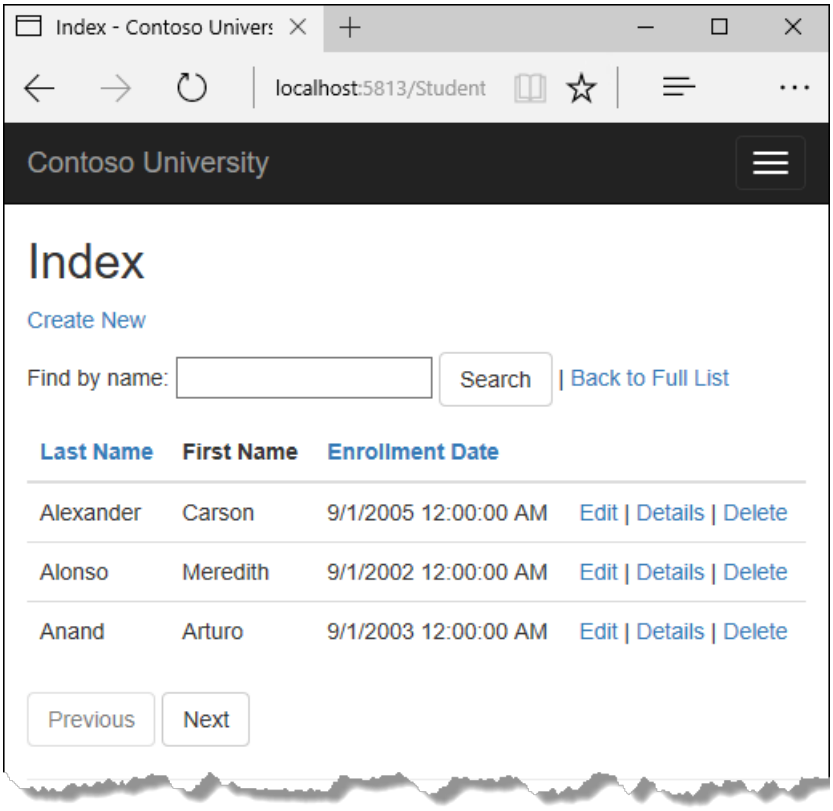
Next steps

In the next tutorial, the app uses migrations to update the data model.

PREVIOUS TUTORIAL NEXT TUTORIAL

In this tutorial, sorting, filtering, grouping, and paging, functionality is added.

The following illustration shows a completed page. The column headings are clickable links to sort the column. Clicking a column heading repeatedly switches between ascending and descending sort order.



If you run into problems you can't solve, download the completed app.

Add sorting to the Index page

Add strings to the *Students/Index.cshtml.cs* `PageModel` to contain the sorting parameters:

```
public class IndexModel : PageModel
{
    private readonly SchoolContext _context;

    public IndexModel(SchoolContext context)
    {
        _context = context;
    }

    public string NameSort { get; set; }
    public string DateSort { get; set; }
    public string CurrentFilter { get; set; }
    public string CurrentSort { get; set; }
```

Update the *Students/Index.cshtml.cs* `OnGetAsync` with the following code:

```
public async Task OnGetAsync(string sortOrder)
{
    NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    DateSort = sortOrder == "Date" ? "date_desc" : "Date";

    IQueryable<Student> studentIQ = from s in _context.Student
                                    select s;

    switch (sortOrder)
    {
        case "name_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            studentIQ = studentIQ.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            studentIQ = studentIQ.OrderBy(s => s.LastName);
            break;
    }

    Student = await studentIQ.AsNoTracking().ToListAsync();
}
```

The preceding code receives a `sortOrder` parameter from the query string in the URL. The URL (including the query string) is generated by the Anchor Tag Helper

The `sortOrder` parameter is either "Name" or "Date." The `sortOrder` parameter is optionally followed by "_desc" to specify descending order. The default sort order is ascending.

When the Index page is requested from the **Students** link, there's no query string. The students are displayed in ascending order by last name. Ascending order by last name is the default (fall-through case) in the `switch` statement. When the user clicks a column heading link, the appropriate `sortOrder` value is provided in the query string value.

`NameSort` and `DateSort` are used by the Razor Page to configure the column heading hyperlinks with the

appropriate query string values:

```
public async Task OnGetAsync(string sortOrder)
{
    NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    DateSort = sortOrder == "Date" ? "date_desc" : "Date";

    IQueryable<Student> studentIQ = from s in _context.Student
                                    select s;

    switch (sortOrder)
    {
        case "name_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            studentIQ = studentIQ.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            studentIQ = studentIQ.OrderBy(s => s.LastName);
            break;
    }

    Student = await studentIQ.AsNoTracking().ToListAsync();
}
```

The following code contains the C# conditional ?: operator:

```
NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
DateSort = sortOrder == "Date" ? "date_desc" : "Date";
```

The first line specifies that when `sortOrder` is null or empty, `NameSort` is set to "name_desc." If `sortOrder` is **not** null or empty, `NameSort` is set to an empty string.

The `?: operator` is also known as the ternary operator.

These two statements enable the page to set the column heading hyperlinks as follows:

CURRENT SORT ORDER	LAST NAME HYPERLINK	DATE HYPERLINK
Last Name ascending	descending	ascending
Last Name descending	ascending	ascending
Date ascending	ascending	descending
Date descending	ascending	ascending

The method uses LINQ to Entities to specify the column to sort by. The code initializes an `IQueryable<Student>` before the switch statement, and modifies it in the switch statement:

```
public async Task OnGetAsync(string sortOrder)
{
    NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    DateSort = sortOrder == "Date" ? "date_desc" : "Date";

    IQueryable<Student> studentIQ = from s in _context.Student
                                    select s;

    switch (sortOrder)
    {
        case "name_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            studentIQ = studentIQ.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            studentIQ = studentIQ.OrderBy(s => s.LastName);
            break;
    }

    Student = await studentIQ.AsNoTracking().ToListAsync();
}
```

When an `IQueryable` is created or modified, no query is sent to the database. The query isn't executed until the `IQueryable` object is converted into a collection. `IQueryable` are converted to a collection by calling a method such as `ToListAsync`. Therefore, the `IQueryable` code results in a single query that's not executed until the following statement:

```
Student = await studentIQ.AsNoTracking().ToListAsync();
```

`OnGetAsync` could get verbose with a large number of sortable columns.

Add column heading hyperlinks to the Student Index page

Replace the code in *Students/Index.cshtml*, with the following highlighted code:

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>
<p>
    <a asp-page="Create">Create New</a>
</p>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort">
                    @Html.DisplayNameFor(model => model.Student[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Student[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort">
                    @Html.DisplayNameFor(model => model.Student[0].EnrollmentDate)
                </a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Student)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

The preceding code:

- Adds hyperlinks to the `LastName` and `EnrollmentDate` column headings.
- Uses the information in `NameSort` and `DateSort` to set up hyperlinks with the current sort order values.

To verify that sorting works:

- Run the app and select the **Students** tab.
- Click **Last Name**.
- Click **Enrollment Date**.

To get a better understanding of the code:

- In *Students/Index.cshtml.cs*, set a breakpoint on `switch (sortOrder)`.
- Add a watch for `NameSort` and `DateSort`.
- In *Students/Index.cshtml*, set a breakpoint on `@Html.DisplayNameFor(model => model.Student[0].LastName)`.

Step through the debugger.

Add a Search Box to the Students Index page

To add filtering to the Students Index page:

- A text box and a submit button is added to the Razor Page. The text box supplies a search string on the first or last name.
- The page model is updated to use the text box value.

Add filtering functionality to the Index method

Update the *Students/Index.cshtml.cs* `OnGetAsync` with the following code:

```
public async Task OnGetAsync(string sortOrder, string searchString)
{
    NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    DateSort = sortOrder == "Date" ? "date_desc" : "Date";
    CurrentFilter = searchString;

    IQueryable<Student> studentIQ = from s in _context.Student
                                    select s;
    if (!String.IsNullOrEmpty(searchString))
    {
        studentIQ = studentIQ.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }

    switch (sortOrder)
    {
        case "name_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            studentIQ = studentIQ.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            studentIQ = studentIQ.OrderBy(s => s.LastName);
            break;
    }

    Student = await studentIQ.AsNoTracking().ToListAsync();
}
```

The preceding code:

- Adds the `searchString` parameter to the `OnGetAsync` method. The search string value is received from a text box that's added in the next section.
- Added to the LINQ statement a `Where` clause. The `Where` clause selects only students whose first name or last name contains the search string. The LINQ statement is executed only if there's a value to search for.

Note: The preceding code calls the `Where` method on an `IQueryable` object, and the filter is processed on the server. In some scenarios, the app might be calling the `Where` method as an extension method on an in-memory

collection. For example, suppose `_context.Students` changes from EF Core `DbSet` to a repository method that returns an `IEnumerable` collection. The result would normally be the same but in some cases may be different.

For example, the .NET Framework implementation of `Contains` performs a case-sensitive comparison by default. In SQL Server, `Contains` case-sensitivity is determined by the collation setting of the SQL Server instance. SQL Server defaults to case-insensitive. `ToUpper` could be called to make the test explicitly case-insensitive:

```
Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())
```

The preceding code would ensure that results are case-insensitive if the code changes to use `IEnumerable`. When `Contains` is called on an `IEnumerable` collection, the .NET Core implementation is used. When `Contains` is called on an `IQueryable` object, the database implementation is used. Returning an `IEnumerable` from a repository can have a significant performance penalty:

1. All the rows are returned from the DB server.
2. The filter is applied to all the returned rows in the application.

There's a performance penalty for calling `ToUpper`. The `ToUpper` code adds a function in the WHERE clause of the TSQL SELECT statement. The added function prevents the optimizer from using an index. Given that SQL is installed as case-insensitive, it's best to avoid the `ToUpper` call when it's not needed.

Add a Search Box to the Student Index page

In *Pages/Students/Index.cshtml*, add the following highlighted code to create a **Search** button and assorted chrome.

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form asp-page="./Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name:
            <input type="text" name="SearchString" value="@Model.CurrentFilter" />
            <input type="submit" value="Search" class="btn btn-default" /> |
            <a asp-page="./Index">Back to full List</a>
        </p>
    </div>
</form>

<table class="table">
```

The preceding code uses the `<form>` tag helper to add the search text box and button. By default, the `<form>` tag helper submits form data with a POST. With POST, the parameters are passed in the HTTP message body and not in the URL. When HTTP GET is used, the form data is passed in the URL as query strings. Passing the data with query strings enables users to bookmark the URL. The W3C guidelines recommend that GET should be used when the action doesn't result in an update.

Test the app:

- Select the **Students** tab and enter a search string.

- Select **Search**.

Notice that the URL contains the search string.

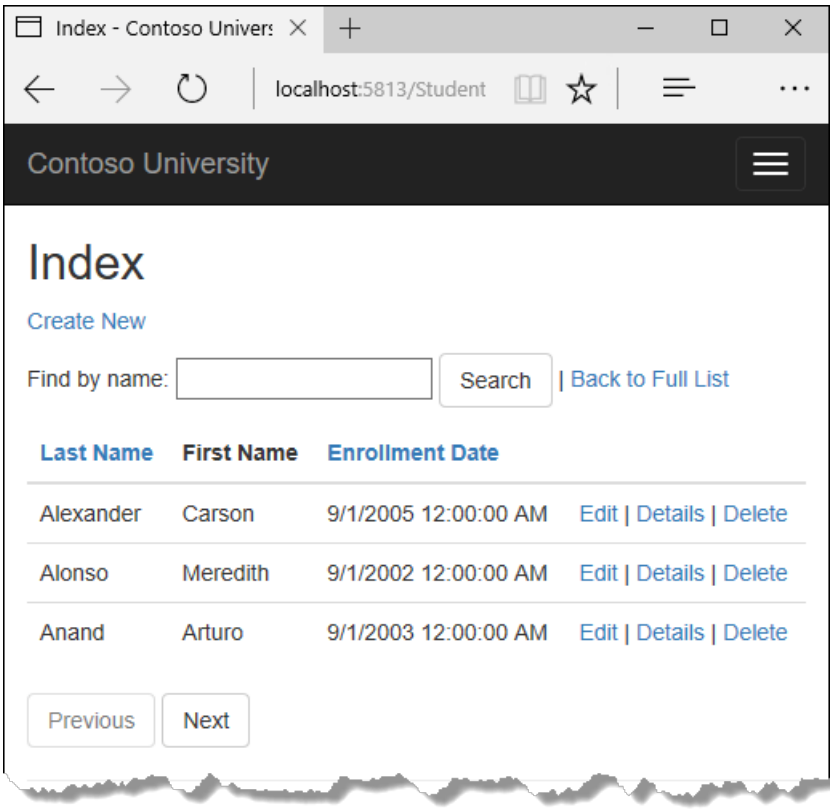
```
http://localhost:5000/Students?SearchString=an
```

If the page is bookmarked, the bookmark contains the URL to the page and the `SearchString` query string. The `method="get"` in the `form` tag is what caused the query string to be generated.

Currently, when a column heading sort link is selected, the filter value from the **Search** box is lost. The lost filter value is fixed in the next section.

Add paging functionality to the Students Index page

In this section, a `PaginatedList` class is created to support paging. The `PaginatedList` class uses `Skip` and `Take` statements to filter data on the server instead of retrieving all rows of the table. The following illustration shows the paging buttons.



In the project folder, create `PaginatedList.cs` with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity
{
    public class PaginatedList<T> : List<T>
    {
        public int PageIndex { get; private set; }
        public int TotalPages { get; private set; }

        public PaginatedList(List<T> items, int count, int pageIndex, int pageSize)
        {
            PageIndex = pageIndex;
            TotalPages = (int)Math.Ceiling(count / (double)pageSize);

            this.AddRange(items);
        }

        public bool HasPreviousPage
        {
            get
            {
                return (PageIndex > 1);
            }
        }

        public bool HasNextPage
        {
            get
            {
                return (PageIndex < TotalPages);
            }
        }

        public static async Task<PaginatedList<T>> CreateAsync(
            IQueryable<T> source, int pageIndex, int pageSize)
        {
            var count = await source.CountAsync();
            var items = await source.Skip(
                (pageIndex - 1) * pageSize)
                .Take(pageSize).ToListAsync();
            return new PaginatedList<T>(items, count, pageIndex, pageSize);
        }
    }
}
```

The `CreateAsync` method in the preceding code takes page size and page number and applies the appropriate `Skip` and `Take` statements to the `IQueryable`. When `ToListAsync` is called on the `IQueryable`, it returns a List containing only the requested page. The properties `HasPreviousPage` and `HasNextPage` are used to enable or disable **Previous** and **Next** paging buttons.

The `CreateAsync` method is used to create the `PaginatedList<T>`. A constructor can't create the `PaginatedList<T>` object, constructors can't run asynchronous code.

Add paging functionality to the Index method

In *Students/Index.cshtml.cs*, update the type of `Student` from `IList<Student>` to `PaginatedList<Student>`:

```
public PaginatedList<Student> Student { get; set; }
```

Update the *Students/Index.cshtml.cs* `OnGetAsync` with the following code:

```
public async Task OnGetAsync(string sortOrder,
    string currentFilter, string searchString, int? pageIndex)
{
    CurrentSort = sortOrder;
    NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    DateSort = sortOrder == "Date" ? "date_desc" : "Date";
    if (searchString != null)
    {
        pageIndex = 1;
    }
    else
    {
        searchString = currentFilter;
    }

    CurrentFilter = searchString;

    IQueryable<Student> studentIQ = from s in _context.Student
                                    select s;
    if (!String.IsNullOrEmpty(searchString))
    {
        studentIQ = studentIQ.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }
    switch (sortOrder)
    {
        case "name_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            studentIQ = studentIQ.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            studentIQ = studentIQ.OrderBy(s => s.LastName);
            break;
    }

    int pageSize = 3;
    Student = await PaginatedList<Student>.CreateAsync(
        studentIQ.AsNoTracking(), pageIndex ?? 1, pageSize);
}
```

The preceding code adds the page index, the current `sortOrder`, and the `currentFilter` to the method signature.

```
public async Task OnGetAsync(string sortOrder,
    string currentFilter, string searchString, int? pageIndex)
```

All the parameters are null when:

- The page is called from the **Students** link.
- The user hasn't clicked a paging or sorting link.

When a paging link is clicked, the page index variable contains the page number to display.

`CurrentSort` provides the Razor Page with the current sort order. The current sort order must be included in the paging links to keep the sort order while paging.

`CurrentFilter` provides the Razor Page with the current filter string. The `CurrentFilter` value:

- Must be included in the paging links in order to maintain the filter settings during paging.
- Must be restored to the text box when the page is redisplayed.

If the search string is changed while paging, the page is reset to 1. The page has to be reset to 1 because the new filter can result in different data to display. When a search value is entered and **Submit** is selected:

- The search string is changed.
- The `searchString` parameter isn't null.

```
if (searchString != null)
{
    pageIndex = 1;
}
else
{
    searchString = currentFilter;
}
```

The `PaginatedList.CreateAsync` method converts the student query to a single page of students in a collection type that supports paging. That single page of students is passed to the Razor Page.

```
Student = await PaginatedList<Student>.CreateAsync(
    studentIQ.AsNoTracking(), pageIndex ?? 1, pageSize);
```

The two question marks in `PaginatedList.CreateAsync` represent the null-coalescing operator. The null-coalescing operator defines a default value for a nullable type. The expression `(pageIndex ?? 1)` means return the value of `pageIndex` if it has a value. If `pageIndex` doesn't have a value, return 1.

Add paging links to the student Razor Page

Update the markup in *Students/Index.cshtml*. The changes are highlighted:

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form asp-page="./Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name: <input type="text" name="SearchString" value="@Model.CurrentFilter" />
            <input type="submit" value="Search" class="btn btn-default" /> |
            <a asp-page="./Index">Back to full List</a>
        </p>
    </div>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort"
```

```
                    asp-route-currentFilter="@Model.CurrentFilter">
                     @Html.DisplayNameFor(model => model.Student[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Student[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort"
                   asp-route-currentFilter="@Model.CurrentFilter">
                    @Html.DisplayNameFor(model => model.Student[0].EnrollmentDate)
                </a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Student)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>

@{
    var prevDisabled = !Model.Student.HasPreviousPage ? "disabled" : "";
    var nextDisabled = !Model.Student.HasNextPage ? "disabled" : "";
}

<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Student.PageIndex - 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-default @prevDisabled">
    Previous
</a>
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Student.PageIndex + 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-default @nextDisabled">
    Next
</a>
```

The column header links use the query string to pass the current search string to the `OnGetAsync` method so that the user can sort within filter results:

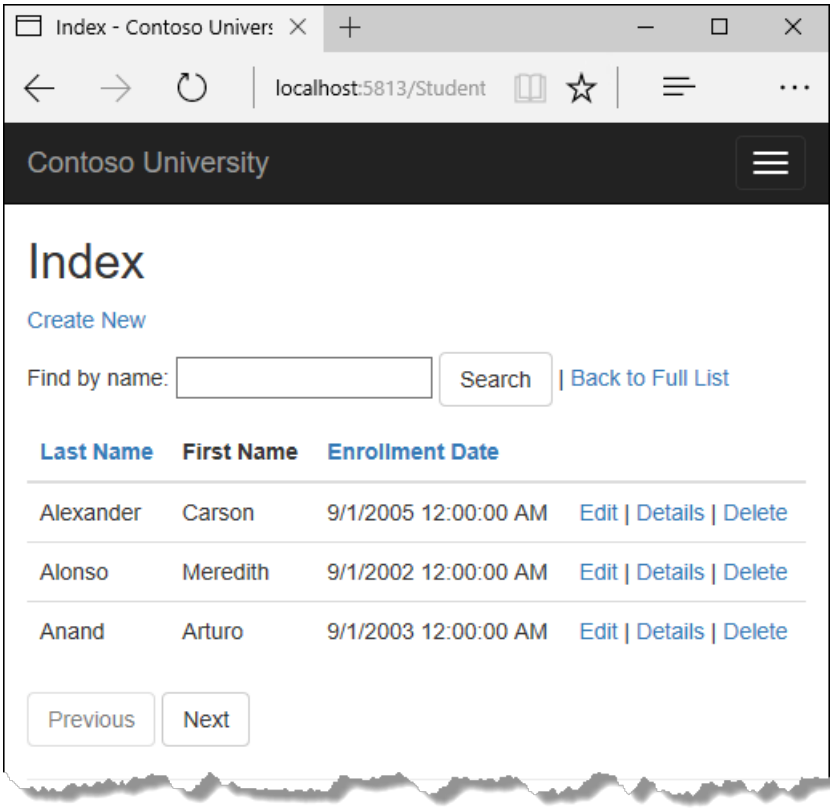
```
<a asp-page="./Index" asp-route-sortOrder="@Model.NameSort"
   asp-route-currentFilter="@Model.CurrentFilter">
    @Html.DisplayNameFor(model => model.Student[0].LastName)
</a>
```

The paging buttons are displayed by tag helpers:

```
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Student.PageIndex - 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-default @prevDisabled">
    Previous
</a>
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Student.PageIndex + 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-default @nextDisabled">
    Next
</a>
```

Run the app and navigate to the students page.

- To make sure paging works, click the paging links in different sort orders.
- To verify that paging works correctly with sorting and filtering, enter a search string and try paging.



To get a better understanding of the code:

- In *Students/Index.cshtml.cs*, set a breakpoint on `switch (sortOrder)`.
- Add a watch for `NameSort`, `DateSort`, `CurrentSort`, and `Model.Student.PageIndex`.
- In *Students/Index.cshtml*, set a breakpoint on `@Html.DisplayNameFor(model => model.Student[0].LastName)`.

Step through the debugger.

Update the About page to show student statistics

In this step, *Pages/About.cshtml* is updated to display how many students have enrolled for each enrollment date. The update uses grouping and includes the following steps:

- Create a view model for the data used by the **About** Page.
- Update the About page to use the view model.

Create the view model

Create a *SchoolViewModels* folder in the *Models* folder.

In the *SchoolViewModels* folder, add a *EnrollmentDateGroup.cs* with the following code:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class EnrollmentDateGroup
    {
        [DataType(DataType.Date)]
        public DateTime? EnrollmentDate { get; set; }

        public int StudentCount { get; set; }
    }
}
```

Update the About page model

The web templates in ASP.NET Core 2.2 do not include the About page. If you are using ASP.NET Core 2.2, create the About Razor Page.

Update the *Pages/About.cshtml.cs* file with the following code:

```
using ContosoUniversity.Models.SchoolViewModels;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using ContosoUniversity.Models;

namespace ContosoUniversity.Pages
{
    public class AboutModel : PageModel
    {
        private readonly SchoolContext _context;

        public AboutModel(SchoolContext context)
        {
            _context = context;
        }

        public IList<EnrollmentDateGroup> Student { get; set; }

        public async Task OnGetAsync()
        {
            IQueryable<EnrollmentDateGroup> data =
                from student in _context.Student
                group student by student.EnrollmentDate into dateGroup
                select new EnrollmentDateGroup()
                {
                    EnrollmentDate = dateGroup.Key,
                    StudentCount = dateGroup.Count()
                };

            Student = await data.AsNoTracking().ToListAsync();
        }
    }
}
```

The LINQ statement groups the student entities by enrollment date, calculates the number of entities in each group, and stores the results in a collection of `EnrollmentDateGroup` view model objects.

Modify the About Razor Page

Replace the code in the *Pages/About.cshtml* file with the following code:

```
@page
@model ContosoUniversity.Pages.AboutModel

@{
    ViewData["Title"] = "Student Body Statistics";
}

<h2>Student Body Statistics</h2>

<table>
    <tr>
        <th>
            Enrollment Date
        </th>
        <th>
            Students
        </th>
    </tr>

    @foreach (var item in Model.Student)
    {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                @item.StudentCount
            </td>
        </tr>
    }
</table>
```

Run the app and navigate to the About page. The count of students for each enrollment date is displayed in a table.

If you run into problems you can't solve, download the completed app for this stage.

Part 4, Razor Pages with EF Core migrations in ASP.NET Core

9/22/2020 • 11 minutes to read • Edit Online

By Tom Dykstra, Jon P Smith, and Rick Anderson

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial introduces the EF Core migrations feature for managing data model changes.

When a new app is developed, the data model changes frequently. Each time the model changes, the model gets out of sync with the database. This tutorial series started by configuring the Entity Framework to create the database if it doesn't exist. Each time the data model changes, you have to drop the database. The next time the app runs, the call to `EnsureCreated` re-creates the database to match the new data model. The `DbInitializer` class then runs to seed the new database.

This approach to keeping the database in sync with the data model works well until you deploy the app to production. When the app is running in production, it's usually storing data that needs to be maintained. The app can't start with a test database each time a change is made (such as adding a new column). The EF Core Migrations feature solves this problem by enabling EF Core to update the database schema instead of creating a new database.

Rather than dropping and recreating the database when the data model changes, migrations updates the schema and retains existing data.

NOTE

SQLite limitations

This tutorial uses the Entity Framework Core *migrations* feature where possible. Migrations updates the database schema to match changes in the data model. However, migrations only does the kinds of changes that the database engine supports, and SQLite's schema change capabilities are limited. For example, adding a column is supported, but removing a column is not supported. If a migration is created to remove a column, the `ef migrations add` command succeeds but the `ef database update` command fails.

The workaround for the SQLite limitations is to manually write migrations code to perform a table rebuild when something in the table changes. The code would go in the `Up` and `Down` methods for a migration and would involve:

- Creating a new table.
- Copying data from the old table to the new table.
- Dropping the old table.
- Renaming the new table.

Writing database-specific code of this type is outside the scope of this tutorial. Instead, this tutorial drops and re-creates the database whenever an attempt to apply a migration would fail. For more information, see the following resources:

- SQLite EF Core Database Provider Limitations
- Customize migration code
- Data seeding
- SQLite ALTER TABLE statement

Drop the database

- Visual Studio
- Visual Studio Code

Use **SQL Server Object Explorer** (SSOX) to delete the database, or run the following command in the **Package Manager Console** (PMC):

```
Drop-Database
```

Create an initial migration

- Visual Studio
- Visual Studio Code

Run the following commands in the PMC:

```
Add-Migration InitialCreate
Update-Database
```

Up and Down methods

The EF Core `migrations add` command generated code to create the database. This migrations code is in the *Migrations<timestamp>_InitialCreate.cs* file. The `Up` method of the `InitialCreate` class creates the database tables that correspond to the data model entity sets. The `Down` method deletes them, as shown in the following example:

```
using System;
```

```
using Microsoft.EntityFrameworkCore.Metadata;
using Microsoft.EntityFrameworkCore.Migrations;

namespace ContosoUniversity.Migrations
{
    public partial class InitialCreate : Migration
    {
        protected override void Up(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.CreateTable(
                name: "Course",
                columns: table => new
                {
                    CourseID = table.Column<int>(nullable: false),
                    Title = table.Column<string>(nullable: true),
                    Credits = table.Column<int>(nullable: false)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_Course", x => x.CourseID);
                });

            migrationBuilder.CreateTable(
                name: "Student",
                columns: table => new
                {
                    ID = table.Column<int>(nullable: false)
                        .Annotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn),
                    LastName = table.Column<string>(nullable: true),
                    FirstMidName = table.Column<string>(nullable: true),
                    EnrollmentDate = table.Column<DateTime>(nullable: false)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_Student", x => x.ID);
                });

            migrationBuilder.CreateTable(
                name: "Enrollment",
                columns: table => new
                {
                    EnrollmentID = table.Column<int>(nullable: false)
                        .Annotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn),
                    CourseID = table.Column<int>(nullable: false),
                    StudentID = table.Column<int>(nullable: false),
                    Grade = table.Column<int>(nullable: true)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_Enrollment", x => x.EnrollmentID);
                    table.ForeignKey(
                        name: "FK_Enrollment_Course_CourseID",
                        column: x => x.CourseID,
                        principalTable: "Course",
                        principalColumn: "CourseID",
                        onDelete: ReferentialAction.Cascade);
                    table.ForeignKey(
                        name: "FK_Enrollment_Student_StudentID",
                        column: x => x.StudentID,
                        principalTable: "Student",
                        principalColumn: "ID",
                        onDelete: ReferentialAction.Cascade);
                });

            migrationBuilder.CreateIndex(
                name: "IX_Enrollment_CourseID",
                table: "Enrollment",
```

```
                column: "CourseID");

            migrationBuilder.CreateIndex(
                name: "IX_Enrollment_StudentID",
                table: "Enrollment",
                column: "StudentID");
        }

        protected override void Down(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.DropTable(
                name: "Enrollment");

            migrationBuilder.DropTable(
                name: "Course");

            migrationBuilder.DropTable(
                name: "Student");
        }
    }
}
```

The preceding code is for the initial migration. The code:

- Was generated by the `migrations add InitialCreate` command.
- Is executed by the `database update` command.
- Creates a database for the data model specified by the database context class.

The migration name parameter ("InitialCreate" in the example) is used for the file name. The migration name can be any valid file name. It's best to choose a word or phrase that summarizes what is being done in the migration. For example, a migration that added a department table might be called "AddDepartmentTable."

The migrations history table

- Use SSOX or your SQLite tool to inspect the database.
- Notice the addition of an `__EFMigrationsHistory` table. The `__EFMigrationsHistory` table keeps track of which migrations have been applied to the database.
- View the data in the `__EFMigrationsHistory` table. It shows one row for the first migration.

The data model snapshot

Migrations creates a *snapshot* of the current data model in *Migrations/SchoolContextModelSnapshot.cs*. When you add a migration, EF determines what changed by comparing the current data model to the snapshot file.

Because the snapshot file tracks the state of the data model, you can't delete a migration by deleting the `<timestamp>_<migrationname>.cs` file. To back out the most recent migration, you have to use the `migrations remove` command. That command deletes the migration and ensures the snapshot is correctly reset. For more information, see dotnet ef migrations remove.

Remove EnsureCreated

This tutorial series started by using `EnsureCreated`. `EnsureCreated` doesn't create a migrations history table and so can't be used with migrations. It's designed for testing or rapid prototyping where the database is dropped and re-created frequently.

From this point forward, the tutorials will use migrations.

In *Data/DBInitializer.cs*, comment out the following line:

```
context.Database.EnsureCreated();
```

Run the app and verify that the database is seeded.

Applying migrations in production

We recommend that production apps **not** call Database.Migrate at application startup. `Migrate` shouldn't be called from an app that is deployed to a server farm. If the app is scaled out to multiple server instances, it's hard to ensure database schema updates don't happen from multiple servers or conflict with read/write access.

Database migration should be done as part of deployment, and in a controlled way. Production database migration approaches include:

- Using migrations to create SQL scripts and using the SQL scripts in deployment.
- Running `dotnet ef database update` from a controlled environment.

Troubleshooting

If the app uses SQL Server LocalDB and displays the following exception:

```
SqlException: Cannot open database "ContosoUniversity" requested by the login.
The login failed.
Login failed for user 'user name'.
```

The solution may be to run `dotnet ef database update` at a command prompt.

Additional resources

- EF Core CLI.
- Package Manager Console (Visual Studio)

Next steps

The next tutorial builds out the data model, adding entity properties and new entities.

PREVIOUS TUTORIAL NEXT TUTORIAL

In this tutorial, the EF Core migrations feature for managing data model changes is used.

If you run into problems you can't solve, download the completed app.

When a new app is developed, the data model changes frequently. Each time the model changes, the model gets out of sync with the database. This tutorial started by configuring the Entity Framework to create the database if it doesn't exist. Each time the data model changes:

- The DB is dropped.
- EF creates a new one that matches the model.
- The app seeds the DB with test data.

This approach to keeping the DB in sync with the data model works well until you deploy the app to production. When the app is running in production, it's usually storing data that needs to be maintained. The app can't start with a test DB each time a change is made (such as adding a new column). The EF Core Migrations feature solves

this problem by enabling EF Core to update the DB schema instead of creating a new DB.

Rather than dropping and recreating the DB when the data model changes, migrations updates the schema and retains existing data.

Drop the database

Use **SQL Server Object Explorer** (SSOX) or the `database drop` command:

- Visual Studio
- Visual Studio Code

In the **Package Manager Console** (PMC), run the following command:

```
Drop-Database
```

Run `Get-Help about_EntityFrameworkCore` from the PMC to get help information.

Create an initial migration and update the DB

Build the project and create the first migration.

- Visual Studio
- Visual Studio Code

```
Add-Migration InitialCreate
Update-Database
```

Examine the Up and Down methods

The EF Core `migrations add` command generated code to create the DB. This migrations code is in the *Migrations<timestamp>_InitialCreate.cs* file. The `Up` method of the `InitialCreate` class creates the DB tables that correspond to the data model entity sets. The `Down` method deletes them, as shown in the following example:

```
public partial class InitialCreate : Migration
{
    protected override void Up(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.CreateTable(
            name: "Course",
            columns: table => new
            {
                CourseID = table.Column<int>(nullable: false),
                Title = table.Column<string>(nullable: true),
                Credits = table.Column<int>(nullable: false)
            },
            constraints: table =>
            {
                table.PrimaryKey("PK_Course", x => x.CourseID);
            });

        migrationBuilder.CreateTable(
    protected override void Down(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.DropTable(
            name: "Enrollment");

        migrationBuilder.DropTable(
            name: "Course");

        migrationBuilder.DropTable(
            name: "Student");
    }
}
```

Migrations calls the `Up` method to implement the data model changes for a migration. When you enter a command to roll back the update, migrations calls the `Down` method.

The preceding code is for the initial migration. That code was created when the `migrations add InitialCreate` command was run. The migration name parameter ("InitialCreate" in the example) is used for the file name. The migration name can be any valid file name. It's best to choose a word or phrase that summarizes what is being done in the migration. For example, a migration that added a department table might be called "AddDepartmentTable."

If the initial migration is created and the DB exists:

- The DB creation code is generated.
- The DB creation code doesn't need to run because the DB already matches the data model. If the DB creation code is run, it doesn't make any changes because the DB already matches the data model.

When the app is deployed to a new environment, the DB creation code must be run to create the DB.

Previously the DB was dropped and doesn't exist, so migrations creates the new DB.

The data model snapshot

Migrations create a *snapshot* of the current database schema in *Migrations/SchoolContextModelSnapshot.cs*. When you add a migration, EF determines what changed by comparing the data model to the snapshot file.

To delete a migration, use the following command:

- Visual Studio
- Visual Studio Code

Remove-Migration

The remove migrations command deletes the migration and ensures the snapshot is correctly reset.

Remove EnsureCreated and test the app

For early development, `EnsureCreated` was used. In this tutorial, migrations are used. `EnsureCreated` has the following limitations:

- Bypasses migrations and creates the DB and schema.
- Doesn't create a migrations table.
- Can *not* be used with migrations.
- Is designed for testing or rapid prototyping where the DB is dropped and re-created frequently.

Remove `EnsureCreated`:

```
context.Database.EnsureCreated();
```

Run the app and verify the DB is seeded.

Inspect the database

Use **SQL Server Object Explorer** to inspect the DB. Notice the addition of an `__EFMigrationsHistory` table. The `__EFMigrationsHistory` table keeps track of which migrations have been applied to the DB. View the data in the `__EFMigrationsHistory` table, it shows one row for the first migration. The last log in the preceding CLI output example shows the INSERT statement that creates this row.

Run the app and verify that everything works.

Applying migrations in production

We recommend production apps should **not** call Database.Migrate at application startup. `Migrate` shouldn't be called from an app in server farm. For example, if the app has been cloud deployed with scale-out (multiple instances of the app are running).

Database migration should be done as part of deployment, and in a controlled way. Production database migration approaches include:

- Using migrations to create SQL scripts and using the SQL scripts in deployment.
- Running `dotnet ef database update` from a controlled environment.

EF Core uses the `__MigrationsHistory` table to see if any migrations need to run. If the DB is up-to-date, no migration is run.

Troubleshooting

Download the completed app.

The app generates the following exception:

```
SqlException: Cannot open database "ContosoUniversity" requested by the login.
The login failed.
Login failed for user 'user name'.
```

Solution: Run `dotnet ef database update`

Part 5, Razor Pages with EF Core in ASP.NET Core - Data Model

9/22/2020 • 57 minutes to read • Edit Online

By Tom Dykstra and Rick Anderson

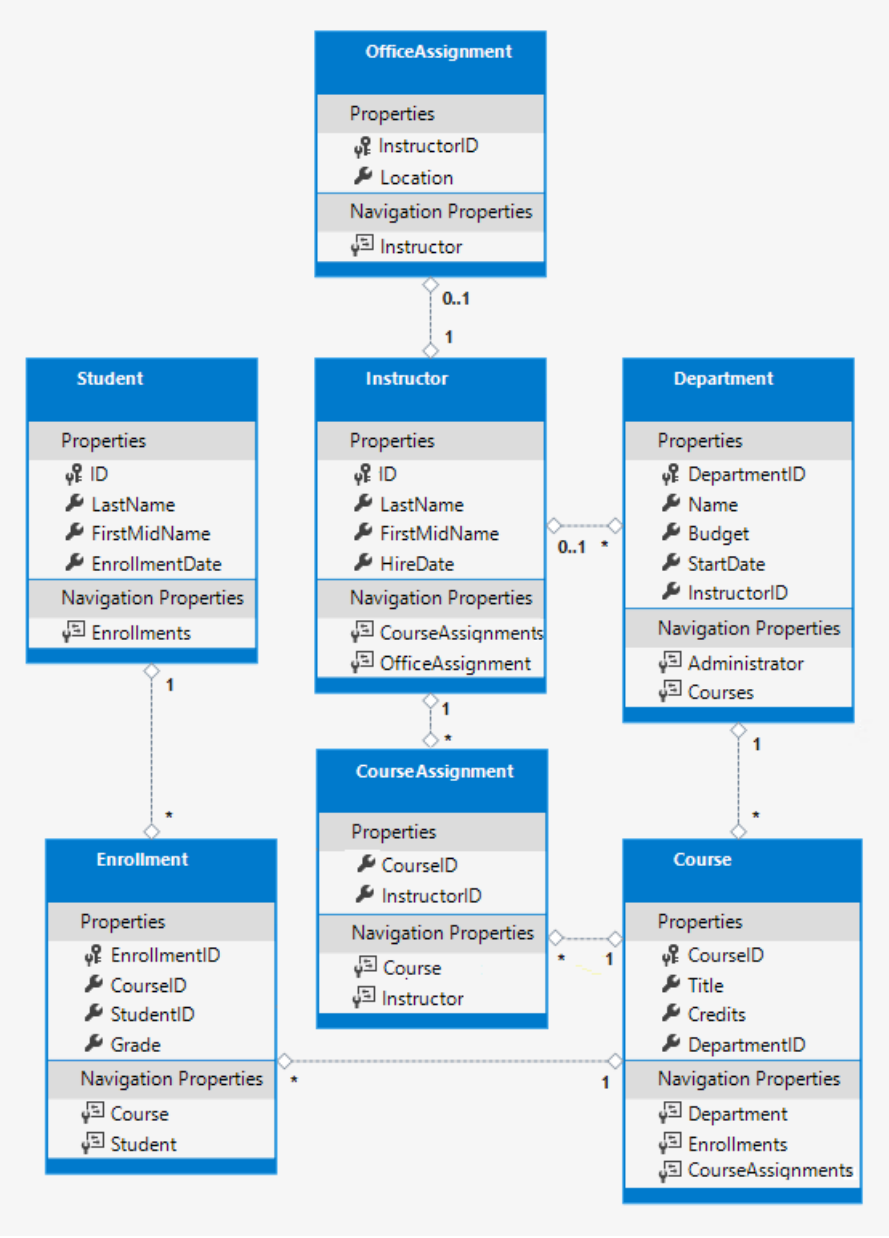
The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

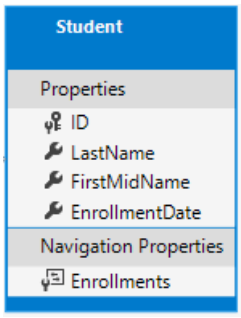
The previous tutorials worked with a basic data model that was composed of three entities. In this tutorial:

- More entities and relationships are added.
- The data model is customized by specifying formatting, validation, and database mapping rules.

The completed data model is shown in the following illustration:



The Student entity



Replace the code in *Models/Student.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [Required]
        [StringLength(50)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }
        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The preceding code adds a `FullName` property and adds the following attributes to existing properties:

- `[DataType]`
- `[DisplayFormat]`
- `[StringLength]`
- `[Column]`
- `[Required]`
- `[Display]`

The FullName calculated property

`FullName` is a calculated property that returns a value that's created by concatenating two other properties.

`FullName` can't be set, so it has only a get accessor. No `FullName` column is created in the database.

The DataType attribute

```
[DataType(DataType.Date)]
```

For student enrollment dates, all of the pages currently display the time of day along with the date, although only the date is relevant. By using data annotation attributes, you can make one code change that will fix the display format in every page that shows the data.

The DataType attribute specifies a data type that's more specific than the database intrinsic type. In this case only the date should be displayed, not the date and time. The DataType Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress, etc. The `DataType` attribute can also enable the app to automatically provide type-specific features. For example:

- The `mailto:` link is automatically created for `DataType.EmailAddress`.
- The date selector is provided for `DataType.Date` in most browsers.

The `DataType` attribute emits HTML 5 `data-` (pronounced data dash) attributes. The `DataType` attributes don't provide validation.

The DisplayFormat attribute

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
```

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the date field is displayed according to the default formats based on the server's CultureInfo.

The `DisplayFormat` attribute is used to explicitly specify the date format. The `ApplyFormatInEditMode` setting specifies that the formatting should also be applied to the edit UI. Some fields shouldn't use `ApplyFormatInEditMode`. For example, the currency symbol should generally not be displayed in an edit text box.

The `DisplayFormat` attribute can be used by itself. It's generally a good idea to use the `DataType` attribute with the `DisplayFormat` attribute. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen. The `DataType` attribute provides the following benefits that are not available in `DisplayFormat`:

- The browser can enable HTML5 features. For example, show a calendar control, the locale-appropriate currency symbol, email links, and client-side input validation.
- By default, the browser renders data using the correct format based on the locale.

For more information, see the <input> Tag Helper documentation.

The StringLength attribute

```
[StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
```

Data validation rules and validation error messages can be specified with attributes. The StringLength attribute specifies the minimum and maximum length of characters that are allowed in a data field. The code shown limits names to no more than 50 characters. An example that sets the minimum string length is shown later.

The `StringLength` attribute also provides client-side and server-side validation. The minimum value has no impact on the database schema.

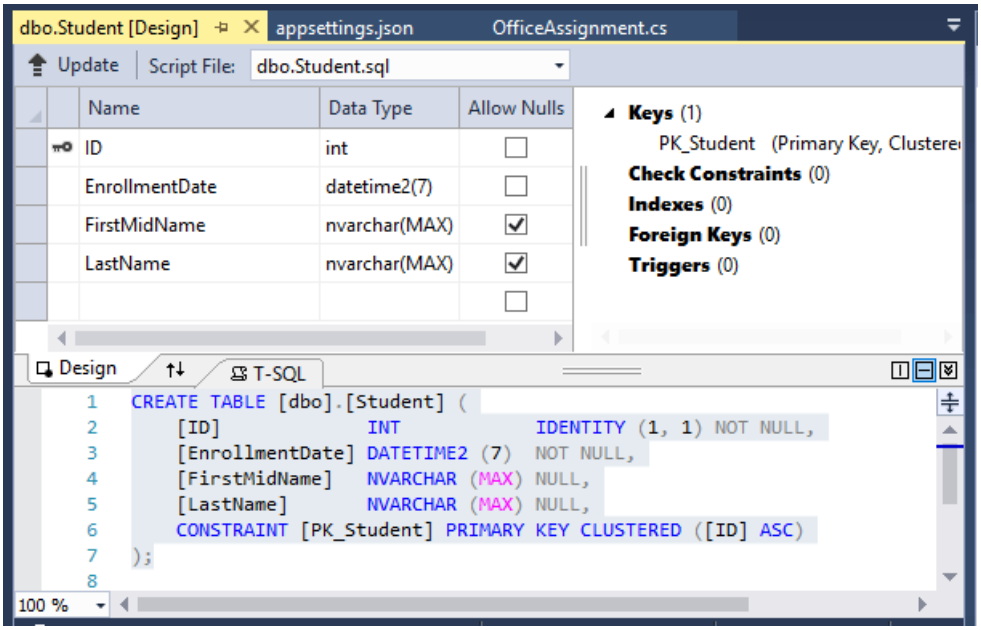
The `StringLength` attribute doesn't prevent a user from entering white space for a name. The RegularExpression attribute can be used to apply restrictions to the input. For example, the following code requires the first

character to be upper case and the remaining characters to be alphabetical:

```
[RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
```

- Visual Studio
- Visual Studio Code

In **SQL Server Object Explorer** (SSOX), open the Student table designer by double-clicking the **Student** table.



The preceding image shows the schema for the `Student` table. The name fields have type `nvarchar(MAX)`. When a migration is created and applied later in this tutorial, the name fields become `nvarchar(50)` as a result of the string length attributes.

The Column attribute

```
[Column("FirstName")]
public string FirstMidName { get; set; }
```

Attributes can control how classes and properties are mapped to the database. In the `Student` model, the `Column` attribute is used to map the name of the `FirstMidName` property to "FirstName" in the database.

When the database is created, property names on the model are used for column names (except when the `Column` attribute is used). The `Student` model uses `FirstMidName` for the first-name field because the field might also contain a middle name.

With the `[Column]` attribute, `Student.FirstMidName` in the data model maps to the `FirstName` column of the `Student` table. The addition of the `Column` attribute changes the model backing the `SchoolContext`. The model backing the `SchoolContext` no longer matches the database. That discrepancy will be resolved by adding a migration later in this tutorial.

The Required attribute

```
[Required]
```

The `Required` attribute makes the name properties required fields. The `Required` attribute isn't needed for non-nullable types such as value types (for example, `DateTime`, `int`, and `double`). Types that can't be null are automatically treated as required fields.

The `Required` attribute must be used with `MinimumLength` for the `MinimumLength` to be enforced.

```
[Display(Name = "Last Name")]
[Required]
[StringLength(50, MinimumLength=2)]
public string LastName { get; set; }
```

`MinimumLength` and `Required` allow whitespace to satisfy the validation. Use the `RegularExpression` attribute for full control over the string.

The Display attribute

```
[Display(Name = "Last Name")]
```

The `Display` attribute specifies that the caption for the text boxes should be "First Name", "Last Name", "Full Name", and "Enrollment Date." The default captions had no space dividing the words, for example "Lastname."

Create a migration

Run the app and go to the Students page. An exception is thrown. The `[Column]` attribute causes EF to expect to find a column named `FirstName`, but the column name in the database is still `FirstMidName`.

- Visual Studio
- Visual Studio Code

The error message is similar to the following example:

```
SqlException: Invalid column name 'FirstName'.
```

- In the PMC, enter the following commands to create a new migration and update the database:

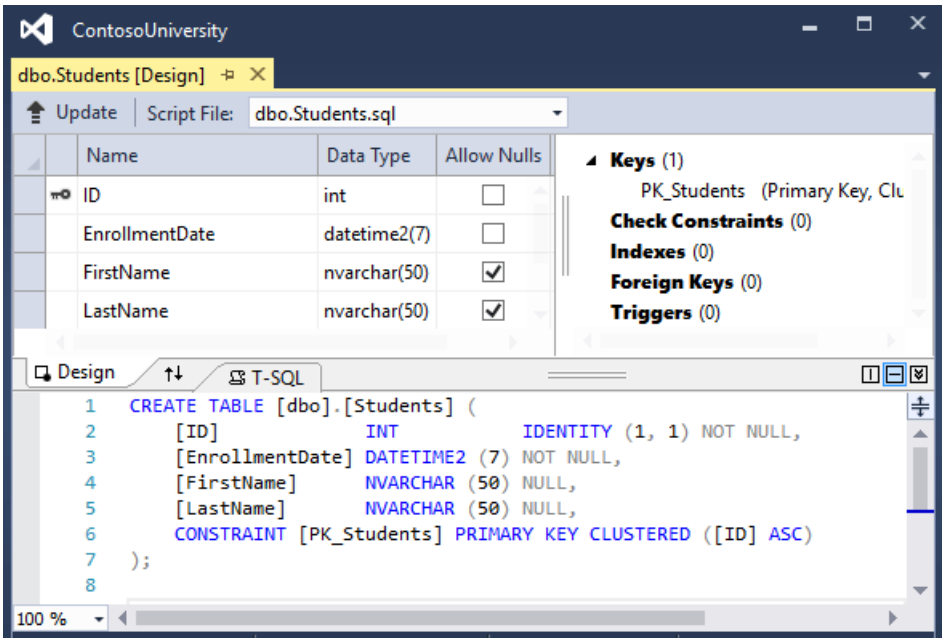
  ```
  Add-Migration ColumnFirstName
  Update-Database
  ```

  The first of these commands generates the following warning message:

  ```
  An operation was scaffolded that may result in the loss of data.
  Please review the migration for accuracy.
  ```

  The warning is generated because the name fields are now limited to 50 characters. If a name in the database had more than 50 characters, the 51 to last character would be lost.

- Open the Student table in SSOX:

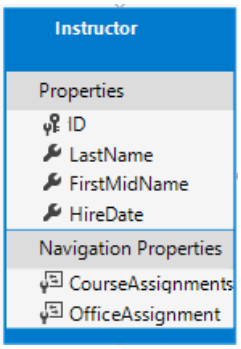


Before the migration was applied, the name columns were of type nvarchar(MAX). The name columns are now `nvarchar(50)`. The column name has changed from `FirstMidName` to `FirstName`.

- Run the app and go to the Students page.
- Notice that times are not input or displayed along with dates.
- Select **Create New**, and try to enter a name longer than 50 characters.

> **NOTE**
> In the following sections, building the app at some stages generates compiler errors. The instructions specify when to build the app.

The Instructor Entity



Create *Models/Instructor.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor
    {
        public int ID { get; set; }

        [Required]
        [Display(Name = "Last Name")]
        [StringLength(50)]
        public string LastName { get; set; }

        [Required]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        [StringLength(50)]
        public string FirstMidName { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get { return LastName + ", " + FirstMidName; }
        }

        public ICollection<CourseAssignment> CourseAssignments { get; set; }
        public OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Multiple attributes can be on one line. The `HireDate` attributes could be written as follows:

```
[DataType(DataType.Date),Display(Name = "Hire Date"),DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
```

Navigation properties

The `CourseAssignments` and `OfficeAssignment` properties are navigation properties.

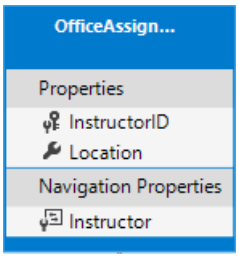
An instructor can teach any number of courses, so `CourseAssignments` is defined as a collection.

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

An instructor can have at most one office, so the `OfficeAssignment` property holds a single `OfficeAssignment` entity. `OfficeAssignment` is null if no office is assigned.

```
public OfficeAssignment OfficeAssignment { get; set; }
```

The OfficeAssignment entity



Create *Models/OfficeAssignment.cs* with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class OfficeAssignment
    {
        [Key]
        public int InstructorID { get; set; }
        [StringLength(50)]
        [Display(Name = "Office Location")]
        public string Location { get; set; }

        public Instructor Instructor { get; set; }
    }
}
```

The Key attribute

The `[Key]` attribute is used to identify a property as the primary key (PK) when the property name is something other than classnameID or ID.

There's a one-to-zero-or-one relationship between the `Instructor` and `OfficeAssignment` entities. An office assignment only exists in relation to the instructor it's assigned to. The `OfficeAssignment` PK is also its foreign key (FK) to the `Instructor` entity.

EF Core can't automatically recognize `InstructorID` as the PK of `OfficeAssignment` because `InstructorID` doesn't follow the ID or classnameID naming convention. Therefore, the `Key` attribute is used to identify `InstructorID` as the PK:

```
[Key]
public int InstructorID { get; set; }
```

By default, EF Core treats the key as non-database-generated because the column is for an identifying relationship.

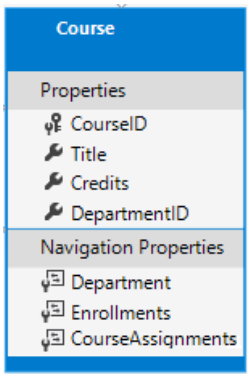
The Instructor navigation property

The `Instructor.OfficeAssignment` navigation property can be null because there might not be an `OfficeAssignment` row for a given instructor. An instructor might not have an office assignment.

The `OfficeAssignment.Instructor` navigation property will always have an instructor entity because the foreign key `InstructorID` type is `int`, a non-nullable value type. An office assignment can't exist without an instructor.

When an `Instructor` entity has a related `OfficeAssignment` entity, each entity has a reference to the other one in its navigation property.

The Course Entity



Update *Models/Course.cs* with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        [Display(Name = "Number")]
        public int CourseID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Title { get; set; }

        [Range(0, 5)]
        public int Credits { get; set; }

        public int DepartmentID { get; set; }

        public Department Department { get; set; }
        public ICollection<Enrollment> Enrollments { get; set; }
        public ICollection<CourseAssignment> CourseAssignments { get; set; }
    }
}
```

The `Course` entity has a foreign key (FK) property `DepartmentID`. `DepartmentID` points to the related `Department` entity. The `Course` entity has a `Department` navigation property.

EF Core doesn't require a foreign key property for a data model when the model has a navigation property for a related entity. EF Core automatically creates FKs in the database wherever they're needed. EF Core creates shadow properties for automatically created FKs. However, explicitly including the FK in the data model can make updates simpler and more efficient. For example, consider a model where the FK property `DepartmentID` is *not* included. When a course entity is fetched to edit:

- The `Department` property is null if it's not explicitly loaded.
- To update the course entity, the `Department` entity must first be fetched.

When the FK property `DepartmentID` is included in the data model, there's no need to fetch the `Department` entity before an update.

The DatabaseGenerated attribute

The `[DatabaseGenerated(DatabaseGeneratedOption.None)]` attribute specifies that the PK is provided by the application rather than generated by the database.

```
[DatabaseGenerated(DatabaseGeneratedOption.None)]
[Display(Name = "Number")]
public int CourseID { get; set; }
```

By default, EF Core assumes that PK values are generated by the database. Database-generated is generally the best approach. For `Course` entities, the user specifies the PK. For example, a course number such as a 1000 series for the math department, a 2000 series for the English department.

The `DatabaseGenerated` attribute can also be used to generate default values. For example, the database can automatically generate a date field to record the date a row was created or updated. For more information, see Generated Properties.

Foreign key and navigation properties

The foreign key (FK) properties and navigation properties in the `Course` entity reflect the following relationships:

A course is assigned to one department, so there's a `DepartmentID` FK and a `Department` navigation property.

```
public int DepartmentID { get; set; }
public Department Department { get; set; }
```

A course can have any number of students enrolled in it, so the `Enrollments` navigation property is a collection:

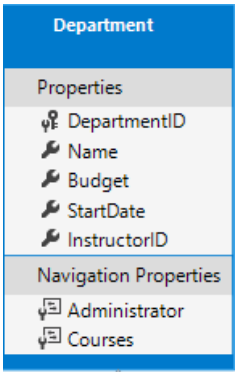
```
public ICollection<Enrollment> Enrollments { get; set; }
```

A course may be taught by multiple instructors, so the `CourseAssignments` navigation property is a collection:

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

`CourseAssignment` is explained later.

The Department entity



Create *Models/Department.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The Column attribute

Previously the `Column` attribute was used to change column name mapping. In the code for the `Department` entity, the `Column` attribute is used to change SQL data type mapping. The `Budget` column is defined using the SQL Server money type in the database:

```
[Column(TypeName="money")]
public decimal Budget { get; set; }
```

Column mapping is generally not required. EF Core chooses the appropriate SQL Server data type based on the CLR type for the property. The CLR `decimal` type maps to a SQL Server `decimal` type. `Budget` is for currency, and the money data type is more appropriate for currency.

Foreign key and navigation properties

The FK and navigation properties reflect the following relationships:

- A department may or may not have an administrator.
- An administrator is always an instructor. Therefore the `InstructorID` property is included as the FK to the `Instructor` entity.

The navigation property is named `Administrator` but holds an `Instructor` entity:

```
public int? InstructorID { get; set; }
public Instructor Administrator { get; set; }
```

The question mark (?) in the preceding code specifies the property is nullable.

A department may have many courses, so there's a Courses navigation property:

```
public ICollection<Course> Courses { get; set; }
```

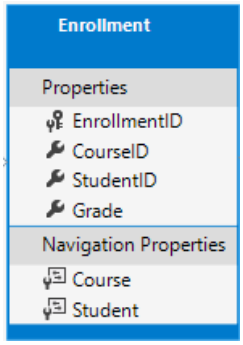
By convention, EF Core enables cascade delete for non-nullable FKs and for many-to-many relationships. This default behavior can result in circular cascade delete rules. Circular cascade delete rules cause an exception when a migration is added.

For example, if the `Department.InstructorID` property was defined as non-nullable, EF Core would configure a cascade delete rule. In that case, the department would be deleted when the instructor assigned as its administrator is deleted. In this scenario, a restrict rule would make more sense. The following fluent API would set a restrict rule and disable cascade delete.

```
modelBuilder.Entity<Department>()
   .HasOne(d => d.Administrator)
   .WithMany()
   .OnDelete(DeleteBehavior.Restrict)
```

The Enrollment entity

An enrollment record is for one course taken by one student.



Update *Models/Enrollment.cs* with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        [DisplayFormat(NullDisplayText = "No grade")]
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

Foreign key and navigation properties

The FK properties and navigation properties reflect the following relationships:

An enrollment record is for one course, so there's a `CourseID` FK property and a `Course` navigation property:

```
public int CourseID { get; set; }
public Course Course { get; set; }
```

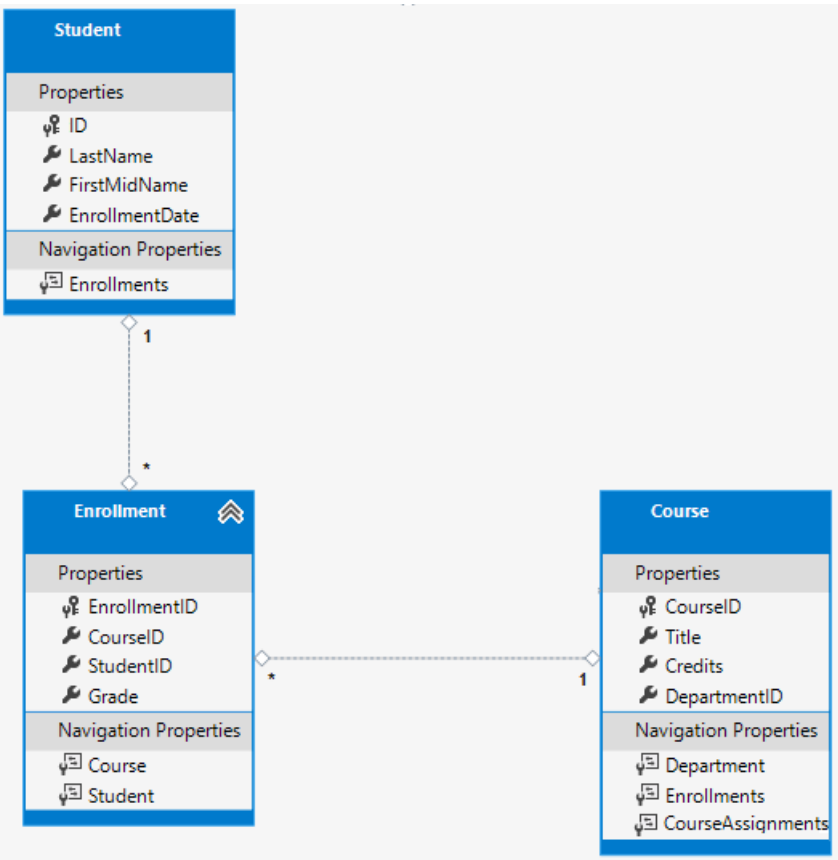
An enrollment record is for one student, so there's a `StudentID` FK property and a `Student` navigation property:

```
public int StudentID { get; set; }
public Student Student { get; set; }
```

Many-to-Many Relationships

There's a many-to-many relationship between the `Student` and `Course` entities. The `Enrollment` entity functions as a many-to-many join table *with payload* in the database. "With payload" means that the `Enrollment` table contains additional data besides FKs for the joined tables (in this case, the PK and `Grade`).

The following illustration shows what these relationships look like in an entity diagram. (This diagram was generated using EF Power Tools for EF 6.x. Creating the diagram isn't part of the tutorial.)



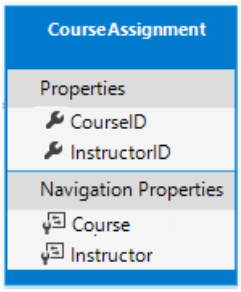
Each relationship line has a 1 at one end and an asterisk (*) at the other, indicating a one-to-many relationship.

If the `Enrollment` table didn't include grade information, it would only need to contain the two FKs (`CourseID` and `StudentID`). A many-to-many join table without payload is sometimes called a pure join table (PJT).

The `Instructor` and `Course` entities have a many-to-many relationship using a pure join table.

Note: EF 6.x supports implicit join tables for many-to-many relationships, but EF Core doesn't. For more information, see Many-to-many relationships in EF Core 2.0.

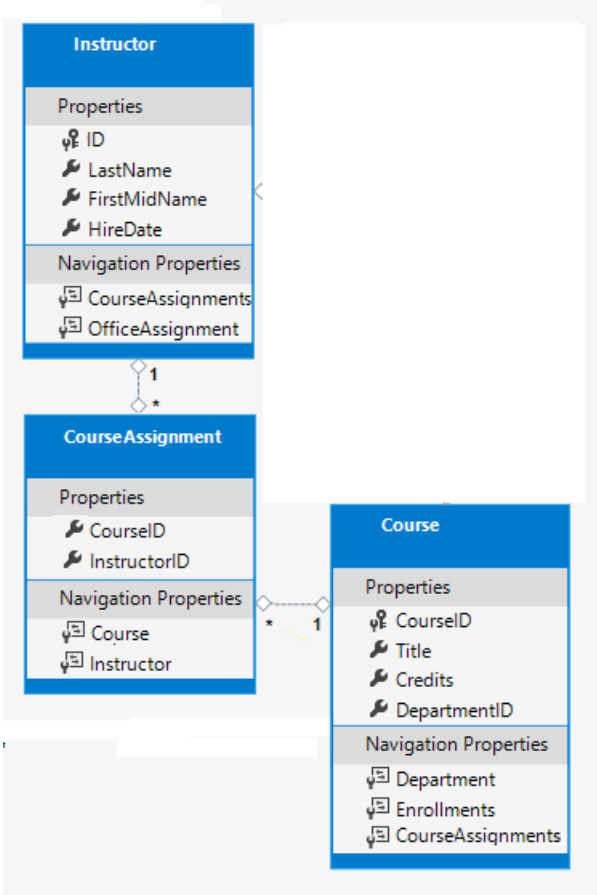
The CourseAssignment entity



Create *Models/CourseAssignment.cs* with the following code:

```
namespace ContosoUniversity.Models
{
    public class CourseAssignment
    {
        public int InstructorID { get; set; }
        public int CourseID { get; set; }
        public Instructor Instructor { get; set; }
        public Course Course { get; set; }
    }
}
```

The Instructor-to-Courses many-to-many relationship requires a join table, and the entity for that join table is CourseAssignment.



It's common to name a join entity `EntityName1EntityName2`. For example, the Instructor-to-Courses join table using this pattern would be `CourseInstructor`. However, we recommend using a name that describes the relationship.

Data models start out simple and grow. Join tables without payload (PJTs) frequently evolve to include payload. By starting with a descriptive entity name, the name doesn't need to change when the join table changes. Ideally, the join entity would have its own natural (possibly single word) name in the business domain. For example,

Books and Customers could be linked with a join entity called Ratings. For the Instructor-to-Courses many-to-many relationship, `CourseAssignment` is preferred over `CourseInstructor`.

Composite key

The two FKs in `CourseAssignment` (`InstructorID` and `CourseID`) together uniquely identify each row of the `CourseAssignment` table. `CourseAssignment` doesn't require a dedicated PK. The `InstructorID` and `CourseID` properties function as a composite PK. The only way to specify composite PKs to EF Core is with the *fluent API*. The next section shows how to configure the composite PK.

The composite key ensures that:

- Multiple rows are allowed for one course.
- Multiple rows are allowed for one instructor.
- Multiple rows aren't allowed for the same instructor and course.

The `Enrollment` join entity defines its own PK, so duplicates of this sort are possible. To prevent such duplicates:

- Add a unique index on the FK fields, or
- Configure `Enrollment` with a primary composite key similar to `CourseAssignment`. For more information, see Indexes.

Update the database context

Update *Data/SchoolContext.cs* with the following code:

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) : base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
        public DbSet<Department> Departments { get; set; }
        public DbSet<Instructor> Instructors { get; set; }
        public DbSet<OfficeAssignment> OfficeAssignments { get; set; }
        public DbSet<CourseAssignment> CourseAssignments { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
            modelBuilder.Entity<Department>().ToTable("Department");
            modelBuilder.Entity<Instructor>().ToTable("Instructor");
            modelBuilder.Entity<OfficeAssignment>().ToTable("OfficeAssignment");
            modelBuilder.Entity<CourseAssignment>().ToTable("CourseAssignment");

            modelBuilder.Entity<CourseAssignment>()
                .HasKey(c => new { c.CourseID, c.InstructorID });
        }
    }
}
```

The preceding code adds the new entities and configures the `CourseAssignment` entity's composite PK.

Fluent API alternative to attributes

The `OnModelCreating` method in the preceding code uses the *fluent API* to configure EF Core behavior. The API is called "fluent" because it's often used by stringing a series of method calls together into a single statement. The following code is an example of the fluent API:

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    modelBuilder.Entity<Blog>()
        .Property(b => b.Url)
        .IsRequired();
}
```

In this tutorial, the fluent API is used only for database mapping that can't be done with attributes. However, the fluent API can specify most of the formatting, validation, and mapping rules that can be done with attributes.

Some attributes such as `MinimumLength` can't be applied with the fluent API. `MinimumLength` doesn't change the schema, it only applies a minimum length validation rule.

Some developers prefer to use the fluent API exclusively so that they can keep their entity classes "clean." Attributes and the fluent API can be mixed. There are some configurations that can only be done with the fluent API (specifying a composite PK). There are some configurations that can only be done with attributes (`MinimumLength`). The recommended practice for using fluent API or attributes:

- Choose one of these two approaches.
- Use the chosen approach consistently as much as possible.

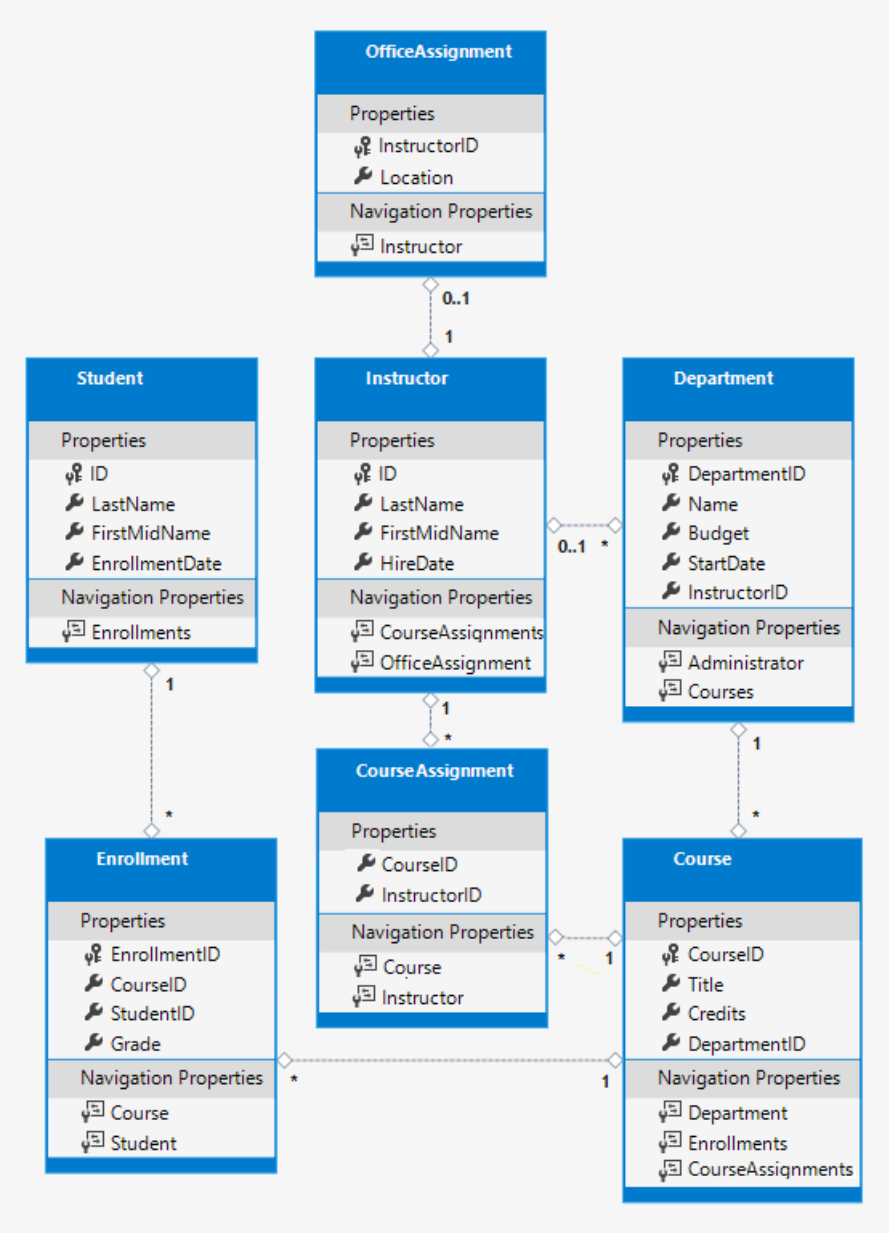
Some of the attributes used in this tutorial are used for:

- Validation only (for example, `MinimumLength`).
- EF Core configuration only (for example, `HasKey`).
- Validation and EF Core configuration (for example, `[StringLength(50)]`).

For more information about attributes vs. fluent API, see Methods of configuration.

Entity diagram

The following illustration shows the diagram that EF Power Tools create for the completed School model.



The preceding diagram shows:

- Several one-to-many relationship lines (1 to *).
- The one-to-zero-or-one relationship line (1 to 0..1) between the `Instructor` and `OfficeAssignment` entities.
- The zero-or-one-to-many relationship line (0..1 to *) between the `Instructor` and `Department` entities.

Seed the database

Update the code in *Data/DbInitializer.cs*:

```
using System;
using System.Linq;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            //context.Database.EnsureCreated();
```

```
            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
                new Student { FirstMidName = "Carson",   LastName = "Alexander",
                    EnrollmentDate = DateTime.Parse("2016-09-01") },
                new Student { FirstMidName = "Meredith", LastName = "Alonso",
                    EnrollmentDate = DateTime.Parse("2018-09-01") },
                new Student { FirstMidName = "Arturo",   LastName = "Anand",
                    EnrollmentDate = DateTime.Parse("2019-09-01") },
                new Student { FirstMidName = "Gytis",    LastName = "Barzdukas",
                    EnrollmentDate = DateTime.Parse("2018-09-01") },
                new Student { FirstMidName = "Yan",      LastName = "Li",
                    EnrollmentDate = DateTime.Parse("2018-09-01") },
                new Student { FirstMidName = "Peggy",    LastName = "Justice",
                    EnrollmentDate = DateTime.Parse("2017-09-01") },
                new Student { FirstMidName = "Laura",    LastName = "Norman",
                    EnrollmentDate = DateTime.Parse("2019-09-01") },
                new Student { FirstMidName = "Nino",     LastName = "Olivetto",
                    EnrollmentDate = DateTime.Parse("2011-09-01") }
            };

            context.Students.AddRange(students);
            context.SaveChanges();

            var instructors = new Instructor[]
            {
                new Instructor { FirstMidName = "Kim",     LastName = "Abercrombie",
                    HireDate = DateTime.Parse("1995-03-11") },
                new Instructor { FirstMidName = "Fadi",    LastName = "Fakhouri",
                    HireDate = DateTime.Parse("2002-07-06") },
                new Instructor { FirstMidName = "Roger",   LastName = "Harui",
                    HireDate = DateTime.Parse("1998-07-01") },
                new Instructor { FirstMidName = "Candace", LastName = "Kapoor",
                    HireDate = DateTime.Parse("2001-01-15") },
                new Instructor { FirstMidName = "Roger",   LastName = "Zheng",
                    HireDate = DateTime.Parse("2004-02-12") }
            };

            context.Instructors.AddRange(instructors);
            context.SaveChanges();

            var departments = new Department[]
            {
                new Department { Name = "English",     Budget = 350000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Abercrombie").ID },
                new Department { Name = "Mathematics", Budget = 100000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Fakhouri").ID },
                new Department { Name = "Engineering", Budget = 350000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Harui").ID },
                new Department { Name = "Economics",   Budget = 100000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Kapoor").ID }
            };

            context.Departments.AddRange(departments);
            context.SaveChanges();

            var courses = new Course[]
            {
                new Course {CourseID = 1050, Title = "Chemistry",      Credits = 3,
                    DepartmentID = departments.Single( s => s.Name == "Engineering").DepartmentID
```

```
        },
        new Course {CourseID = 4022, Title = "Microeconomics", Credits = 3,
            DepartmentID = departments.Single( s => s.Name == "Economics").DepartmentID
        },
        new Course {CourseID = 4041, Title = "Macroeconomics", Credits = 3,
            DepartmentID = departments.Single( s => s.Name == "Economics").DepartmentID
        },
        new Course {CourseID = 1045, Title = "Calculus",       Credits = 4,
            DepartmentID = departments.Single( s => s.Name == "Mathematics").DepartmentID
        },
        new Course {CourseID = 3141, Title = "Trigonometry",   Credits = 4,
            DepartmentID = departments.Single( s => s.Name == "Mathematics").DepartmentID
        },
        new Course {CourseID = 2021, Title = "Composition",    Credits = 3,
            DepartmentID = departments.Single( s => s.Name == "English").DepartmentID
        },
        new Course {CourseID = 2042, Title = "Literature",     Credits = 4,
            DepartmentID = departments.Single( s => s.Name == "English").DepartmentID
        },
    };

    context.Courses.AddRange(courses);
    context.SaveChanges();

    var officeAssignments = new OfficeAssignment[]
    {
        new OfficeAssignment {
            InstructorID = instructors.Single( i => i.LastName == "Fakhouri").ID,
            Location = "Smith 17" },
        new OfficeAssignment {
            InstructorID = instructors.Single( i => i.LastName == "Harui").ID,
            Location = "Gowan 27" },
        new OfficeAssignment {
            InstructorID = instructors.Single( i => i.LastName == "Kapoor").ID,
            Location = "Thompson 304" },
    };

    context.OfficeAssignments.AddRange(officeAssignments);
    context.SaveChanges();

    var courseInstructors = new CourseAssignment[]
    {
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Kapoor").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Harui").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Microeconomics" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Zheng").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Macroeconomics" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Zheng").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Calculus" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Fakhouri").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Trigonometry" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Harui").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Composition" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Abercrombie").ID
```

```
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Literature" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Abercrombie").ID
            },
    };

    context.CourseAssignments.AddRange(courseInstructors);
    context.SaveChanges();

    var enrollments = new Enrollment[]
    {
        new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alexander").ID,
            CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID,
            Grade = Grade.A
        },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alexander").ID,
            CourseID = courses.Single(c => c.Title == "Microeconomics" ).CourseID,
            Grade = Grade.C
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alexander").ID,
            CourseID = courses.Single(c => c.Title == "Macroeconomics" ).CourseID,
            Grade = Grade.B
            },
            new Enrollment {
                StudentID = students.Single(s => s.LastName == "Alonso").ID,
            CourseID = courses.Single(c => c.Title == "Calculus" ).CourseID,
            Grade = Grade.B
            },
            new Enrollment {
                StudentID = students.Single(s => s.LastName == "Alonso").ID,
            CourseID = courses.Single(c => c.Title == "Trigonometry" ).CourseID,
            Grade = Grade.B
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alonso").ID,
            CourseID = courses.Single(c => c.Title == "Composition" ).CourseID,
            Grade = Grade.B
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Anand").ID,
            CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Anand").ID,
            CourseID = courses.Single(c => c.Title == "Microeconomics").CourseID,
            Grade = Grade.B
            },
        new Enrollment {
            StudentID = students.Single(s => s.LastName == "Barzdukas").ID,
            CourseID = courses.Single(c => c.Title == "Chemistry").CourseID,
            Grade = Grade.B
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Li").ID,
            CourseID = courses.Single(c => c.Title == "Composition").CourseID,
            Grade = Grade.B
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Justice").ID,
            CourseID = courses.Single(c => c.Title == "Literature").CourseID,
            Grade = Grade.B
            }
    };

    foreach (Enrollment e in enrollments)
```

```
            foreach (Enrollment e in enrollments)
            {
                var enrollmentInDataBase = context.Enrollments.Where(
                    s =>
                            s.Student.ID == e.StudentID &&
                            s.Course.CourseID == e.CourseID).SingleOrDefault();
                if (enrollmentInDataBase == null)
                {
                    context.Enrollments.Add(e);
                }
            }
            context.SaveChanges();
        }
    }
}
```

The preceding code provides seed data for the new entities. Most of this code creates new entity objects and loads sample data. The sample data is used for testing. See `Enrollments` and `CourseAssignments` for examples of how many-to-many join tables can be seeded.

Add a migration

Build the project.

- Visual Studio
- Visual Studio Code

In PMC, run the following command.

```
Add-Migration ComplexDataModel
```

The preceding command displays a warning about possible data loss.

```
An operation was scaffolded that may result in the loss of data.
Please review the migration for accuracy.
To undo this action, use 'ef migrations remove'
```

If the `database update` command is run, the following error is produced:

```
The ALTER TABLE statement conflicted with the FOREIGN KEY constraint
"FK_dbo.Course_dbo.Department_DepartmentID". The conflict occurred in
database "ContosoUniversity", table "dbo.Department", column 'DepartmentID'.
```

In the next section, you see what to do about this error.

Apply the migration or drop and re-create

Now that you have an existing database, you need to think about how to apply changes to it. This tutorial shows two alternatives:

- Drop and re-create the database. Choose this section if you're using SQLite.
- Apply the migration to the existing database. The instructions in this section work for SQL Server only, **not for SQLite**.

Either choice works for SQL Server. While the apply-migration method is more complex and time-consuming, it's the preferred approach for real-world, production environments.

Drop and re-create the database

Skip this section if you're using SQL Server and want to do the apply-migration approach in the following section.

To force EF Core to create a new database, drop and update the database:

- Visual Studio
- Visual Studio Code

- In the **Package Manager Console** (PMC), run the following command:

```
Drop-Database
```

- Delete the *Migrations* folder, then run the following command:

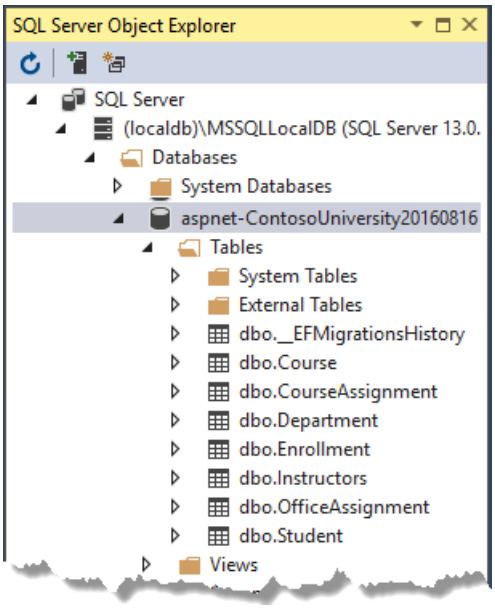
```
Add-Migration InitialCreate
Update-Database
```

Run the app. Running the app runs the `DbInitializer.Initialize` method. The `DbInitializer.Initialize` populates the new database.

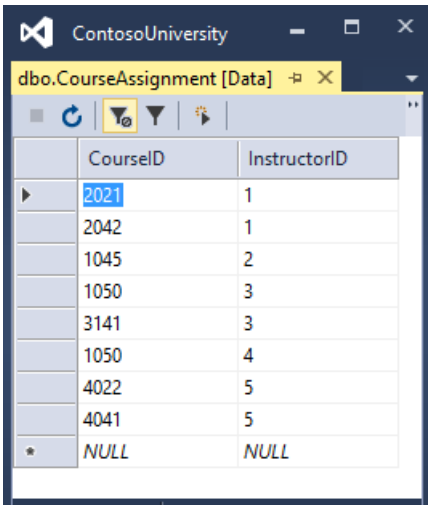
- Visual Studio
- Visual Studio Code

Open the database in SSOX:

- If SSOX was opened previously, click the **Refresh** button.
- Expand the **Tables** node. The created tables are displayed.



- Examine the **CourseAssignment** table:
  - Right-click the **CourseAssignment** table and select **View Data**.
  - Verify the **CourseAssignment** table contains data.



Apply the migration

This section is optional. These steps work only for SQL Server LocalDB and only if you skipped the preceding Drop and re-create the database section.

When migrations are run with existing data, there may be FK constraints that are not satisfied with the existing data. With production data, steps must be taken to migrate the existing data. This section provides an example of fixing FK constraint violations. Don't make these code changes without a backup. Don't make these code changes if you completed the preceding Drop and re-create the database section.

The *{timestamp}_ComplexDataModel.cs* file contains the following code:

```
migrationBuilder.AddColumn<int>(
    name: "DepartmentID",
    table: "Course",
    type: "int",
    nullable: false,
    defaultValue: 0);
```

The preceding code adds a non-nullable `DepartmentID` FK to the `Course` table. The database from the previous tutorial contains rows in `Course`, so that table cannot be updated by migrations.

To make the `ComplexDataModel` migration work with existing data:

- Change the code to give the new column (`DepartmentID`) a default value.
- Create a fake department named "Temp" to act as the default department.

Fix the foreign key constraints

In the `ComplexDataModel` migration class, update the `Up` method:

- Open the *{timestamp}_ComplexDataModel.cs* file.
- Comment out the line of code that adds the `DepartmentID` column to the `Course` table.

```
migrationBuilder.AlterColumn<string>(
    name: "Title",
    table: "Course",
    maxLength: 50,
    nullable: true,
    oldClrType: typeof(string),
    oldNullable: true);

//migrationBuilder.AddColumn<int>(
//    name: "DepartmentID",
//    table: "Course",
//    nullable: false,
//    defaultValue: 0);
```

Add the following highlighted code. The new code goes after the `.CreateTable( name: "Department"` block:

```
migrationBuilder.CreateTable(
    name: "Department",
    columns: table => new
    {
        DepartmentID = table.Column<int>(type: "int", nullable: false)
            .Annotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn),
        Budget = table.Column<decimal>(type: "money", nullable: false),
        InstructorID = table.Column<int>(type: "int", nullable: true),
        Name = table.Column<string>(type: "nvarchar(50)", maxLength: 50, nullable: true),
        StartDate = table.Column<DateTime>(type: "datetime2", nullable: false)
    },
    constraints: table =>
    {
        table.PrimaryKey("PK_Department", x => x.DepartmentID);
        table.ForeignKey(
            name: "FK_Department_Instructor_InstructorID",
            column: x => x.InstructorID,
            principalTable: "Instructor",
            principalColumn: "ID",
            onDelete: ReferentialAction.Restrict);
    });

 migrationBuilder.Sql("INSERT INTO dbo.Department (Name, Budget, StartDate) VALUES ('Temp', 0.00,
GETDATE())");
// Default value for FK points to department created above, with
// defaultValue changed to 1 in following AddColumn statement.

migrationBuilder.AddColumn<int>(
    name: "DepartmentID",
    table: "Course",
    nullable: false,
    defaultValue: 1);
```

With the preceding changes, existing `Course` rows will be related to the "Temp" department after the `ComplexDataModel.Up` method runs.

The way of handling the situation shown here is simplified for this tutorial. A production app would:

- Include code or scripts to add `Department` rows and related `Course` rows to the new `Department` rows.
- Not use the "Temp" department or the default value for `Course.DepartmentID`.

- Visual Studio
- Visual Studio Code

- In the **Package Manager Console** (PMC), run the following command:

```
Update-Database
```

Because the `DbInitializer.Initialize` method is designed to work only with an empty database, use SSOX to delete all the rows in the Student and Course tables. (Cascade delete will take care of the Enrollment table.)

Run the app. Running the app runs the `DbInitializer.Initialize` method. The `DbInitializer.Initialize` populates the new database.

Next steps

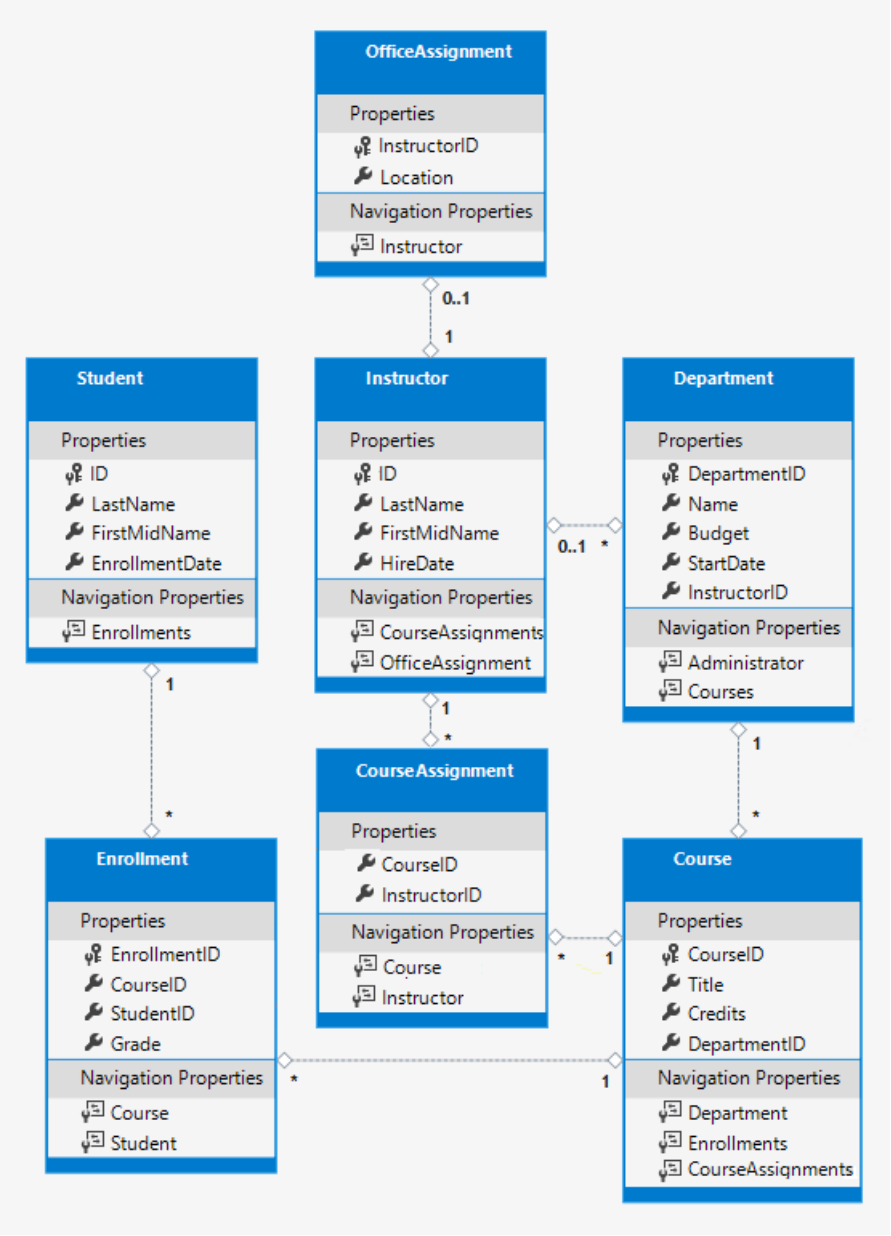
The next two tutorials show how to read and update related data.

PREVIOUS TUTORIAL NEXT TUTORIAL

The previous tutorials worked with a basic data model that was composed of three entities. In this tutorial:

- More entities and relationships are added.
- The data model is customized by specifying formatting, validation, and database mapping rules.

The entity classes for the completed data model are shown in the following illustration:



If you run into problems you can't solve, download the completed app.

Customize the data model with attributes

In this section, the data model is customized using attributes.

The DataType attribute

The student pages currently displays the time of the enrollment date. Typically, date fields show only the date and not the time.

Update *Models/Student.cs* with the following highlighted code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The DataType attribute specifies a data type that's more specific than the database intrinsic type. In this case only the date should be displayed, not the date and time. The DataType Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress, etc. The `DataType` attribute can also enable the app to automatically provide type-specific features. For example:

- The `mailto:` link is automatically created for `DataType.EmailAddress`.
- The date selector is provided for `DataType.Date` in most browsers.

The `DataType` attribute emits HTML 5 `data-` (pronounced data dash) attributes that HTML 5 browsers consume. The `DataType` attributes don't provide validation.

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the date field is displayed according to the default formats based on the server's CultureInfo.

The `DisplayFormat` attribute is used to explicitly specify the date format:

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
```

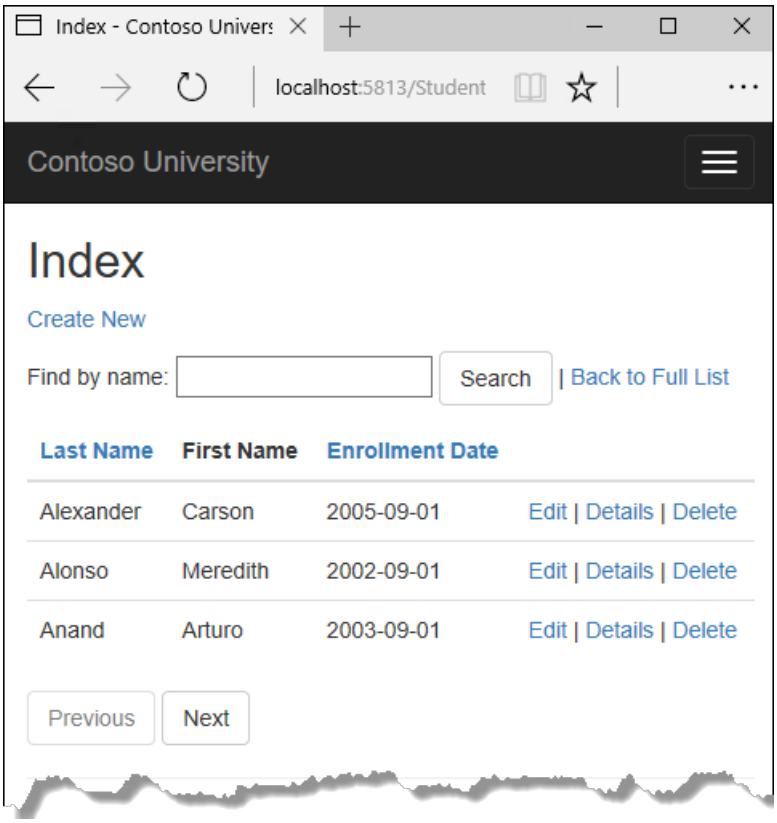
The `ApplyFormatInEditMode` setting specifies that the formatting should also be applied to the edit UI. Some fields shouldn't use `ApplyFormatInEditMode`. For example, the currency symbol should generally not be displayed in an edit text box.

The `DisplayFormat` attribute can be used by itself. It's generally a good idea to use the `DataType` attribute with the `DisplayFormat` attribute. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen. The `DataType` attribute provides the following benefits that are not available in `DisplayFormat`:

- The browser can enable HTML5 features. For example, show a calendar control, the locale-appropriate currency symbol, email links, client-side input validation, etc.
- By default, the browser renders data using the correct format based on the locale.

For more information, see the <input> Tag Helper documentation.

Run the app. Navigate to the Students Index page. Times are no longer displayed. Every view that uses the `Student` model displays the date without time.



The StringLength attribute

Data validation rules and validation error messages can be specified with attributes. The StringLength attribute specifies the minimum and maximum length of characters that are allowed in a data field. The `StringLength` attribute also provides client-side and server-side validation. The minimum value has no impact on the database schema.

Update the `Student` model with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

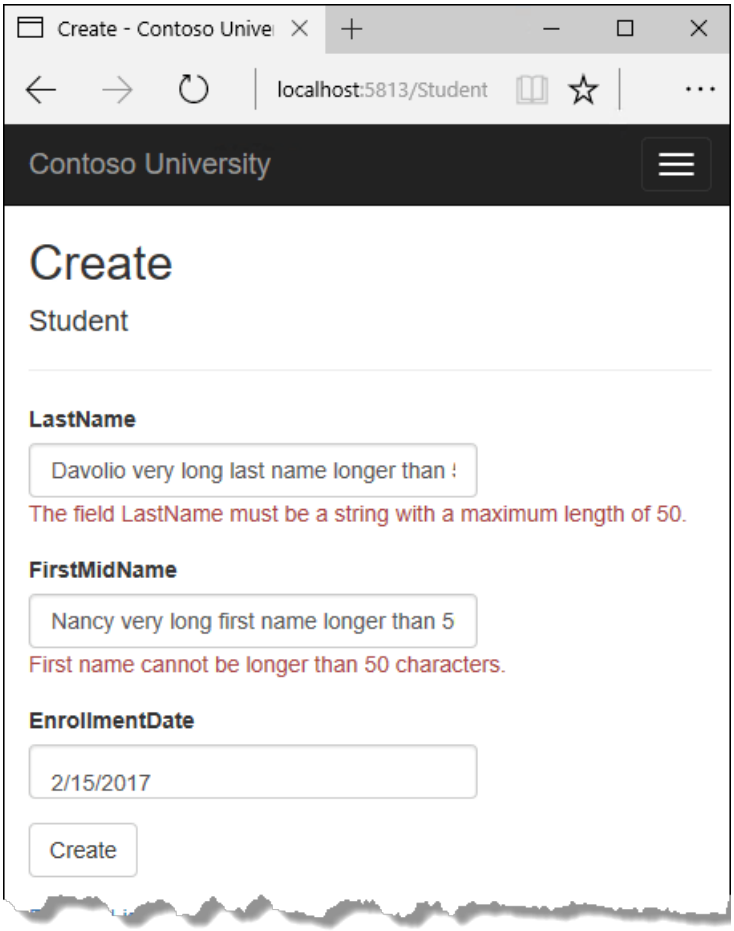
        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The preceding code limits names to no more than 50 characters. The `StringLength` attribute doesn't prevent a user from entering white space for a name. The RegularExpression attribute is used to apply restrictions to the input. For example, the following code requires the first character to be upper case and the remaining characters to be alphabetical:

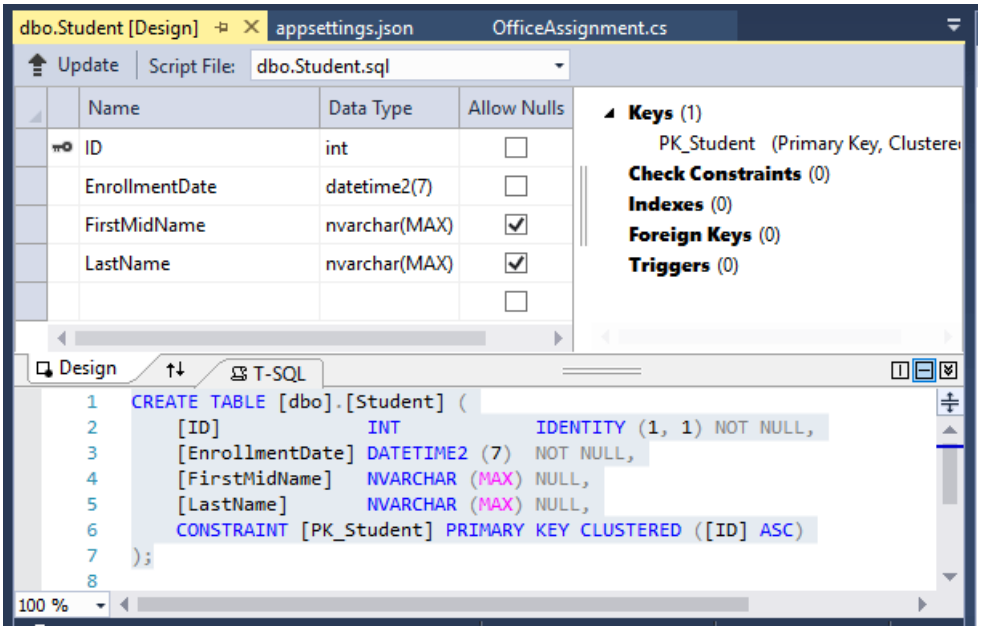
```
[RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
```

Run the app:

- Navigate to the Students page.
- Select **Create New**, and enter a name longer than 50 characters.
- Select **Create**, client-side validation shows an error message.



In **SQL Server Object Explorer** (SSOX), open the Student table designer by double-clicking the **Student** table.



The preceding image shows the schema for the `Student` table. The name fields have type `nvarchar(MAX)` because migrations has not been run on the DB. When migrations are run later in this tutorial, the name fields

become `nvarchar(50)`.

The Column attribute

Attributes can control how classes and properties are mapped to the database. In this section, the `Column` attribute is used to map the name of the `FirstMidName` property to "FirstName" in the DB.

When the DB is created, property names on the model are used for column names (except when the `Column` attribute is used).

The `Student` model uses `FirstMidName` for the first-name field because the field might also contain a middle name.

Update the *Student.cs* file with the following highlighted code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        [Column("FirstName")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

With the preceding change, `Student.FirstMidName` in the app maps to the `FirstName` column of the `Student` table.

The addition of the `Column` attribute changes the model backing the `SchoolContext`. The model backing the `SchoolContext` no longer matches the database. If the app is run before applying migrations, the following exception is generated:

```
SqlException: Invalid column name 'FirstName'.
```

To update the DB:

- Build the project.
- Open a command window in the project folder. Enter the following commands to create a new migration and update the DB:

- Visual Studio
- Visual Studio Code

```
Add-Migration ColumnFirstName
Update-Database
```

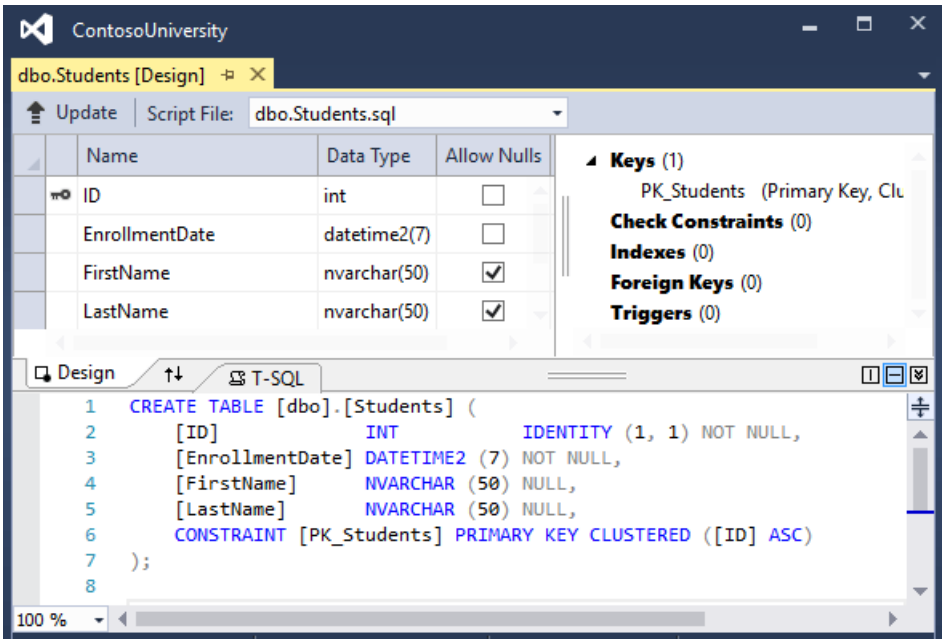
The `migrations add ColumnFirstName` command generates the following warning message:

```
An operation was scaffolded that may result in the loss of data.
Please review the migration for accuracy.
```

The warning is generated because the name fields are now limited to 50 characters. If a name in the DB had more than 50 characters, the 51 to last character would be lost.

- Test the app.

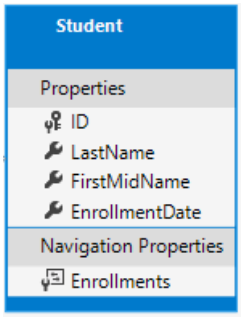
Open the Student table in SSOX:



Before migration was applied, the name columns were of type nvarchar(MAX). The name columns are now `nvarchar(50)`. The column name has changed from `FirstMidName` to `FirstName`.

> **NOTE**
> In the following section, building the app at some stages generates compiler errors. The instructions specify when to build the app.

Student entity update



Update *Models/Student.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [Required]
        [StringLength(50)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }
        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The Required attribute

The `Required` attribute makes the name properties required fields. The `Required` attribute isn't needed for non-nullable types such as value types (`DateTime` , `int` , `double` , etc.). Types that can't be null are automatically treated as required fields.

The `Required` attribute could be replaced with a minimum length parameter in the `StringLength` attribute:

```
[Display(Name = "Last Name")]
[StringLength(50, MinimumLength=1)]
public string LastName { get; set; }
```

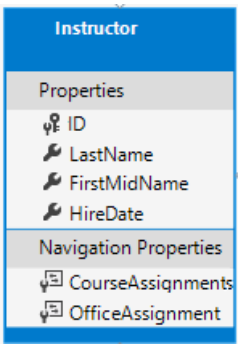
The Display attribute

The `Display` attribute specifies that the caption for the text boxes should be "First Name", "Last Name", "Full Name", and "Enrollment Date." The default captions had no space dividing the words, for example "Lastname."

The FullName calculated property

`FullName` is a calculated property that returns a value that's created by concatenating two other properties. `FullName` cannot be set, it has only a get accessor. No `FullName` column is created in the database.

Create the Instructor Entity



Create *Models/Instructor.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor
    {
        public int ID { get; set; }

        [Required]
        [Display(Name = "Last Name")]
        [StringLength(50)]
        public string LastName { get; set; }

        [Required]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        [StringLength(50)]
        public string FirstMidName { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get { return LastName + ", " + FirstMidName; }
        }

        public ICollection<CourseAssignment> CourseAssignments { get; set; }
        public OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Multiple attributes can be on one line. The `HireDate` attributes could be written as follows:

```
[DataType(DataType.Date),Display(Name = "Hire Date"),DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
```

The CourseAssignments and OfficeAssignment navigation properties

The `CourseAssignments` and `OfficeAssignment` properties are navigation properties.

An instructor can teach any number of courses, so `CourseAssignments` is defined as a collection.

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

If a navigation property holds multiple entities:

- It must be a list type where the entries can be added, deleted, and updated.

Navigation property types include:

- `ICollection<T>`
- `List<T>`
- `HashSet<T>`

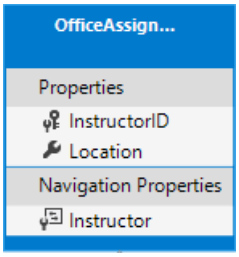
If `ICollection<T>` is specified, EF Core creates a `HashSet<T>` collection by default.

The `CourseAssignment` entity is explained in the section on many-to-many relationships.

Contoso University business rules state that an instructor can have at most one office. The `OfficeAssignment` property holds a single `OfficeAssignment` entity. `OfficeAssignment` is null if no office is assigned.

```
public OfficeAssignment OfficeAssignment { get; set; }
```

Create the OfficeAssignment entity



Create *Models/OfficeAssignment.cs* with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class OfficeAssignment
    {
        [Key]
        public int InstructorID { get; set; }
        [StringLength(50)]
        [Display(Name = "Office Location")]
        public string Location { get; set; }

        public Instructor Instructor { get; set; }
    }
}
```

The Key attribute

The `[Key]` attribute is used to identify a property as the primary key (PK) when the property name is something other than classnameID or ID.

There's a one-to-zero-or-one relationship between the `Instructor` and `OfficeAssignment` entities. An office assignment only exists in relation to the instructor it's assigned to. The `OfficeAssignment` PK is also its foreign key

(FK) to the `Instructor` entity. EF Core can't automatically recognize `InstructorID` as the PK of `OfficeAssignment` because:

- `InstructorID` doesn't follow the ID or classnameID naming convention.

Therefore, the `Key` attribute is used to identify `InstructorID` as the PK:

```
[Key]
public int InstructorID { get; set; }
```

By default, EF Core treats the key as non-database-generated because the column is for an identifying relationship.

The Instructor navigation property

The `OfficeAssignment` navigation property for the `Instructor` entity is nullable because:

- Reference types (such as classes are nullable).
- An instructor might not have an office assignment.

The `OfficeAssignment` entity has a non-nullable `Instructor` navigation property because:

- `InstructorID` is non-nullable.
- An office assignment can't exist without an instructor.

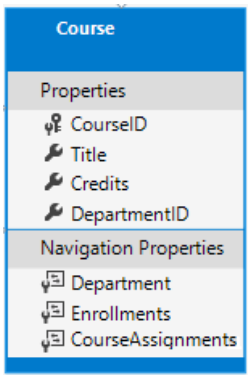
When an `Instructor` entity has a related `OfficeAssignment` entity, each entity has a reference to the other one in its navigation property.

The `[Required]` attribute could be applied to the `Instructor` navigation property:

```
[Required]
public Instructor Instructor { get; set; }
```

The preceding code specifies that there must be a related instructor. The preceding code is unnecessary because the `InstructorID` foreign key (which is also the PK) is non-nullable.

Modify the Course Entity



Update *Models/Course.cs* with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        [Display(Name = "Number")]
        public int CourseID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Title { get; set; }

        [Range(0, 5)]
        public int Credits { get; set; }

        public int DepartmentID { get; set; }

        public Department Department { get; set; }
        public ICollection<Enrollment> Enrollments { get; set; }
        public ICollection<CourseAssignment> CourseAssignments { get; set; }
    }
}
```

The `Course` entity has a foreign key (FK) property `DepartmentID`. `DepartmentID` points to the related `Department` entity. The `Course` entity has a `Department` navigation property.

EF Core doesn't require a FK property for a data model when the model has a navigation property for a related entity.

EF Core automatically creates FKs in the database wherever they're needed. EF Core creates shadow properties for automatically created FKs. Having the FK in the data model can make updates simpler and more efficient. For example, consider a model where the FK property `DepartmentID` is *not* included. When a course entity is fetched to edit:

- The `Department` entity is null if it's not explicitly loaded.
- To update the course entity, the `Department` entity must first be fetched.

When the FK property `DepartmentID` is included in the data model, there's no need to fetch the `Department` entity before an update.

The DatabaseGenerated attribute

The `[DatabaseGenerated(DatabaseGeneratedOption.None)]` attribute specifies that the PK is provided by the application rather than generated by the database.

```
[DatabaseGenerated(DatabaseGeneratedOption.None)]
[Display(Name = "Number")]
public int CourseID { get; set; }
```

By default, EF Core assumes that PK values are generated by the DB. DB generated PK values is generally the best approach. For `Course` entities, the user specifies the PK. For example, a course number such as a 1000 series for the math department, a 2000 series for the English department.

The `DatabaseGenerated` attribute can also be used to generate default values. For example, the DB can automatically generate a date field to record the date a row was created or updated. For more information, see Generated Properties.

Foreign key and navigation properties

The foreign key (FK) properties and navigation properties in the `Course` entity reflect the following relationships:

A course is assigned to one department, so there's a `DepartmentID` FK and a `Department` navigation property.

```
public int DepartmentID { get; set; }
public Department Department { get; set; }
```

A course can have any number of students enrolled in it, so the `Enrollments` navigation property is a collection:

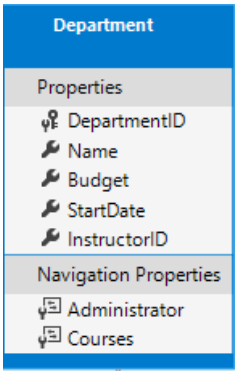
```
public ICollection<Enrollment> Enrollments { get; set; }
```

A course may be taught by multiple instructors, so the `CourseAssignments` navigation property is a collection:

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

`CourseAssignment` is explained later.

Create the Department entity



Create *Models/Department.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The Column attribute

Previously the `Column` attribute was used to change column name mapping. In the code for the `Department` entity, the `Column` attribute is used to change SQL data type mapping. The `Budget` column is defined using the SQL Server money type in the DB:

```
[Column(TypeName="money")]
public decimal Budget { get; set; }
```

Column mapping is generally not required. EF Core generally chooses the appropriate SQL Server data type based on the CLR type for the property. The CLR `decimal` type maps to a SQL Server `decimal` type. `Budget` is for currency, and the money data type is more appropriate for currency.

Foreign key and navigation properties

The FK and navigation properties reflect the following relationships:

- A department may or may not have an administrator.
- An administrator is always an instructor. Therefore the `InstructorID` property is included as the FK to the `Instructor` entity.

The navigation property is named `Administrator` but holds an `Instructor` entity:

```
public int? InstructorID { get; set; }
public Instructor Administrator { get; set; }
```

The question mark (?) in the preceding code specifies the property is nullable.

A department may have many courses, so there's a Courses navigation property:

```
public ICollection<Course> Courses { get; set; }
```

Note: By convention, EF Core enables cascade delete for non-nullable FKs and for many-to-many relationships. Cascading delete can result in circular cascade delete rules. Circular cascade delete rules causes an exception when a migration is added.

For example, if the `Department.InstructorID` property was defined as non-nullable:

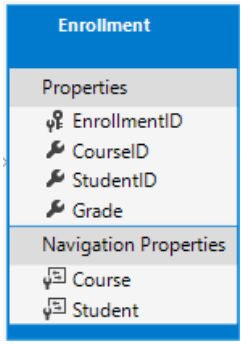
- EF Core configures a cascade delete rule to delete the department when the instructor is deleted.
- Deleting the department when the instructor is deleted isn't the intended behavior.
- The following fluent API would set a restrict rule instead of cascade.

```
modelBuilder.Entity<Department>()
    .HasOne(d => d.Administrator)
    .WithMany()
    .OnDelete(DeleteBehavior.Restrict)
```

The preceding code disables cascade delete on the department-instructor relationship.

Update the Enrollment entity

An enrollment record is for one course taken by one student.



Update *Models/Enrollment.cs* with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        [DisplayFormat(NullDisplayText = "No grade")]
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

Foreign key and navigation properties

The FK properties and navigation properties reflect the following relationships:

An enrollment record is for one course, so there's a `CourseID` FK property and a `Course` navigation property:

```
public int CourseID { get; set; }
public Course Course { get; set; }
```

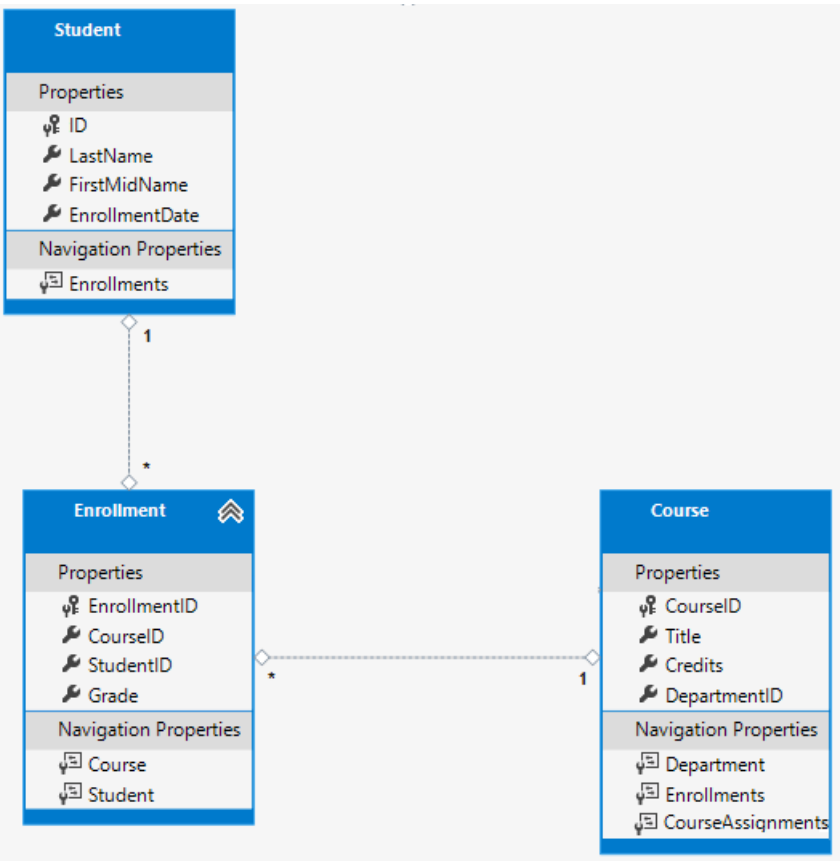
An enrollment record is for one student, so there's a `StudentID` FK property and a `Student` navigation property:

```
public int StudentID { get; set; }
public Student Student { get; set; }
```

Many-to-Many Relationships

There's a many-to-many relationship between the `Student` and `Course` entities. The `Enrollment` entity functions as a many-to-many join table *with payload* in the database. "With payload" means that the `Enrollment` table contains additional data besides FKs for the joined tables (in this case, the PK and `Grade`).

The following illustration shows what these relationships look like in an entity diagram. (This diagram was generated using EF Power Tools for EF 6.x. Creating the diagram isn't part of the tutorial.)



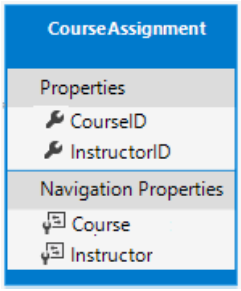
Each relationship line has a 1 at one end and an asterisk (*) at the other, indicating a one-to-many relationship.

If the `Enrollment` table didn't include grade information, it would only need to contain the two FKs (`CourseID` and `StudentID`). A many-to-many join table without payload is sometimes called a pure join table (PJT).

The `Instructor` and `Course` entities have a many-to-many relationship using a pure join table.

Note: EF 6.x supports implicit join tables for many-to-many relationships, but EF Core doesn't. For more information, see Many-to-many relationships in EF Core 2.0.

The CourseAssignment entity

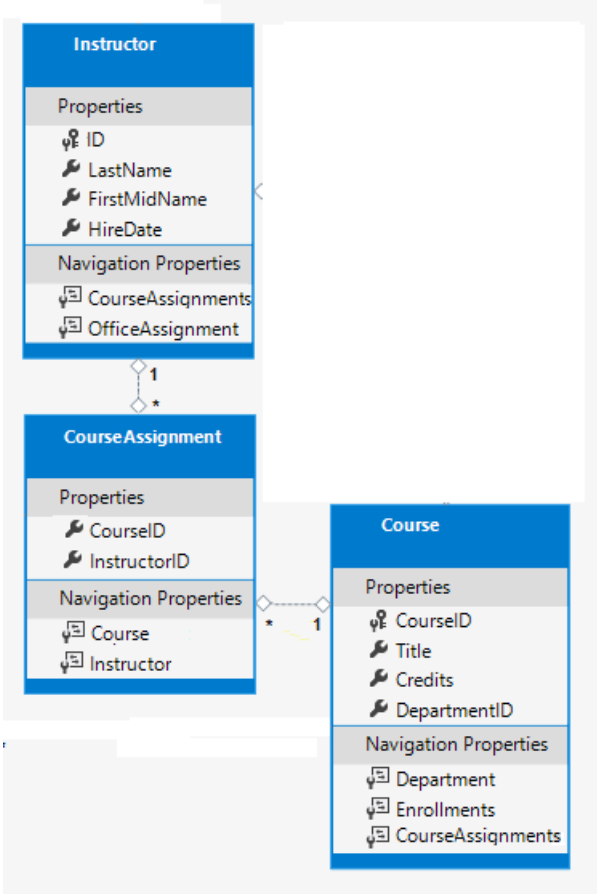


Create *Models/CourseAssignment.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class CourseAssignment
    {
        public int InstructorID { get; set; }
        public int CourseID { get; set; }
        public Instructor Instructor { get; set; }
        public Course Course { get; set; }
    }
}
```

Instructor-to-Courses



The Instructor-to-Courses many-to-many relationship:

- Requires a join table that must be represented by an entity set.
- Is a pure join table (table without payload).

It's common to name a join entity `EntityName1EntityName2`. For example, the Instructor-to-Courses join table using this pattern is `CourseInstructor`. However, we recommend using a name that describes the relationship.

Data models start out simple and grow. No-payload joins (PJTs) frequently evolve to include payload. By starting with a descriptive entity name, the name doesn't need to change when the join table changes. Ideally, the join entity would have its own natural (possibly single word) name in the business domain. For example, Books and Customers could be linked with a join entity called Ratings. For the Instructor-to-Courses many-to-many relationship, `CourseAssignment` is preferred over `CourseInstructor`.

Composite key

FKs are not nullable. The two FKs in `CourseAssignment` (`InstructorID` and `CourseID`) together uniquely identify each row of the `CourseAssignment` table. `CourseAssignment` doesn't require a dedicated PK. The `InstructorID` and `CourseID` properties function as a composite PK. The only way to specify composite PKs to EF Core is with the *fluent API*. The next section shows how to configure the composite PK.

The composite key ensures:

- Multiple rows are allowed for one course.
- Multiple rows are allowed for one instructor.
- Multiple rows for the same instructor and course isn't allowed.

The `Enrollment` join entity defines its own PK, so duplicates of this sort are possible. To prevent such duplicates:

- Add a unique index on the FK fields, or
- Configure `Enrollment` with a primary composite key similar to `CourseAssignment`. For more information, see Indexes.

Update the DB context

Add the following highlighted code to *Data/SchoolContext.cs*:

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Models
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) : base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollment { get; set; }
        public DbSet<Student> Student { get; set; }
        public DbSet<Department> Departments { get; set; }
        public DbSet<Instructor> Instructors { get; set; }
        public DbSet<OfficeAssignment> OfficeAssignments { get; set; }
        public DbSet<CourseAssignment> CourseAssignments { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
            modelBuilder.Entity<Department>().ToTable("Department");
            modelBuilder.Entity<Instructor>().ToTable("Instructor");
            modelBuilder.Entity<OfficeAssignment>().ToTable("OfficeAssignment");
            modelBuilder.Entity<CourseAssignment>().ToTable("CourseAssignment");

            modelBuilder.Entity<CourseAssignment>()
                .HasKey(c => new { c.CourseID, c.InstructorID });
        }
    }
}
```

The preceding code adds the new entities and configures the `CourseAssignment` entity's composite PK.

Fluent API alternative to attributes

The `OnModelCreating` method in the preceding code uses the *fluent API* to configure EF Core behavior. The API is

called "fluent" because it's often used by stringing a series of method calls together into a single statement. The following code is an example of the fluent API:

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    modelBuilder.Entity<Blog>()
        .Property(b => b.Url)
        .IsRequired();
}
```

In this tutorial, the fluent API is used only for DB mapping that can't be done with attributes. However, the fluent API can specify most of the formatting, validation, and mapping rules that can be done with attributes.

Some attributes such as `MinimumLength` can't be applied with the fluent API. `MinimumLength` doesn't change the schema, it only applies a minimum length validation rule.

Some developers prefer to use the fluent API exclusively so that they can keep their entity classes "clean." Attributes and the fluent API can be mixed. There are some configurations that can only be done with the fluent API (specifying a composite PK). There are some configurations that can only be done with attributes (`MinimumLength`). The recommended practice for using fluent API or attributes:

- Choose one of these two approaches.
- Use the chosen approach consistently as much as possible.

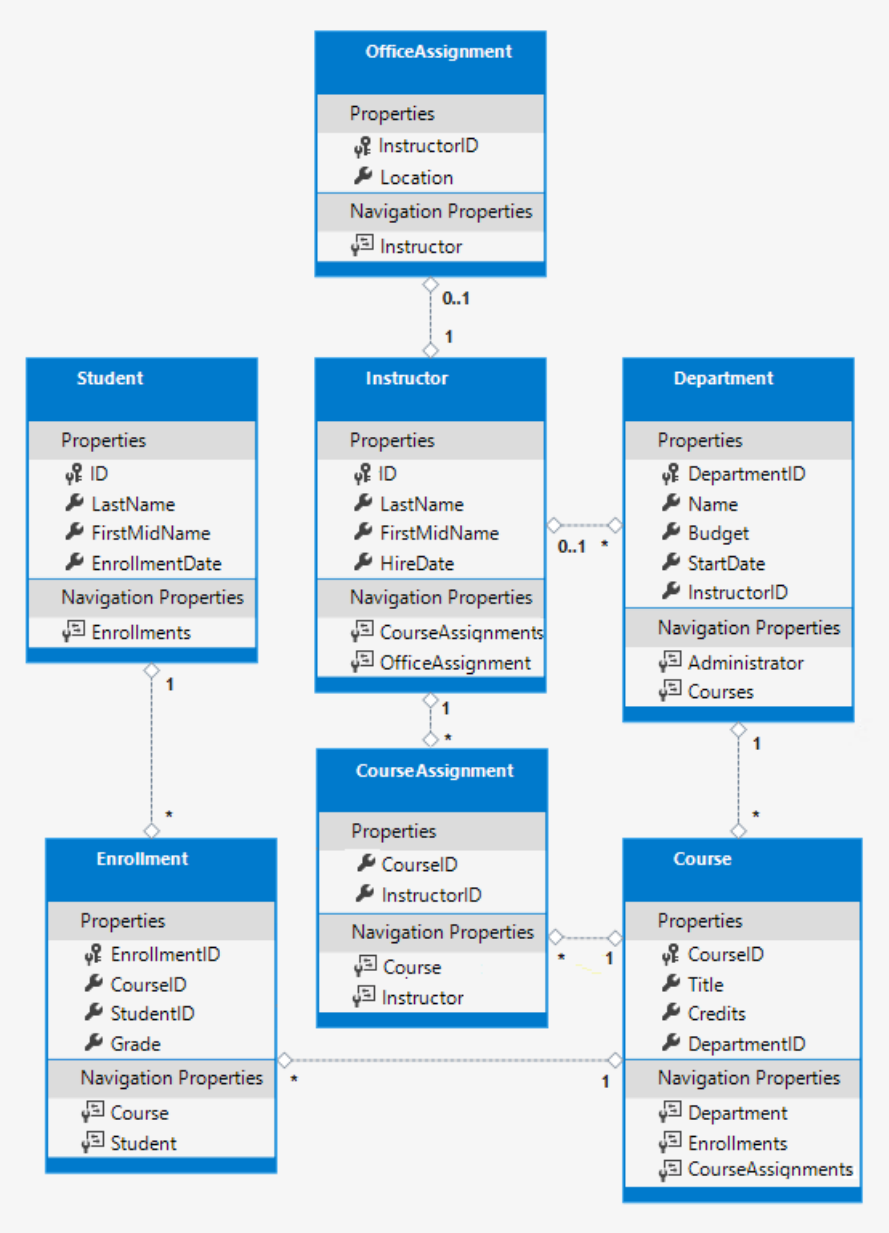
Some of the attributes used in the this tutorial are used for:

- Validation only (for example, `MinimumLength`).
- EF Core configuration only (for example, `HasKey`).
- Validation and EF Core configuration (for example, `[StringLength(50)]`).

For more information about attributes vs. fluent API, see Methods of configuration.

Entity Diagram Showing Relationships

The following illustration shows the diagram that EF Power Tools create for the completed School model.



The preceding diagram shows:

- Several one-to-many relationship lines (1 to *).
- The one-to-zero-or-one relationship line (1 to 0..1) between the `Instructor` and `OfficeAssignment` entities.
- The zero-or-one-to-many relationship line (0..1 to *) between the `Instructor` and `Department` entities.

Seed the DB with Test Data

Update the code in *Data/DbInitializer.cs*:

```
using System;
using System.Linq;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            //context.Database.EnsureCreated();
```

```
            // Look for any students.
            if (context.Student.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
                new Student { FirstMidName = "Carson",   LastName = "Alexander",
                    EnrollmentDate = DateTime.Parse("2010-09-01") },
                new Student { FirstMidName = "Meredith", LastName = "Alonso",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Arturo",   LastName = "Anand",
                    EnrollmentDate = DateTime.Parse("2013-09-01") },
                new Student { FirstMidName = "Gytis",    LastName = "Barzdukas",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Yan",      LastName = "Li",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Peggy",    LastName = "Justice",
                    EnrollmentDate = DateTime.Parse("2011-09-01") },
                new Student { FirstMidName = "Laura",    LastName = "Norman",
                    EnrollmentDate = DateTime.Parse("2013-09-01") },
                new Student { FirstMidName = "Nino",     LastName = "Olivetto",
                    EnrollmentDate = DateTime.Parse("2005-09-01") }
            };

            foreach (Student s in students)
            {
                context.Student.Add(s);
            }
            context.SaveChanges();

            var instructors = new Instructor[]
            {
                new Instructor { FirstMidName = "Kim",     LastName = "Abercrombie",
                    HireDate = DateTime.Parse("1995-03-11") },
                new Instructor { FirstMidName = "Fadi",    LastName = "Fakhouri",
                    HireDate = DateTime.Parse("2002-07-06") },
                new Instructor { FirstMidName = "Roger",   LastName = "Harui",
                    HireDate = DateTime.Parse("1998-07-01") },
                new Instructor { FirstMidName = "Candace", LastName = "Kapoor",
                    HireDate = DateTime.Parse("2001-01-15") },
                new Instructor { FirstMidName = "Roger",   LastName = "Zheng",
                    HireDate = DateTime.Parse("2004-02-12") }
            };

            foreach (Instructor i in instructors)
            {
                context.Instructors.Add(i);
            }
            context.SaveChanges();

            var departments = new Department[]
            {
                new Department { Name = "English",     Budget = 350000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Abercrombie").ID },
                new Department { Name = "Mathematics", Budget = 100000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Fakhouri").ID },
                new Department { Name = "Engineering", Budget = 350000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Harui").ID },
                new Department { Name = "Economics",   Budget = 100000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Kapoor").ID }
            };

            foreach (Department d in departments)
```

```
{
    context.Departments.Add(d);
}
context.SaveChanges();

var courses = new Course[]
{
    new Course {CourseID = 1050, Title = "Chemistry",      Credits = 3,
        DepartmentID = departments.Single( s => s.Name == "Engineering").DepartmentID
    },
    new Course {CourseID = 4022, Title = "Microeconomics", Credits = 3,
        DepartmentID = departments.Single( s => s.Name == "Economics").DepartmentID
    },
    new Course {CourseID = 4041, Title = "Macroeconomics", Credits = 3,
        DepartmentID = departments.Single( s => s.Name == "Economics").DepartmentID
    },
    new Course {CourseID = 1045, Title = "Calculus",       Credits = 4,
        DepartmentID = departments.Single( s => s.Name == "Mathematics").DepartmentID
    },
    new Course {CourseID = 3141, Title = "Trigonometry",   Credits = 4,
        DepartmentID = departments.Single( s => s.Name == "Mathematics").DepartmentID
    },

            Grade = Grade.B
            },
            new Enrollment {
                StudentID = students.Single(s => s.LastName == "Alonso").ID,
            CourseID = courses.Single(c => c.Title == "Trigonometry" ).CourseID,
            Grade = Grade.B
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alonso").ID,
            CourseID = courses.Single(c => c.Title == "Composition" ).CourseID,
            Grade = Grade.B
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Anand").ID,
            CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Anand").ID,
            CourseID = courses.Single(c => c.Title == "Microeconomics").CourseID,
            Grade = Grade.B
            },
```

```
                    },
                new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Barzdukas").ID,
                    CourseID = courses.Single(c => c.Title == "Chemistry").CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Li").ID,
                    CourseID = courses.Single(c => c.Title == "Composition").CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Justice").ID,
                    CourseID = courses.Single(c => c.Title == "Literature").CourseID,
                    Grade = Grade.B
                    }
            };

            foreach (Enrollment e in enrollments)
            {
                var enrollmentInDataBase = context.Enrollment.Where(
                    s =>
                            s.Student.ID == e.StudentID &&
                            s.Course.CourseID == e.CourseID).SingleOrDefault();
                if (enrollmentInDataBase == null)
                {
                    context.Enrollment.Add(e);
                }
            }
            context.SaveChanges();
        }
    }
}
```

The preceding code provides seed data for the new entities. Most of this code creates new entity objects and loads sample data. The sample data is used for testing. See `Enrollments` and `CourseAssignments` for examples of how many-to-many join tables can be seeded.

Add a migration

Build the project.

- Visual Studio
- Visual Studio Code

```
Add-Migration ComplexDataModel
```

The preceding command displays a warning about possible data loss.

```
An operation was scaffolded that may result in the loss of data.
Please review the migration for accuracy.
Done. To undo this action, use 'ef migrations remove'
```

If the `database update` command is run, the following error is produced:

```
The ALTER TABLE statement conflicted with the FOREIGN KEY constraint
"FK_dbo.Course_dbo.Department_DepartmentID". The conflict occurred in
database "ContosoUniversity", table "dbo.Department", column 'DepartmentID'.
```

Apply the migration

Now that you have an existing database, you need to think about how to apply future changes to it. This tutorial shows two approaches:

- Drop and re-create the database
- Apply the migration to the existing database. While this method is more complex and time-consuming, it's the preferred approach for real-world, production environments. **Note**: This is an optional section of the tutorial. You can do the drop and re-create steps and skip this section. If you do want to follow the steps in this section, don't do the drop and re-create steps.

Drop and re-create the database

The code in the updated `DbInitializer` adds seed data for the new entities. To force EF Core to create a new DB, drop and update the DB:

- Visual Studio
- Visual Studio Code

In the **Package Manager Console** (PMC), run the following command:

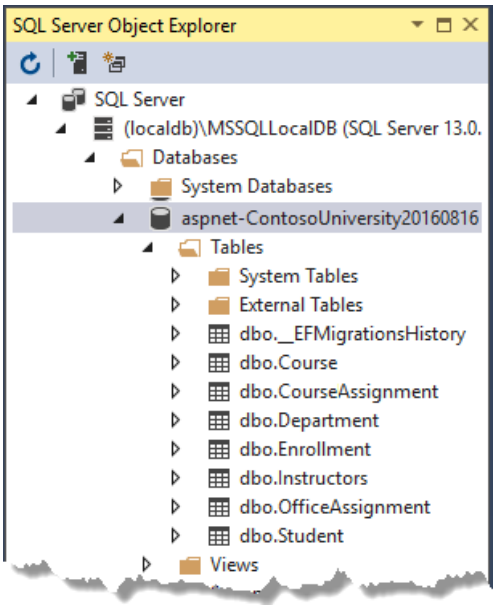
```
Drop-Database
Update-Database
```

Run `Get-Help about_EntityFrameworkCore` from the PMC to get help information.

Run the app. Running the app runs the `DbInitializer.Initialize` method. The `DbInitializer.Initialize` populates the new DB.

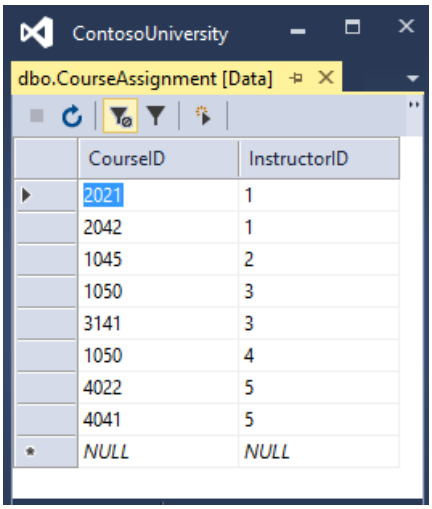
Open the DB in SSOX:

- If SSOX was opened previously, click the **Refresh** button.
- Expand the **Tables** node. The created tables are displayed.



Examine the **CourseAssignment** table:

- Right-click the **CourseAssignment** table and select **View Data**.
- Verify the **CourseAssignment** table contains data.



Apply the migration to the existing database

This section is optional. These steps work only if you skipped the preceding Drop and re-create the database section.

When migrations are run with existing data, there may be FK constraints that are not satisfied with the existing data. With production data, steps must be taken to migrate the existing data. This section provides an example of fixing FK constraint violations. Don't make these code changes without a backup. Don't make these code changes if you completed the previous section and updated the database.

The *{timestamp}_ComplexDataModel.cs* file contains the following code:

```
migrationBuilder.AddColumn<int>(
    name: "DepartmentID",
    table: "Course",
    type: "int",
    nullable: false,
    defaultValue: 0);
```

The preceding code adds a non-nullable `DepartmentID` FK to the `Course` table. The DB from the previous tutorial contains rows in `Course`, so that table cannot be updated by migrations.

To make the `ComplexDataModel` migration work with existing data:

- Change the code to give the new column (`DepartmentID`) a default value.
- Create a fake department named "Temp" to act as the default department.

Fix the foreign key constraints

Update the `ComplexDataModel` classes `Up` method:

- Open the *{timestamp}_ComplexDataModel.cs* file.
- Comment out the line of code that adds the `DepartmentID` column to the `Course` table.

```
migrationBuilder.AlterColumn<string>(
    name: "Title",
    table: "Course",
    maxLength: 50,
    nullable: true,
    oldClrType: typeof(string),
    oldNullable: true);

//migrationBuilder.AddColumn<int>(
//    name: "DepartmentID",
//    table: "Course",
//    nullable: false,
//    defaultValue: 0);
```

Add the following highlighted code. The new code goes after the `.CreateTable( name: "Department"` block:

```
migrationBuilder.CreateTable(
    name: "Department",
    columns: table => new
    {
        DepartmentID = table.Column<int>(type: "int", nullable: false)
            .Annotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn),
        Budget = table.Column<decimal>(type: "money", nullable: false),
        InstructorID = table.Column<int>(type: "int", nullable: true),
        Name = table.Column<string>(type: "nvarchar(50)", maxLength: 50, nullable: true),
        StartDate = table.Column<DateTime>(type: "datetime2", nullable: false)
    },
    constraints: table =>
    {
        table.PrimaryKey("PK_Department", x => x.DepartmentID);
        table.ForeignKey(
            name: "FK_Department_Instructor_InstructorID",
            column: x => x.InstructorID,
            principalTable: "Instructor",
            principalColumn: "ID",
            onDelete: ReferentialAction.Restrict);
    });

 migrationBuilder.Sql("INSERT INTO dbo.Department (Name, Budget, StartDate) VALUES ('Temp', 0.00,
GETDATE())");
// Default value for FK points to department created above, with
// defaultValue changed to 1 in following AddColumn statement.

migrationBuilder.AddColumn<int>(
    name: "DepartmentID",
    table: "Course",
    nullable: false,
    defaultValue: 1);
```

With the preceding changes, existing `Course` rows will be related to the "Temp" department after the `ComplexDataModel` `Up` method runs.

A production app would:

- Include code or scripts to add `Department` rows and related `Course` rows to the new `Department` rows.
- Not use the "Temp" department or the default value for `Course.DepartmentID`.

The next tutorial covers related data.

Part 6, Razor Pages with EF Core in ASP.NET Core - Read Related Data

9/22/2020 • 28 minutes to read • Edit Online

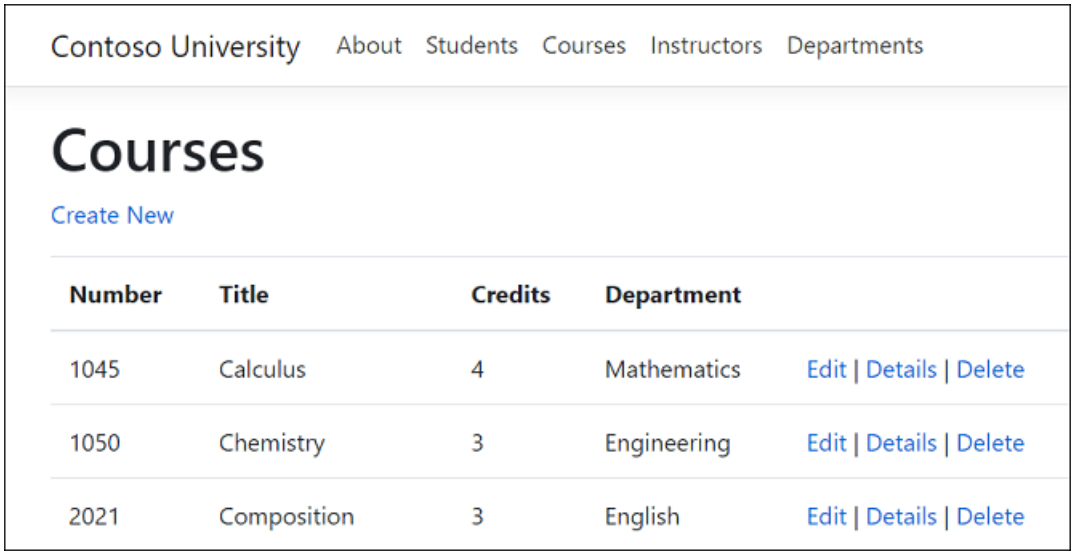
By Tom Dykstra, Jon P Smith, and Rick Anderson

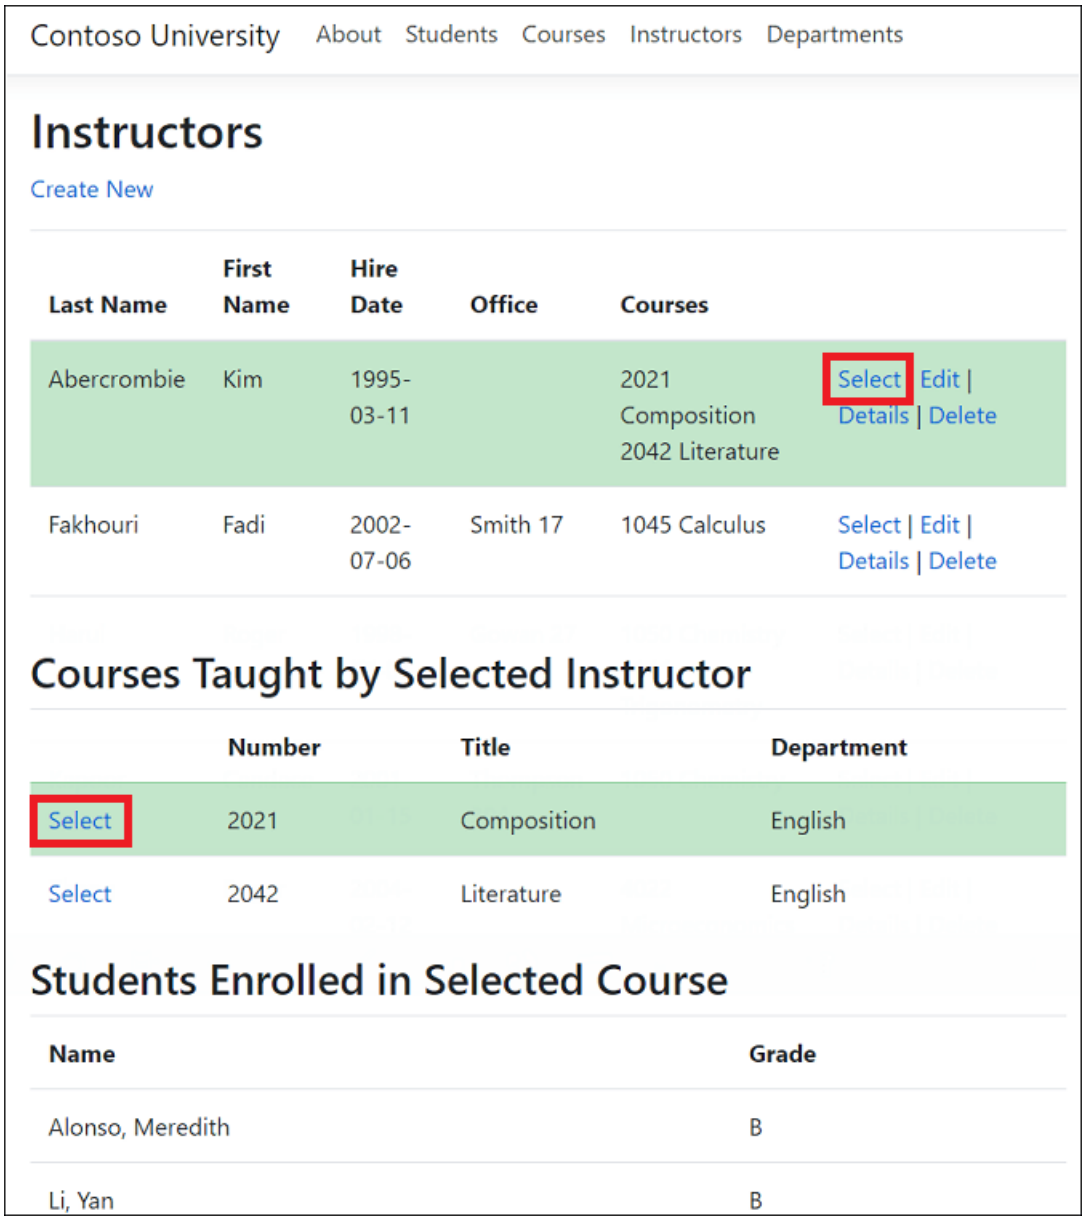
The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial shows how to read and display related data. Related data is data that EF Core loads into navigation properties.

The following illustrations show the completed pages for this tutorial:





Eager, explicit, and lazy loading

There are several ways that EF Core can load related data into the navigation properties of an entity:

- Eager loading. Eager loading is when a query for one type of entity also loads related entities. When an entity is read, its related data is retrieved. This typically results in a single join query that retrieves all of the data that's needed. EF Core will issue multiple queries for some types of eager loading. Issuing multiple queries can be more efficient than a giant single query. Eager loading is specified with the `Include` and `ThenInclude` methods.

```
var departments = _context.Departments.Include(d => d.Courses);
foreach (Department d in departments)
{
    foreach(Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

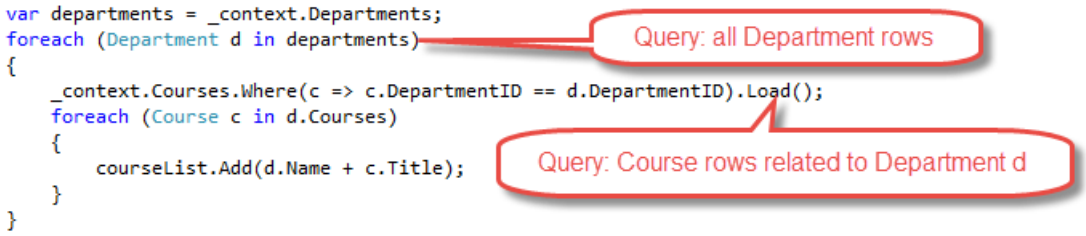
Query: all Department entities and related Course entities

  Eager loading sends multiple queries when a collection navigation is included:

  - One query for the main query
  - One query for each collection "edge" in the load tree.

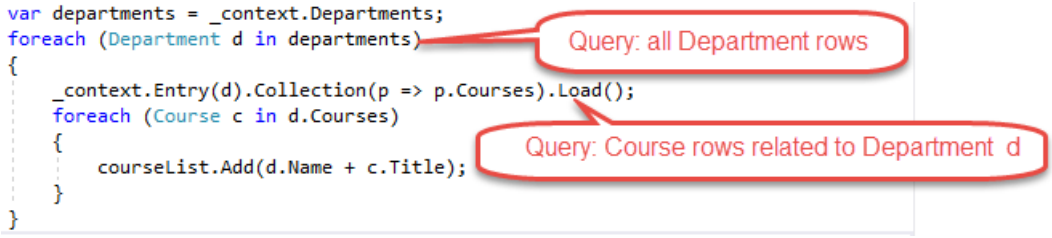
- Separate queries with `Load`: The data can be retrieved in separate queries, and EF Core "fixes up" the navigation properties. "Fixes up" means that EF Core automatically populates the navigation properties.

Separate queries with `Load` is more like explicit loading than eager loading.



Note: EF Core automatically fixes up navigation properties to any other entities that were previously loaded into the context instance. Even if the data for a navigation property is *not* explicitly included, the property may still be populated if some or all of the related entities were previously loaded.

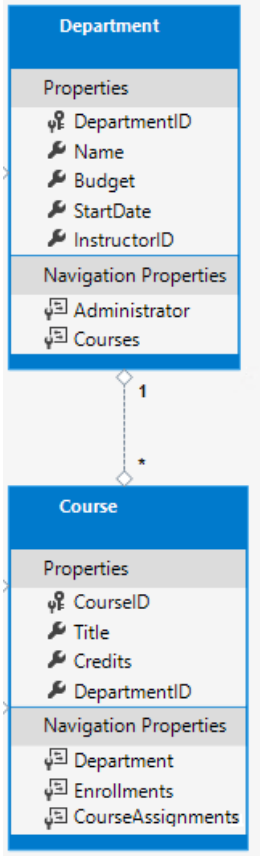
- Explicit loading. When the entity is first read, related data isn't retrieved. Code must be written to retrieve the related data when it's needed. Explicit loading with separate queries results in multiple queries sent to the database. With explicit loading, the code specifies the navigation properties to be loaded. Use the `Load` method to do explicit loading. For example:



- Lazy loading. When the entity is first read, related data isn't retrieved. The first time a navigation property is accessed, the data required for that navigation property is automatically retrieved. A query is sent to the database each time a navigation property is accessed for the first time. Lazy loading can hurt performance, for example when developers use N+1 patterns, loading a parent and enumerating through children.

Create Course pages

The `Course` entity includes a navigation property that contains the related `Department` entity.



To display the name of the assigned department for a course:

- Load the related `Department` entity into the `Course.Department` navigation property.
- Get the name from the `Department` entity's `Name` property.

Scaffold Course pages

- Visual Studio
- Visual Studio Code

- Follow the instructions in Scaffold Student pages with the following exceptions:
  - Create a *Pages/Courses* folder.
  - Use `Course` for the model class.
  - Use the existing context class instead of creating a new one.

- Open *Pages/Courses/Index.cshtml.cs* and examine the `OnGetAsync` method. The scaffolding engine specified eager loading for the `Department` navigation property. The `Include` method specifies eager loading.

- Run the app and select the **Courses** link. The department column displays the `DepartmentID`, which isn't useful.

Display the department name

Update Pages/Courses/Index.cshtml.cs with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class IndexModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public IndexModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public IList<Course> Courses { get; set; }

        public async Task OnGetAsync()
        {
            Courses = await _context.Courses
                .Include(c => c.Department)
                .AsNoTracking()
                .ToListAsync();
        }
    }
}
```

The preceding code changes the `Course` property to `Courses` and adds `AsNoTracking`. `AsNoTracking` improves performance because the entities returned are not tracked. The entities don't need to be tracked because they're not updated in the current context.

Update *Pages/Courses/Index.cshtml* with the following code.

```
@page
@model ContosoUniversity.Pages.Courses.IndexModel

@{
    ViewData["Title"] = "Courses";
}

<h1>Courses</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].CourseID)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].Credits)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].Department)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model.Courses)
{
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.CourseID)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Credits)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Department.Name)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.CourseID">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.CourseID">Details</a> |
                <a asp-page="./Delete" asp-route-id="@item.CourseID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

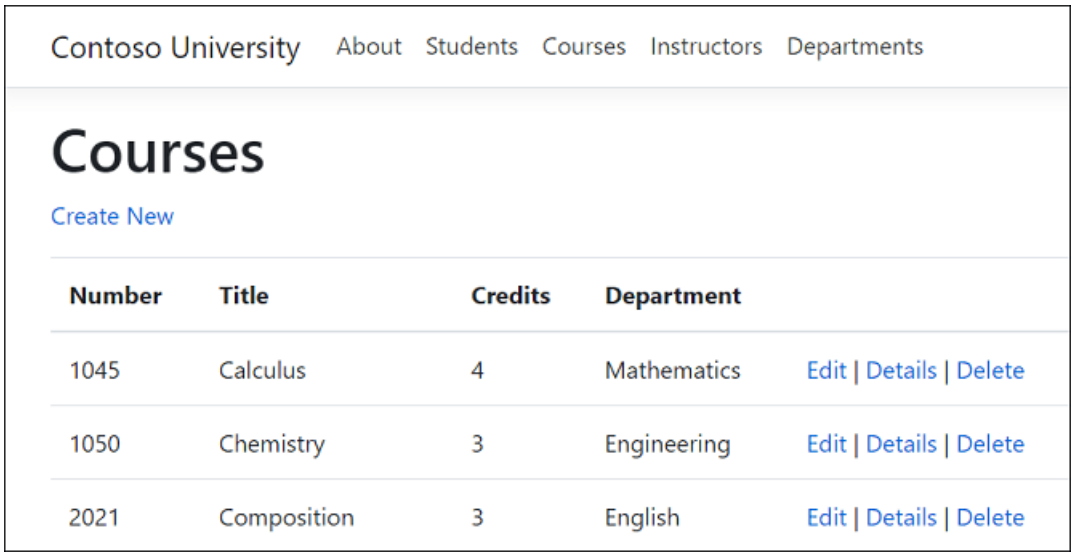
The following changes have been made to the scaffolded code:

- Changed the `Course` property name to `Courses`.
- Added a **Number** column that shows the `CourseID` property value. By default, primary keys aren't scaffolded because normally they're meaningless to end users. However, in this case the primary key is meaningful.
- Changed the **Department** column to display the department name. The code displays the `Name` property

of the `Department` entity that's loaded into the `Department` navigation property:

```
@Html.DisplayFor(modelItem => item.Department.Name)
```

Run the app and select the **Courses** tab to see the list with department names.



Loading related data with Select

The `OnGetAsync` method loads related data with the `Include` method. The `Select` method is an alternative that loads only the related data needed. For single items, like the `Department.Name` it uses a SQL INNER JOIN. For collections, it uses another database access, but so does the `Include` operator on collections.

The following code loads related data with the `Select` method:

```
public IList<CourseViewModel> CourseVM { get; set; }

public async Task OnGetAsync()
{
    CourseVM = await _context.Courses
            .Select(p => new CourseViewModel
            {
                CourseID = p.CourseID,
                Title = p.Title,
                Credits = p.Credits,
                DepartmentName = p.Department.Name
            }).ToListAsync();
}
```

The preceding code doesn't return any entity types, therefore no tracking is done. For more information about the EF tracking, see Tracking vs. No-Tracking Queries.

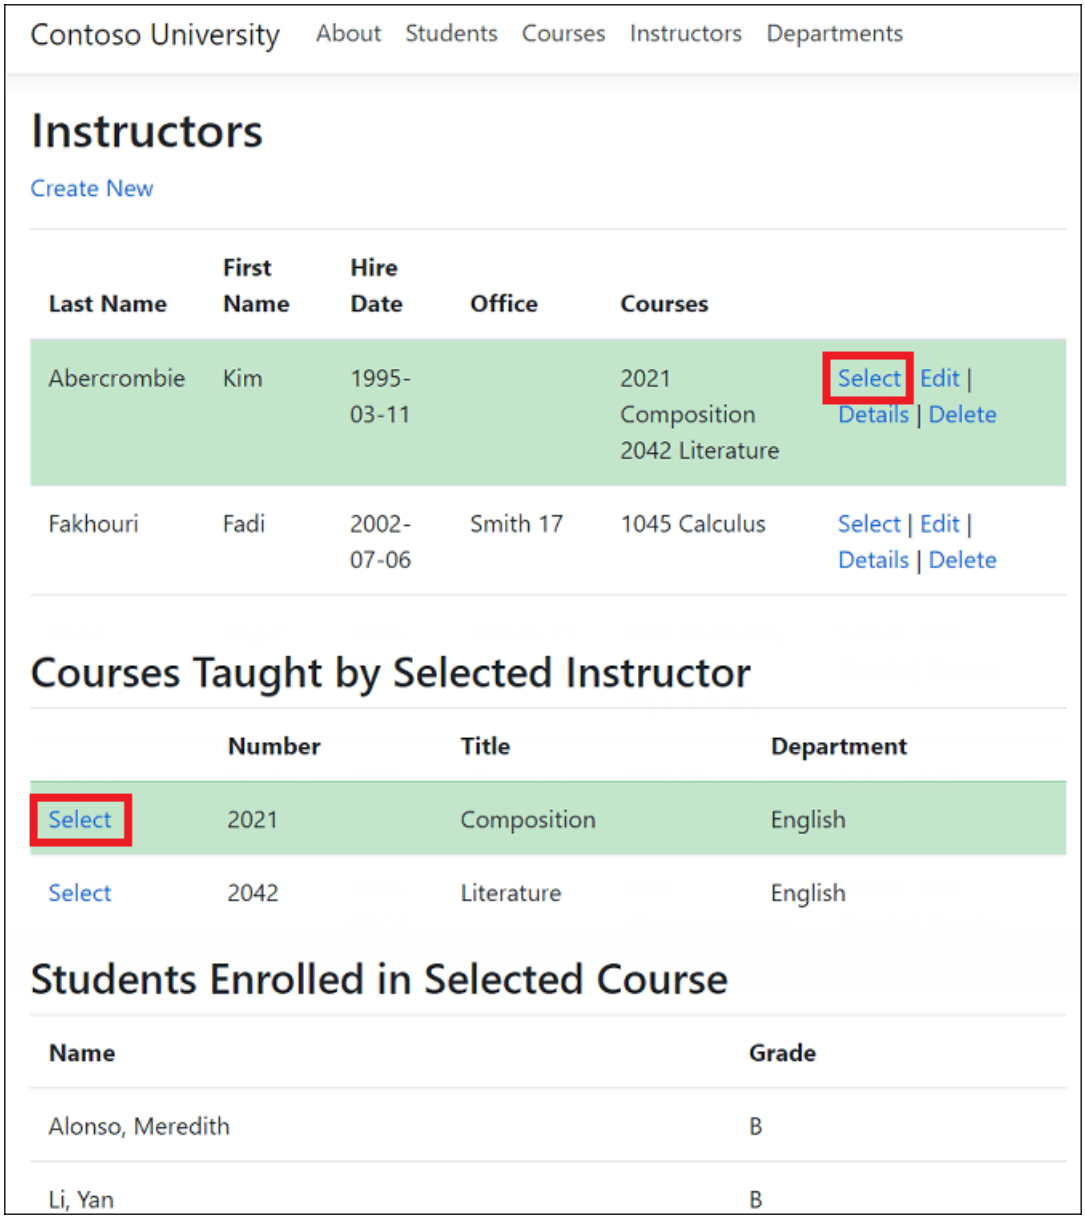
The `CourseViewModel`:

```
public class CourseViewModel
{
    public int CourseID { get; set; }
    public string Title { get; set; }
    public int Credits { get; set; }
    public string DepartmentName { get; set; }
}
```

See IndexSelect.cshtml and IndexSelect.cshtml.cs for a complete example.

Create Instructor pages

This section scaffolds Instructor pages and adds related Courses and Enrollments to the Instructors Index page.



This page reads and displays related data in the following ways:

- The list of instructors displays related data from the `OfficeAssignment` entity (Office in the preceding image). The `Instructor` and `OfficeAssignment` entities are in a one-to-zero-or-one relationship. Eager loading is used for the `OfficeAssignment` entities. Eager loading is typically more efficient when the related data needs to be displayed. In this case, office assignments for the instructors are displayed.
- When the user selects an instructor, related `Course` entities are displayed. The `Instructor` and `Course` entities are in a many-to-many relationship. Eager loading is used for the `Course` entities and their related `Department` entities. In this case, separate queries might be more efficient because only courses for the selected instructor are needed. This example shows how to use eager loading for navigation properties in entities that are in navigation properties.
- When the user selects a course, related data from the `Enrollments` entity is displayed. In the preceding image, student name and grade are displayed. The `Course` and `Enrollment` entities are in a one-to-many relationship.

Create a view model

The instructors page shows data from three different tables. A view model is needed that includes three properties representing the three tables.

Create *SchoolViewModels/InstructorIndexData.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class InstructorIndexData
    {
        public IEnumerable<Instructor> Instructors { get; set; }
        public IEnumerable<Course> Courses { get; set; }
        public IEnumerable<Enrollment> Enrollments { get; set; }
    }
}
```

Scaffold Instructor pages

- Visual Studio
- Visual Studio Code

- Follow the instructions in Scaffold the student pages with the following exceptions:
    - Create a *Pages/Instructors* folder.
    - Use `Instructor` for the model class.
    - Use the existing context class instead of creating a new one.

To see what the scaffolded page looks like before you update it, run the app and navigate to the Instructors page.

Update *Pages/Instructors/Index.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using ContosoUniversity.Models.SchoolViewModels;  // Add VM
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class IndexModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public IndexModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public InstructorIndexData InstructorData { get; set; }
        public int InstructorID { get; set; }
        public int CourseID { get; set; }

        public async Task OnGetAsync(int? id, int? courseID)
        {
            InstructorData = new InstructorIndexData();
            InstructorData.Instructors = await _context.Instructors
                .Include(i => i.OfficeAssignment)
                .Include(i => i.CourseAssignments)
                    .ThenInclude(i => i.Course)
                        .ThenInclude(i => i.Department)
                .Include(i => i.CourseAssignments)
                    .ThenInclude(i => i.Course)
                        .ThenInclude(i => i.Enrollments)
                            .ThenInclude(i => i.Student)
                .AsNoTracking()
                .OrderBy(i => i.LastName)
                .ToListAsync();

            if (id != null)
            {
                InstructorID = id.Value;
                Instructor instructor = InstructorData.Instructors
                    .Where(i => i.ID == id.Value).Single();
                InstructorData.Courses = instructor.CourseAssignments.Select(s => s.Course);
            }

            if (courseID != null)
            {
                CourseID = courseID.Value;
                var selectedCourse = InstructorData.Courses
                    .Where(x => x.CourseID == courseID).Single();
                InstructorData.Enrollments = selectedCourse.Enrollments;
            }
        }
    }
}
```

The `OnGetAsync` method accepts optional route data for the ID of the selected instructor.

Examine the query in the *Pages/Instructors/Index.cshtml.cs* file:

```
InstructorData.Instructors = await _context.Instructors
    .Include(i => i.OfficeAssignment)
    .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
    .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
    .AsNoTracking()
    .OrderBy(i => i.LastName)
    .ToListAsync();
```

The code specifies eager loading for the following navigation properties:

- `Instructor.OfficeAssignment`
- `Instructor.CourseAssignments`
  - `CourseAssignments.Course`
    - `Course.Department`
    - `Course.Enrollments`
      - `Enrollment.Student`

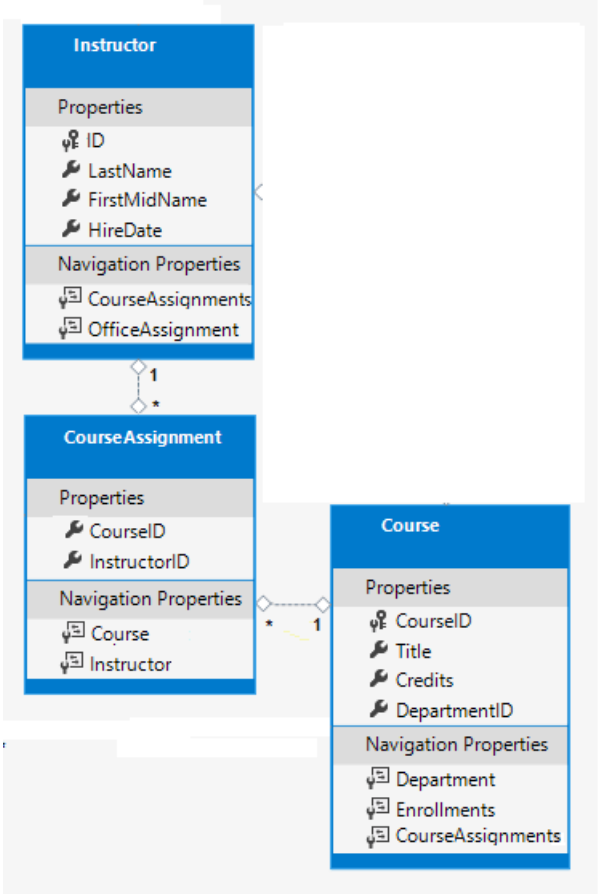
Notice the repetition of `Include` and `ThenInclude` methods for `CourseAssignments` and `Course`. This repetition is necessary to specify eager loading for two navigation properties of the `Course` entity.

The following code executes when an instructor is selected (`id != null`).

```
if (id != null)
{
    InstructorID = id.Value;
    Instructor instructor = InstructorData.Instructors
        .Where(i => i.ID == id.Value).Single();
    InstructorData.Courses = instructor.CourseAssignments.Select(s => s.Course);
}
```

The selected instructor is retrieved from the list of instructors in the view model. The view model's `Courses` property is loaded with the `Course` entities from that instructor's `CourseAssignments` navigation property.

The `Where` method returns a collection. But in this case, the filter will select a single entity, so the `Single` method is called to convert the collection into a single `Instructor` entity. The `Instructor` entity provides access to the `CourseAssignments` property. `CourseAssignments` provides access to the related `Course` entities.



The `Single` method is used on a collection when the collection has only one item. The `Single` method throws an exception if the collection is empty or if there's more than one item. An alternative is `SingleOrDefault`, which returns a default value (null in this case) if the collection is empty.

The following code populates the view model's `Enrollments` property when a course is selected:

```
if (courseID != null)
{
    CourseID = courseID.Value;
    var selectedCourse = InstructorData.Courses
        .Where(x => x.CourseID == courseID).Single();
    InstructorData.Enrollments = selectedCourse.Enrollments;
}
```

Update the instructors Index page

Update *Pages/Instructors/Index.cshtml* with the following code.

```
@page "{id:int?}"
@model ContosoUniversity.Pages.Instructors.IndexModel

@{
    ViewData["Title"] = "Instructors";
}

<h2>Instructors</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>Last Name</th>
            <th>First Name</th>
```

```
            <th>Hire Date</th>
            <th>Office</th>
            <th>Courses</th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.InstructorData.Instructors)
        {
            string selectedRow = "";
            if (item.ID == Model.InstructorID)
            {
                selectedRow = "table-success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.HireDate)
                </td>
                <td>
                    @if (item.OfficeAssignment != null)
                    {
                        @item.OfficeAssignment.Location
                    }
                </td>
                <td>
                    @{
                        foreach (var course in item.CourseAssignments)
                        {
                            @course.Course.CourseID @:  @course.Course.Title <br />
                        }
                    }
                </td>
                <td>
                    <a asp-page="./Index" asp-route-id="@item.ID">Select</a> |
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>

@if (Model.InstructorData.Courses != null)
{
    <h3>Courses Taught by Selected Instructor</h3>
    <table class="table">
        <tr>
            <th></th>
            <th>Number</th>
            <th>Title</th>
            <th>Department</th>
        </tr>

        @foreach (var item in Model.InstructorData.Courses)
        {
            string selectedRow = "";
            if (item.CourseID == Model.CourseID)
            {
                selectedRow = "table-success";
            }
            <tr class="@selectedRow">
                <td>
```

```
                    <a asp-page="./Index" asp-route-courseID="@item.CourseID">Select</a>
                </td>
                <td>
                    @item.CourseID
                </td>
                <td>
                    @item.Title
                </td>
                <td>
                    @item.Department.Name
                </td>
            </tr>
        }

    </table>
}

@if (Model.InstructorData.Enrollments != null)
{
    <h3>
        Students Enrolled in Selected Course
    </h3>
    <table class="table">
        <tr>
            <th>Name</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.InstructorData.Enrollments)
        {
            <tr>
                <td>
                    @item.Student.FullName
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
}
```

The preceding code makes the following changes:

- Updates the `page` directive from `@page` to `@page "{id:int?}"`. `"{id:int?}"` is a route template. The route template changes integer query strings in the URL to route data. For example, clicking on the **Select** link for an instructor with only the `@page` directive produces a URL like the following:

  `https://localhost:5001/Instructors?id=2`

  When the page directive is `@page "{id:int?}"`, the URL is:

  `https://localhost:5001/Instructors/2`

- Adds an **Office** column that displays `item.OfficeAssignment.Location` only if `item.OfficeAssignment` isn't null. Because this is a one-to-zero-or-one relationship, there might not be a related OfficeAssignment entity.

  ```
  @if (item.OfficeAssignment != null)
  {
      @item.OfficeAssignment.Location
  }
  ```

- Adds a **Courses** column that displays courses taught by each instructor. See Explicit line transition for

more about this razor syntax.

- Adds code that dynamically adds `class="success"` to the `tr` element of the selected instructor and course. This sets a background color for the selected row using a Bootstrap class.

```
string selectedRow = "";
if (item.CourseID == Model.CourseID)
{
    selectedRow = "success";
}
<tr class="@selectedRow">
```

- Adds a new hyperlink labeled **Select**. This link sends the selected instructor's ID to the `Index` method and sets a background color.

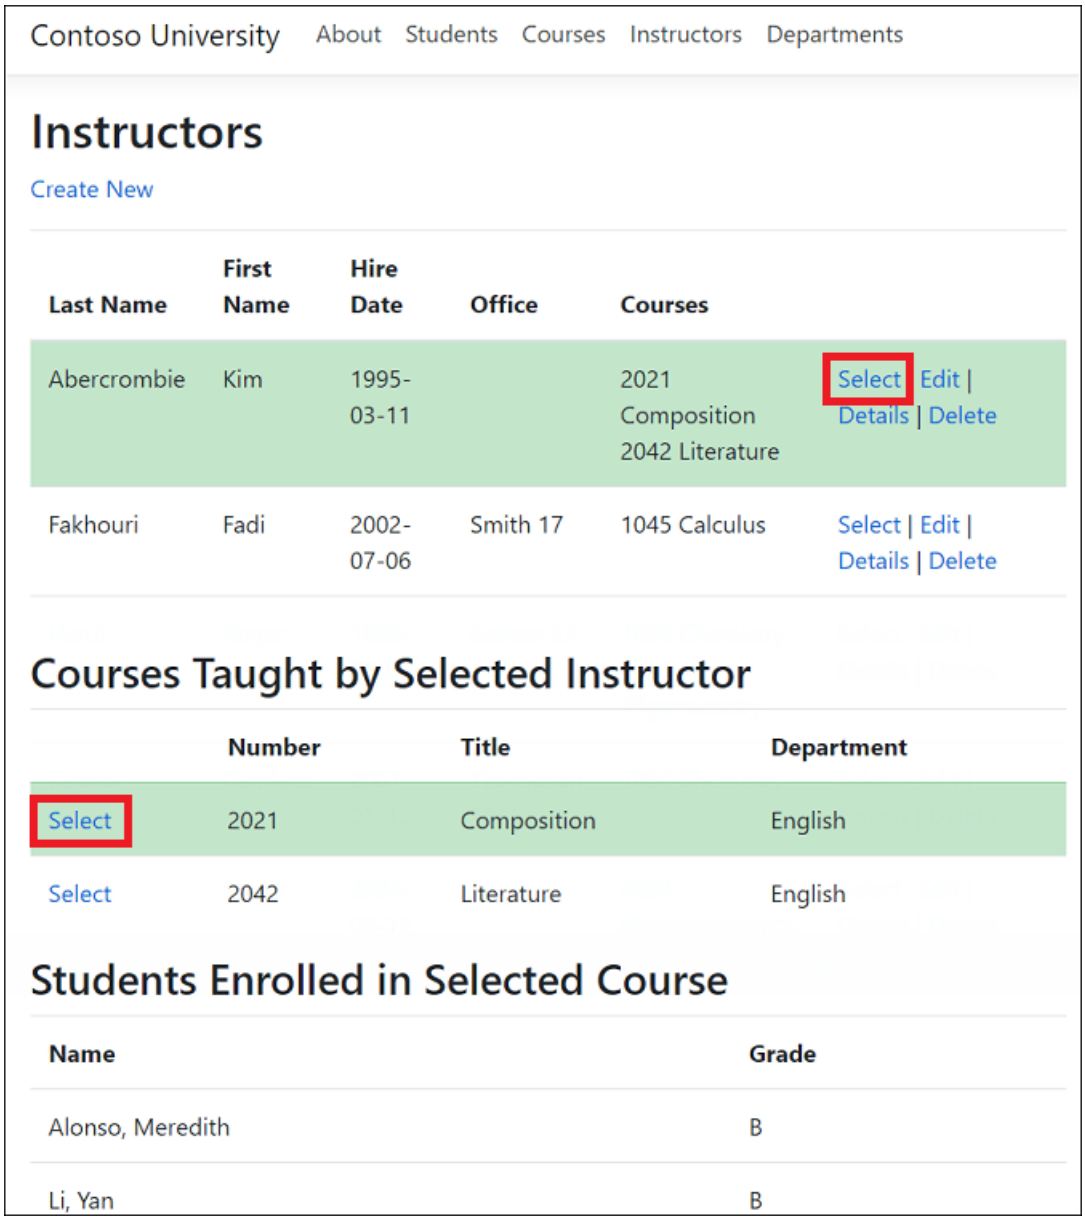
```
<a asp-action="Index" asp-route-id="@item.ID">Select</a> |
```

- Adds a table of courses for the selected Instructor.
- Adds a table of student enrollments for the selected course.

Run the app and select the **Instructors** tab. The page displays the `Location` (office) from the related `OfficeAssignment` entity. If `OfficeAssignment` is null, an empty table cell is displayed.

Click on the **Select** link for an instructor. The row style changes and courses assigned to that instructor are displayed.

Select a course to see the list of enrolled students and their grades.



Using Single

The `Single` method can pass in the `Where` condition instead of calling the `Where` method separately:

```
public async Task OnGetAsync(int? id, int? courseID)
{
    InstructorData = new InstructorIndexData();

    InstructorData.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
            .Include(i => i.CourseAssignments)
                .ThenInclude(i => i.Course)
                    .ThenInclude(i => i.Enrollments)
                        .ThenInclude(i => i.Student)
          .AsNoTracking()
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        InstructorID = id.Value;
        Instructor instructor = InstructorData.Instructors.Single(
            i => i.ID == id.Value);
        InstructorData.Courses = instructor.CourseAssignments.Select(
            s => s.Course);
    }

    if (courseID != null)
    {
        CourseID = courseID.Value;
        InstructorData.Enrollments = InstructorData.Courses.Single(
            x => x.CourseID == courseID).Enrollments;
    }
}
```

Use of `Single` with a Where condition is a matter of personal preference. It provides no benefits over using the `Where` method.

Explicit loading

The current code specifies eager loading for `Enrollments` and `Students`:

```
InstructorData.Instructors = await _context.Instructors
    .Include(i => i.OfficeAssignment)
    .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
    .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
    .AsNoTracking()
    .OrderBy(i => i.LastName)
    .ToListAsync();
```

Suppose users rarely want to see enrollments in a course. In that case, an optimization would be to only load the enrollment data if it's requested. In this section, the `OnGetAsync` is updated to use explicit loading of `Enrollments` and `Students`.

Update *Pages/Instructors/Index.cshtml.cs* with the following code.

```
using ContosoUniversity.Models;
using ContosoUniversity.Models.SchoolViewModels;  // Add VM
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class IndexModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public IndexModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public InstructorIndexData InstructorData { get; set; }
        public int InstructorID { get; set; }
        public int CourseID { get; set; }

        public async Task OnGetAsync(int? id, int? courseID)
        {
            InstructorData = new InstructorIndexData();
            InstructorData.Instructors = await _context.Instructors
                .Include(i => i.OfficeAssignment)
                .Include(i => i.CourseAssignments)
                    .ThenInclude(i => i.Course)
                        .ThenInclude(i => i.Department)
                //.Include(i => i.CourseAssignments)
                //    .ThenInclude(i => i.Course)
                //        .ThenInclude(i => i.Enrollments)
                //            .ThenInclude(i => i.Student)
                //.AsNoTracking()
                .OrderBy(i => i.LastName)
                .ToListAsync();

            if (id != null)
            {
                InstructorID = id.Value;
                Instructor instructor = InstructorData.Instructors
                    .Where(i => i.ID == id.Value).Single();
                InstructorData.Courses = instructor.CourseAssignments.Select(s => s.Course);
            }

            if (courseID != null)
            {
                CourseID = courseID.Value;
                var selectedCourse = InstructorData.Courses
                    .Where(x => x.CourseID == courseID).Single();
                await _context.Entry(selectedCourse).Collection(x => x.Enrollments).LoadAsync();
                foreach (Enrollment enrollment in selectedCourse.Enrollments)
                {
                    await _context.Entry(enrollment).Reference(x => x.Student).LoadAsync();
                }
                InstructorData.Enrollments = selectedCourse.Enrollments;
            }
        }
    }
}
```

The preceding code drops the *ThenInclude* method calls for enrollment and student data. If a course is selected, the explicit loading code retrieves:

- The `Enrollment` entities for the selected course.

- The `Student` entities for each `Enrollment`.

Notice that the preceding code comments out `.AsNoTracking()`. Navigation properties can only be explicitly loaded for tracked entities.

Test the app. From a user's perspective, the app behaves identically to the previous version.

Next steps

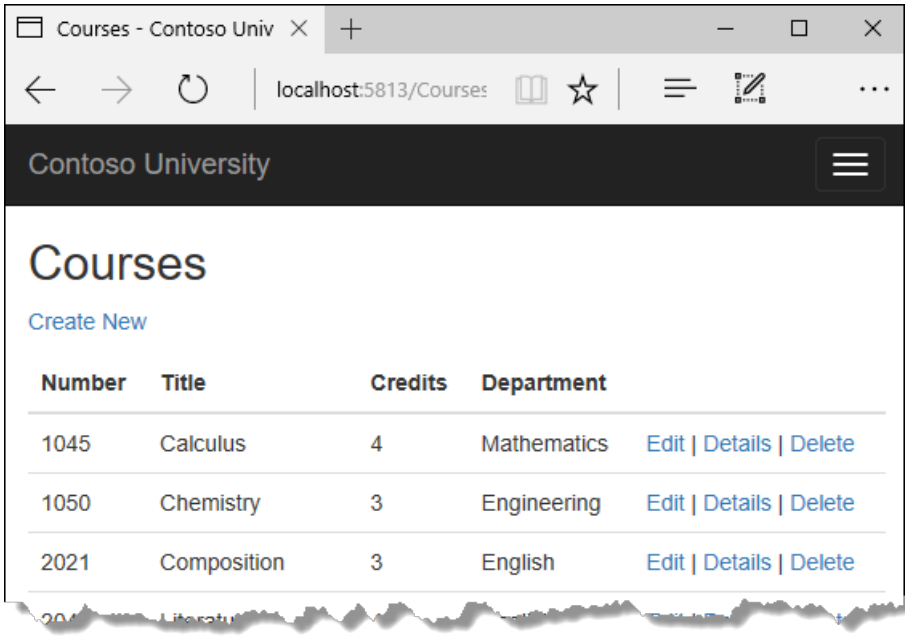
The next tutorial shows how to update related data.

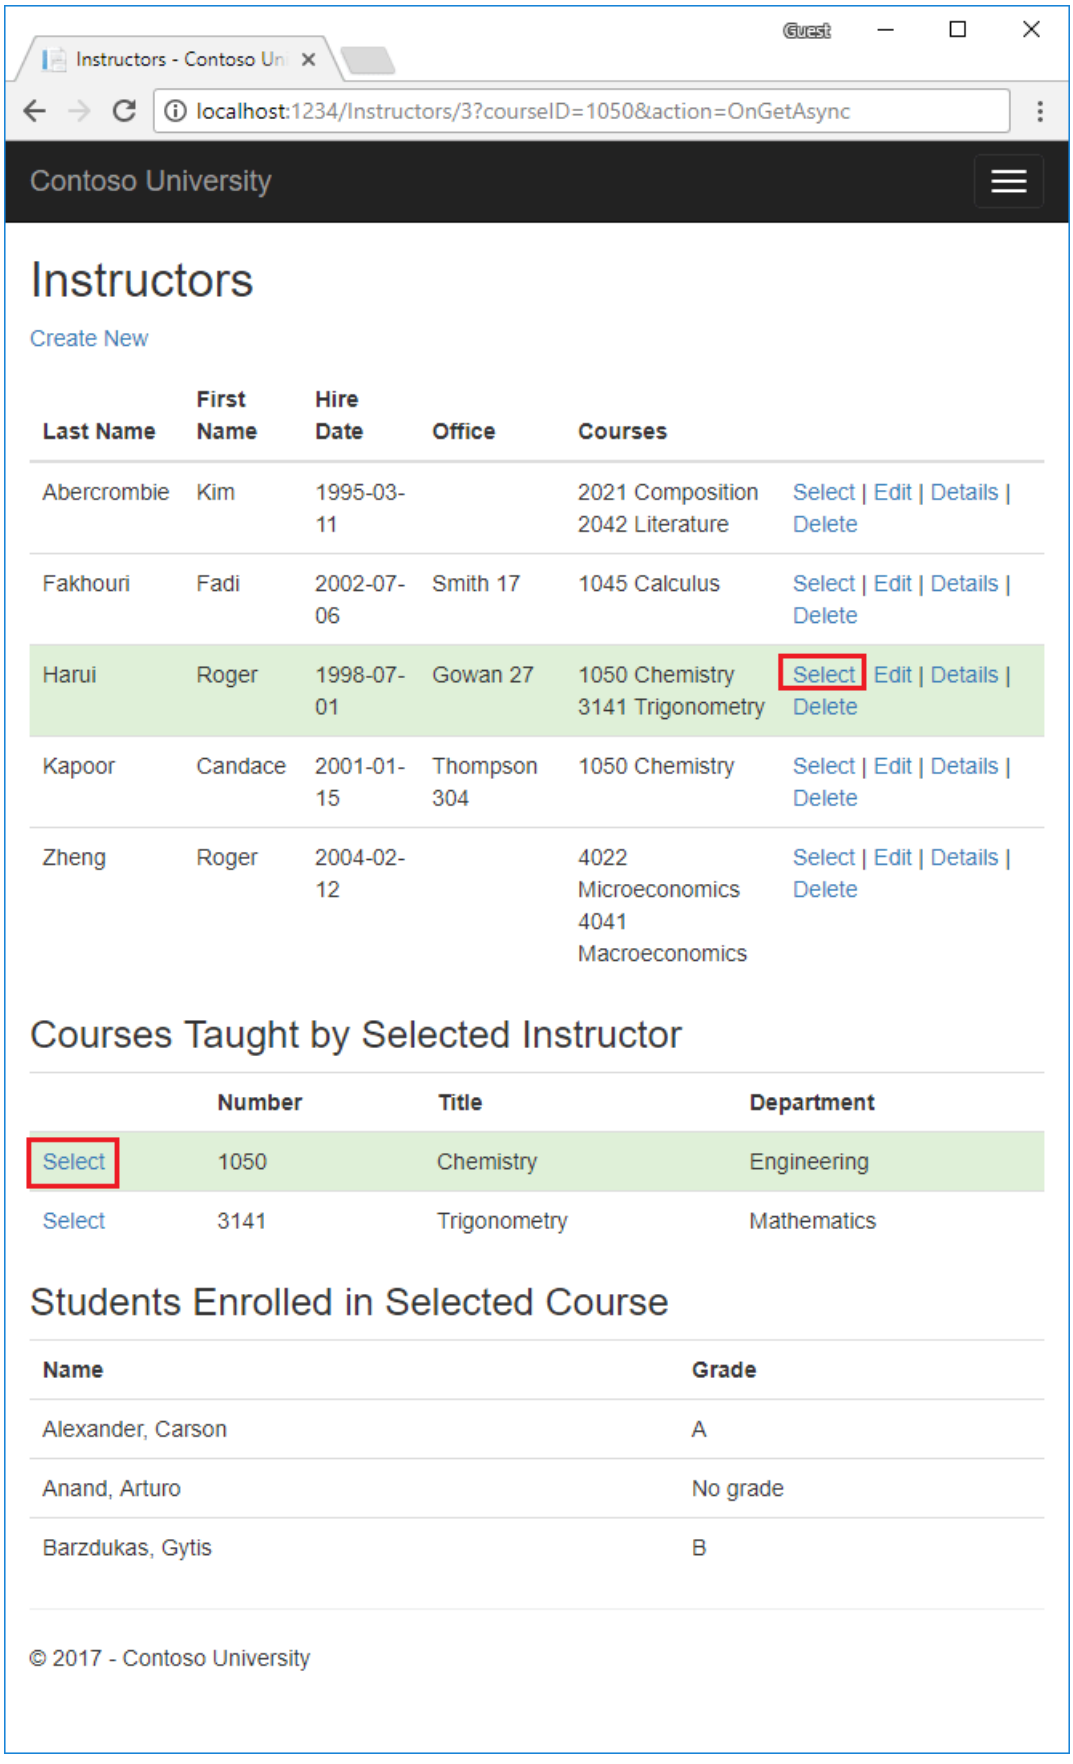
PREVIOUS TUTORIAL NEXT TUTORIAL

In this tutorial, related data is read and displayed. Related data is data that EF Core loads into navigation properties.

If you run into problems you can't solve, download or view the completed app. Download instructions.

The following illustrations show the completed pages for this tutorial:





Eager, explicit, and lazy Loading of related data

There are several ways that EF Core can load related data into the navigation properties of an entity:

- Eager loading. Eager loading is when a query for one type of entity also loads related entities. When the entity is read, its related data is retrieved. This typically results in a single join query that retrieves all of the data that's needed. EF Core will issue multiple queries for some types of eager loading. Issuing multiple queries can be more efficient than was the case for some queries in EF6 where there was a single

query. Eager loading is specified with the `Include` and `ThenInclude` methods.

```
var departments = _context.Departments.Include(d => d.Courses);
foreach (Department d in departments)
{
    foreach(Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department entities and related Course entities

Eager loading sends multiple queries when a collection navigation is included:

- One query for the main query
- One query for each collection "edge" in the load tree.

- Separate queries with `Load`: The data can be retrieved in separate queries, and EF Core "fixes up" the navigation properties. "fixes up" means that EF Core automatically populates the navigation properties. Separate queries with `Load` is more like explicit loading than eager loading.

```
var departments = _context.Departments;
foreach (Department d in departments)
{
    _context.Courses.Where(c => c.DepartmentID == d.DepartmentID).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows

Query: Course rows related to Department d

Note: EF Core automatically fixes up navigation properties to any other entities that were previously loaded into the context instance. Even if the data for a navigation property is *not* explicitly included, the property may still be populated if some or all of the related entities were previously loaded.

- Explicit loading. When the entity is first read, related data isn't retrieved. Code must be written to retrieve the related data when it's needed. Explicit loading with separate queries results in multiple queries sent to the DB. With explicit loading, the code specifies the navigation properties to be loaded. Use the `Load` method to do explicit loading. For example:

```
var departments = _context.Departments;
foreach (Department d in departments)
{
    _context.Entry(d).Collection(p => p.Courses).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows

Query: Course rows related to Department d

- Lazy loading. Lazy loading was added to EF Core in version 2.1. When the entity is first read, related data isn't retrieved. The first time a navigation property is accessed, the data required for that navigation property is automatically retrieved. A query is sent to the DB each time a navigation property is accessed for the first time.

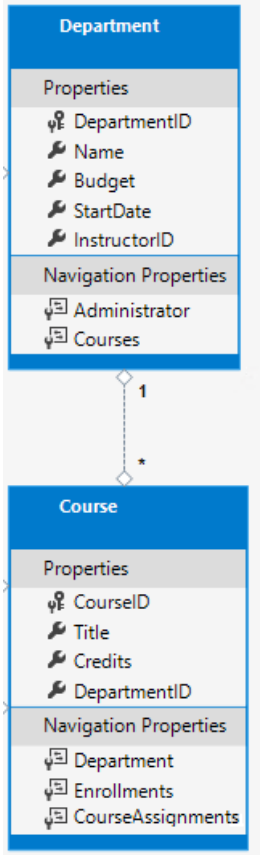
- The `Select` operator loads only the related data needed.

Create a Course page that displays department name

The Course entity includes a navigation property that contains the `Department` entity. The `Department` entity contains the department that the course is assigned to.

To display the name of the assigned department in a list of courses:

- Get the `Name` property from the `Department` entity.
- The `Department` entity comes from the `Course.Department` navigation property.



Scaffold the Course model

- Visual Studio
- Visual Studio Code

Follow the instructions in Scaffold the student model and use `Course` for the model class.

The preceding command scaffolds the `Course` model. Open the project in Visual Studio.

Open *Pages/Courses/Index.cshtml.cs* and examine the `OnGetAsync` method. The scaffolding engine specified eager loading for the `Department` navigation property. The `Include` method specifies eager loading.

Run the app and select the **Courses** link. The department column displays the `DepartmentID`, which isn't useful.

Update the `OnGetAsync` method with the following code:

```
public async Task OnGetAsync()
{
    Course = await _context.Courses
        .Include(c => c.Department)
        .AsNoTracking()
        .ToListAsync();
}
```

The preceding code adds `AsNoTracking`. `AsNoTracking` improves performance because the entities returned are not tracked. The entities are not tracked because they're not updated in the current context.

Update *Pages/Courses/Index.cshtml* with the following highlighted markup:

```
@page
@model ContosoUniversity.Pages.Courses.IndexModel
@{
    ViewData["Title"] = "Courses";
}

<h2>Courses</h2>

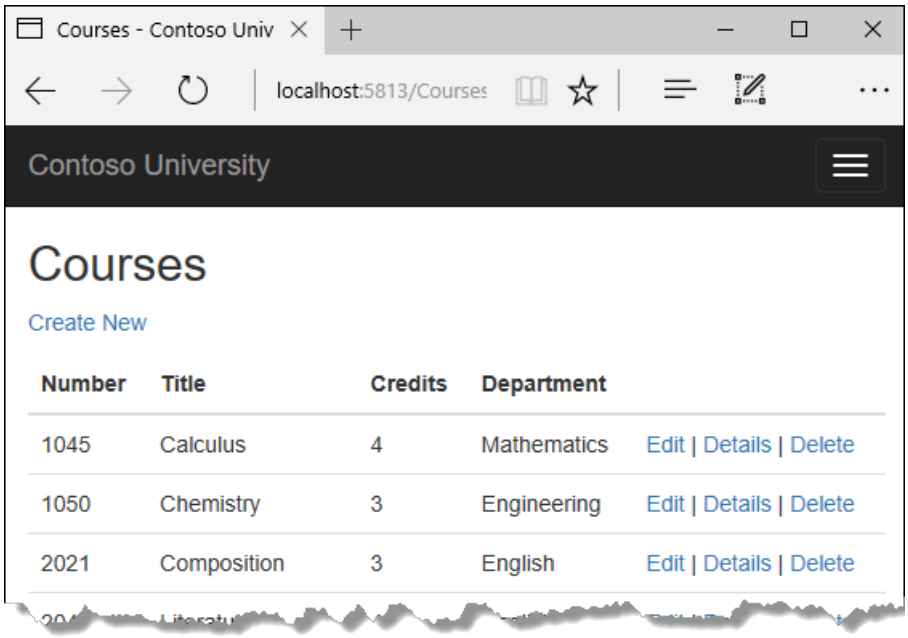
<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Course[0].CourseID)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Course[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Course[0].Credits)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Course[0].Department)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Course)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.CourseID)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Credits)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Department.Name)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.CourseID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.CourseID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.CourseID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

The following changes have been made to the scaffolded code:

- Changed the heading from Index to Courses.
- Added a **Number** column that shows the `CourseID` property value. By default, primary keys aren't scaffolded because normally they're meaningless to end users. However, in this case the primary key is meaningful.
- Changed the **Department** column to display the department name. The code displays the `Name` property of the `Department` entity that's loaded into the `Department` navigation property:

```
@Html.DisplayFor(modelItem => item.Department.Name)
```

Run the app and select the **Courses** tab to see the list with department names.



Loading related data with Select

The `OnGetAsync` method loads related data with the `Include` method:

```
public async Task OnGetAsync()
{
    Course = await _context.Courses
        .Include(c => c.Department)
        .AsNoTracking()
        .ToListAsync();
}
```

The `Select` operator loads only the related data needed. For single items, like the `Department.Name` it uses a SQL INNER JOIN. For collections, it uses another database access, but so does the `Include` operator on collections.

The following code loads related data with the `Select` method:

```
public IList<CourseViewModel> CourseVM { get; set; }

public async Task OnGetAsync()
{
    CourseVM = await _context.Courses
            .Select(p => new CourseViewModel
            {
                CourseID = p.CourseID,
                Title = p.Title,
                Credits = p.Credits,
                DepartmentName = p.Department.Name
            }).ToListAsync();
}
```

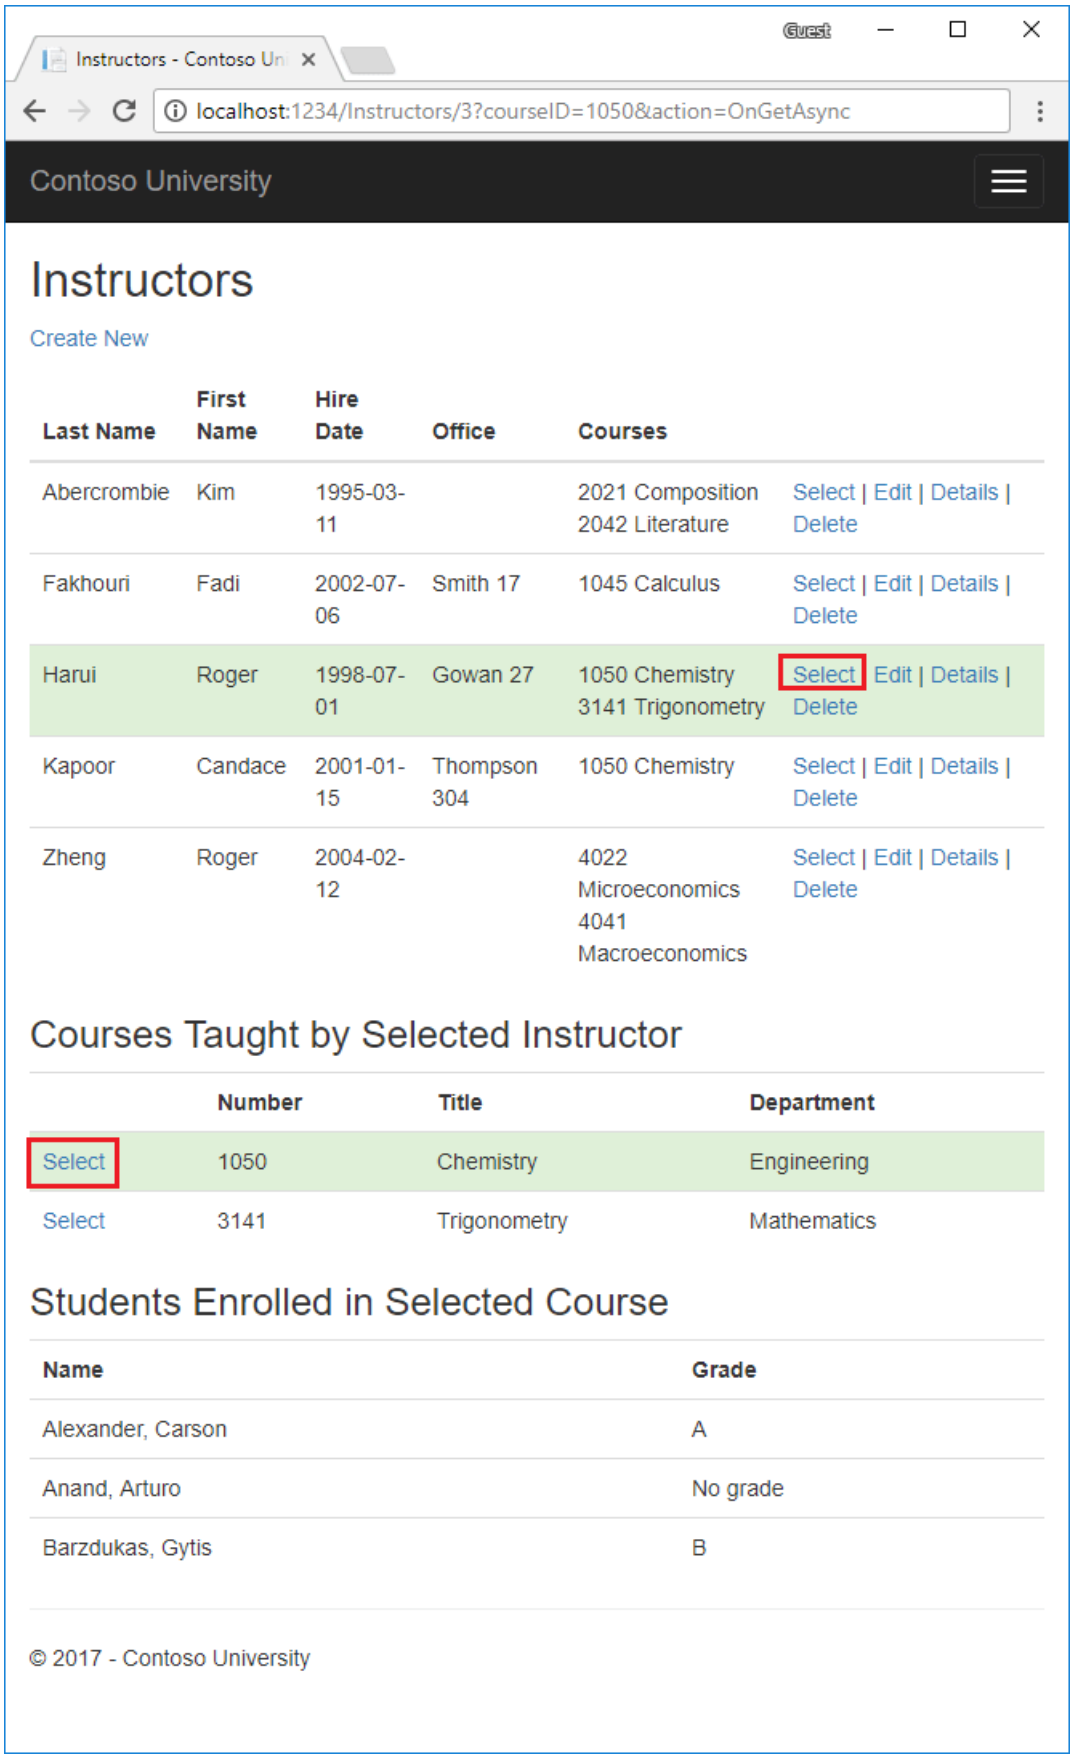
The `CourseViewModel`:

```
public class CourseViewModel
{
    public int CourseID { get; set; }
    public string Title { get; set; }
    public int Credits { get; set; }
    public string DepartmentName { get; set; }
}
```

See IndexSelect.cshtml and IndexSelect.cshtml.cs for a complete example.

Create an Instructors page that shows Courses and Enrollments

In this section, the Instructors page is created.



This page reads and displays related data in the following ways:

- The list of instructors displays related data from the `OfficeAssignment` entity (Office in the preceding image). The `Instructor` and `OfficeAssignment` entities are in a one-to-zero-or-one relationship. Eager loading is used for the `OfficeAssignment` entities. Eager loading is typically more efficient when the related data needs to be displayed. In this case, office assignments for the instructors are displayed.
- When the user selects an instructor (Harui in the preceding image), related `Course` entities are displayed. The

`Instructor` and `Course` entities are in a many-to-many relationship. Eager loading is used for the `Course` entities and their related `Department` entities. In this case, separate queries might be more efficient because only courses for the selected instructor are needed. This example shows how to use eager loading for navigation properties in entities that are in navigation properties.

- When the user selects a course (Chemistry in the preceding image), related data from the `Enrollments` entity is displayed. In the preceding image, student name and grade are displayed. The `Course` and `Enrollment` entities are in a one-to-many relationship.

Create a view model for the Instructor Index view

The instructors page shows data from three different tables. A view model is created that includes the three entities representing the three tables.

In the *SchoolViewModels* folder, create *InstructorIndexData.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class InstructorIndexData
    {
        public IEnumerable<Instructor> Instructors { get; set; }
        public IEnumerable<Course> Courses { get; set; }
        public IEnumerable<Enrollment> Enrollments { get; set; }
    }
}
```

Scaffold the Instructor model

- Visual Studio
- Visual Studio Code

Follow the instructions in Scaffold the student model and use `Instructor` for the model class.

The preceding command scaffolds the `Instructor` model. Run the app and navigate to the instructors page.

Replace *Pages/Instructors/Index.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using ContosoUniversity.Models.SchoolViewModels;  // Add VM
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class IndexModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public IndexModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public InstructorIndexData Instructor { get; set; }
        public int InstructorID { get; set; }

        public async Task OnGetAsync(int? id)
        {
            Instructor = new InstructorIndexData();
            Instructor.Instructors = await _context.Instructors
                  .Include(i => i.OfficeAssignment)
                  .Include(i => i.CourseAssignments)
                    .ThenInclude(i => i.Course)
                  .AsNoTracking()
                  .OrderBy(i => i.LastName)
                  .ToListAsync();

            if (id != null)
            {
                InstructorID = id.Value;
            }
        }
    }
}
```

The `OnGetAsync` method accepts optional route data for the ID of the selected instructor.

Examine the query in the *Pages/Instructors/Index.cshtml.cs* file:

```
Instructor.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

The query has two includes:

- `OfficeAssignment`: Displayed in the instructors view.
- `CourseAssignments`: Which brings in the courses taught.

Update the instructors Index page

Update *Pages/Instructors/Index.cshtml* with the following markup:

```
@page "{id:int?}"
@model ContosoUniversity.Pages.Instructors.IndexModel

@{
    ViewData["Title"] = "Instructors";
}

<h2>Instructors</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>Last Name</th>
            <th>First Name</th>
            <th>Hire Date</th>
            <th>Office</th>
            <th>Courses</th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Instructor.Instructors)
        {
            string selectedRow = "";
            if (item.ID == Model.InstructorID)
            {
                selectedRow = "success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.HireDate)
                </td>
                <td>
                    @if (item.OfficeAssignment != null)
                    {
                        @item.OfficeAssignment.Location
                    }
                </td>
                <td>
                    @{
                        foreach (var course in item.CourseAssignments)
                        {
                            @course.Course.CourseID @:  @course.Course.Title <br />
                        }
                    }
                </td>
                <td>
                    <a asp-page="./Index" asp-route-id="@item.ID">Select</a> |
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

The preceding markup makes the following changes:

- Updates the `page` directive from `@page` to `@page "{id:int?}"`. `"{id:int?}"` is a route template. The route template changes integer query strings in the URL to route data. For example, clicking on the **Select** link for an instructor with only the `@page` directive produces a URL like the following:

  `http://localhost:1234/Instructors?id=2`

  When the page directive is `@page "{id:int?}"`, the previous URL is:

  `http://localhost:1234/Instructors/2`

- Page title is **Instructors**.
- Added an **Office** column that displays `item.OfficeAssignment.Location` only if `item.OfficeAssignment` isn't null. Because this is a one-to-zero-or-one relationship, there might not be a related OfficeAssignment entity.

  ```
  @if (item.OfficeAssignment != null)
  {
      @item.OfficeAssignment.Location
  }
  ```

- Added a **Courses** column that displays courses taught by each instructor. See Explicit line transition for more about this razor syntax.
- Added code that dynamically adds `class="success"` to the `tr` element of the selected instructor. This sets a background color for the selected row using a Bootstrap class.

  ```
  string selectedRow = "";
  if (item.CourseID == Model.CourseID)
  {
      selectedRow = "success";
  }
  <tr class="@selectedRow">
  ```

- Added a new hyperlink labeled **Select**. This link sends the selected instructor's ID to the `Index` method and sets a background color.

  ```
  <a asp-action="Index" asp-route-id="@item.ID">Select</a> |
  ```

Run the app and select the **Instructors** tab. The page displays the `Location` (office) from the related `OfficeAssignment` entity. If OfficeAssignment` is null, an empty table cell is displayed.

Click on the **Select** link. The row style changes.

Add courses taught by selected instructor

Update the `OnGetAsync` method in *Pages/Instructors/Index.cshtml.cs* with the following code:

```
public async Task OnGetAsync(int? id, int? courseID)
{
    Instructor = new InstructorIndexData();
    Instructor.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
          .AsNoTracking()
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        InstructorID = id.Value;
        Instructor instructor = Instructor.Instructors.Where(
            i => i.ID == id.Value).Single();
        Instructor.Courses = instructor.CourseAssignments.Select(s => s.Course);
    }

    if (courseID != null)
    {
        CourseID = courseID.Value;
        Instructor.Enrollments = Instructor.Courses.Where(
            x => x.CourseID == courseID).Single().Enrollments;
    }
}
```

Add `public int CourseID { get; set; }`

```
public class IndexModel : PageModel
{
    private readonly ContosoUniversity.Data.SchoolContext _context;

    public IndexModel(ContosoUniversity.Data.SchoolContext context)
    {
        _context = context;
    }

    public InstructorIndexData Instructor { get; set; }
    public int InstructorID { get; set; }
    public int CourseID { get; set; }

    public async Task OnGetAsync(int? id, int? courseID)
    {
        Instructor = new InstructorIndexData();
        Instructor.Instructors = await _context.Instructors
              .Include(i => i.OfficeAssignment)
              .Include(i => i.CourseAssignments)
                .ThenInclude(i => i.Course)
                    .ThenInclude(i => i.Department)
              .AsNoTracking()
              .OrderBy(i => i.LastName)
              .ToListAsync();

        if (id != null)
        {
            InstructorID = id.Value;
            Instructor instructor = Instructor.Instructors.Where(
                i => i.ID == id.Value).Single();
            Instructor.Courses = instructor.CourseAssignments.Select(s => s.Course);
        }

        if (courseID != null)
        {
            CourseID = courseID.Value;
            Instructor.Enrollments = Instructor.Courses.Where(
                x => x.CourseID == courseID).Single().Enrollments;
        }
    }
```

Examine the updated query:

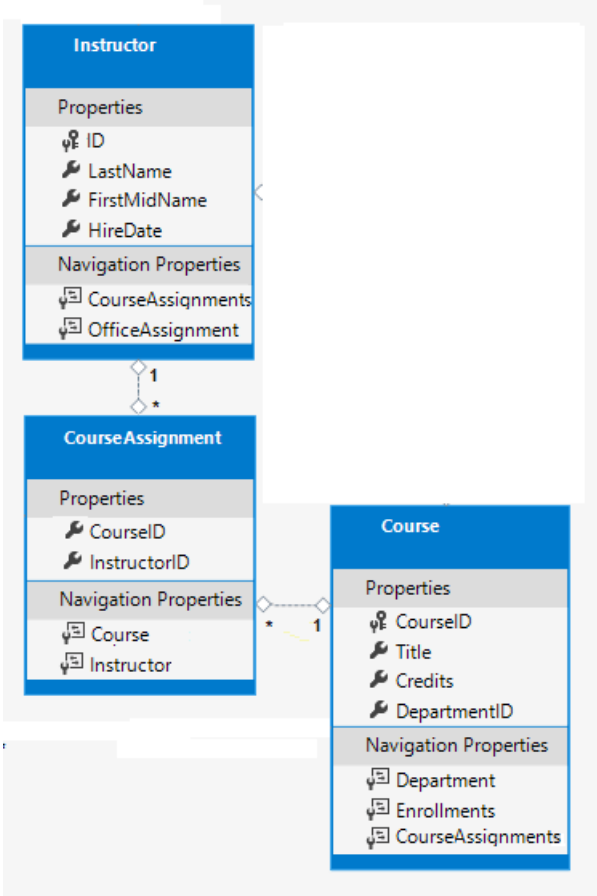
```
Instructor.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

The preceding query adds the `Department` entities.

The following code executes when an instructor is selected (`id != null`). The selected instructor is retrieved from the list of instructors in the view model. The view model's `Courses` property is loaded with the `Course` entities from that instructor's `CourseAssignments` navigation property.

```
if (id != null)
{
    InstructorID = id.Value;
    Instructor instructor = Instructor.Instructors.Where(
        i => i.ID == id.Value).Single();
    Instructor.Courses = instructor.CourseAssignments.Select(s => s.Course);
}
```

The `Where` method returns a collection. In the preceding `Where` method, only a single `Instructor` entity is returned. The `Single` method converts the collection into a single `Instructor` entity. The `Instructor` entity provides access to the `CourseAssignments` property. `CourseAssignments` provides access to the related `Course` entities.



The `Single` method is used on a collection when the collection has only one item. The `Single` method throws an exception if the collection is empty or if there's more than one item. An alternative is `SingleOrDefault`, which returns a default value (null in this case) if the collection is empty. Using `SingleOrDefault` on an empty collection:

- Results in an exception (from trying to find a `Courses` property on a null reference).
- The exception message would less clearly indicate the cause of the problem.

The following code populates the view model's `Enrollments` property when a course is selected:

```
if (courseID != null)
{
    CourseID = courseID.Value;
    Instructor.Enrollments = Instructor.Courses.Where(
        x => x.CourseID == courseID).Single().Enrollments;
}
```

Add the following markup to the end of the *Pages/Instructors/Index.cshtml* Razor Page:

```
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>

@if (Model.Instructor.Courses != null)
{
    <h3>Courses Taught by Selected Instructor</h3>
    <table class="table">
        <tr>
            <th></th>
            <th>Number</th>
            <th>Title</th>
            <th>Department</th>
        </tr>

        @foreach (var item in Model.Instructor.Courses)
        {
            string selectedRow = "";
            if (item.CourseID == Model.CourseID)
            {
                selectedRow = "success";
            }
            <tr class="@selectedRow">
                <td>
                    <a asp-page="./Index" asp-route-courseID="@item.CourseID">Select</a>
                </td>
                <td>
                    @item.CourseID
                </td>
                <td>
                    @item.Title
                </td>
                <td>
                    @item.Department.Name
                </td>
            </tr>
        }

    </table>
}
```

The preceding markup displays a list of courses related to an instructor when an instructor is selected.

Test the app. Click on a **Select** link on the instructors page.

Show student data

In this section, the app is updated to show the student data for a selected course.

Update the query in the `OnGetAsync` method in *Pages/Instructors/Index.cshtml.cs* with the following code:

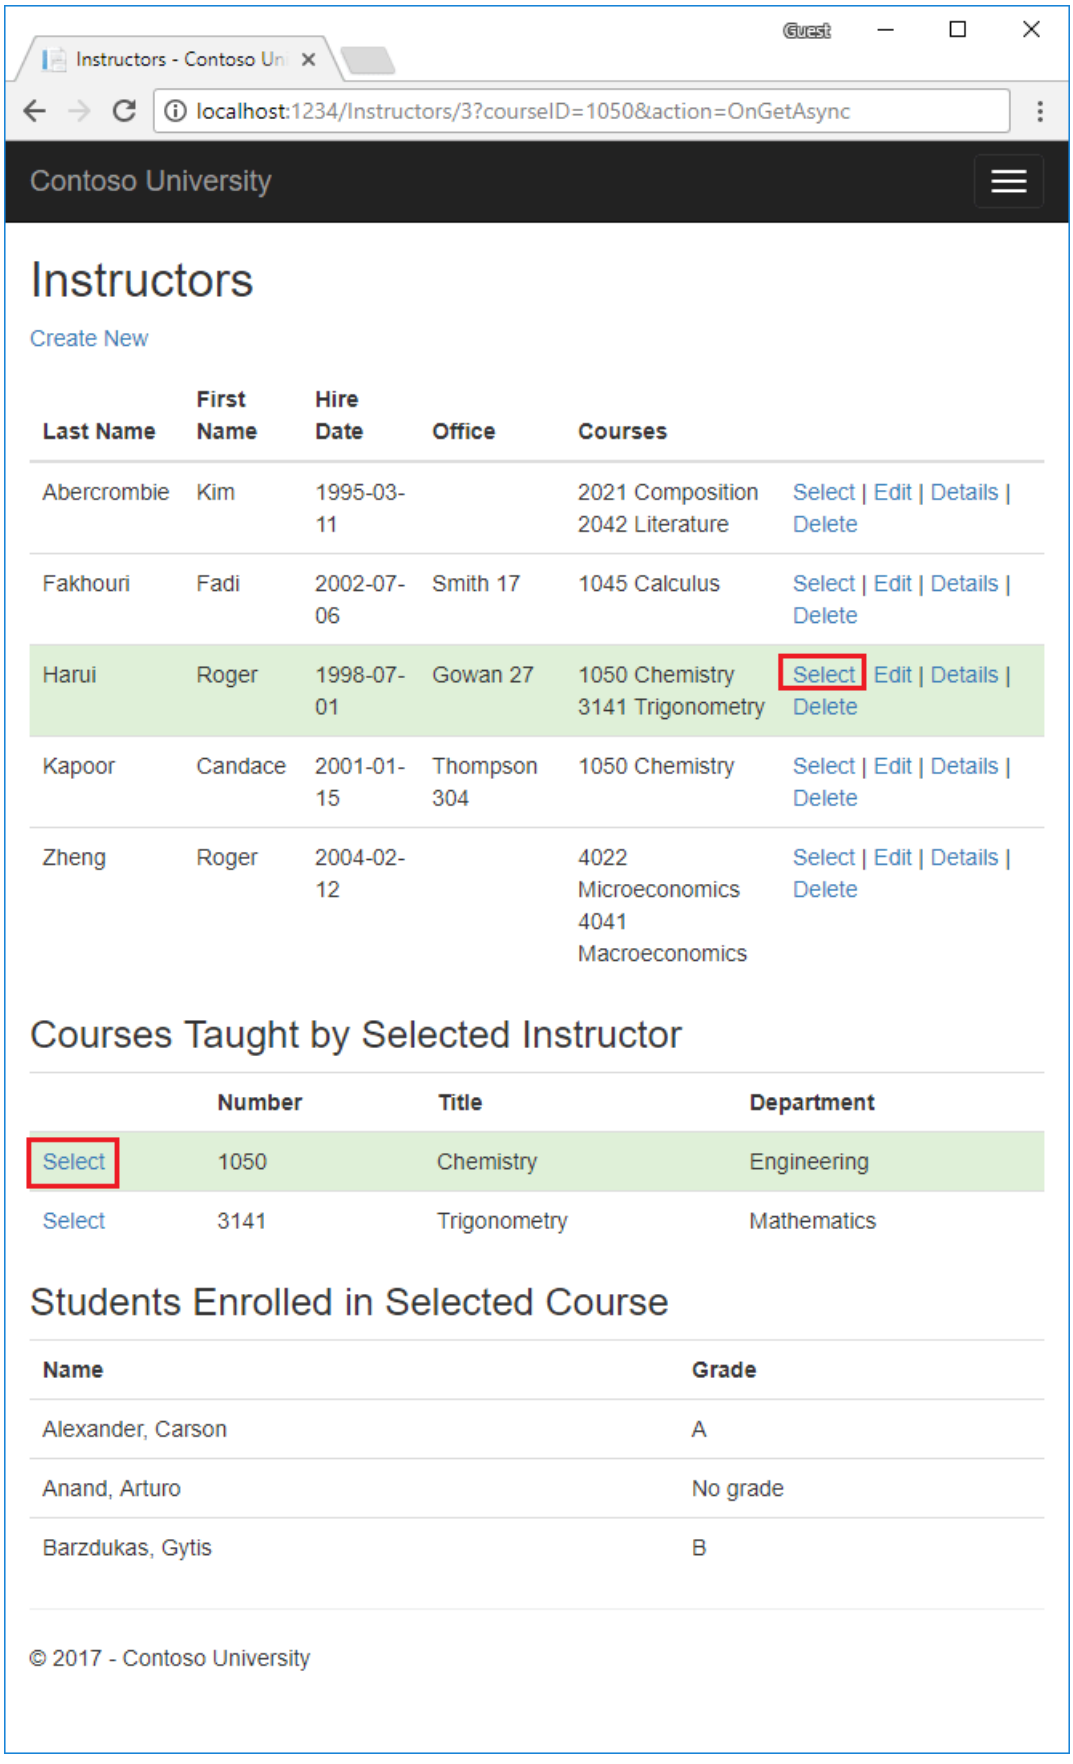
```
Instructor.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
        .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Enrollments)
                    .ThenInclude(i => i.Student)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

Update *Pages/Instructors/Index.cshtml*. Add the following markup to the end of the file:

```
@if (Model.Instructor.Enrollments != null)
{
    <h3>
        Students Enrolled in Selected Course
    </h3>
    <table class="table">
        <tr>
            <th>Name</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.Instructor.Enrollments)
        {
            <tr>
                <td>
                    @item.Student.FullName
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
}
```

The preceding markup displays a list of the students who are enrolled in the selected course.

Refresh the page and select an instructor. Select a course to see the list of enrolled students and their grades.



Using Single

The `Single` method can pass in the `Where` condition instead of calling the `Where` method separately:

```
public async Task OnGetAsync(int? id, int? courseID)
{
    Instructor = new InstructorIndexData();

    Instructor.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
            .Include(i => i.CourseAssignments)
                .ThenInclude(i => i.Course)
                    .ThenInclude(i => i.Enrollments)
                        .ThenInclude(i => i.Student)
          .AsNoTracking()
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        InstructorID = id.Value;
        Instructor instructor = Instructor.Instructors.Single(
            i => i.ID == id.Value);
        Instructor.Courses = instructor.CourseAssignments.Select(
            s => s.Course);
    }

    if (courseID != null)
    {
        CourseID = courseID.Value;
        Instructor.Enrollments = Instructor.Courses.Single(
            x => x.CourseID == courseID).Enrollments;
    }
}
```

The preceding `Single` approach provides no benefits over using `Where`. Some developers prefer the `Single` approach style.

Explicit loading

The current code specifies eager loading for `Enrollments` and `Students`:

```
Instructor.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
        .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Enrollments)
                    .ThenInclude(i => i.Student)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

Suppose users rarely want to see enrollments in a course. In that case, an optimization would be to only load the enrollment data if it's requested. In this section, the `OnGetAsync` is updated to use explicit loading of `Enrollments` and `Students`.

Update the `OnGetAsync` with the following code:

```
public async Task OnGetAsync(int? id, int? courseID)
{
    Instructor = new InstructorIndexData();
    Instructor.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
            //.Include(i => i.CourseAssignments)
            //    .ThenInclude(i => i.Course)
            //        .ThenInclude(i => i.Enrollments)
            //            .ThenInclude(i => i.Student)
         // .AsNoTracking()
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        InstructorID = id.Value;
        Instructor instructor = Instructor.Instructors.Where(
            i => i.ID == id.Value).Single();
        Instructor.Courses = instructor.CourseAssignments.Select(s => s.Course);
    }

    if (courseID != null)
    {
        CourseID = courseID.Value;
        var selectedCourse = Instructor.Courses.Where(x => x.CourseID == courseID).Single();
        await _context.Entry(selectedCourse).Collection(x => x.Enrollments).LoadAsync();
        foreach (Enrollment enrollment in selectedCourse.Enrollments)
        {
            await _context.Entry(enrollment).Reference(x => x.Student).LoadAsync();
        }
        Instructor.Enrollments = selectedCourse.Enrollments;
    }
}
```

The preceding code drops the *ThenInclude* method calls for enrollment and student data. If a course is selected, the highlighted code retrieves:

- The `Enrollment` entities for the selected course.
- The `Student` entities for each `Enrollment`.

Notice the preceding code comments out `.AsNoTracking()`. Navigation properties can only be explicitly loaded for tracked entities.

Test the app. From a users perspective, the app behaves identically to the previous version.

The next tutorial shows how to update related data.

Part 7, Razor Pages with EF Core in ASP.NET Core - Update Related Data

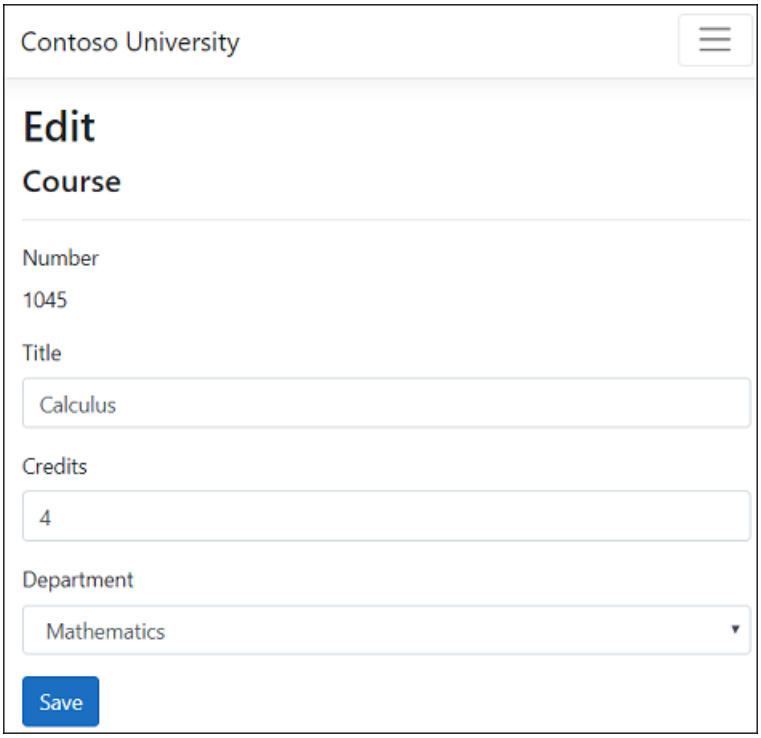
9/22/2020 • 32 minutes to read • Edit Online

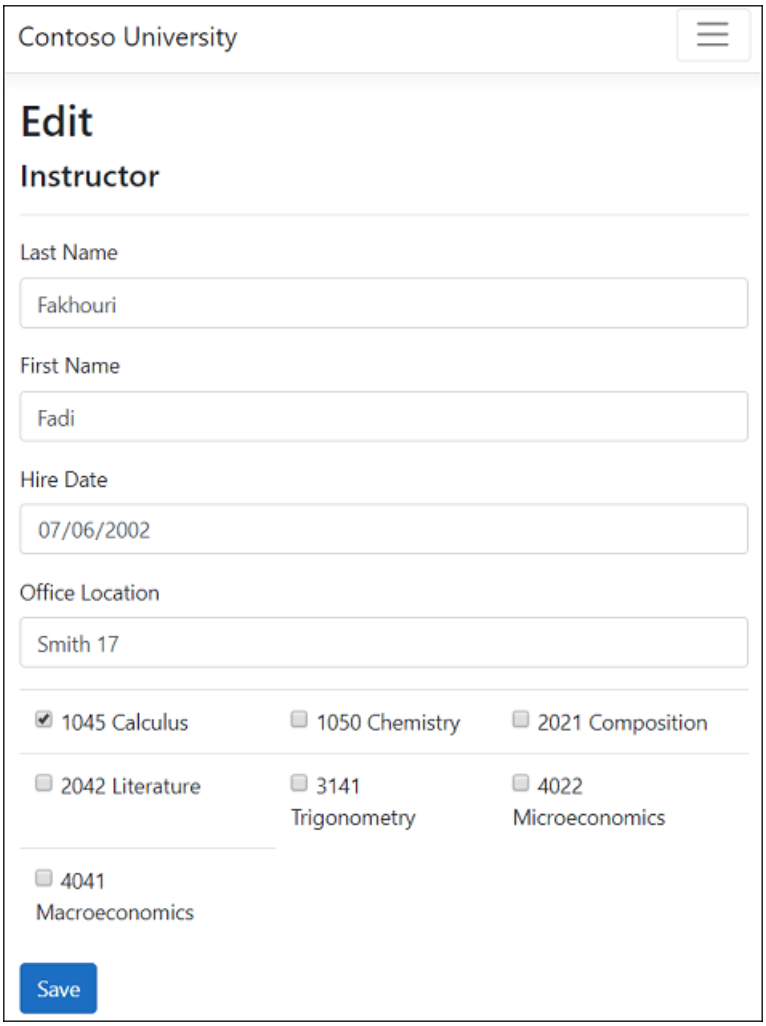
By Tom Dykstra, and Rick Anderson

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial shows how to update related data. The following illustrations show some of the completed pages.





Update the Course Create and Edit pages

The scaffolded code for the Course Create and Edit pages has a Department drop-down list that shows Department ID (an integer). The drop-down should show the Department name, so both of these pages need a list of department names. To provide that list, use a base class for the Create and Edit pages.

Create a base class for Course Create and Edit

Create a *Pages/Courses/DepartmentNamePageModel.cs* file with the following code:

```
using ContosoUniversity.Data;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;
using Microsoft.EntityFrameworkCore;
using System.Linq;

namespace ContosoUniversity.Pages.Courses
{
    public class DepartmentNamePageModel : PageModel
    {
        public SelectList DepartmentNameSL { get; set; }

        public void PopulateDepartmentsDropDownList(SchoolContext _context,
            object selectedDepartment = null)
        {
            var departmentsQuery = from d in _context.Departments
                                   orderby d.Name // Sort by name.
                                   select d;

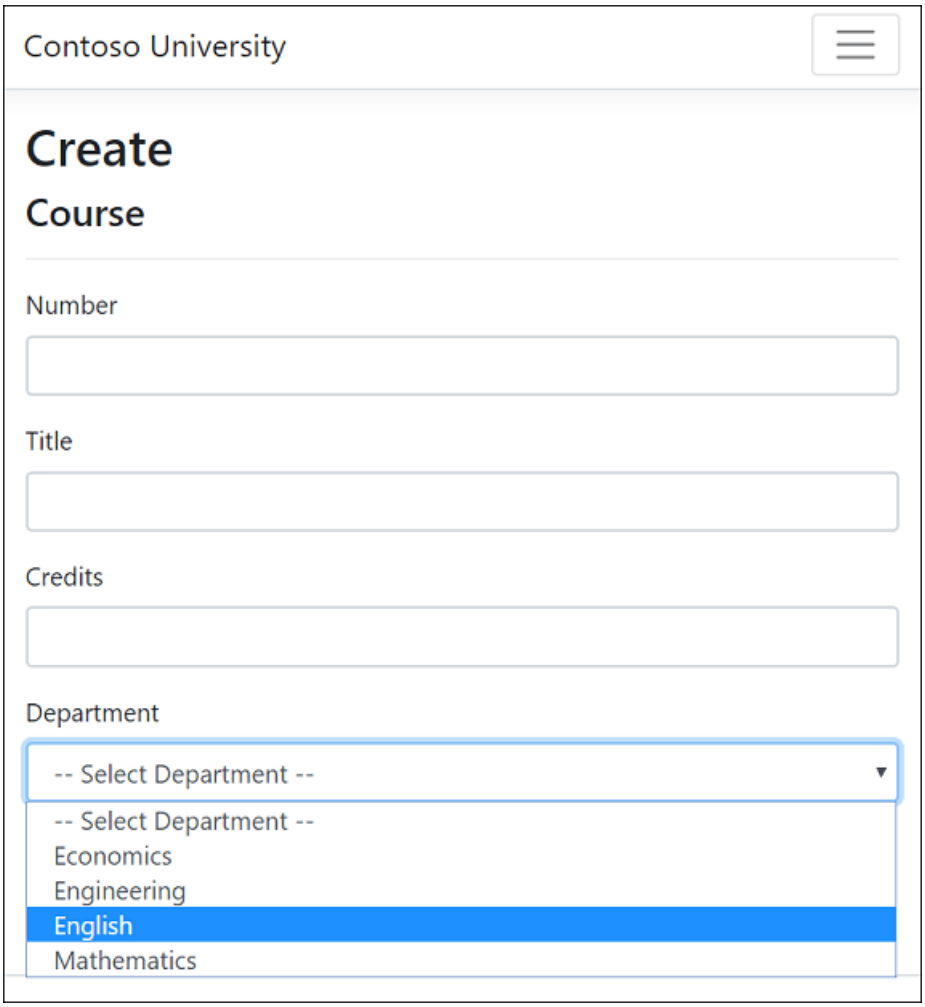
            DepartmentNameSL = new SelectList(departmentsQuery.AsNoTracking(),
                        "DepartmentID", "Name", selectedDepartment);
        }
    }
}
```

The preceding code creates a SelectList to contain the list of department names. If `selectedDepartment` is specified, that department is selected in the `SelectList`.

The Create and Edit page model classes will derive from `DepartmentNamePageModel`.

Update the Course Create page model

A Course is assigned to a Department. The base class for the Create and Edit pages provides a `SelectList` for selecting the department. The drop-down list that uses the `SelectList` sets the `Course.DepartmentID` foreign key (FK) property. EF Core uses the `Course.DepartmentID` FK to load the `Department` navigation property.



Update *Pages/Courses/Create.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class CreateModel : DepartmentNamePageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public CreateModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            PopulateDepartmentsDropDownList(_context);
            return Page();
        }

        [BindProperty]
        public Course Course { get; set; }

        public async Task<IActionResult> OnPostAsync()
        {
            var emptyCourse = new Course();

            if (await TryUpdateModelAsync<Course>(
                 emptyCourse,
                 "course",   // Prefix for form value.
                 s => s.CourseID, s => s.DepartmentID, s => s.Title, s => s.Credits))
            {
                _context.Courses.Add(emptyCourse);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }

            // Select DepartmentID if TryUpdateModelAsync fails.
            PopulateDepartmentsDropDownList(_context, emptyCourse.DepartmentID);
            return Page();
        }
      }
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

The preceding code:

- Derives from `DepartmentNamePageModel`.
- Uses `TryUpdateModelAsync` to prevent overposting.
- Removes `ViewData["DepartmentID"]`. `DepartmentNameSL` from the base class is a strongly typed model and will be used by the Razor page. Strongly typed models are preferred over weakly typed. For more information, see Weakly typed data (ViewData and ViewBag).

Update the Course Create Razor page

Update *Pages/Courses/Create.cshtml* with the following code:

```
@page
@model ContosoUniversity.Pages.Courses.CreateModel
@{
    ViewData["Title"] = "Create Course";
}
<h2>Create</h2>
<h4>Course</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Course.CourseID" class="control-label"></label>
                <input asp-for="Course.CourseID" class="form-control" />
                <span asp-validation-for="Course.CourseID" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Title" class="control-label"></label>
                <input asp-for="Course.Title" class="form-control" />
                <span asp-validation-for="Course.Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Credits" class="control-label"></label>
                <input asp-for="Course.Credits" class="form-control" />
                <span asp-validation-for="Course.Credits" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Department" class="control-label"></label>
                <select asp-for="Course.DepartmentID" class="form-control"
                        asp-items="@Model.DepartmentNameSL">
                    <option value="">-- Select Department --</option>
                </select>
                <span asp-validation-for="Course.DepartmentID" class="text-danger" />
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>
<div>
    <a asp-page="Index">Back to List</a>
</div>
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code makes the following changes:

- Changes the caption from **DepartmentID** to **Department**.
- Replaces `"ViewBag.DepartmentID"` with `DepartmentNameSL` (from the base class).
- Adds the "Select Department" option. This change renders "Select Department" in the drop-down when no department has been selected yet, rather than the first department.
- Adds a validation message when the department isn't selected.

The Razor Page uses the Select Tag Helper:

```
<div class="form-group">
    <label asp-for="Course.Department" class="control-label"></label>
    <select asp-for="Course.DepartmentID" class="form-control"
            asp-items="@Model.DepartmentNameSL">
        <option value="">-- Select Department --</option>
    </select>
    <span asp-validation-for="Course.DepartmentID" class="text-danger" />
</div>
```

Test the Create page. The Create page displays the department name rather than the department ID.

Update the Course Edit page model

Update *Pages/Courses/Edit.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class EditModel : DepartmentNamePageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Course Course { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Course = await _context.Courses
                .Include(c => c.Department).FirstOrDefaultAsync(m => m.CourseID == id);

            if (Course == null)
            {
                return NotFound();
            }

            // Select current DepartmentID.
            PopulateDepartmentsDropDownList(_context, Course.DepartmentID);
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            var courseToUpdate = await _context.Courses.FindAsync(id);

            if (courseToUpdate == null)
            {
                return NotFound();
            }
```

```
            }

            if (await TryUpdateModelAsync<Course>(
                 courseToUpdate,
                 "course",   // Prefix for form value.
                   c => c.Credits, c => c.DepartmentID, c => c.Title))
            {
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }

            // Select DepartmentID if TryUpdateModelAsync fails.
            PopulateDepartmentsDropDownList(_context, courseToUpdate.DepartmentID);
            return Page();
        }
    }
}
```

The changes are similar to those made in the Create page model. In the preceding code, `PopulateDepartmentsDropDownList` passes in the department ID, which selects that department in the drop-down list.

Update the Course Edit Razor page

Update *Pages/Courses/Edit.cshtml* with the following code:

```
@page
@model ContosoUniversity.Pages.Courses.EditModel

@{
    ViewData["Title"] = "Edit";
}

<h2>Edit</h2>

<h4>Course</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Course.CourseID" />
            <div class="form-group">
                <label asp-for="Course.CourseID" class="control-label"></label>
                <div>@Html.DisplayFor(model => model.Course.CourseID)</div>
            </div>
            <div class="form-group">
                <label asp-for="Course.Title" class="control-label"></label>
                <input asp-for="Course.Title" class="form-control" />
                <span asp-validation-for="Course.Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Credits" class="control-label"></label>
                <input asp-for="Course.Credits" class="form-control" />
                <span asp-validation-for="Course.Credits" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Department" class="control-label"></label>
                <select asp-for="Course.DepartmentID" class="form-control"
                        asp-items="@Model.DepartmentNameSL"></select>
                <span asp-validation-for="Course.DepartmentID" class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code makes the following changes:

- Displays the course ID. Generally the Primary Key (PK) of an entity isn't displayed. PKs are usually meaningless to users. In this case, the PK is the course number.
- Changes the caption for the Department drop-down from **DepartmentID** to **Department**.
- Replaces `"ViewBag.DepartmentID"` with `DepartmentNameSL` (from the base class).

The page contains a hidden field (`<input type="hidden">`) for the course number. Adding a `<label>` tag helper with `asp-for="Course.CourseID"` doesn't eliminate the need for the hidden field. `<input type="hidden">` is required for the course number to be included in the posted data when the user clicks **Save**.

Update the Course Details and Delete pages

AsNoTracking can improve performance when tracking isn't required.

Update the Course page models

Update *Pages/Courses/Delete.cshtml.cs* with the following code to add `AsNoTracking`:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Course Course { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Course = await _context.Courses
                .AsNoTracking()
                .Include(c => c.Department)
                .FirstOrDefaultAsync(m => m.CourseID == id);

            if (Course == null)
            {
                return NotFound();
            }
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Course = await _context.Courses.FindAsync(id);

            if (Course != null)
            {
                _context.Courses.Remove(Course);
                await _context.SaveChangesAsync();
            }

            return RedirectToPage("./Index");
        }
    }
}
```

Make the same change in the *Pages/Courses/Details.cshtml.cs* file:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class DetailsModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DetailsModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public Course Course { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Course = await _context.Courses
                 .AsNoTracking()
                 .Include(c => c.Department)
                 .FirstOrDefaultAsync(m => m.CourseID == id);

            if (Course == null)
            {
                return NotFound();
            }
            return Page();
        }
    }
}
```

Update the Course Razor pages

Update *Pages/Courses/Delete.cshtml* with the following code:

```
@page
@model ContosoUniversity.Pages.Courses.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Course</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.CourseID)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.CourseID)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Credits)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Credits)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Department)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Department.Name)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Course.CourseID" />
        <input type="submit" value="Delete" class="btn btn-danger" /> |
        <a asp-page="./Index">Back to List</a>
    </form>
</div>
```

Make the same changes to the Details page.

```
@page
@model ContosoUniversity.Pages.Courses.DetailsModel

@{
    ViewData["Title"] = "Details";
}

<h2>Details</h2>

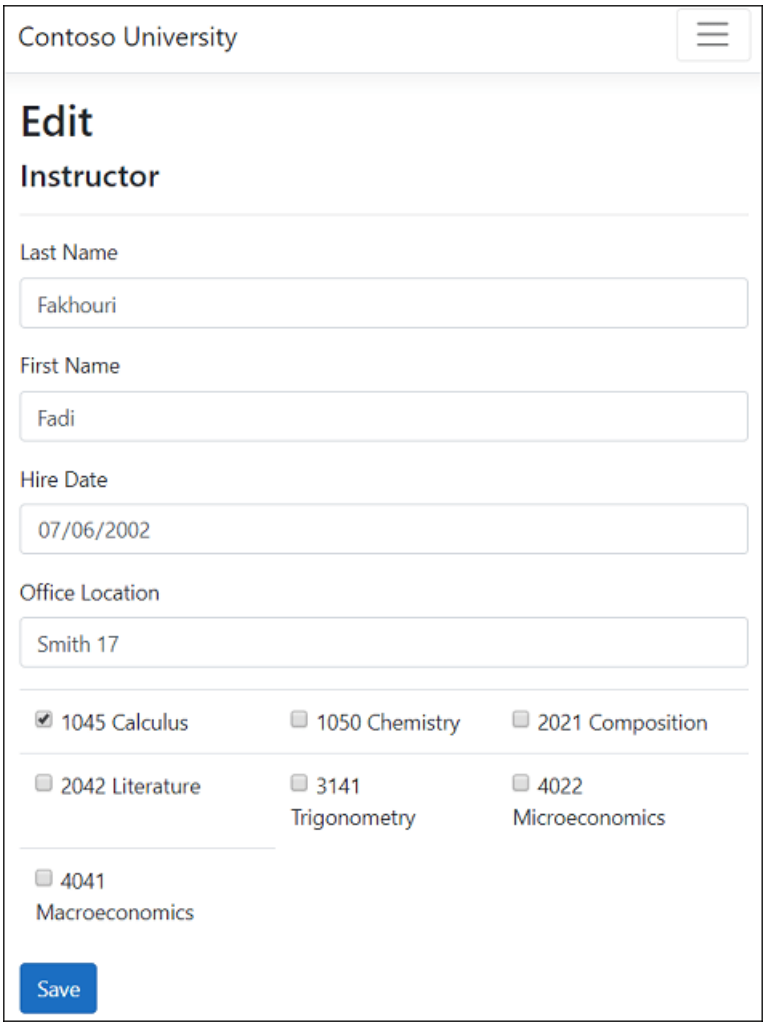
<div>
    <h4>Course</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.CourseID)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.CourseID)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Credits)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Credits)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Department)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Department.Name)
        </dd>
    </dl>
</div>
<div>
    <a asp-page="./Edit" asp-route-id="@Model.Course.CourseID">Edit</a> |
    <a asp-page="./Index">Back to List</a>
</div>
```

Test the Course pages

Test the create, edit, details, and delete pages.

Update the instructor Create and Edit pages

Instructors may teach any number of courses. The following image shows the instructor Edit page with an array of course checkboxes.



The checkboxes enable changes to courses an instructor is assigned to. A checkbox is displayed for every course in the database. Courses that the instructor is assigned to are selected. The user can select or clear checkboxes to change course assignments. If the number of courses were much greater, a different UI might work better. But the method of managing a many-to-many relationship shown here wouldn't change. To create or delete relationships, you manipulate a join entity.

Create a class for assigned courses data

Create *SchoolViewModels/AssignedCourseData.cs* with the following code:

```
namespace ContosoUniversity.Models.SchoolViewModels
{
    public class AssignedCourseData
    {
        public int CourseID { get; set; }
        public string Title { get; set; }
        public bool Assigned { get; set; }
    }
}
```

The `AssignedCourseData` class contains data to create the check boxes for courses assigned to an instructor.

Create an Instructor page model base class

Create the *Pages/Instructors/InstructorCoursesPageModel.cs* base class:

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using ContosoUniversity.Models.SchoolViewModels;
using Microsoft.AspNetCore.Mvc.RazorPages;
using System.Collections.Generic;
```

```
using System.Linq;

namespace ContosoUniversity.Pages.Instructors
{
    public class InstructorCoursesPageModel : PageModel
    {

        public List<AssignedCourseData> AssignedCourseDataList;

        public void PopulateAssignedCourseData(SchoolContext context,
                                               Instructor instructor)
        {
            var allCourses = context.Courses;
            var instructorCourses = new HashSet<int>(
                instructor.CourseAssignments.Select(c => c.CourseID));
            AssignedCourseDataList = new List<AssignedCourseData>();
            foreach (var course in allCourses)
            {
                AssignedCourseDataList.Add(new AssignedCourseData
                {
                    CourseID = course.CourseID,
                    Title = course.Title,
                    Assigned = instructorCourses.Contains(course.CourseID)
                });
            }
        }

        public void UpdateInstructorCourses(SchoolContext context,
            string[] selectedCourses, Instructor instructorToUpdate)
        {
            if (selectedCourses == null)
            {
                instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
                return;
            }

            var selectedCoursesHS = new HashSet<string>(selectedCourses);
            var instructorCourses = new HashSet<int>
                (instructorToUpdate.CourseAssignments.Select(c => c.Course.CourseID));
            foreach (var course in context.Courses)
            {
                if (selectedCoursesHS.Contains(course.CourseID.ToString()))
                {
                    if (!instructorCourses.Contains(course.CourseID))
                    {
                        instructorToUpdate.CourseAssignments.Add(
                            new CourseAssignment
                            {
                                InstructorID = instructorToUpdate.ID,
                                CourseID = course.CourseID
                            });
                    }
                }
                else
                {
                    if (instructorCourses.Contains(course.CourseID))
                    {
                        CourseAssignment courseToRemove
                            = instructorToUpdate
                                .CourseAssignments
                                .SingleOrDefault(i => i.CourseID == course.CourseID);
                        context.Remove(courseToRemove);
                    }
                }
            }
        }
    }
}
```

The `InstructorCoursesPageModel` is the base class you will use for the Edit and Create page models. `PopulateAssignedCourseData` reads all `Course` entities to populate `AssignedCourseDataList`. For each course, the code sets the `CourseID`, title, and whether or not the instructor is assigned to the course. A HashSet is used for efficient lookups.

Since the Razor page doesn't have a collection of Course entities, the model binder can't automatically update the `CourseAssignments` navigation property. Instead of using the model binder to update the `CourseAssignments` navigation property, you do that in the new `UpdateInstructorCourses` method. Therefore you need to exclude the `CourseAssignments` property from model binding. This doesn't require any change to the code that calls `TryUpdateModel` because you're using the overload with declared properties and `CourseAssignments` isn't in the include list.

If no check boxes were selected, the code in `UpdateInstructorCourses` initializes the `CourseAssignments` navigation property with an empty collection and returns:

```
if (selectedCourses == null)
{
    instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
    return;
}
```

The code then loops through all courses in the database and checks each course against the ones currently assigned to the instructor versus the ones that were selected in the page. To facilitate efficient lookups, the latter two collections are stored in `HashSet` objects.

If the check box for a course was selected but the course isn't in the `Instructor.CourseAssignments` navigation property, the course is added to the collection in the navigation property.

```
if (selectedCoursesHS.Contains(course.CourseID.ToString()))
{
    if (!instructorCourses.Contains(course.CourseID))
    {
        instructorToUpdate.CourseAssignments.Add(
            new CourseAssignment
            {
                InstructorID = instructorToUpdate.ID,
                CourseID = course.CourseID
            });
    }
}
```

If the check box for a course wasn't selected, but the course is in the `Instructor.CourseAssignments` navigation property, the course is removed from the navigation property.

```
else
{
    if (instructorCourses.Contains(course.CourseID))
    {
        CourseAssignment courseToRemove
            = instructorToUpdate
                .CourseAssignments
                .SingleOrDefault(i => i.CourseID == course.CourseID);
        context.Remove(courseToRemove);
    }
}
```

Handle office location

Another relationship the edit page has to handle is the one-to-zero-or-one relationship that the Instructor entity has with the `OfficeAssignment` entity. The instructor edit code must handle the following scenarios:

- If the user clears the office assignment, delete the `OfficeAssignment` entity.
- If the user enters an office assignment and it was empty, create a new `OfficeAssignment` entity.
- If the user changes the office assignment, update the `OfficeAssignment` entity.

Update the Instructor Edit page model

Update *Pages/Instructors/Edit.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using System;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class EditModel : InstructorCoursesPageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Instructor = await _context.Instructors
                .Include(i => i.OfficeAssignment)
                .Include(i => i.CourseAssignments).ThenInclude(i => i.Course)
                .AsNoTracking()
                .FirstOrDefaultAsync(m => m.ID == id);

            if (Instructor == null)
            {
                return NotFound();
            }
            PopulateAssignedCourseData(_context, Instructor);
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id, string[] selectedCourses)
        {
            if (id == null)
            {
                return NotFound();
            }

            var instructorToUpdate = await _context.Instructors
                .Include(i => i.OfficeAssignment)
                .Include(i => i.CourseAssignments)
                    .ThenInclude(i => i.Course)
                .FirstOrDefaultAsync(s => s.ID == id);

            if (instructorToUpdate == null)
            {
```

```
            {
                return NotFound();
            }

            if (await TryUpdateModelAsync<Instructor>(
                instructorToUpdate,
                "Instructor",
                i => i.FirstMidName, i => i.LastName,
                i => i.HireDate, i => i.OfficeAssignment))
            {
                if (String.IsNullOrWhiteSpace(
                    instructorToUpdate.OfficeAssignment?.Location))
                {
                    instructorToUpdate.OfficeAssignment = null;
                }
                UpdateInstructorCourses(_context, selectedCourses, instructorToUpdate);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }
            UpdateInstructorCourses(_context, selectedCourses, instructorToUpdate);
            PopulateAssignedCourseData(_context, instructorToUpdate);
            return Page();
        }
    }
}
```

The preceding code:

- Gets the current `Instructor` entity from the database using eager loading for the `OfficeAssignment`, `CourseAssignment`, and `CourseAssignment.Course` navigation properties.
- Updates the retrieved `Instructor` entity with values from the model binder. `TryUpdateModel` prevents overposting.
- If the office location is blank, sets `Instructor.OfficeAssignment` to null. When `Instructor.OfficeAssignment` is null, the related row in the `OfficeAssignment` table is deleted.
- Calls `PopulateAssignedCourseData` in `OnGetAsync` to provide information for the checkboxes using the `AssignedCourseData` view model class.
- Calls `UpdateInstructorCourses` in `OnPostAsync` to apply information from the checkboxes to the Instructor entity being edited.
- Calls `PopulateAssignedCourseData` and `UpdateInstructorCourses` in `OnPostAsync` if `TryUpdateModel` fails. These method calls restore the assigned course data entered on the page when it is redisplayed with an error message.

Update the Instructor Edit Razor page

Update *Pages/Instructors/Edit.cshtml* with the following code:

```
@page
@model ContosoUniversity.Pages.Instructors.EditModel
@{
    ViewData["Title"] = "Edit";
}
<h2>Edit</h2>
<h4>Instructor</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Instructor.ID" />
            <div class="form-group">
                <label asp-for="Instructor.LastName" class="control-label"></label>
                <input asp-for="Instructor.LastName" class="form-control" />
                <span asp-validation-for="Instructor.LastName" class="text-danger"></span>
```

```
            </div>
            <div class="form-group">
                <label asp-for="Instructor.FirstMidName" class="control-label"></label>
                <input asp-for="Instructor.FirstMidName" class="form-control" />
                <span asp-validation-for="Instructor.FirstMidName" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.HireDate" class="control-label"></label>
                <input asp-for="Instructor.HireDate" class="form-control" />
                <span asp-validation-for="Instructor.HireDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.OfficeAssignment.Location" class="control-label"></label>
                <input asp-for="Instructor.OfficeAssignment.Location" class="form-control" />
                <span asp-validation-for="Instructor.OfficeAssignment.Location" class="text-danger" />
            </div>
            <div class="form-group">
                <div class="table">
                    <table>
                        <tr>
                            @{
                                int cnt = 0;

                                foreach (var course in Model.AssignedCourseDataList)
                                {
                                    if (cnt++ % 3 == 0)
                                    {
                                        @:</tr><tr>
                                    }
                                    @:<td>
                                        <input type="checkbox"
                                               name="selectedCourses"
                                               value="@course.CourseID"
                                               @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                                               @course.CourseID @:  @course.Title
                                    @:</td>
                                }
                                @:</tr>
                            }
                    </table>
                </div>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code creates an HTML table that has three columns. Each column has a checkbox and a caption containing the course number and title. The checkboxes all have the same name ("selectedCourses"). Using the same name informs the model binder to treat them as a group. The value attribute of each checkbox is set to `CourseID`. When the page is posted, the model binder passes an array that consists of the `CourseID` values for only the checkboxes that are selected.

When the checkboxes are initially rendered, courses assigned to the instructor are selected.

Note: The approach taken here to edit instructor course data works well when there's a limited number of

courses. For collections that are much larger, a different UI and a different updating method would be more useable and efficient.

Run the app and test the updated Instructors Edit page. Change some course assignments. The changes are reflected on the Index page.

Update the Instructor Create page

Update the Instructor Create page model and Razor page with code similar to the Edit page:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using System.Collections.Generic;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class CreateModel : InstructorCoursesPageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public CreateModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            var instructor = new Instructor();
            instructor.CourseAssignments = new List<CourseAssignment>();

            // Provides an empty collection for the foreach loop
            // foreach (var course in Model.AssignedCourseDataList)
            // in the Create Razor page.
            PopulateAssignedCourseData(_context, instructor);
            return Page();
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnPostAsync(string[] selectedCourses)
        {
            var newInstructor = new Instructor();
            if (selectedCourses != null)
            {
                newInstructor.CourseAssignments = new List<CourseAssignment>();
                foreach (var course in selectedCourses)
                {
                    var courseToAdd = new CourseAssignment
                    {
                        CourseID = int.Parse(course)
                    };
                    newInstructor.CourseAssignments.Add(courseToAdd);
                }
            }

            if (await TryUpdateModelAsync<Instructor>(
                newInstructor,
                "Instructor",
                i => i.FirstMidName, i => i.LastName,
                i => i.HireDate, i => i.OfficeAssignment))
            {
                _context.Instructors.Add(newInstructor);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }
            PopulateAssignedCourseData(_context, newInstructor);
            return Page();
        }
    }
}
```

```
@page
@model ContosoUniversity.Pages.Instructors.CreateModel
```

```
@{
    ViewData["Title"] = "Create";
}

<h2>Create</h2>

<h4>Instructor</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Instructor.LastName" class="control-label"></label>
                <input asp-for="Instructor.LastName" class="form-control" />
                <span asp-validation-for="Instructor.LastName" class="text-danger"></span>
            </div>

            <div class="form-group">
                <div class="table">
                    <table>
                        <tr>
                            @{
                                int cnt = 0;

                                foreach (var course in Model.AssignedCourseDataList)
                                {
                                    if (cnt++ % 3 == 0)
                                    {
                                        @:</tr><tr>
                                    }
                                    @:<td>
                                        <input type="checkbox"
                                               name="selectedCourses"
                                               value="@course.CourseID"
                                               @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                                               @course.CourseID @:  @course.Title
                                    @:</td>
                                }
                                @:</tr>
                            }
                    </table>
                </div>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="Index">Back to List</a>
</div>
```

```
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Test the instructor Create page.

Update the Instructor Delete page

Update *Pages/Instructors/Delete.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Instructor = await _context.Instructors.FirstOrDefaultAsync(m => m.ID == id);

            if (Instructor == null)
            {
                return NotFound();
            }
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Instructor instructor = await _context.Instructors
                .Include(i => i.CourseAssignments)
                .SingleAsync(i => i.ID == id);

            if (instructor == null)
            {
                return RedirectToPage("./Index");
            }

            var departments = await _context.Departments
                .Where(d => d.InstructorID == id)
                .ToListAsync();
            departments.ForEach(d => d.InstructorID = null);

            _context.Instructors.Remove(instructor);

            await _context.SaveChangesAsync();
            return RedirectToPage("./Index");
        }
    }
}
```

The preceding code makes the following changes:

- Uses eager loading for the `CourseAssignments` navigation property. `CourseAssignments` must be included or they aren't deleted when the instructor is deleted. To avoid needing to read them, configure cascade delete in the database.
- If the instructor to be deleted is assigned as administrator of any departments, removes the instructor assignment from those departments.

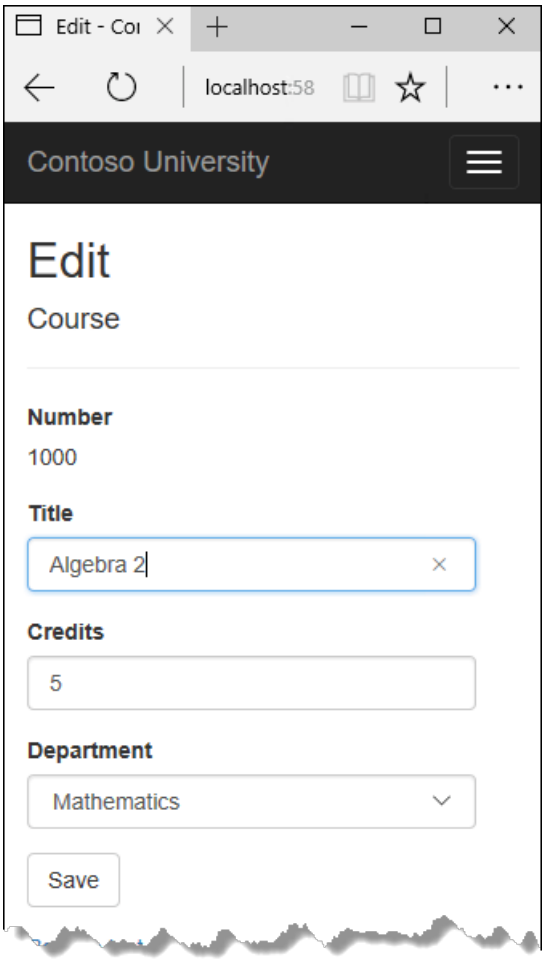
Run the app and test the Delete page.

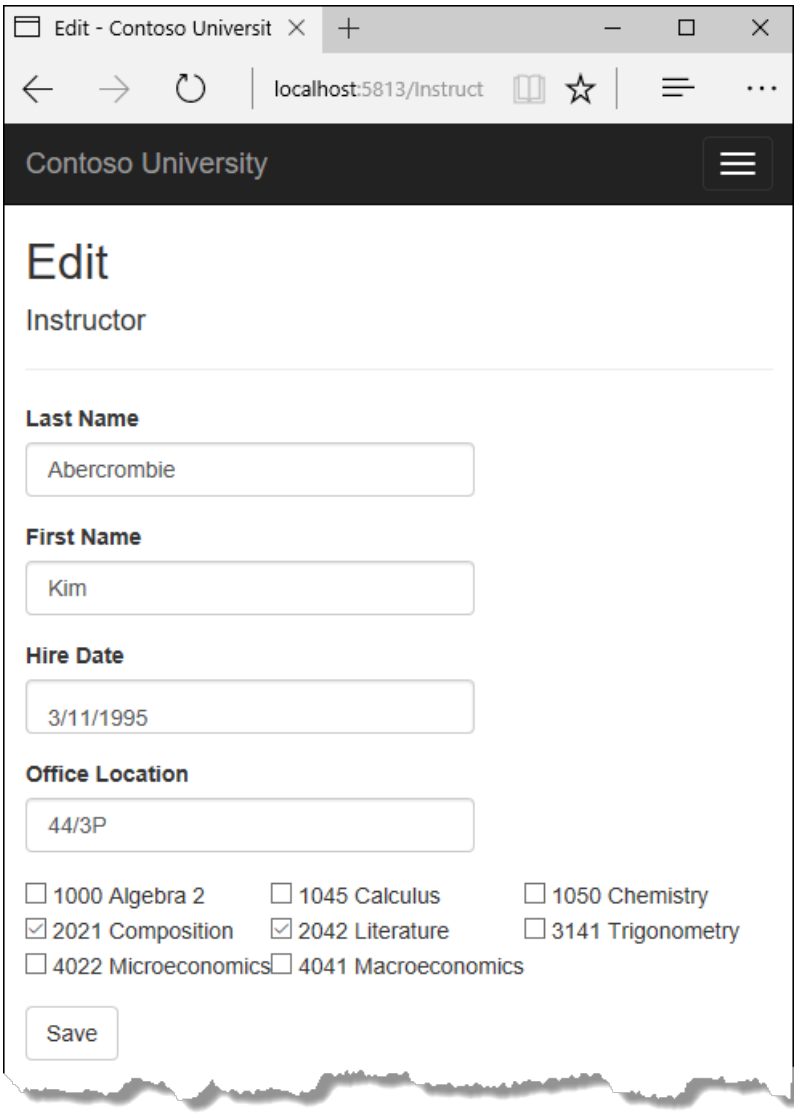
Next steps

PREVIOUS TUTORIAL NEXT TUTORIAL

This tutorial demonstrates updating related data. If you run into problems you can't solve, download or view the completed app. Download instructions.

The following illustrations shows some of the completed pages.





Examine and test the Create and Edit course pages. Create a new course. The department is selected by its primary key (an integer), not its name. Edit the new course. When you have finished testing, delete the new course.

Create a base class to share common code

The Courses/Create and Courses/Edit pages each need a list of department names. Create the *Pages/Courses/DepartmentNamePageModel.cshtml.cs* base class for the Create and Edit pages:

```
using ContosoUniversity.Data;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;
using Microsoft.EntityFrameworkCore;
using System.Linq;

namespace ContosoUniversity.Pages.Courses
{
    public class DepartmentNamePageModel : PageModel
    {
        public SelectList DepartmentNameSL { get; set; }

        public void PopulateDepartmentsDropDownList(SchoolContext _context,
            object selectedDepartment = null)
        {
            var departmentsQuery = from d in _context.Departments
                                   orderby d.Name // Sort by name.
                                   select d;

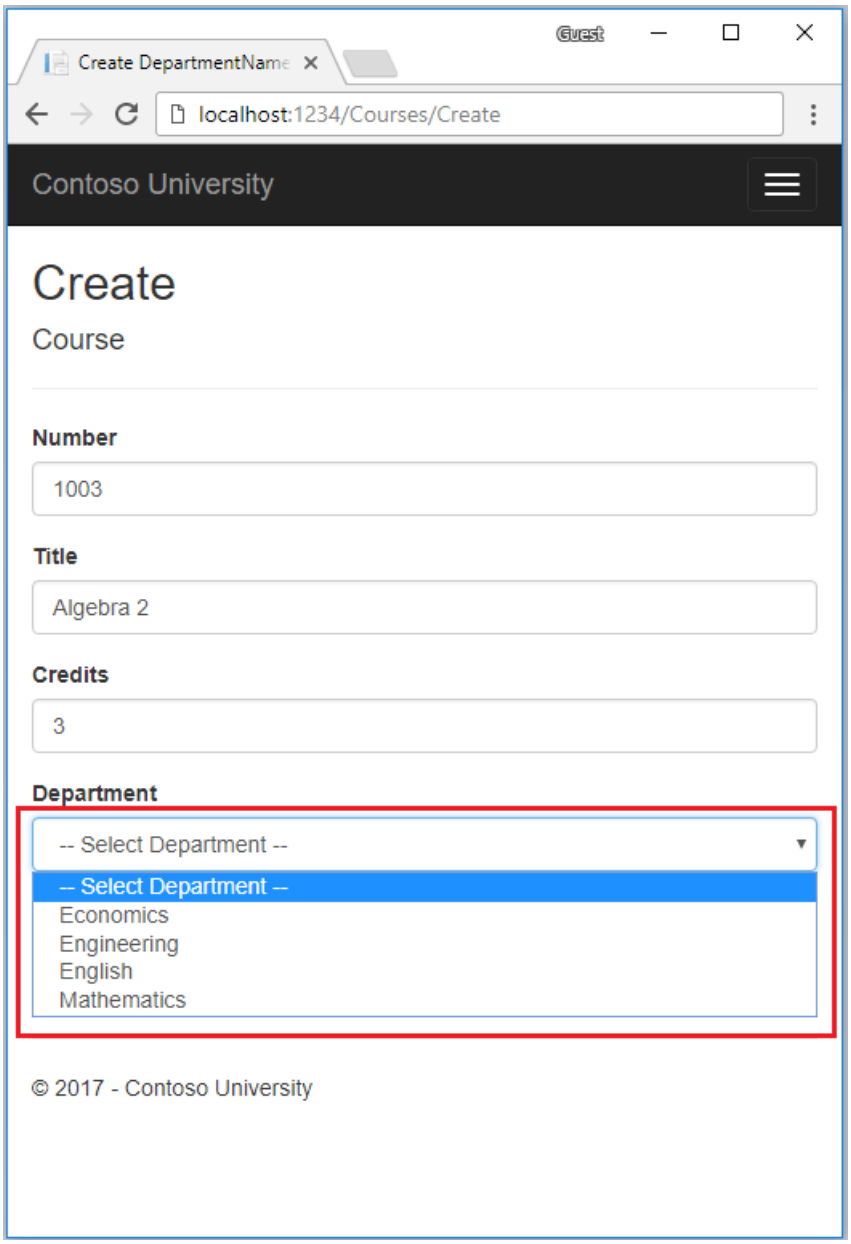
            DepartmentNameSL = new SelectList(departmentsQuery.AsNoTracking(),
                        "DepartmentID", "Name", selectedDepartment);
        }
    }
}
```

The preceding code creates a SelectList to contain the list of department names. If `selectedDepartment` is specified, that department is selected in the `SelectList`.

The Create and Edit page model classes will derive from `DepartmentNamePageModel`.

Customize the Courses Pages

When a new course entity is created, it must have a relationship to an existing department. To add a department while creating a course, the base class for Create and Edit contains a drop-down list for selecting the department. The drop-down list sets the `Course.DepartmentID` foreign key (FK) property. EF Core uses the `Course.DepartmentID` FK to load the `Department` navigation property.



Update the Create page model with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class CreateModel : DepartmentNamePageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public CreateModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            PopulateDepartmentsDropDownList(_context);
            return Page();
        }

        [BindProperty]
        public Course Course { get; set; }

        public async Task<IActionResult> OnPostAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            var emptyCourse = new Course();

            if (await TryUpdateModelAsync<Course>(
                 emptyCourse,
                 "course",   // Prefix for form value.
                 s => s.CourseID, s => s.DepartmentID, s => s.Title, s => s.Credits))
            {
                _context.Courses.Add(emptyCourse);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }

            // Select DepartmentID if TryUpdateModelAsync fails.
            PopulateDepartmentsDropDownList(_context, emptyCourse.DepartmentID);
            return Page();
        }
      }
}
```

The preceding code:

- Derives from `DepartmentNamePageModel`.
- Uses `TryUpdateModelAsync` to prevent overposting.
- Replaces `ViewData["DepartmentID"]` with `DepartmentNameSL` (from the base class).

`ViewData["DepartmentID"]` is replaced with the strongly typed `DepartmentNameSL`. Strongly typed models are preferred over weakly typed. For more information, see Weakly typed data (ViewData and ViewBag).

Update the Courses Create page

Update *Pages/Courses/Create.cshtml* with the following code:

```
@page
@model ContosoUniversity.Pages.Courses.CreateModel
@{
    ViewData["Title"] = "Create Course";
}
<h2>Create</h2>
<h4>Course</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Course.CourseID" class="control-label"></label>
                <input asp-for="Course.CourseID" class="form-control" />
                <span asp-validation-for="Course.CourseID" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Title" class="control-label"></label>
                <input asp-for="Course.Title" class="form-control" />
                <span asp-validation-for="Course.Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Credits" class="control-label"></label>
                <input asp-for="Course.Credits" class="form-control" />
                <span asp-validation-for="Course.Credits" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Department" class="control-label"></label>
                <select asp-for="Course.DepartmentID" class="form-control"
                        asp-items="@Model.DepartmentNameSL">
                    <option value="">-- Select Department --</option>
                </select>
                <span asp-validation-for="Course.DepartmentID" class="text-danger" />
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>
<div>
    <a asp-page="Index">Back to List</a>
</div>
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding markup makes the following changes:

- Changes the caption from **DepartmentID** to **Department**.
- Replaces `"ViewBag.DepartmentID"` with `DepartmentNameSL` (from the base class).
- Adds the "Select Department" option. This change renders "Select Department" rather than the first department.
- Adds a validation message when the department isn't selected.

The Razor Page uses the Select Tag Helper:

```
<div class="form-group">
    <label asp-for="Course.Department" class="control-label"></label>
    <select asp-for="Course.DepartmentID" class="form-control"
            asp-items="@Model.DepartmentNameSL">
        <option value="">-- Select Department --</option>
    </select>
    <span asp-validation-for="Course.DepartmentID" class="text-danger" />
</div>
```

Test the Create page. The Create page displays the department name rather than the department ID.

Update the Courses Edit page.

Replace the code in *Pages/Courses/Edit.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class EditModel : DepartmentNamePageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Course Course { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Course = await _context.Courses
                .Include(c => c.Department).FirstOrDefaultAsync(m => m.CourseID == id);

            if (Course == null)
            {
                return NotFound();
            }

            // Select current DepartmentID.
            PopulateDepartmentsDropDownList(_context,Course.DepartmentID);
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            var courseToUpdate = await _context.Courses.FindAsync(id);

            if (await TryUpdateModelAsync<Course>(
                 courseToUpdate,
                 "course",   // Prefix for form value.
                   c => c.Credits, c => c.DepartmentID, c => c.Title))
            {
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }

            // Select DepartmentID if TryUpdateModelAsync fails.
            PopulateDepartmentsDropDownList(_context, courseToUpdate.DepartmentID);
            return Page();
        }
    }
}
```

The changes are similar to those made in the Create page model. In the preceding code, `PopulateDepartmentsDropDownList` passes in the department ID, which select the department specified in the drop-

down list.

Update *Pages/Courses/Edit.cshtml* with the following markup:

```
@page
@model ContosoUniversity.Pages.Courses.EditModel

@{
    ViewData["Title"] = "Edit";
}

<h2>Edit</h2>

<h4>Course</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Course.CourseID" />
            <div class="form-group">
                <label asp-for="Course.CourseID" class="control-label"></label>
                <div>@Html.DisplayFor(model => model.Course.CourseID)</div>
            </div>
            <div class="form-group">
                <label asp-for="Course.Title" class="control-label"></label>
                <input asp-for="Course.Title" class="form-control" />
                <span asp-validation-for="Course.Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Credits" class="control-label"></label>
                <input asp-for="Course.Credits" class="form-control" />
                <span asp-validation-for="Course.Credits" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Department" class="control-label"></label>
                <select asp-for="Course.DepartmentID" class="form-control"
                        asp-items="@Model.DepartmentNameSL"></select>
                <span asp-validation-for="Course.DepartmentID" class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding markup makes the following changes:

- Displays the course ID. Generally the Primary Key (PK) of an entity isn't displayed. PKs are usually meaningless to users. In this case, the PK is the course number.
- Changes the caption from **DepartmentID** to **Department**.
- Replaces `"ViewBag.DepartmentID"` with `DepartmentNameSL` (from the base class).

The page contains a hidden field (`<input type="hidden">`) for the course number. Adding a `<label>` tag helper with `asp-for="Course.CourseID"` doesn't eliminate the need for the hidden field. `<input type="hidden">` is

required for the course number to be included in the posted data when the user clicks **Save**.

Test the updated code. Create, edit, and delete a course.

Add AsNoTracking to the Details and Delete page models

AsNoTracking can improve performance when tracking isn't required. Add `AsNoTracking` to the Delete and Details page model. The following code shows the updated Delete page model:

```
public class DeleteModel : PageModel
{
    private readonly ContosoUniversity.Data.SchoolContext _context;

    public DeleteModel(ContosoUniversity.Data.SchoolContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Course Course { get; set; }

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Course = await _context.Courses
            .AsNoTracking()
            .Include(c => c.Department)
            .FirstOrDefaultAsync(m => m.CourseID == id);

        if (Course == null)
        {
            return NotFound();
        }
        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Course = await _context.Courses
            .AsNoTracking()
            .FirstOrDefaultAsync(m => m.CourseID == id);

        if (Course != null)
        {
            _context.Courses.Remove(Course);
            await _context.SaveChangesAsync();
        }

        return RedirectToPage("./Index");
    }
}
```

Update the `OnGetAsync` method in the *Pages/Courses/Details.cshtml.cs* file:

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    Course = await _context.Courses
         .AsNoTracking()
         .Include(c => c.Department)
         .FirstOrDefaultAsync(m => m.CourseID == id);

    if (Course == null)
    {
        return NotFound();
    }
    return Page();
}
```

Modify the Delete and Details pages

Update the Delete Razor page with the following markup:

```
@page
@model ContosoUniversity.Pages.Courses.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Course</h4>
    <hr />
    <dl class="dl-horizontal">
        <dt>
            @Html.DisplayNameFor(model => model.Course.CourseID)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Course.CourseID)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Course.Title)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Course.Title)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Course.Credits)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Course.Credits)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Course.Department)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Course.Department.DepartmentID)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Course.CourseID" />
        <input type="submit" value="Delete" class="btn btn-default" /> |
        <a asp-page="./Index">Back to List</a>
    </form>
</div>
```

Make the same changes to the Details page.

Test the Course pages

Test create, edit, details, and delete.

Update the instructor pages

The following sections update the instructor pages.

Add office location

When editing an instructor record, you may want to update the instructor's office assignment. The `Instructor` entity has a one-to-zero-or-one relationship with the `OfficeAssignment` entity. The instructor code must handle:

- If the user clears the office assignment, delete the `OfficeAssignment` entity.
- If the user enters an office assignment and it was empty, create a new `OfficeAssignment` entity.

- If the user changes the office assignment, update the `OfficeAssignment` entity.

Update the instructors Edit page model with the following code:

```
public class EditModel : PageModel
{
    private readonly ContosoUniversity.Data.SchoolContext _context;

    public EditModel(ContosoUniversity.Data.SchoolContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Instructor Instructor { get; set; }

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Instructor = await _context.Instructors
            .Include(i => i.OfficeAssignment)
            .AsNoTracking()
            .FirstOrDefaultAsync(m => m.ID == id);

        if (Instructor == null)
        {
            return NotFound();
        }
        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int? id)
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        var instructorToUpdate = await _context.Instructors
            .Include(i => i.OfficeAssignment)
            .FirstOrDefaultAsync(s => s.ID == id);

        if (await TryUpdateModelAsync<Instructor>(
            instructorToUpdate,
            "Instructor",
            i => i.FirstMidName, i => i.LastName,
            i => i.HireDate, i => i.OfficeAssignment))
        {
            if (String.IsNullOrWhiteSpace(
                instructorToUpdate.OfficeAssignment?.Location))
            {
                instructorToUpdate.OfficeAssignment = null;
            }
            await _context.SaveChangesAsync();
        }
        return RedirectToPage("./Index");

    }
}
```

The preceding code:

- Gets the current `Instructor` entity from the database using eager loading for the `OfficeAssignment` navigation property.
- Updates the retrieved `Instructor` entity with values from the model binder. `TryUpdateModel` prevents overposting.
- If the office location is blank, sets `Instructor.OfficeAssignment` to null. When `Instructor.OfficeAssignment` is null, the related row in the `OfficeAssignment` table is deleted.

Update the instructor Edit page

Update *Pages/Instructors/Edit.cshtml* with the office location:

```
@page
@model ContosoUniversity.Pages.Instructors.EditModel
@{
    ViewData["Title"] = "Edit";
}
<h2>Edit</h2>
<h4>Instructor</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Instructor.ID" />
            <div class="form-group">
                <label asp-for="Instructor.LastName" class="control-label"></label>
                <input asp-for="Instructor.LastName" class="form-control" />
                <span asp-validation-for="Instructor.LastName" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.FirstMidName" class="control-label"></label>
                <input asp-for="Instructor.FirstMidName" class="form-control" />
                <span asp-validation-for="Instructor.FirstMidName" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.HireDate" class="control-label"></label>
                <input asp-for="Instructor.HireDate" class="form-control" />
                <span asp-validation-for="Instructor.HireDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.OfficeAssignment.Location" class="control-label"></label>
                <input asp-for="Instructor.OfficeAssignment.Location" class="form-control" />
                <span asp-validation-for="Instructor.OfficeAssignment.Location" class="text-danger" />
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

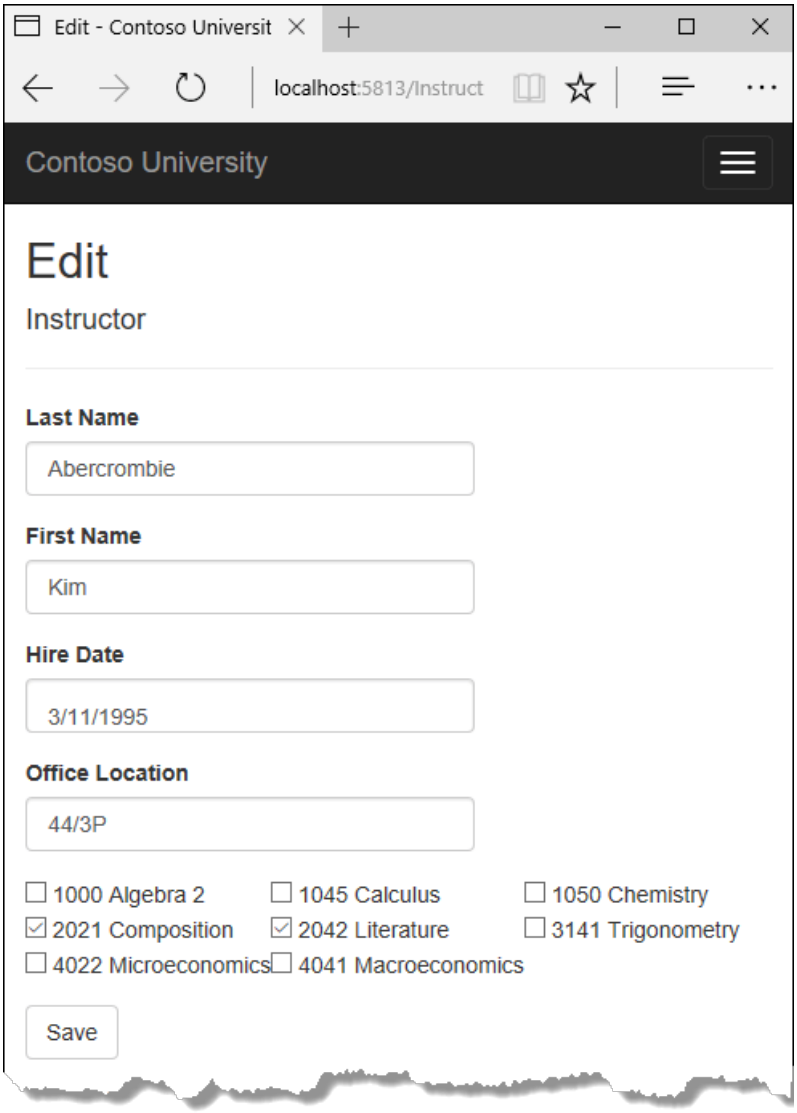
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Verify you can change an instructors office location.

Add Course assignments to the instructor Edit page

Instructors may teach any number of courses. In this section, you add the ability to change course assignments.

The following image shows the updated instructor Edit page:



`Course` and `Instructor` has a many-to-many relationship. To add and remove relationships, you add and remove entities from the `CourseAssignments` join entity set.

Check boxes enable changes to courses an instructor is assigned to. A check box is displayed for every course in the database. Courses that the instructor is assigned to are checked. The user can select or clear check boxes to change course assignments. If the number of courses were much greater:

- You'd probably use a different user interface to display the courses.
- The method of manipulating a join entity to create or delete relationships wouldn't change.

Add classes to support Create and Edit instructor pages

Create *SchoolViewModels/AssignedCourseData.cs* with the following code:

```
namespace ContosoUniversity.Models.SchoolViewModels
{
    public class AssignedCourseData
    {
        public int CourseID { get; set; }
        public string Title { get; set; }
        public bool Assigned { get; set; }
    }
}
```

The `AssignedCourseData` class contains data to create the check boxes for assigned courses by an instructor.

Create the *Pages/Instructors/InstructorCoursesPageModel.cshtml.cs* base class:

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using ContosoUniversity.Models.SchoolViewModels;
using Microsoft.AspNetCore.Mvc.RazorPages;
using System.Collections.Generic;
using System.Linq;

namespace ContosoUniversity.Pages.Instructors
{
    public class InstructorCoursesPageModel : PageModel
    {

        public List<AssignedCourseData> AssignedCourseDataList;

        public void PopulateAssignedCourseData(SchoolContext context,
                                               Instructor instructor)
        {
            var allCourses = context.Courses;
            var instructorCourses = new HashSet<int>(
                instructor.CourseAssignments.Select(c => c.CourseID));
            AssignedCourseDataList = new List<AssignedCourseData>();
            foreach (var course in allCourses)
            {
                AssignedCourseDataList.Add(new AssignedCourseData
                {
                    CourseID = course.CourseID,
                    Title = course.Title,
                    Assigned = instructorCourses.Contains(course.CourseID)
                });
            }
        }

        public void UpdateInstructorCourses(SchoolContext context,
            string[] selectedCourses, Instructor instructorToUpdate)
        {
            if (selectedCourses == null)
            {
                instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
                return;
            }

            var selectedCoursesHS = new HashSet<string>(selectedCourses);
            var instructorCourses = new HashSet<int>
                (instructorToUpdate.CourseAssignments.Select(c => c.Course.CourseID));
            foreach (var course in context.Courses)
            {
                if (selectedCoursesHS.Contains(course.CourseID.ToString()))
                {
                    if (!instructorCourses.Contains(course.CourseID))
                    {
                        instructorToUpdate.CourseAssignments.Add(
                            new CourseAssignment
                            {
                                InstructorID = instructorToUpdate.ID,
                                CourseID = course.CourseID
                            });
                    }
                }
                else
                {
                    if (instructorCourses.Contains(course.CourseID))
                    {
                        CourseAssignment courseToRemove
                            = instructorToUpdate
                                .CourseAssignments
                                .SingleOrDefault(i => i.CourseID == course.CourseID);
```

```
                        context.Remove(courseToRemove);
                    }
                }
            }
        }
    }
}
```

The `InstructorCoursesPageModel` is the base class you will use for the Edit and Create page models. `PopulateAssignedCourseData` reads all `Course` entities to populate `AssignedCourseDataList`. For each course, the code sets the `CourseID`, title, and whether or not the instructor is assigned to the course. A HashSet is used to create efficient lookups.

Instructors Edit page model

Update the instructor Edit page model with the following code:

```
public class EditModel : InstructorCoursesPageModel
{
    private readonly ContosoUniversity.Data.SchoolContext _context;

    public EditModel(ContosoUniversity.Data.SchoolContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Instructor Instructor { get; set; }

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Instructor = await _context.Instructors
            .Include(i => i.OfficeAssignment)
            .Include(i => i.CourseAssignments).ThenInclude(i => i.Course)
            .AsNoTracking()
            .FirstOrDefaultAsync(m => m.ID == id);

        if (Instructor == null)
        {
            return NotFound();
        }
        PopulateAssignedCourseData(_context, Instructor);
        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int? id, string[] selectedCourses)
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        var instructorToUpdate = await _context.Instructors
            .Include(i => i.OfficeAssignment)
            .Include(i => i.CourseAssignments)
                .ThenInclude(i => i.Course)
            .FirstOrDefaultAsync(s => s.ID == id);

        if (await TryUpdateModelAsync<Instructor>(
            instructorToUpdate,
            "Instructor",
            i => i.FirstMidName, i => i.LastName,
            i => i.HireDate, i => i.OfficeAssignment))
        {
            if (String.IsNullOrWhiteSpace(
                instructorToUpdate.OfficeAssignment?.Location))
            {
                instructorToUpdate.OfficeAssignment = null;
            }
            UpdateInstructorCourses(_context, selectedCourses, instructorToUpdate);
            await _context.SaveChangesAsync();
            return RedirectToPage("./Index");
        }
        UpdateInstructorCourses(_context, selectedCourses, instructorToUpdate);
        PopulateAssignedCourseData(_context, instructorToUpdate);
        return Page();
    }
}
```

The preceding code handles office assignment changes.

Update the instructor Razor View:

```
@page
@model ContosoUniversity.Pages.Instructors.EditModel
@{
    ViewData["Title"] = "Edit";
}
<h2>Edit</h2>
<h4>Instructor</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Instructor.ID" />
            <div class="form-group">
                <label asp-for="Instructor.LastName" class="control-label"></label>
                <input asp-for="Instructor.LastName" class="form-control" />
                <span asp-validation-for="Instructor.LastName" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.FirstMidName" class="control-label"></label>
                <input asp-for="Instructor.FirstMidName" class="form-control" />
                <span asp-validation-for="Instructor.FirstMidName" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.HireDate" class="control-label"></label>
                <input asp-for="Instructor.HireDate" class="form-control" />
                <span asp-validation-for="Instructor.HireDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.OfficeAssignment.Location" class="control-label"></label>
                <input asp-for="Instructor.OfficeAssignment.Location" class="form-control" />
                <span asp-validation-for="Instructor.OfficeAssignment.Location" class="text-danger" />
            </div>
            <div class="form-group">
                <div class="col-md-offset-2 col-md-10">
                    <table>
                        <tr>
                            @{
                                int cnt = 0;

                                foreach (var course in Model.AssignedCourseDataList)
                                {
                                    if (cnt++ % 3 == 0)
                                    {
                                        @:</tr><tr>
                                    }
                                    @:<td>
                                        <input type="checkbox"
                                               name="selectedCourses"
                                               value="@course.CourseID"
                                               @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                                               @course.CourseID @:  @course.Title
                                    @:</td>
                                }
                                @:</tr>
                            }
                    </table>
                </div>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </form>
    </div>
```

```
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

> **NOTE**
>
> When you paste the code in Visual Studio, line breaks are changed in a way that breaks the code. Press Ctrl+Z one time to undo the automatic formatting. Ctrl+Z fixes the line breaks so that they look like what you see here. The indentation doesn't have to be perfect, but the `@:</tr><tr>`, `@:<td>`, `@:</td>`, and `@:</tr>` lines must each be on a single line as shown. With the block of new code selected, press Tab three times to line up the new code with the existing code. Vote on or review the status of this bug with this link.

The preceding code creates an HTML table that has three columns. Each column has a check box and a caption containing the course number and title. The check boxes all have the same name ("selectedCourses"). Using the same name informs the model binder to treat them as a group. The value attribute of each check box is set to `CourseID`. When the page is posted, the model binder passes an array that consists of the `CourseID` values for only the check boxes that are selected.

When the check boxes are initially rendered, courses assigned to the instructor have checked attributes.

Run the app and test the updated instructors Edit page. Change some course assignments. The changes are reflected on the Index page.

Note: The approach taken here to edit instructor course data works well when there's a limited number of courses. For collections that are much larger, a different UI and a different updating method would be more useable and efficient.

Update the instructors Create page

Update the instructor Create page model with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using System.Collections.Generic;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class CreateModel : InstructorCoursesPageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public CreateModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            var instructor = new Instructor();
            instructor.CourseAssignments = new List<CourseAssignment>();

            // Provides an empty collection for the foreach loop
            // foreach (var course in Model.AssignedCourseDataList)
            // in the Create Razor page.
            PopulateAssignedCourseData( context, instructor);
```

```
            return Page();
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnPostAsync(string[] selectedCourses)
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            var newInstructor = new Instructor();
            if (selectedCourses != null)
            {
                newInstructor.CourseAssignments = new List<CourseAssignment>();
                foreach (var course in selectedCourses)
                {
                    var courseToAdd = new CourseAssignment
                    {
                        CourseID = int.Parse(course)
                    };
                    newInstructor.CourseAssignments.Add(courseToAdd);
                }
            }

            if (await TryUpdateModelAsync<Instructor>(
                newInstructor,
                "Instructor",
                i => i.FirstMidName, i => i.LastName,
                i => i.HireDate, i => i.OfficeAssignment))
            {
                _context.Instructors.Add(newInstructor);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }
            PopulateAssignedCourseData(_context, newInstructor);
            return Page();
        }
    }
}
```

The preceding code is similar to the *Pages/Instructors/Edit.cshtml.cs* code.

Update the instructor Create Razor page with the following markup:

```
@page
@model ContosoUniversity.Pages.Instructors.CreateModel

@{
    ViewData["Title"] = "Create";
}

<h2>Create</h2>

<h4>Instructor</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Instructor.LastName" class="control-label"></label>
                <input asp-for="Instructor.LastName" class="form-control" />
                <span asp-validation-for="Instructor.LastName" class="text-danger"></span>
            </div>
```

```
            <div class="form-group">
                <label asp-for="Instructor.FirstMidName" class="control-label"></label>
                <input asp-for="Instructor.FirstMidName" class="form-control" />
                <span asp-validation-for="Instructor.FirstMidName" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.HireDate" class="control-label"></label>
                <input asp-for="Instructor.HireDate" class="form-control" />
                <span asp-validation-for="Instructor.HireDate" class="text-danger"></span>
            </div>

            <div class="form-group">
                <label asp-for="Instructor.OfficeAssignment.Location" class="control-label"></label>
                <input asp-for="Instructor.OfficeAssignment.Location" class="form-control" />
                <span asp-validation-for="Instructor.OfficeAssignment.Location" class="text-danger" />
            </div>
            <div class="form-group">
                <div class="col-md-offset-2 col-md-10">
                    <table>
                        <tr>
                            @{
                                int cnt = 0;

                                foreach (var course in Model.AssignedCourseDataList)
                                {
                                    if (cnt++ % 3 == 0)
                                    {
                                        @:</tr><tr>
                                    }
                                    @:<td>
                                        <input type="checkbox"
                                               name="selectedCourses"
                                               value="@course.CourseID"
                                               @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                                               @course.CourseID @:  @course.Title
                                    @:</td>
                                }
                                @:</tr>
                            }
                    </table>
                </div>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Test the instructor Create page.

Update the Delete page

Update the Delete page model with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Instructor = await _context.Instructors.SingleAsync(m => m.ID == id);

            if (Instructor == null)
            {
                return NotFound();
            }
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int id)
        {
            Instructor instructor = await _context.Instructors
                .Include(i => i.CourseAssignments)
                .SingleAsync(i => i.ID == id);

            var departments = await _context.Departments
                .Where(d => d.InstructorID == id)
                .ToListAsync();
            departments.ForEach(d => d.InstructorID = null);

            _context.Instructors.Remove(instructor);

            await _context.SaveChangesAsync();
            return RedirectToPage("./Index");
        }
    }
}
```

The preceding code makes the following changes:

- Uses eager loading for the `CourseAssignments` navigation property. `CourseAssignments` must be included or they aren't deleted when the instructor is deleted. To avoid needing to read them, configure cascade delete in the database.
- If the instructor to be deleted is assigned as administrator of any departments, removes the instructor assignment from those departments.

Part 8, Razor Pages with EF Core in ASP.NET Core - Concurrency

9/22/2020 • 36 minutes to read • Edit Online

By Rick Anderson, Tom Dykstra, and Jon P Smith

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial shows how to handle conflicts when multiple users update an entity concurrently (at the same time).

Concurrency conflicts

A concurrency conflict occurs when:

- A user navigates to the edit page for an entity.
- Another user updates the same entity before the first user's change is written to the database.

If concurrency detection isn't enabled, whoever updates the database last overwrites the other user's changes. If this risk is acceptable, the cost of programming for concurrency might outweigh the benefit.

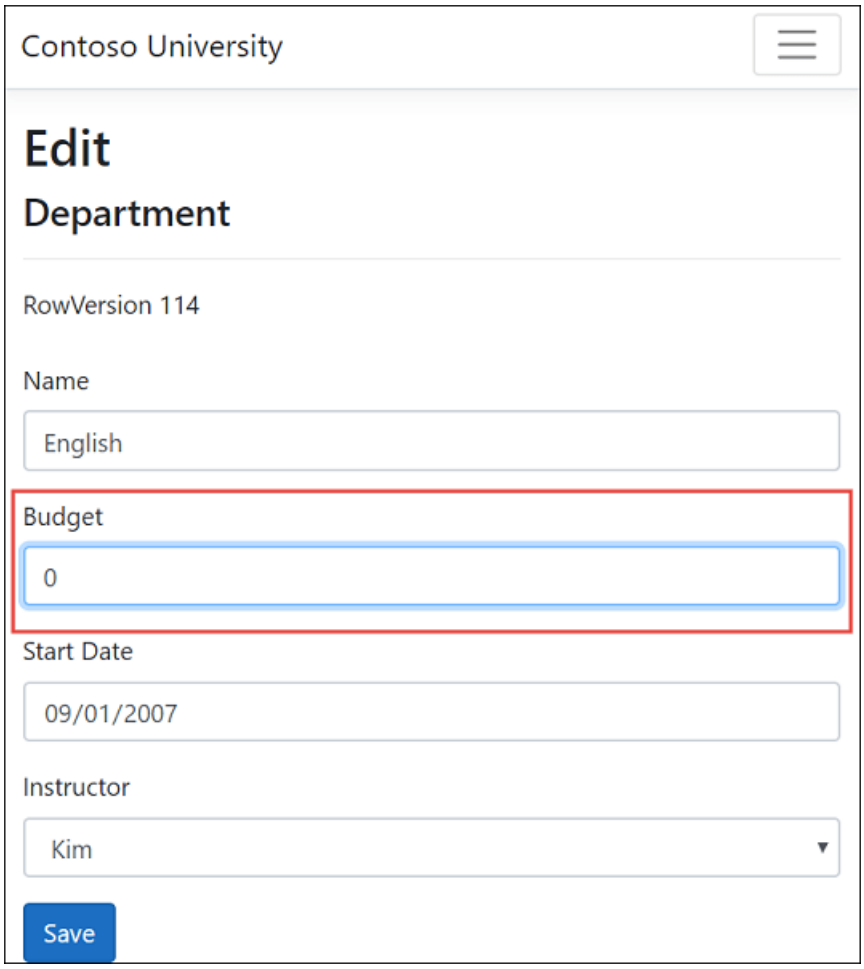
Pessimistic concurrency (locking)

One way to prevent concurrency conflicts is to use database locks. This is called pessimistic concurrency. Before the app reads a database row that it intends to update, it requests a lock. Once a row is locked for update access, no other users are allowed to lock the row until the first lock is released.

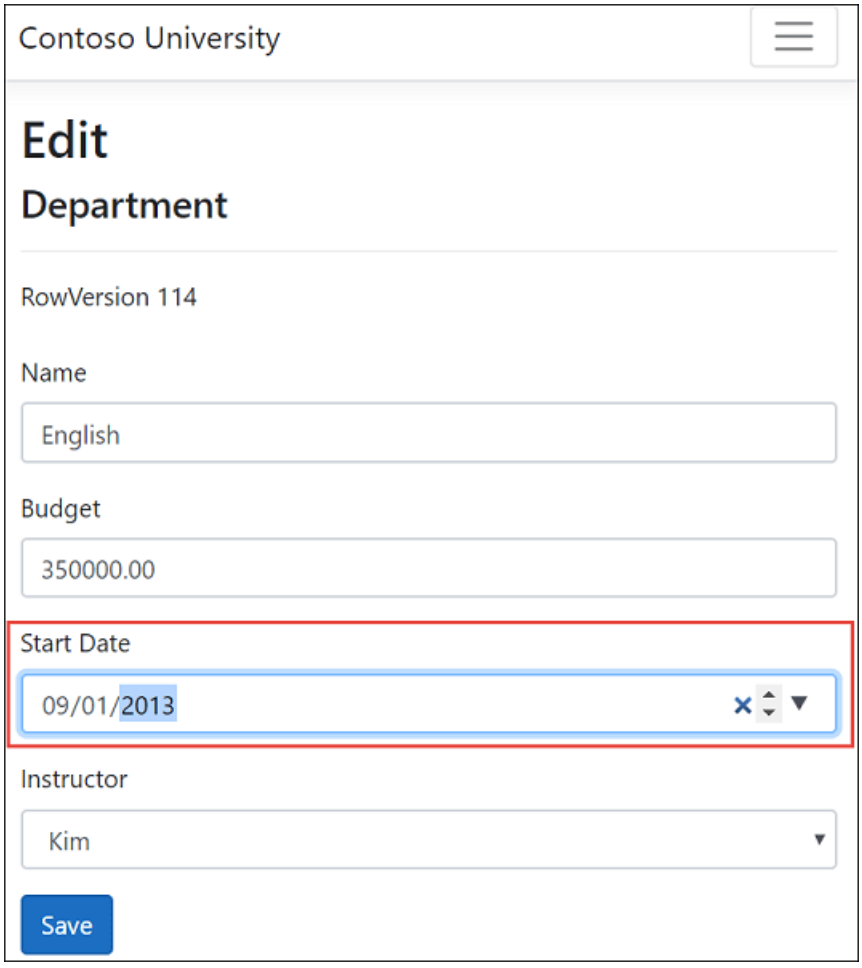
Managing locks has disadvantages. It can be complex to program and can cause performance problems as the number of users increases. Entity Framework Core provides no built-in support for it, and this tutorial doesn't show how to implement it.

Optimistic concurrency

Optimistic concurrency allows concurrency conflicts to happen, and then reacts appropriately when they do. For example, Jane visits the Department edit page and changes the budget for the English department from $350,000.00 to $0.00.



Before Jane clicks **Save**, John visits the same page and changes the Start Date field from 9/1/2007 to 9/1/2013.



Jane clicks **Save** first and sees her change take effect, since the browser displays the Index page with zero as the

Budget amount.

John clicks **Save** on an Edit page that still shows a budget of $350,000.00. What happens next is determined by how you handle concurrency conflicts:

- You can keep track of which property a user has modified and update only the corresponding columns in the database.

  In the scenario, no data would be lost. Different properties were updated by the two users. The next time someone browses the English department, they will see both Jane's and John's changes. This method of updating can reduce the number of conflicts that could result in data loss. This approach has some disadvantages:

  - Can't avoid data loss if competing changes are made to the same property.
  - Is generally not practical in a web app. It requires maintaining significant state in order to keep track of all fetched values and new values. Maintaining large amounts of state can affect app performance.
  - Can increase app complexity compared to concurrency detection on an entity.
- You can let John's change overwrite Jane's change.

  The next time someone browses the English department, they will see 9/1/2013 and the fetched $350,000.00 value. This approach is called a *Client Wins* or *Last in Wins* scenario. (All values from the client take precedence over what's in the data store.) If you don't do any coding for concurrency handling, Client Wins happens automatically.
- You can prevent John's change from being updated in the database. Typically, the app would:

  - Display an error message.
  - Show the current state of the data.
  - Allow the user to reapply the changes.

  This is called a *Store Wins* scenario. (The data-store values take precedence over the values submitted by the client.) You implement the Store Wins scenario in this tutorial. This method ensures that no changes are overwritten without a user being alerted.

Conflict detection in EF Core

EF Core throws `DbConcurrencyException` exceptions when it detects conflicts. The data model has to be configured to enable conflict detection. Options for enabling conflict detection include the following:

- Configure EF Core to include the original values of columns configured as concurrency tokens in the Where clause of Update and Delete commands.

  When `SaveChanges` is called, the Where clause looks for the original values of any properties annotated with the ConcurrencyCheckAttribute attribute. The update statement won't find a row to update if any of the concurrency token properties changed since the row was first read. EF Core interprets that as a concurrency conflict. For database tables that have many columns, this approach can result in very large Where clauses, and can require large amounts of state. Therefore this approach is generally not recommended, and it isn't the method used in this tutorial.
- In the database table, include a tracking column that can be used to determine when a row has been changed.

  In a SQL Server database, the data type of the tracking column is `rowversion`. The `rowversion` value is a sequential number that's incremented each time the row is updated. In an Update or Delete command, the Where clause includes the original value of the tracking column (the original row version number). If the row being updated has been changed by another user, the value in the `rowversion` column is different than the original value. In that case, the Update or Delete statement can't find the row to update because

of the Where clause. EF Core throws a concurrency exception when no rows are affected by an Update or Delete command.

Add a tracking property

In *Models/Department.cs*, add a tracking property named RowVersion:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        [Timestamp]
        public byte[] RowVersion { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The TimestampAttribute attribute is what identifies the column as a concurrency tracking column. The fluent API is an alternative way to specify the tracking property:

```
modelBuilder.Entity<Department>()
  .Property<byte[]>("RowVersion")
  .IsRowVersion();
```

- Visual Studio
- Visual Studio Code

For a SQL Server database, the `[Timestamp]` attribute on an entity property defined as byte array:

- Causes the column to be included in DELETE and UPDATE WHERE clauses.
- Sets the column type in the database to rowversion.

The database generates a sequential row version number that's incremented each time the row is updated. In an `Update` or `Delete` command, the `Where` clause includes the fetched row version value. If the row being updated has changed since it was fetched:

- The current row version value doesn't match the fetched value.

- The `Update` or `Delete` commands don't find a row because the `Where` clause looks for the fetched row version value.
- A `DbUpdateConcurrencyException` is thrown.

The following code shows a portion of the T-SQL generated by EF Core when the Department name is updated:

```
SET NOCOUNT ON;
UPDATE [Department] SET [Name] = @p0
WHERE [DepartmentID] = @p1 AND [RowVersion] = @p2;
SELECT [RowVersion]
FROM [Department]
WHERE @@ROWCOUNT = 1 AND [DepartmentID] = @p1;
```

The preceding highlighted code shows the `WHERE` clause containing `RowVersion`. If the database `RowVersion` doesn't equal the `RowVersion` parameter (`@p2`), no rows are updated.

The following highlighted code shows the T-SQL that verifies exactly one row was updated:

```
SET NOCOUNT ON;
UPDATE [Department] SET [Name] = @p0
WHERE [DepartmentID] = @p1 AND [RowVersion] = @p2;
SELECT [RowVersion]
FROM [Department]
WHERE @@ROWCOUNT = 1 AND [DepartmentID] = @p1;
```

@@ROWCOUNT returns the number of rows affected by the last statement. If no rows are updated, EF Core throws a `DbUpdateConcurrencyException`.

Update the database

Adding the `RowVersion` property changes the data model, which requires a migration.

Build the project.

- Visual Studio
- Visual Studio Code

- Run the following command in the PMC:

  ```
  Add-Migration RowVersion
  ```

This command:

- Creates the *Migrations/{time stamp}_RowVersion.cs* migration file.
- Updates the *Migrations/SchoolContextModelSnapshot.cs* file. The update adds the following highlighted code to the `BuildModel` method:

```
modelBuilder.Entity("ContosoUniversity.Models.Department", b =>
    {
        b.Property<int>("DepartmentID")
            .ValueGeneratedOnAdd()
            .HasAnnotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn);

        b.Property<decimal>("Budget")
            .HasColumnType("money");

        b.Property<int?>("InstructorID");

        b.Property<string>("Name")
            .HasMaxLength(50);

        b.Property<byte[]>("RowVersion")
            .IsConcurrencyToken()
            .ValueGeneratedOnAddOrUpdate();

        b.Property<DateTime>("StartDate");

        b.HasKey("DepartmentID");

        b.HasIndex("InstructorID");

        b.ToTable("Department");
    });
```

- Visual Studio
- Visual Studio Code
- Run the following command in the PMC:

```
Update-Database
```

Scaffold Department pages

- Visual Studio
- Visual Studio Code
- Follow the instructions in Scaffold Student pages with the following exceptions:
- Create a *Pages/Departments* folder.
- Use `Department` for the model class.
  - Use the existing context class instead of creating a new one.

Build the project.

Update the Index page

The scaffolding tool created a `RowVersion` column for the Index page, but that field wouldn't be displayed in a production app. In this tutorial, the last byte of the `RowVersion` is displayed to help show how concurrency handling works. The last byte isn't guaranteed to be unique by itself.

Update *Pages\Departments\Index.cshtml* page:

- Replace Index with Departments.

- Change the code containing `RowVersion` to show just the last byte of the byte array.
- Replace FirstMidName with FullName.

The following code shows the updated page:

```
@page
@model ContosoUniversity.Pages.Departments.IndexModel

@{
    ViewData["Title"] = "Departments";
}

<h2>Departments</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
                <th>
                    @Html.DisplayNameFor(model => model.Department[0].Name)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.Department[0].Budget)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.Department[0].StartDate)
                </th>
            <th>
                @Html.DisplayNameFor(model => model.Department[0].Administrator)
            </th>
            <th>
                RowVersion
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Department)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Name)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Budget)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.StartDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Administrator.FullName)
                </td>
                <td>
                    @item.RowVersion[7]
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.DepartmentID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.DepartmentID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.DepartmentID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

Update the Edit page model

Update *Pages\Departments\Edit.cshtml.cs* with the following code:

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Departments
{
    public class EditModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Department Department { get; set; }
        // Replace ViewData["InstructorID"]
        public SelectList InstructorNameSL { get; set; }

        public async Task<IActionResult> OnGetAsync(int id)
        {
            Department = await _context.Departments
                .Include(d => d.Administrator)  // eager loading
                .AsNoTracking()                 // tracking not required
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (Department == null)
            {
                return NotFound();
            }

            // Use strongly typed data rather than ViewData.
            InstructorNameSL = new SelectList(_context.Instructors,
                "ID", "FirstMidName");

            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int id)
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            var departmentToUpdate = await _context.Departments
                .Include(i => i.Administrator)
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (departmentToUpdate == null)
            {
                return HandleDeletedDepartment();
            }

            _context.Entry(departmentToUpdate)
                .Property("RowVersion").OriginalValue = Department.RowVersion;

            if (
```

```
            if (await TryUpdateModelAsync<Department>(
                departmentToUpdate,
                "Department",
                s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
            {
                try
                {
                    await _context.SaveChangesAsync();
                    return RedirectToPage("./Index");
                }
                catch (DbUpdateConcurrencyException ex)
                {
                    var exceptionEntry = ex.Entries.Single();
                    var clientValues = (Department)exceptionEntry.Entity;
                    var databaseEntry = exceptionEntry.GetDatabaseValues();
                    if (databaseEntry == null)
                    {
                        ModelState.AddModelError(string.Empty, "Unable to save. " +
                            "The department was deleted by another user.");
                        return Page();
                    }

                    var dbValues = (Department)databaseEntry.ToObject();
                    await setDbErrorMessage(dbValues, clientValues, _context);

                    // Save the current RowVersion so next postback
                    // matches unless an new concurrency issue happens.
                    Department.RowVersion = (byte[])dbValues.RowVersion;
                    // Clear the model error for the next postback.
                    ModelState.Remove("Department.RowVersion");
                }
            }

            InstructorNameSL = new SelectList(_context.Instructors,
                "ID", "FullName", departmentToUpdate.InstructorID);

            return Page();
        }

        private IActionResult HandleDeletedDepartment()
        {
            var deletedDepartment = new Department();
            // ModelState contains the posted data because of the deletion error
            // and will overide the Department instance values when displaying Page().
            ModelState.AddModelError(string.Empty,
                "Unable to save. The department was deleted by another user.");
            InstructorNameSL = new SelectList(_context.Instructors, "ID", "FullName",
Department.InstructorID);
            return Page();
        }

        private async Task setDbErrorMessage(Department dbValues,
                Department clientValues, SchoolContext context)
        {

            if (dbValues.Name != clientValues.Name)
            {
                ModelState.AddModelError("Department.Name",
                    $"Current value: {dbValues.Name}");
            }
            if (dbValues.Budget != clientValues.Budget)
            {
                ModelState.AddModelError("Department.Budget",
                    $"Current value: {dbValues.Budget:c}");
            }
            if (dbValues.StartDate != clientValues.StartDate)
            {
                ModelState.AddModelError("Department.StartDate",
                    $"Current value: {dbValues.StartDate:d}");
```

```
            }
            if (dbValues.InstructorID != clientValues.InstructorID)
            {
                Instructor dbInstructor = await _context.Instructors
                   .FindAsync(dbValues.InstructorID);
                ModelState.AddModelError("Department.InstructorID",
                    $"Current value: {dbInstructor?.FullName}");
            }

            ModelState.AddModelError(string.Empty,
                "The record you attempted to edit "
              + "was modified by another user after you. The "
              + "edit operation was canceled and the current values in the database "
              + "have been displayed. If you still want to edit this record, click "
              + "the Save button again.");
        }
    }
}
```

The OriginalValue is updated with the `rowVersion` value from the entity when it was fetched in the `OnGet` method. EF Core generates a SQL UPDATE command with a WHERE clause containing the original `RowVersion` value. If no rows are affected by the UPDATE command (no rows have the original `RowVersion` value), a `DbUpdateConcurrencyException` exception is thrown.

```
public async Task<IActionResult> OnPostAsync(int id)
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    var departmentToUpdate = await _context.Departments
        .Include(i => i.Administrator)
        .FirstOrDefaultAsync(m => m.DepartmentID == id);

    if (departmentToUpdate == null)
    {
        return HandleDeletedDepartment();
    }

    _context.Entry(departmentToUpdate)
        .Property("RowVersion").OriginalValue = Department.RowVersion;
```

In the preceding highlighted code:

- The value in `Department.RowVersion` is what was in the entity when it was originally fetched in the Get request for the Edit page. The value is provided to the `OnPost` method by a hidden field in the Razor page that displays the entity to be edited. The hidden field value is copied to `Department.RowVersion` by the model binder.
- `OriginalValue` is what EF Core will use in the Where clause. Before the highlighted line of code executes, `OriginalValue` has the value that was in the database when `FirstOrDefaultAsync` was called in this method, which might be different from what was displayed on the Edit page.
- The highlighted code makes sure that EF Core uses the original `RowVersion` value from the displayed `Department` entity in the SQL UPDATE statement's Where clause.

When a concurrency error happens, the following highlighted code gets the client values (the values posted to this method) and the database values.

```
if (await TryUpdateModelAsync<Department>(
    departmentToUpdate,
    "Department",
    s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
{
    try
    {
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }
    catch (DbUpdateConcurrencyException ex)
    {
        var exceptionEntry = ex.Entries.Single();
        var clientValues = (Department)exceptionEntry.Entity;
        var databaseEntry = exceptionEntry.GetDatabaseValues();
        if (databaseEntry == null)
        {
            ModelState.AddModelError(string.Empty, "Unable to save. " +
                "The department was deleted by another user.");
            return Page();
        }

        var dbValues = (Department)databaseEntry.ToObject();
        await setDbErrorMessage(dbValues, clientValues, _context);

        // Save the current RowVersion so next postback
        // matches unless an new concurrency issue happens.
        Department.RowVersion = (byte[])dbValues.RowVersion;
        // Clear the model error for the next postback.
        ModelState.Remove("Department.RowVersion");
    }
```

The following code adds a custom error message for each column that has database values different from what was posted to `OnPostAsync`:

```
private async Task setDbErrorMessage(Department dbValues,
        Department clientValues, SchoolContext context)
{

    if (dbValues.Name != clientValues.Name)
    {
        ModelState.AddModelError("Department.Name",
            $"Current value: {dbValues.Name}");
    }
    if (dbValues.Budget != clientValues.Budget)
    {
        ModelState.AddModelError("Department.Budget",
            $"Current value: {dbValues.Budget:c}");
    }
    if (dbValues.StartDate != clientValues.StartDate)
    {
        ModelState.AddModelError("Department.StartDate",
            $"Current value: {dbValues.StartDate:d}");
    }
    if (dbValues.InstructorID != clientValues.InstructorID)
    {
        Instructor dbInstructor = await _context.Instructors
           .FindAsync(dbValues.InstructorID);
        ModelState.AddModelError("Department.InstructorID",
            $"Current value: {dbInstructor?.FullName}");
    }

    ModelState.AddModelError(string.Empty,
        "The record you attempted to edit "
      + "was modified by another user after you. The "
      + "edit operation was canceled and the current values in the database "
      + "have been displayed. If you still want to edit this record, click "
      + "the Save button again.");
}
```

The following highlighted code sets the `RowVersion` value to the new value retrieved from the database. The next time the user clicks **Save**, only concurrency errors that happen since the last display of the Edit page will be caught.

```
if (await TryUpdateModelAsync<Department>(
    departmentToUpdate,
    "Department",
    s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
{
    try
    {
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }
    catch (DbUpdateConcurrencyException ex)
    {
        var exceptionEntry = ex.Entries.Single();
        var clientValues = (Department)exceptionEntry.Entity;
        var databaseEntry = exceptionEntry.GetDatabaseValues();
        if (databaseEntry == null)
        {
            ModelState.AddModelError(string.Empty, "Unable to save. " +
                "The department was deleted by another user.");
            return Page();
        }

        var dbValues = (Department)databaseEntry.ToObject();
        await setDbErrorMessage(dbValues, clientValues, _context);

        // Save the current RowVersion so next postback
        // matches unless an new concurrency issue happens.
        Department.RowVersion = (byte[])dbValues.RowVersion;
        // Clear the model error for the next postback.
        ModelState.Remove("Department.RowVersion");
    }
```

The `ModelState.Remove` statement is required because `ModelState` has the old `RowVersion` value. In the Razor Page, the `ModelState` value for a field takes precedence over the model property values when both are present.

Update the Edit page

Update *Pages/Departments/Edit.cshtml* with the following code:

```
@page "{id:int}"
@model ContosoUniversity.Pages.Departments.EditModel
@{
    ViewData["Title"] = "Edit";
}
<h2>Edit</h2>
<h4>Department</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Department.DepartmentID" />
            <input type="hidden" asp-for="Department.RowVersion" />
            <div class="form-group">
                <label>RowVersion</label>
                @Model.Department.RowVersion[7]
            </div>
            <div class="form-group">
                <label asp-for="Department.Name" class="control-label"></label>
                <input asp-for="Department.Name" class="form-control" />
                <span asp-validation-for="Department.Name" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Department.Budget" class="control-label"></label>
                <input asp-for="Department.Budget" class="form-control" />
                <span asp-validation-for="Department.Budget" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Department.StartDate" class="control-label"></label>
                <input asp-for="Department.StartDate" class="form-control" />
                <span asp-validation-for="Department.StartDate" class="text-danger">
                </span>
            </div>
            <div class="form-group">
                <label class="control-label">Instructor</label>
                <select asp-for="Department.InstructorID" class="form-control"
                        asp-items="@Model.InstructorNameSL"></select>
                <span asp-validation-for="Department.InstructorID" class="text-danger">
                </span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>
<div>
    <a asp-page="./Index">Back to List</a>
</div>
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code:

- Updates the `page` directive from `@page` to `@page "{id:int}"`.
- Adds a hidden row version. `RowVersion` must be added so postback binds the value.
- Displays the last byte of `RowVersion` for debugging purposes.
- Replaces `ViewData` with the strongly-typed `InstructorNameSL`.

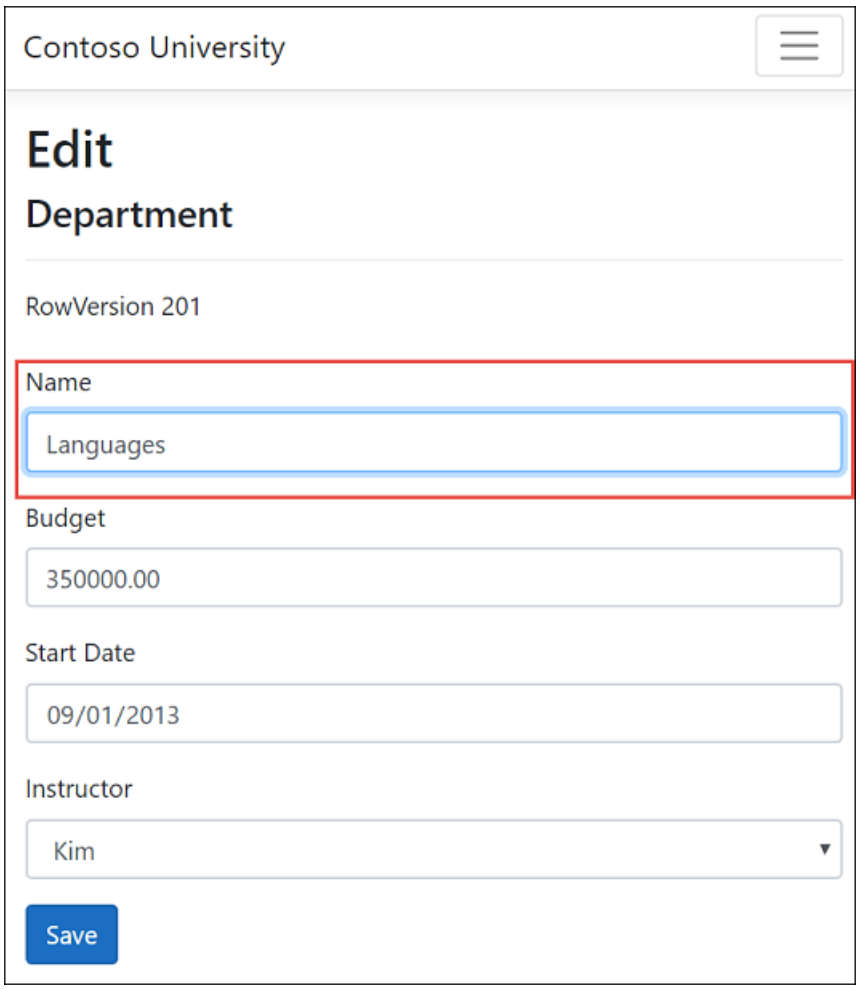
Test concurrency conflicts with the Edit page

Open two browsers instances of Edit on the English department:

- Run the app and select Departments.
- Right-click the **Edit** hyperlink for the English department and select **Open in new tab**.
- In the first tab, click the **Edit** hyperlink for the English department.

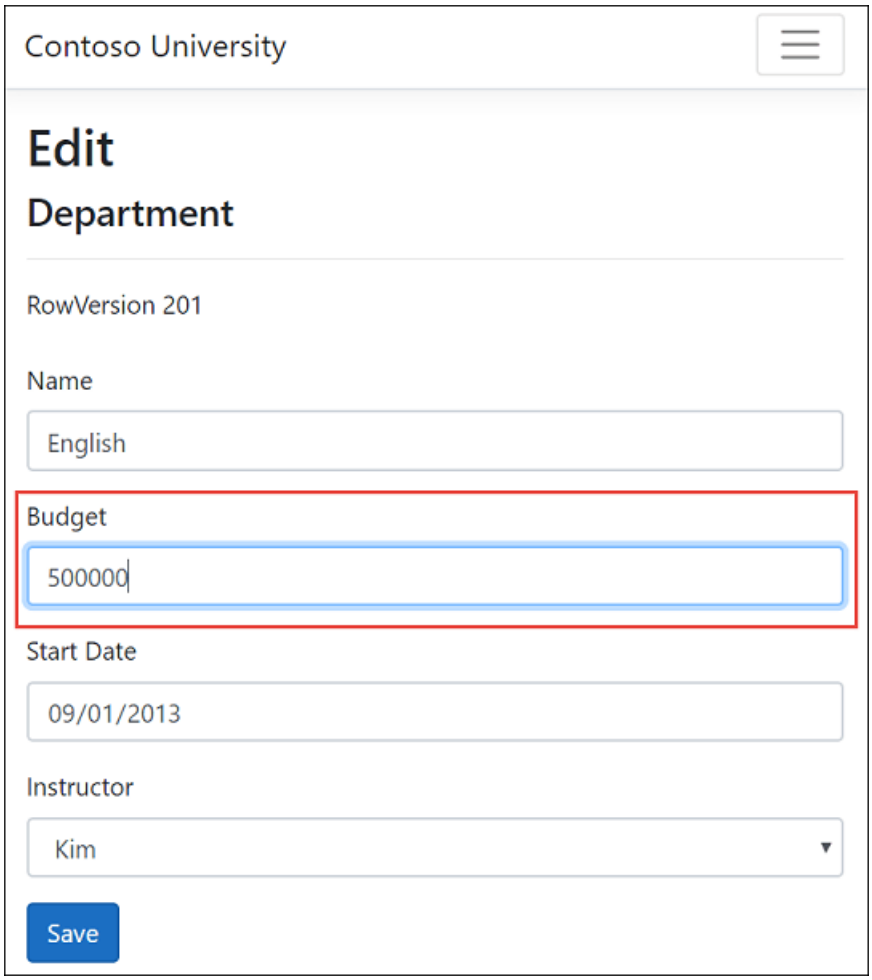
The two browser tabs display the same information.

Change the name in the first browser tab and click **Save**.

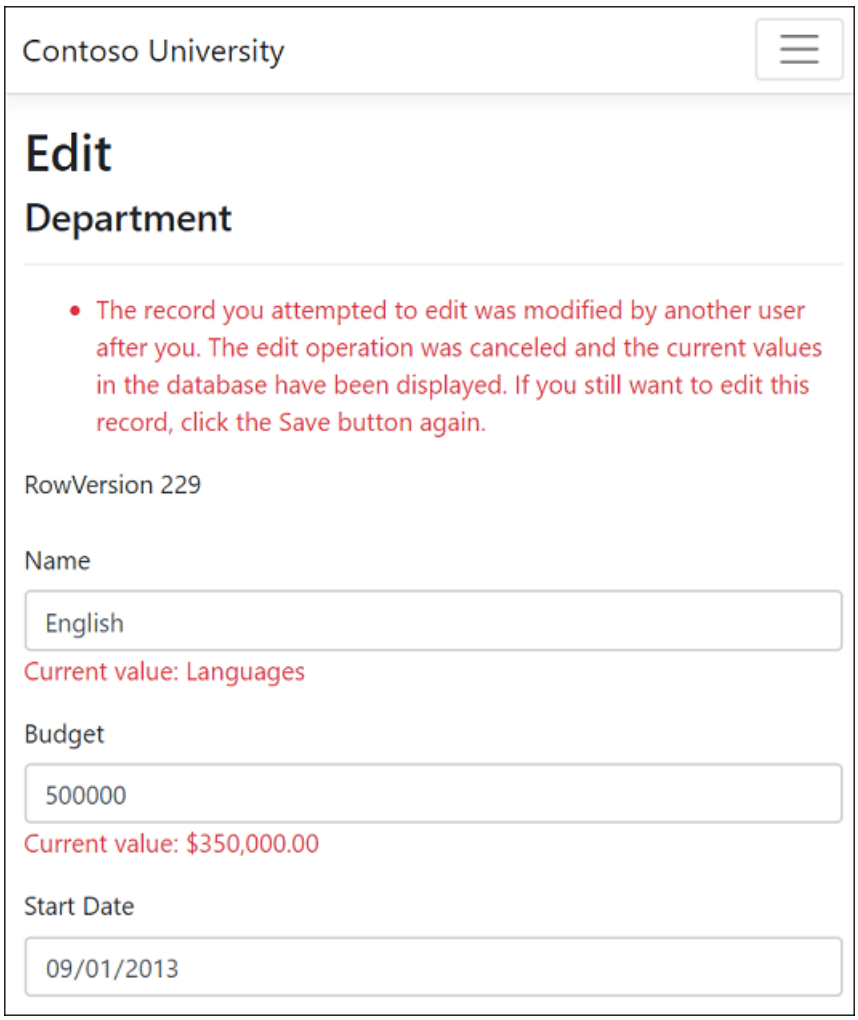


The browser shows the Index page with the changed value and updated rowVersion indicator. Note the updated rowVersion indicator, it's displayed on the second postback in the other tab.

Change a different field in the second browser tab.



Click **Save**. You see error messages for all fields that don't match the database values:



This browser window didn't intend to change the Name field. Copy and paste the current value (Languages) into the Name field. Tab out. Client-side validation removes the error message.

Click **Save** again. The value you entered in the second browser tab is saved. You see the saved values in the Index page.

Update the Delete page model

Update *Pages/Departments/Delete.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Departments
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Department Department { get; set; }
        public string ConcurrencyErrorMessage { get; set; }

        public async Task<IActionResult> OnGetAsync(int id, bool? concurrencyError)
        {
            Department = await _context.Departments
                .Include(d => d.Administrator)
                .AsNoTracking()
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (Department == null)
            {
                 return NotFound();
            }

            if (concurrencyError.GetValueOrDefault())
            {
                ConcurrencyErrorMessage = "The record you attempted to delete "
                  + "was modified by another user after you selected delete. "
                  + "The delete operation was canceled and the current values in the "
                  + "database have been displayed. If you still want to delete this "
                  + "record, click the Delete button again.";
            }
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int id)
        {
            try
            {
                if (await _context.Departments.AnyAsync(
                    m => m.DepartmentID == id))
                {
                    // Department.rowVersion value is from when the entity
                    // was fetched. If it doesn't match the DB, a
                    // DbUpdateConcurrencyException exception is thrown.
                    _context.Departments.Remove(Department);
                    await _context.SaveChangesAsync();
```

```
                }
                return RedirectToPage("./Index");
            }
            catch (DbUpdateConcurrencyException)
            {
                return RedirectToPage("./Delete",
                    new { concurrencyError = true, id = id });
            }
        }
    }
}
```

The Delete page detects concurrency conflicts when the entity has changed after it was fetched. `Department.RowVersion` is the row version when the entity was fetched. When EF Core creates the SQL DELETE command, it includes a WHERE clause with `RowVersion`. If the SQL DELETE command results in zero rows affected:

- The `RowVersion` in the SQL DELETE command doesn't match `RowVersion` in the database.
- A DbUpdateConcurrencyException exception is thrown.
- `OnGetAsync` is called with the `concurrencyError`.

Update the Delete page

Update *Pages/Departments/Delete.cshtml* with the following code:

```
@page "{id:int}"
@model ContosoUniversity.Pages.Departments.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

<p class="text-danger">@Model.ConcurrencyErrorMessage</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Department</h4>
    <hr />
    <dl class="dl-horizontal">
        <dt>
            @Html.DisplayNameFor(model => model.Department.Name)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.Name)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.Budget)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.Budget)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.StartDate)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.StartDate)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.RowVersion)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.RowVersion[7])
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.Administrator)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.Administrator.FullName)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Department.DepartmentID" />
        <input type="hidden" asp-for="Department.RowVersion" />
        <div class="form-actions no-color">
            <input type="submit" value="Delete" class="btn btn-danger" /> |
            <a asp-page="./Index">Back to List</a>
        </div>
</form>
</div>
```

The preceding code makes the following changes:

- Updates the `page` directive from `@page` to `@page "{id:int}"`.
- Adds an error message.
- Replaces FirstMidName with FullName in the **Administrator** field.
- Changes `RowVersion` to display the last byte.

- Adds a hidden row version. `RowVersion` must be added so postback binds the value.

Test concurrency conflicts

Create a test department.

Open two browsers instances of Delete on the test department:

- Run the app and select Departments.
- Right-click the **Delete** hyperlink for the test department and select **Open in new tab**.
- Click the **Edit** hyperlink for the test department.

The two browser tabs display the same information.

Change the budget in the first browser tab and click **Save**.

The browser shows the Index page with the changed value and updated rowVersion indicator. Note the updated rowVersion indicator, it's displayed on the second postback in the other tab.

Delete the test department from the second tab. A concurrency error is display with the current values from the database. Clicking **Delete** deletes the entity, unless `RowVersion` has been updated.

Next steps

This is the last tutorial in the series. Additional topics are covered in the MVC version of this tutorial series.

PREVIOUS TUTORIAL

This tutorial shows how to handle conflicts when multiple users update an entity concurrently (at the same time). If you run into problems you can't solve, download or view the completed app. Download instructions.

Concurrency conflicts

A concurrency conflict occurs when:

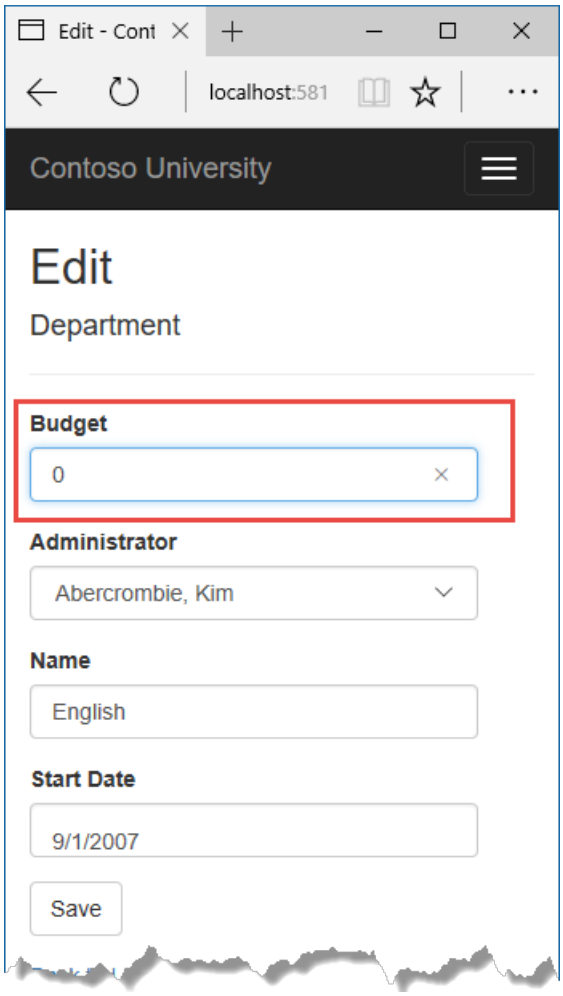
- A user navigates to the edit page for an entity.
- Another user updates the same entity before the first user's change is written to the DB.

If concurrency detection isn't enabled, when concurrent updates occur:

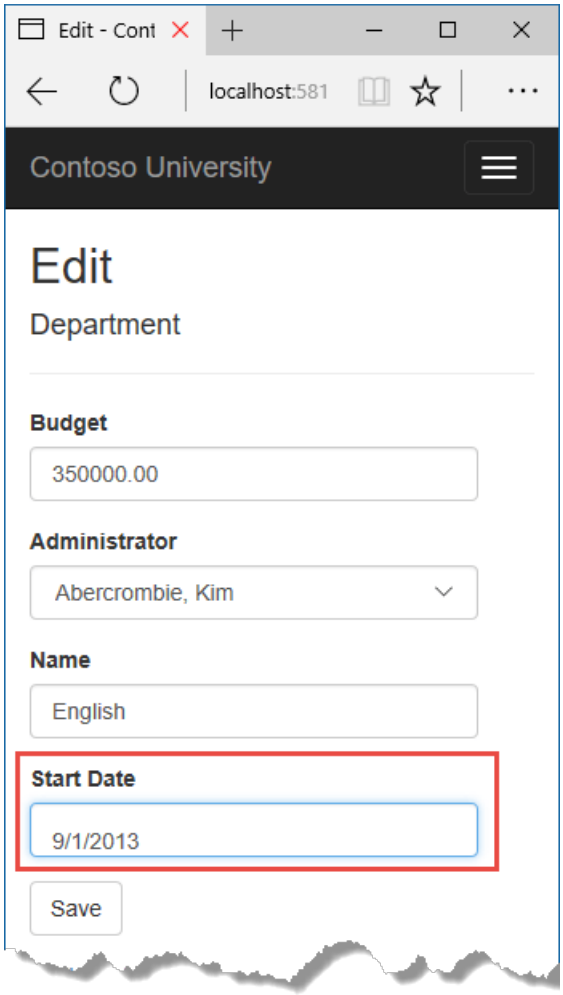
- The last update wins. That is, the last update values are saved to the DB.
- The first of the current updates are lost.

Optimistic concurrency

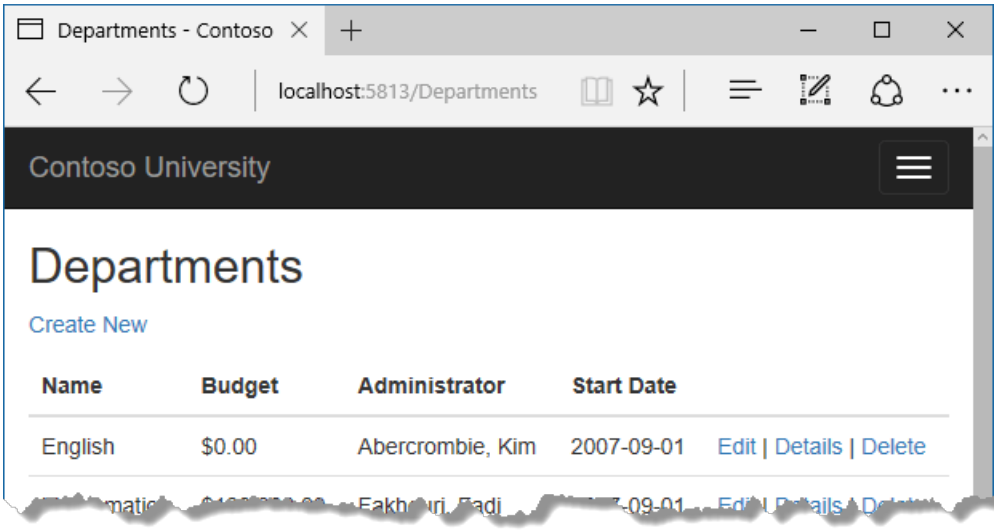
Optimistic concurrency allows concurrency conflicts to happen, and then reacts appropriately when they do. For example, Jane visits the Department edit page and changes the budget for the English department from $350,000.00 to $0.00.



Before Jane clicks **Save**, John visits the same page and changes the Start Date field from 9/1/2007 to 9/1/2013.



Jane clicks **Save** first and sees her change when the browser displays the Index page.



John clicks **Save** on an Edit page that still shows a budget of $350,000.00. What happens next is determined by how you handle concurrency conflicts.

Optimistic concurrency includes the following options:

- You can keep track of which property a user has modified and update only the corresponding columns in the DB.

  In the scenario, no data would be lost. Different properties were updated by the two users. The next time someone browses the English department, they will see both Jane's and John's changes. This method of updating can reduce the number of conflicts that could result in data loss. This approach:

  - Can't avoid data loss if competing changes are made to the same property.
  - Is generally not practical in a web app. It requires maintaining significant state in order to keep track of all fetched values and new values. Maintaining large amounts of state can affect app performance.
  - Can increase app complexity compared to concurrency detection on an entity.
- You can let John's change overwrite Jane's change.

  The next time someone browses the English department, they will see 9/1/2013 and the fetched $350,000.00 value. This approach is called a *Client Wins* or *Last in Wins* scenario. (All values from the client take precedence over what's in the data store.) If you don't do any coding for concurrency handling, Client Wins happens automatically.
- You can prevent John's change from being updated in the DB. Typically, the app would:

  - Display an error message.
  - Show the current state of the data.
  - Allow the user to reapply the changes.

  This is called a *Store Wins* scenario. (The data-store values take precedence over the values submitted by the client.) You implement the Store Wins scenario in this tutorial. This method ensures that no changes are overwritten without a user being alerted.

Handling concurrency

When a property is configured as a concurrency token:

- EF Core verifies that property has not been modified after it was fetched. The check occurs when SaveChanges or SaveChangesAsync is called.
- If the property has been changed after it was fetched, a DbUpdateConcurrencyException is thrown.

The DB and data model must be configured to support throwing `DbUpdateConcurrencyException`.

Detecting concurrency conflicts on a property

Concurrency conflicts can be detected at the property level with the ConcurrencyCheck attribute. The attribute can be applied to multiple properties on the model. For more information, see Data Annotations-ConcurrencyCheck.

The `[ConcurrencyCheck]` attribute isn't used in this tutorial.

Detecting concurrency conflicts on a row

To detect concurrency conflicts, a rowversion tracking column is added to the model. `rowversion`:

- Is SQL Server specific. Other databases may not provide a similar feature.
- Is used to determine that an entity has not been changed since it was fetched from the DB.

The DB generates a sequential `rowversion` number that's incremented each time the row is updated. In an `Update` or `Delete` command, the `Where` clause includes the fetched value of `rowversion`. If the row being updated has changed:

- `rowversion` doesn't match the fetched value.
- The `Update` or `Delete` commands don't find a row because the `Where` clause includes the fetched `rowversion`.
- A `DbUpdateConcurrencyException` is thrown.

In EF Core, when no rows have been updated by an `Update` or `Delete` command, a concurrency exception is thrown.

Add a tracking property to the Department entity

In *Models/Department.cs*, add a tracking property named RowVersion:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        [Timestamp]
        public byte[] RowVersion { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The Timestamp attribute specifies that this column is included in the `Where` clause of `Update` and `Delete` commands. The attribute is called `Timestamp` because previous versions of SQL Server used a SQL `timestamp` data type before the SQL `rowversion` type replaced it.

The fluent API can also specify the tracking property:

```
modelBuilder.Entity<Department>()
  .Property<byte[]>("RowVersion")
  .IsRowVersion();
```

The following code shows a portion of the T-SQL generated by EF Core when the Department name is updated:

```
SET NOCOUNT ON;
UPDATE [Department] SET [Name] = @p0
WHERE [DepartmentID] = @p1 AND [RowVersion] = @p2;
SELECT [RowVersion]
FROM [Department]
WHERE @@ROWCOUNT = 1 AND [DepartmentID] = @p1;
```

The preceding highlighted code shows the `WHERE` clause containing `RowVersion`. If the DB `RowVersion` doesn't equal the `RowVersion` parameter (`@p2`), no rows are updated.

The following highlighted code shows the T-SQL that verifies exactly one row was updated:

```
SET NOCOUNT ON;
UPDATE [Department] SET [Name] = @p0
WHERE [DepartmentID] = @p1 AND [RowVersion] = @p2;
SELECT [RowVersion]
FROM [Department]
WHERE @@ROWCOUNT = 1 AND [DepartmentID] = @p1;
```

@@ROWCOUNT returns the number of rows affected by the last statement. In no rows are updated, EF Core throws a `DbUpdateConcurrencyException`.

You can see the T-SQL EF Core generates in the output window of Visual Studio.

Update the DB

Adding the `RowVersion` property changes the DB model, which requires a migration.

Build the project. Enter the following in a command window:

```
dotnet ef migrations add RowVersion
dotnet ef database update
```

The preceding commands:

- Adds the *Migrations/{time stamp}_RowVersion.cs* migration file.
- Updates the *Migrations/SchoolContextModelSnapshot.cs* file. The update adds the following highlighted code to the `BuildModel` method:

  ```
  
  ```

- Runs migrations to update the DB.

Scaffold the Departments model

- Visual Studio
- Visual Studio Code

Follow the instructions in Scaffold the student model and use `Department` for the model class.

The preceding command scaffolds the `Department` model. Open the project in Visual Studio.

Build the project.

Update the Departments Index page

The scaffolding engine created a `RowVersion` column for the Index page, but that field shouldn't be displayed. In this tutorial, the last byte of the `RowVersion` is displayed to help understand concurrency. The last byte isn't guaranteed to be unique. A real app wouldn't display `RowVersion` or the last byte of `RowVersion`.

Update the Index page:

- Replace Index with Departments.
- Replace the markup containing `RowVersion` with the last byte of `RowVersion`.
- Replace FirstMidName with FullName.

The following markup shows the updated page:

```
@page
@model ContosoUniversity.Pages.Departments.IndexModel

@{
    ViewData["Title"] = "Departments";
}

<h2>Departments</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
                <th>
                    @Html.DisplayNameFor(model => model.Department[0].Name)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.Department[0].Budget)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.Department[0].StartDate)
                </th>
            <th>
                @Html.DisplayNameFor(model => model.Department[0].Administrator)
            </th>
            <th>
                RowVersion
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model.Department) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Name)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Budget)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.StartDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Administrator.FullName)
            </td>
            <td>
                @item.RowVersion[7]
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.DepartmentID">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.DepartmentID">Details</a> |
                <a asp-page="./Delete" asp-route-id="@item.DepartmentID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Update the Edit page model

Update *Pages\Departments\Edit.cshtml.cs* with the following code:

```
using ContosoUniversity.Data;
```

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Departments
{
    public class EditModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Department Department { get; set; }
        // Replace ViewData["InstructorID"]
        public SelectList InstructorNameSL { get; set; }

        public async Task<IActionResult> OnGetAsync(int id)
        {
            Department = await _context.Departments
                .Include(d => d.Administrator)  // eager loading
                .AsNoTracking()                 // tracking not required
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (Department == null)
            {
                return NotFound();
            }

            // Use strongly typed data rather than ViewData.
            InstructorNameSL = new SelectList(_context.Instructors,
                "ID", "FirstMidName");

            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int id)
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            var departmentToUpdate = await _context.Departments
                .Include(i => i.Administrator)
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            // null means Department was deleted by another user.
            if (departmentToUpdate == null)
            {
                return HandleDeletedDepartment();
            }

            // Update the RowVersion to the value when this entity was
            // fetched. If the entity has been updated after it was
            // fetched, RowVersion won't match the DB RowVersion and
            // a DbUpdateConcurrencyException is thrown.
            // A second postback will make them match, unless a new
            // concurrency issue happens.
            _context.Entry(departmentToUpdate)
                .Property("RowVersion").OriginalValue = Department.RowVersion;
```

```
            if (await TryUpdateModelAsync<Department>(
                departmentToUpdate,
                "Department",
                s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
            {
                try
                {
                    await _context.SaveChangesAsync();
                    return RedirectToPage("./Index");
                }
                catch (DbUpdateConcurrencyException ex)
                {
                    var exceptionEntry = ex.Entries.Single();
                    var clientValues = (Department)exceptionEntry.Entity;
                    var databaseEntry = exceptionEntry.GetDatabaseValues();
                    if (databaseEntry == null)
                    {
                        ModelState.AddModelError(string.Empty, "Unable to save. " +
                            "The department was deleted by another user.");
                        return Page();
                    }

                    var dbValues = (Department)databaseEntry.ToObject();
                    await setDbErrorMessage(dbValues, clientValues, _context);

                    // Save the current RowVersion so next postback
                    // matches unless an new concurrency issue happens.
                    Department.RowVersion = (byte[])dbValues.RowVersion;
                    // Must clear the model error for the next postback.
                    ModelState.Remove("Department.RowVersion");
                }
            }

            InstructorNameSL = new SelectList(_context.Instructors,
                "ID", "FullName", departmentToUpdate.InstructorID);

            return Page();
        }

        private IActionResult HandleDeletedDepartment()
        {
            var deletedDepartment = new Department();
            // ModelState contains the posted data because of the deletion error and will overide the
Department instance values when displaying Page().
            ModelState.AddModelError(string.Empty,
                "Unable to save. The department was deleted by another user.");
            InstructorNameSL = new SelectList(_context.Instructors, "ID", "FullName",
Department.InstructorID);
            return Page();
        }

        private async Task setDbErrorMessage(Department dbValues,
                Department clientValues, SchoolContext context)
        {

            if (dbValues.Name != clientValues.Name)
            {
                ModelState.AddModelError("Department.Name",
                    $"Current value: {dbValues.Name}");
            }
            if (dbValues.Budget != clientValues.Budget)
            {
                ModelState.AddModelError("Department.Budget",
                    $"Current value: {dbValues.Budget:c}");
            }
            if (dbValues.StartDate != clientValues.StartDate)
            {
                ModelState.AddModelError("Department.StartDate",
                    $"Current value: {dbValues.StartDate:d}");
```

```
            }
            if (dbValues.InstructorID != clientValues.InstructorID)
            {
                Instructor dbInstructor = await _context.Instructors
                   .FindAsync(dbValues.InstructorID);
                ModelState.AddModelError("Department.InstructorID",
                    $"Current value: {dbInstructor?.FullName}");
            }

            ModelState.AddModelError(string.Empty,
                "The record you attempted to edit "
              + "was modified by another user after you. The "
              + "edit operation was canceled and the current values in the database "
              + "have been displayed. If you still want to edit this record, click "
              + "the Save button again.");
        }
    }
}
```

To detect a concurrency issue, the OriginalValue is updated with the `rowVersion` value from the entity it was fetched. EF Core generates a SQL UPDATE command with a WHERE clause containing the original `RowVersion` value. If no rows are affected by the UPDATE command (no rows have the original `RowVersion` value), a `DbUpdateConcurrencyException` exception is thrown.

```
public async Task<IActionResult> OnPostAsync(int id)
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    var departmentToUpdate = await _context.Departments
        .Include(i => i.Administrator)
        .FirstOrDefaultAsync(m => m.DepartmentID == id);

    // null means Department was deleted by another user.
    if (departmentToUpdate == null)
    {
        return HandleDeletedDepartment();
    }

    // Update the RowVersion to the value when this entity was
    // fetched. If the entity has been updated after it was
    // fetched, RowVersion won't match the DB RowVersion and
    // a DbUpdateConcurrencyException is thrown.
    // A second postback will make them match, unless a new
    // concurrency issue happens.
    _context.Entry(departmentToUpdate)
        .Property("RowVersion").OriginalValue = Department.RowVersion;
```

In the preceding code, `Department.RowVersion` is the value when the entity was fetched. `OriginalValue` is the value in the DB when `FirstOrDefaultAsync` was called in this method.

The following code gets the client values (the values posted to this method) and the DB values:

```
try
{
    await _context.SaveChangesAsync();
    return RedirectToPage("./Index");
}
catch (DbUpdateConcurrencyException ex)
{
    var exceptionEntry = ex.Entries.Single();
    var clientValues = (Department)exceptionEntry.Entity;
    var databaseEntry = exceptionEntry.GetDatabaseValues();
    if (databaseEntry == null)
    {
        ModelState.AddModelError(string.Empty, "Unable to save. " +
            "The department was deleted by another user.");
        return Page();
    }

    var dbValues = (Department)databaseEntry.ToObject();
    await setDbErrorMessage(dbValues, clientValues, _context);

    // Save the current RowVersion so next postback
    // matches unless an new concurrency issue happens.
    Department.RowVersion = (byte[])dbValues.RowVersion;
    // Must clear the model error for the next postback.
    ModelState.Remove("Department.RowVersion");
}
```

The following code adds a custom error message for each column that has DB values different from what was posted to `OnPostAsync`:

```
private async Task setDbErrorMessage(Department dbValues,
        Department clientValues, SchoolContext context)
{

    if (dbValues.Name != clientValues.Name)
    {
        ModelState.AddModelError("Department.Name",
            $"Current value: {dbValues.Name}");
    }
    if (dbValues.Budget != clientValues.Budget)
    {
        ModelState.AddModelError("Department.Budget",
            $"Current value: {dbValues.Budget:c}");
    }
    if (dbValues.StartDate != clientValues.StartDate)
    {
        ModelState.AddModelError("Department.StartDate",
            $"Current value: {dbValues.StartDate:d}");
    }
    if (dbValues.InstructorID != clientValues.InstructorID)
    {
        Instructor dbInstructor = await _context.Instructors
           .FindAsync(dbValues.InstructorID);
        ModelState.AddModelError("Department.InstructorID",
            $"Current value: {dbInstructor?.FullName}");
    }

    ModelState.AddModelError(string.Empty,
        "The record you attempted to edit "
      + "was modified by another user after you. The "
      + "edit operation was canceled and the current values in the database "
      + "have been displayed. If you still want to edit this record, click "
      + "the Save button again.");
}
```

The following highlighted code sets the `RowVersion` value to the new value retrieved from the DB. The next time the user clicks **Save**, only concurrency errors that happen since the last display of the Edit page will be caught.

```
try
{
    await _context.SaveChangesAsync();
    return RedirectToPage("./Index");
}
catch (DbUpdateConcurrencyException ex)
{
    var exceptionEntry = ex.Entries.Single();
    var clientValues = (Department)exceptionEntry.Entity;
    var databaseEntry = exceptionEntry.GetDatabaseValues();
    if (databaseEntry == null)
    {
        ModelState.AddModelError(string.Empty, "Unable to save. " +
            "The department was deleted by another user.");
        return Page();
    }

    var dbValues = (Department)databaseEntry.ToObject();
    await setDbErrorMessage(dbValues, clientValues, _context);

    // Save the current RowVersion so next postback
    // matches unless an new concurrency issue happens.
    Department.RowVersion = (byte[])dbValues.RowVersion;
    // Must clear the model error for the next postback.
    ModelState.Remove("Department.RowVersion");
}
```

The `ModelState.Remove` statement is required because `ModelState` has the old `RowVersion` value. In the Razor Page, the `ModelState` value for a field takes precedence over the model property values when both are present.

Update the Edit page

Update *Pages/Departments/Edit.cshtml* with the following markup:

```
@page "{id:int}"
@model ContosoUniversity.Pages.Departments.EditModel
@{
    ViewData["Title"] = "Edit";
}
<h2>Edit</h2>
<h4>Department</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Department.DepartmentID" />
            <input type="hidden" asp-for="Department.RowVersion" />
            <div class="form-group">
                <label>RowVersion</label>
                @Model.Department.RowVersion[7]
            </div>
            <div class="form-group">
                <label asp-for="Department.Name" class="control-label"></label>
                <input asp-for="Department.Name" class="form-control" />
                <span asp-validation-for="Department.Name" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Department.Budget" class="control-label"></label>
                <input asp-for="Department.Budget" class="form-control" />
                <span asp-validation-for="Department.Budget" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Department.StartDate" class="control-label"></label>
                <input asp-for="Department.StartDate" class="form-control" />
                <span asp-validation-for="Department.StartDate" class="text-danger">
                </span>
            </div>
            <div class="form-group">
                <label class="control-label">Instructor</label>
                <select asp-for="Department.InstructorID" class="form-control"
                        asp-items="@Model.InstructorNameSL"></select>
                <span asp-validation-for="Department.InstructorID" class="text-danger">
                </span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>
<div>
    <a asp-page="./Index">Back to List</a>
</div>
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding markup:

- Updates the `page` directive from `@page` to `@page "{id:int}"`.
- Adds a hidden row version. `RowVersion` must be added so post back binds the value.
- Displays the last byte of `RowVersion` for debugging purposes.
- Replaces `ViewData` with the strongly-typed `InstructorNameSL`.

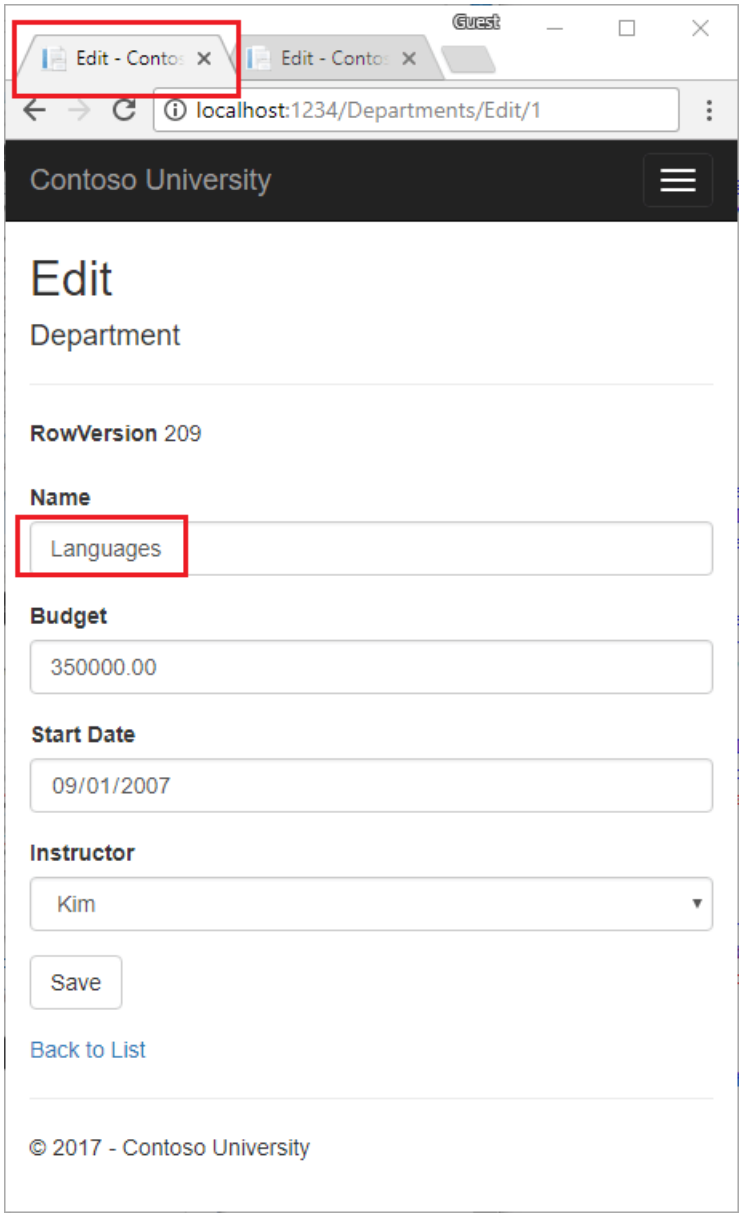
Test concurrency conflicts with the Edit page

Open two browsers instances of Edit on the English department:

- Run the app and select Departments.
- Right-click the **Edit** hyperlink for the English department and select **Open in new tab**.
- In the first tab, click the **Edit** hyperlink for the English department.

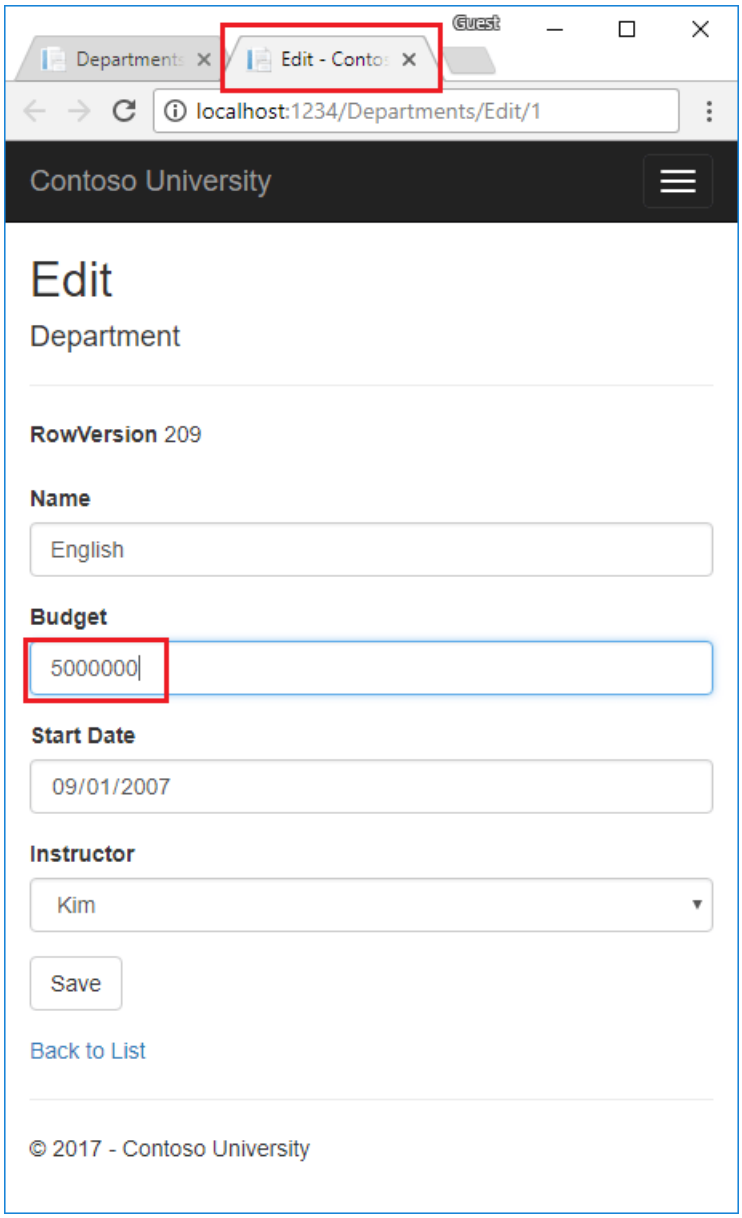
The two browser tabs display the same information.

Change the name in the first browser tab and click **Save**.

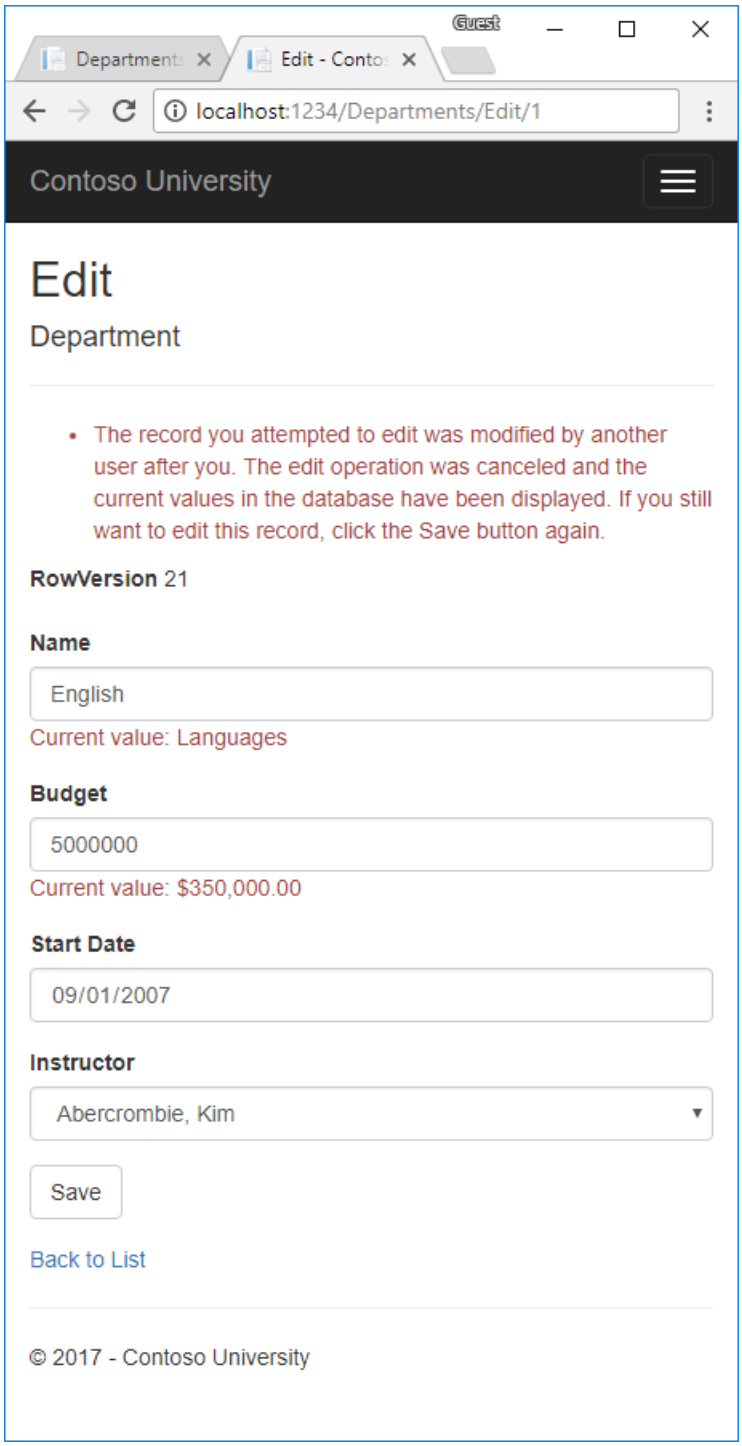


The browser shows the Index page with the changed value and updated rowVersion indicator. Note the updated rowVersion indicator, it's displayed on the second postback in the other tab.

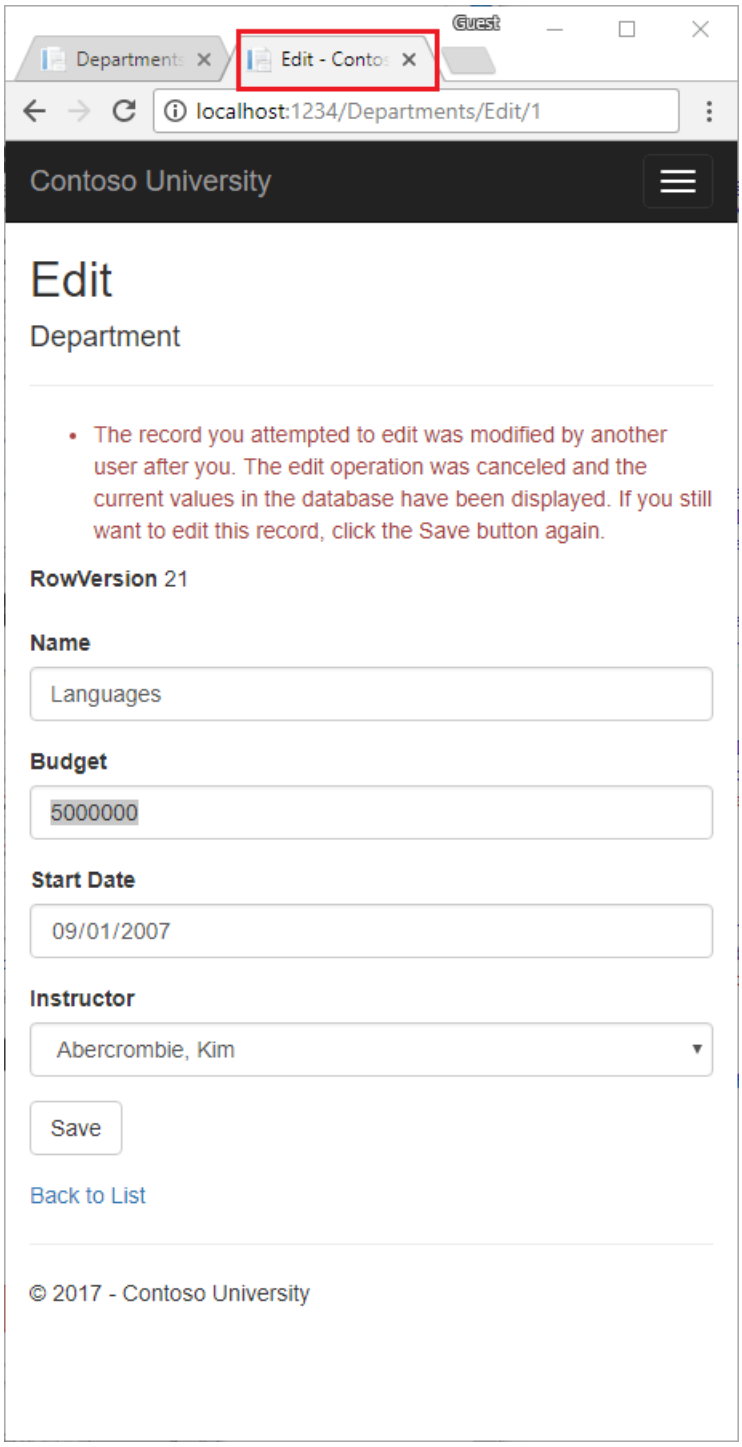
Change a different field in the second browser tab.



Click **Save**. You see error messages for all fields that don't match the DB values:



This browser window didn't intend to change the Name field. Copy and paste the current value (Languages) into the Name field. Tab out. Client-side validation removes the error message.



Click **Save** again. The value you entered in the second browser tab is saved. You see the saved values in the Index page.

Update the Delete page

Update the Delete page model with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Departments
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;
```

```
        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Department Department { get; set; }
        public string ConcurrencyErrorMessage { get; set; }

        public async Task<IActionResult> OnGetAsync(int id, bool? concurrencyError)
        {
            Department = await _context.Departments
                .Include(d => d.Administrator)
                .AsNoTracking()
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (Department == null)
            {
                 return NotFound();
            }

            if (concurrencyError.GetValueOrDefault())
            {
                ConcurrencyErrorMessage = "The record you attempted to delete "
                  + "was modified by another user after you selected delete. "
                  + "The delete operation was canceled and the current values in the "
                  + "database have been displayed. If you still want to delete this "
                  + "record, click the Delete button again.";
            }
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int id)
        {
            try
            {
                if (await _context.Departments.AnyAsync(
                    m => m.DepartmentID == id))
                {
                    // Department.rowVersion value is from when the entity
                    // was fetched. If it doesn't match the DB, a
                    // DbUpdateConcurrencyException exception is thrown.
                    _context.Departments.Remove(Department);
                    await _context.SaveChangesAsync();
                }
                return RedirectToPage("./Index");
            }
            catch (DbUpdateConcurrencyException)
            {
                return RedirectToPage("./Delete",
                    new { concurrencyError = true, id = id });
            }
        }
    }
}
```

The Delete page detects concurrency conflicts when the entity has changed after it was fetched. `Department.RowVersion` is the row version when the entity was fetched. When EF Core creates the SQL DELETE command, it includes a WHERE clause with `RowVersion`. If the SQL DELETE command results in zero rows affected:

- The `RowVersion` in the SQL DELETE command doesn't match `RowVersion` in the DB.
- A DbUpdateConcurrencyException exception is thrown.
- `OnGetAsync` is called with the `concurrencyError`.

Update the Delete page

Update *Pages/Departments/Delete.cshtml* with the following code:

```
@page "{id:int}"
@model ContosoUniversity.Pages.Departments.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

<p class="text-danger">@Model.ConcurrencyErrorMessage</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Department</h4>
    <hr />
    <dl class="dl-horizontal">
        <dt>
            @Html.DisplayNameFor(model => model.Department.Name)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.Name)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.Budget)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.Budget)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.StartDate)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.StartDate)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.RowVersion)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.RowVersion[7])
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.Administrator)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.Administrator.FullName)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Department.DepartmentID" />
        <input type="hidden" asp-for="Department.RowVersion" />
        <div class="form-actions no-color">
            <input type="submit" value="Delete" class="btn btn-default" /> |
            <a asp-page="./Index">Back to List</a>
        </div>
</form>
</div>
```

The preceding code makes the following changes:

- Updates the `page` directive from `@page` to `@page "{id:int}"`.
- Adds an error message.

- Replaces FirstMidName with FullName in the **Administrator** field.
- Changes `RowVersion` to display the last byte.
- Adds a hidden row version. `RowVersion` must be added so post back binds the value.

Test concurrency conflicts with the Delete page

Create a test department.

Open two browsers instances of Delete on the test department:

- Run the app and select Departments.
- Right-click the **Delete** hyperlink for the test department and select **Open in new tab**.
- Click the **Edit** hyperlink for the test department.

The two browser tabs display the same information.

Change the budget in the first browser tab and click **Save**.

The browser shows the Index page with the changed value and updated rowVersion indicator. Note the updated rowVersion indicator, it's displayed on the second postback in the other tab.

Delete the test department from the second tab. A concurrency error is display with the current values from the DB. Clicking **Delete** deletes the entity, unless `RowVersion` has been updated.

See Inheritance on how to inherit a data model.

ASP.NET Core MVC with EF Core - tutorial series

9/22/2020 • 2 minutes to read • Edit Online

This tutorial has **not** been updated to ASP.NET Core 3.0. The Razor Pages version has been updated. For information on when this might be updated, see this GitHub issue.

This tutorial teaches ASP.NET Core MVC and Entity Framework Core with controllers and views. Razor Pages is an alternative programming model that was introduced in ASP.NET Core 2.0. For new development, we recommend Razor Pages over MVC with controllers and views. There is a Razor Pages version of this tutorial. Each tutorial covers some material the other doesn't:

Some things this MVC tutorial has that the Razor Pages tutorial doesn't:

- Implement inheritance in the data model
- Perform raw SQL queries
- Use dynamic LINQ to simplify code

Some things the Razor Pages tutorial has that this one doesn't:

- Use Select method to load related data
- A version available for ASP.NET Core 3.0

1. Get started
2. Create, Read, Update, and Delete operations
3. Sorting, filtering, paging, and grouping
4. Migrations
5. Create a complex data model
6. Reading related data
7. Updating related data
8. Handle concurrency conflicts
9. Inheritance
10. Advanced topics

Tutorial: Get started with EF Core in an ASP.NET MVC web app

9/22/2020 • 21 minutes to read • Edit Online

This tutorial has **not** been updated to ASP.NET Core 3.0. The Razor Pages version has been updated. Most of the code changes for the ASP.NET Core 3.0 and later version of this tutorial:

- Are in the *Startup.cs* and *Program.cs* files.
- Can be found in the Razor Pages version.

For information on when this might be updated, see this GitHub issue.

This tutorial teaches ASP.NET Core MVC and Entity Framework Core with controllers and views. Razor Pages is an alternative programming model that was introduced in ASP.NET Core 2.0. For new development, we recommend Razor Pages over MVC with controllers and views. There is a Razor Pages version of this tutorial. Each tutorial covers some material the other doesn't:

Some things this MVC tutorial has that the Razor Pages tutorial doesn't:

- Implement inheritance in the data model
- Perform raw SQL queries
- Use dynamic LINQ to simplify code

Some things the Razor Pages tutorial has that this one doesn't:

The Contoso University sample web application demonstrates how to create ASP.NET Core 2.2 MVC web applications using Entity Framework (EF) Core 2.2 and Visual Studio 2017 or 2019.

The sample application is a web site for a fictional Contoso University. It includes functionality such as student admission, course creation, and instructor assignments. This is the first in a series of tutorials that explain how to build the Contoso University sample application from scratch.

In this tutorial, you:

- Create an ASP.NET Core MVC web app
- Set up the site style
- Learn about EF Core NuGet packages
- Create the data model
- Create the database context
- Register the context for dependency injection
- Initialize the database with test data
- Create a controller and views
- View the database

Prerequisites

- .NET Core SDK 2.2
- Visual Studio 2019 with the following workloads:

- **ASP.NET and web development** workload
- **.NET Core cross-platform development** workload

Troubleshooting

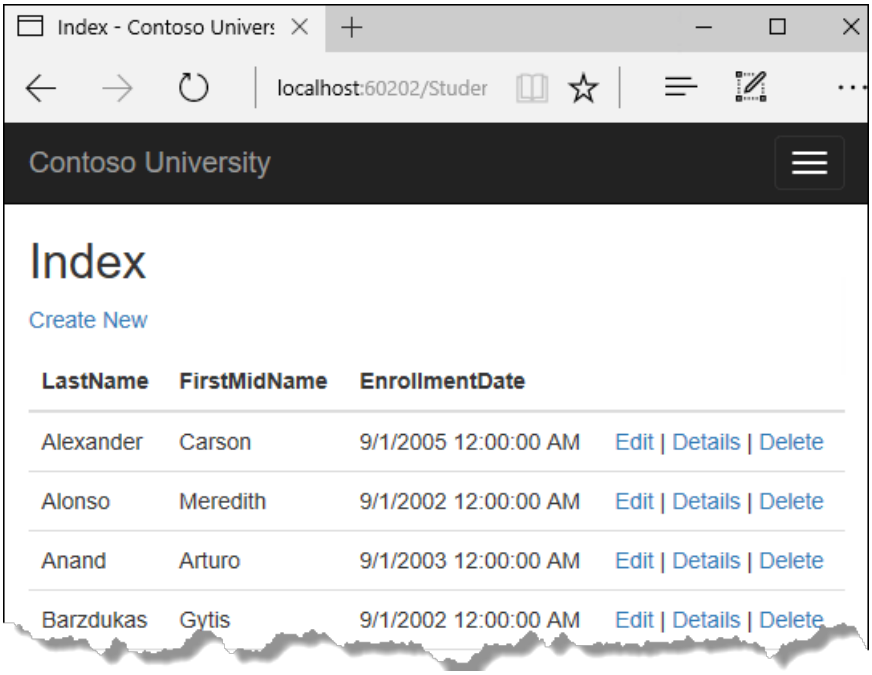
If you run into a problem you can't resolve, you can generally find the solution by comparing your code to the completed project. For a list of common errors and how to solve them, see the Troubleshooting section of the last tutorial in the series. If you don't find what you need there, you can post a question to StackOverflow.com for ASP.NET Core or EF Core.

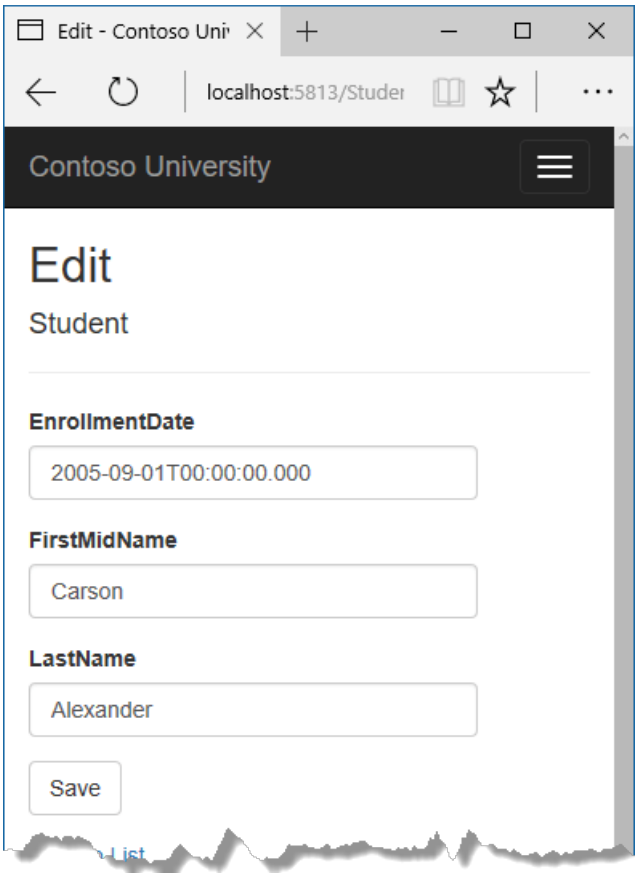
> **TIP**
> This is a series of 10 tutorials, each of which builds on what is done in earlier tutorials. Consider saving a copy of the project after each successful tutorial completion. Then if you run into problems, you can start over from the previous tutorial instead of going back to the beginning of the whole series.

Contoso University web app

The application you'll be building in these tutorials is a simple university web site.

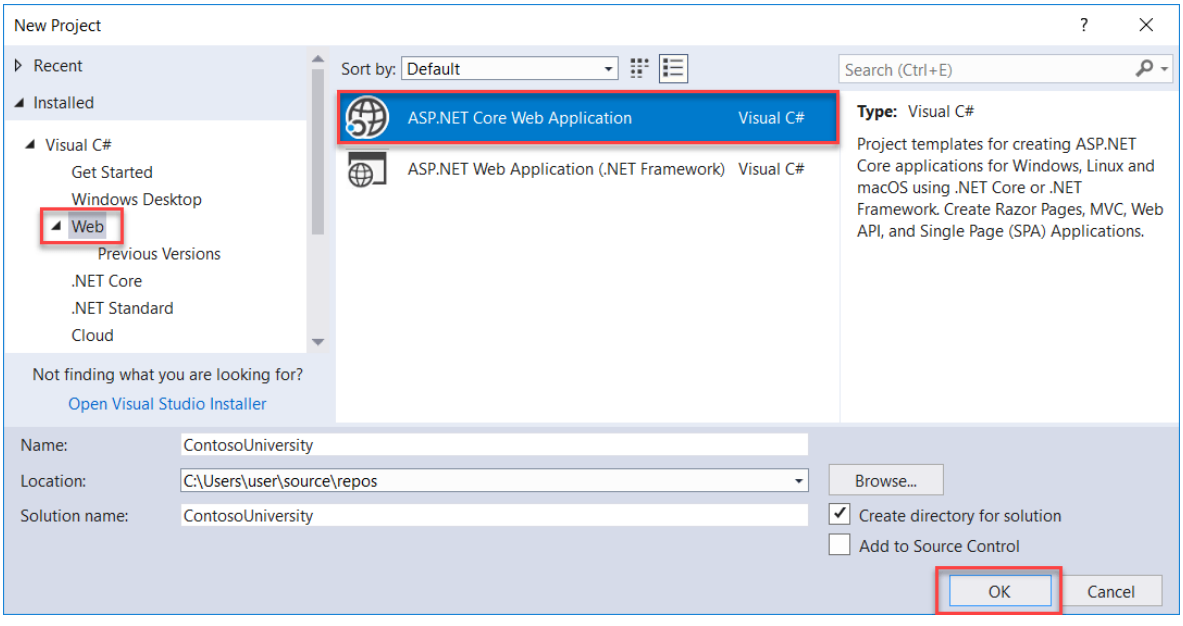
Users can view and update student, course, and instructor information. Here are a few of the screens you'll create.





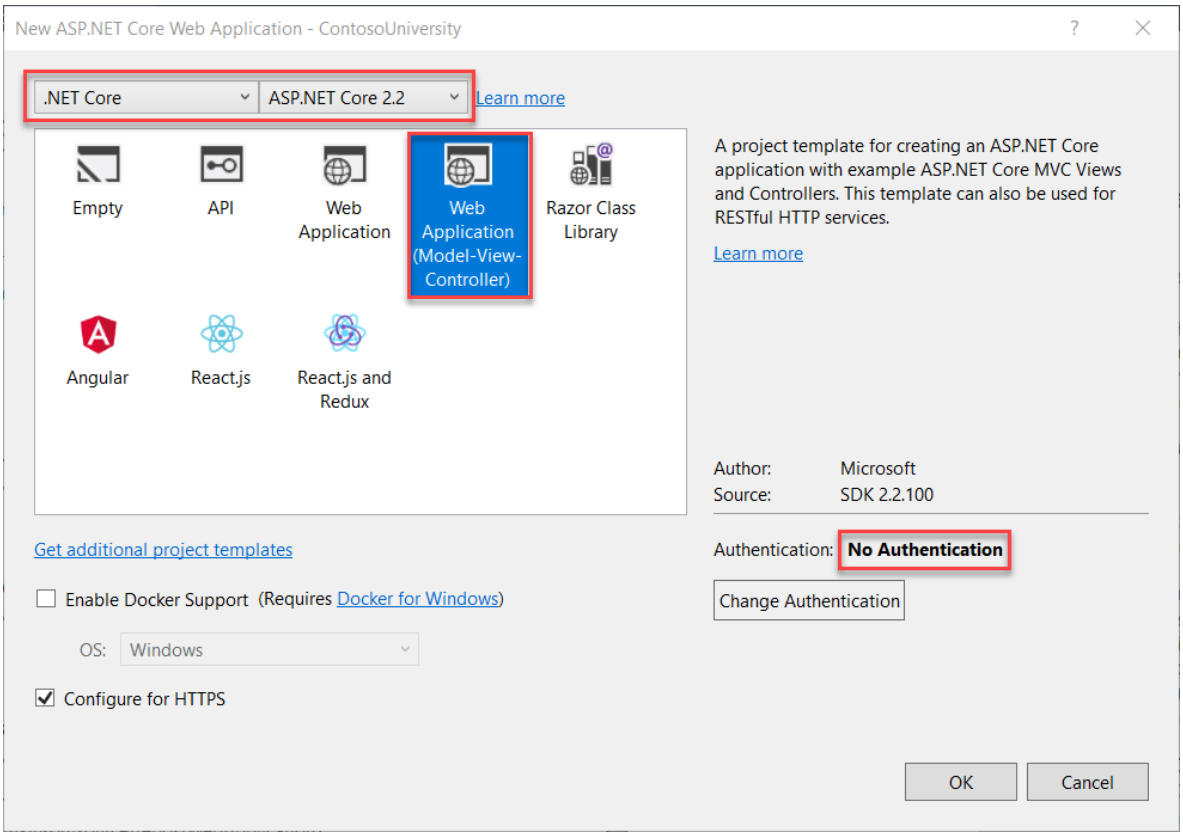
Create web app

- Open Visual Studio.
- From the **File** menu, select **New > Project**.
- From the left pane, select **Installed > Visual C# > Web**.
- Select the **ASP.NET Core Web Application** project template.
- Enter **ContosoUniversity** as the name and click **OK**.



- Wait for the **New ASP.NET Core Web Application** dialog to appear.
- Select **.NET Core**, **ASP.NET Core 2.2** and the **Web Application (Model-View-Controller)** template.

- Make sure **Authentication** is set to **No Authentication**.
- Select **OK**



Set up the site style

A few simple changes will set up the site menu, layout, and home page.

Open *Views/Shared/_Layout.cshtml* and make the following changes:

- Change each occurrence of "ContosoUniversity" to "Contoso University". There are three occurrences.
- Add menu entries for **About**, **Students**, **Courses**, **Instructors**, and **Departments**, and delete the **Privacy** menu entry.

The changes are highlighted.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Contoso University</title>

    <environment include="Development">
        <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />

    </environment>
    <script src="~/js/site.js" asp-append-version="true"></script>

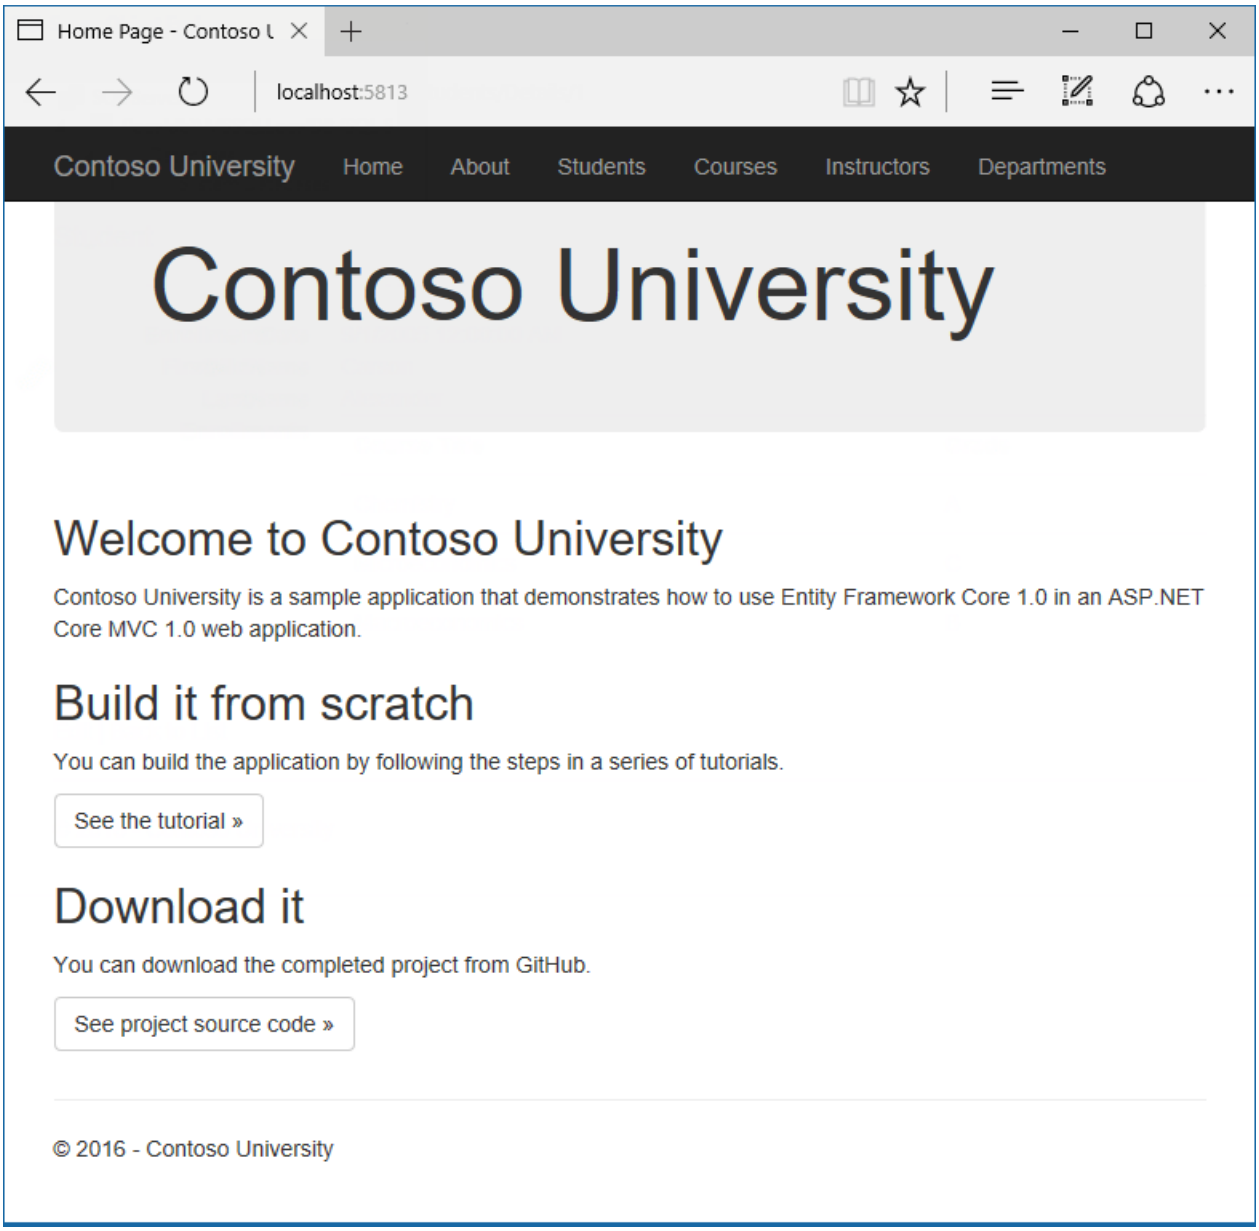
    @RenderSection("Scripts", required: false)
</body>
</html>
```

In *Views/Home/Index.cshtml*, replace the contents of the file with the following code to replace the text about ASP.NET and MVC with text about this application:

```
@{
    ViewData["Title"] = "Home Page";
}

<div class="jumbotron">
    <h1>Contoso University</h1>
</div>
<div class="row">
    <div class="col-md-4">
        <h2>Welcome to Contoso University</h2>
        <p>
            Contoso University is a sample application that
            demonstrates how to use Entity Framework Core in an
            ASP.NET Core MVC web application.
        </p>
    </div>
    <div class="col-md-4">
        <h2>Build it from scratch</h2>
        <p>You can build the application by following the steps in a series of tutorials.</p>
        <p><a class="btn btn-default" href="https://docs.asp.net/en/latest/data/ef-mvc/intro.html">See the
tutorial &raquo;</a></p>
    </div>
    <div class="col-md-4">
        <h2>Download it</h2>
        <p>You can download the completed project from GitHub.</p>
        <p><a class="btn btn-default"
href="https://github.com/dotnet/AspNetCore.Docs/tree/master/aspnetcore/data/ef-mvc/intro/samples/cu-
final">See project source code &raquo;</a></p>
    </div>
</div>
```

Press CTRL+F5 to run the project or choose **Debug > Start Without Debugging** from the menu. You see the home page with tabs for the pages you'll create in these tutorials.



About EF Core NuGet packages

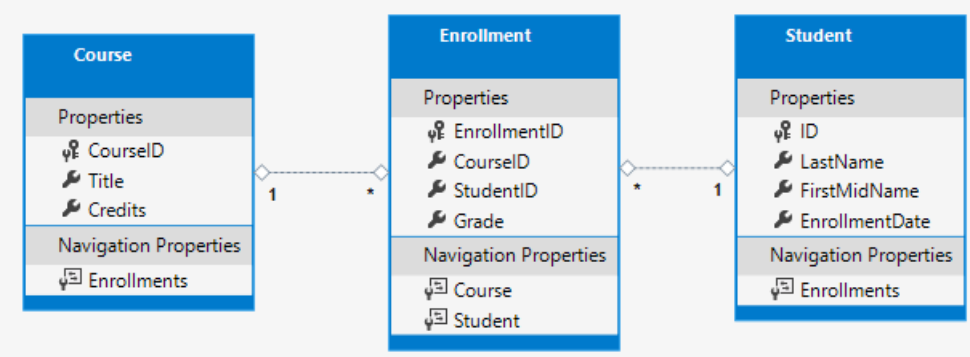
To add EF Core support to a project, install the database provider that you want to target. This tutorial uses SQL Server, and the provider package is Microsoft.EntityFrameworkCore.SqlServer. This package is included in the Microsoft.AspNetCore.App metapackage, so you don't need to reference the package.

The EF SQL Server package and its dependencies (`Microsoft.EntityFrameworkCore` and `Microsoft.EntityFrameworkCore.Relational`) provide runtime support for EF. You'll add a tooling package later, in the Migrations tutorial.

For information about other database providers that are available for Entity Framework Core, see Database providers.

Create the data model

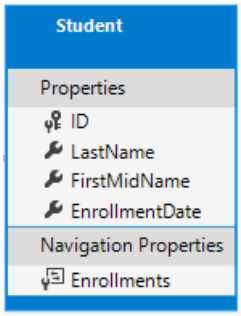
Next you'll create entity classes for the Contoso University application. You'll start with the following three entities.



There's a one-to-many relationship between `Student` and `Enrollment` entities, and there's a one-to-many relationship between `Course` and `Enrollment` entities. In other words, a student can be enrolled in any number of courses, and a course can have any number of students enrolled in it.

In the following sections you'll create a class for each one of these entities.

The Student entity



In the *Models* folder, create a class file named *Student.cs* and replace the template code with the following code.

```
using System;
using System.Collections.Generic;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }

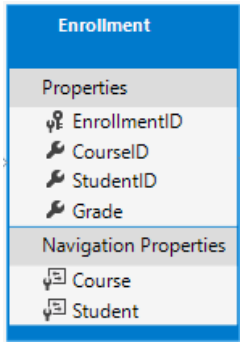
        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `ID` property will become the primary key column of the database table that corresponds to this class. By default, the Entity Framework interprets a property that's named `ID` or `classnameID` as the primary key.

The `Enrollments` property is a navigation property. Navigation properties hold other entities that are related to this entity. In this case, the `Enrollments` property of a `Student entity` will hold all of the `Enrollment` entities that are related to that `Student` entity. In other words, if a given Student row in the database has two related Enrollment rows (rows that contain that student's primary key value in their StudentID foreign key column), that `Student` entity's `Enrollments` navigation property will contain those two `Enrollment` entities.

If a navigation property can hold multiple entities (as in many-to-many or one-to-many relationships), its type must be a list in which entries can be added, deleted, and updated, such as `ICollection<T>`. You can specify `ICollection<T>` or a type such as `List<T>` or `HashSet<T>`. If you specify `ICollection<T>`, EF creates a `HashSet<T>` collection by default.

The Enrollment entity



In the *Models* folder, create *Enrollment.cs* and replace the existing code with the following code:

```
namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

The `EnrollmentID` property will be the primary key; this entity uses the `classnameID` pattern instead of `ID` by itself as you saw in the `Student` entity. Ordinarily you would choose one pattern and use it throughout your data model. Here, the variation illustrates that you can use either pattern. In a later tutorial, you'll see how using ID without classname makes it easier to implement inheritance in the data model.

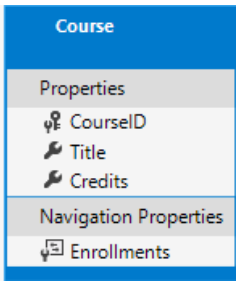
The `Grade` property is an `enum`. The question mark after the `Grade` type declaration indicates that the `Grade` property is nullable. A grade that's null is different from a zero grade -- null means a grade isn't known or hasn't been assigned yet.

The `StudentID` property is a foreign key, and the corresponding navigation property is `Student`. An `Enrollment` entity is associated with one `Student` entity, so the property can only hold a single `Student` entity (unlike the `Student.Enrollments` navigation property you saw earlier, which can hold multiple `Enrollment` entities).

The `CourseID` property is a foreign key, and the corresponding navigation property is `Course`. An `Enrollment` entity is associated with one `Course` entity.

Entity Framework interprets a property as a foreign key property if it's named `<navigation property name><primary key property name>` (for example, `StudentID` for the `Student` navigation property since the `Student` entity's primary key is `ID`). Foreign key properties can also be named simply `<primary key property name>` (for example, `CourseID` since the `Course` entity's primary key is `CourseID`).

The Course entity



In the *Models* folder, create *Course.cs* and replace the existing code with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        public int CourseID { get; set; }
        public string Title { get; set; }
        public int Credits { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `Enrollments` property is a navigation property. A `Course` entity can be related to any number of `Enrollment` entities.

We'll say more about the `DatabaseGenerated` attribute in a later tutorial in this series. Basically, this attribute lets you enter the primary key for the course rather than having the database generate it.

Create the database context

The main class that coordinates Entity Framework functionality for a given data model is the database context class. You create this class by deriving from the `Microsoft.EntityFrameworkCore.DbContext` class. In your code you specify which entities are included in the data model. You can also customize certain Entity Framework behavior. In this project, the class is named `SchoolContext`.

In the project folder, create a folder named *Data*.

In the *Data* folder create a new class file named *SchoolContext.cs*, and replace the template code with the following code:

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) : base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
    }
}
```

This code creates a `DbSet` property for each entity set. In Entity Framework terminology, an entity set typically corresponds to a database table, and an entity corresponds to a row in the table.

You could've omitted the `DbSet<Enrollment>` and `DbSet<Course>` statements and it would work the same. The Entity Framework would include them implicitly because the `Student` entity references the `Enrollment` entity and the `Enrollment` entity references the `Course` entity.

When the database is created, EF creates tables that have names the same as the `DbSet` property names. Property names for collections are typically plural (Students rather than Student), but developers disagree about whether table names should be pluralized or not. For these tutorials you'll override the default behavior by specifying singular table names in the DbContext. To do that, add the following highlighted code after the last DbSet property.

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) : base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
        }
    }
}
```

Register the SchoolContext

ASP.NET Core implements dependency injection by default. Services (such as the EF database context) are registered with dependency injection during application startup. Components that require these services (such as MVC controllers) are provided these services via constructor parameters. You'll see the controller constructor code that gets a context instance later in this tutorial.

To register `SchoolContext` as a service, open *Startup.cs*, and add the highlighted lines to the `ConfigureServices` method.

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddDbContext<SchoolContext>(options =>
        options.UseSqlServer(Configuration.GetConnectionString("DefaultConnection")));

    services.AddMvc();
}
```

The name of the connection string is passed in to the context by calling a method on a `DbContextOptionsBuilder` object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Add `using` statements for `ContosoUniversity.Data` and `Microsoft.EntityFrameworkCore` namespaces, and then build the project.

```
using ContosoUniversity.Data;
using Microsoft.EntityFrameworkCore;
using Microsoft.AspNetCore.Http;
```

Open the *appsettings.json* file and add a connection string as shown in the following example.

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=
(localdb)\\mssqllocaldb;Database=ContosoUniversity1;Trusted_Connection=True;MultipleActiveResultSets=true"
  },
  "Logging": {
    "IncludeScopes": false,
    "LogLevel": {
      "Default": "Warning"
    }
  }
}
```

SQL Server Express LocalDB

The connection string specifies a SQL Server LocalDB database. LocalDB is a lightweight version of the SQL Server Express Database Engine and is intended for application development, not production use. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB creates *.mdf* database files in the `C:/Users/<user>` directory.

Initialize DB with test data

The Entity Framework will create an empty database for you. In this section, you write a method that's called after the database is created in order to populate it with test data.

Here you'll use the `EnsureCreated` method to automatically create the database. In a later tutorial you'll see how to handle model changes by using Code First Migrations to change the database schema instead of dropping and re-creating the database.

In the *Data* folder, create a new class file named *DbInitializer.cs* and replace the template code with the following code, which causes a database to be created when needed and loads test data into the new database.

```
using ContosoUniversity.Models;
using System;
using System.Linq;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            context.Database.EnsureCreated();

            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
            new Student{FirstMidName="Carson",LastName="Alexander",EnrollmentDate=DateTime.Parse("2005-09-
01")},
            new Student{FirstMidName="Meredith",LastName="Alonso",EnrollmentDate=DateTime.Parse("2002-09-
01")},
            new Student{FirstMidName="Arturo",LastName="Anand",EnrollmentDate=DateTime.Parse("2003-09-01")},
            new Student{FirstMidName="Gytis",LastName="Barzdukas",EnrollmentDate=DateTime.Parse("2002-09-
01")},
            new Student{FirstMidName="Yan",LastName="Li",EnrollmentDate=DateTime.Parse("2002-09-01")},
            new Student{FirstMidName="Peggy",LastName="Justice",EnrollmentDate=DateTime.Parse("2001-09-01")},
            new Student{FirstMidName="Laura",LastName="Norman",EnrollmentDate=DateTime.Parse("2003-09-01")},
            new Student{FirstMidName="Nino",LastName="Olivetto",EnrollmentDate=DateTime.Parse("2005-09-01")}
            };
            foreach (Student s in students)
            {
                context.Students.Add(s);
            }
            context.SaveChanges();

            var courses = new Course[]
            {
            new Course{CourseID=1050,Title="Chemistry",Credits=3},
            new Course{CourseID=4022,Title="Microeconomics",Credits=3},
            new Course{CourseID=4041,Title="Macroeconomics",Credits=3},
            new Course{CourseID=1045,Title="Calculus",Credits=4},
            new Course{CourseID=3141,Title="Trigonometry",Credits=4},
            new Course{CourseID=2021,Title="Composition",Credits=3},
            new Course{CourseID=2042,Title="Literature",Credits=4}
            };
            foreach (Course c in courses)
            {
                context.Courses.Add(c);
            }
            context.SaveChanges();

            var enrollments = new Enrollment[]
            {
            new Enrollment{StudentID=1,CourseID=1050,Grade=Grade.A},
            new Enrollment{StudentID=1,CourseID=4022,Grade=Grade.C},
            new Enrollment{StudentID=1,CourseID=4041,Grade=Grade.B},
            new Enrollment{StudentID=2,CourseID=1045,Grade=Grade.B},
            new Enrollment{StudentID=2,CourseID=3141,Grade=Grade.F},
            new Enrollment{StudentID=2,CourseID=2021,Grade=Grade.F},
            new Enrollment{StudentID=3,CourseID=1050},
            new Enrollment{StudentID=4,CourseID=1050},
            new Enrollment{StudentID=4,CourseID=4022,Grade=Grade.F},
```

```
            new Enrollment{StudentID=4,CourseID=4022,Grade=Grade.F},
            new Enrollment{StudentID=5,CourseID=4041,Grade=Grade.C},
            new Enrollment{StudentID=6,CourseID=1045},
            new Enrollment{StudentID=7,CourseID=3141,Grade=Grade.A},
            };
            foreach (Enrollment e in enrollments)
            {
                context.Enrollments.Add(e);
            }
            context.SaveChanges();
        }
    }
}
```

The code checks if there are any students in the database, and if not, it assumes the database is new and needs to be seeded with test data. It loads test data into arrays rather than `List<T>` collections to optimize performance.

In *Program.cs*, modify the `Main` method to do the following on application startup:

- Get a database context instance from the dependency injection container.
- Call the seed method, passing to it the context.
- Dispose the context when the seed method is done.

```
public static void Main(string[] args)
{
     var host = CreateWebHostBuilder(args).Build();

    using (var scope = host.Services.CreateScope())
    {
        var services = scope.ServiceProvider;
        try
        {
            var context = services.GetRequiredService<SchoolContext>();
            DbInitializer.Initialize(context);
        }
        catch (Exception ex)
        {
            var logger = services.GetRequiredService<ILogger<Program>>();
            logger.LogError(ex, "An error occurred while seeding the database.");
        }
    }

    host.Run();
}
```

Add `using` statements:

```
using Microsoft.Extensions.DependencyInjection;
using ContosoUniversity.Data;
```

In older tutorials, you may see similar code in the `Configure` method in *Startup.cs*. We recommend that you use the `Configure` method only to set up the request pipeline. Application startup code belongs in the `Main` method.

Now the first time you run the application, the database will be created and seeded with test data. Whenever you change your data model, you can delete the database, update your seed method, and start afresh with a new database the same way. In later tutorials, you'll see how to modify the database when the data model changes, without deleting and re-creating it.

Create controller and views

Next, you'll use the scaffolding engine in Visual Studio to add an MVC controller and views that will use EF to query and save data.

The automatic creation of CRUD action methods and views is known as scaffolding. Scaffolding differs from code generation in that the scaffolded code is a starting point that you can modify to suit your own requirements, whereas you typically don't modify generated code. When you need to customize generated code, you use partial classes or you regenerate the code when things change.

- Right-click the **Controllers** folder in **Solution Explorer** and select **Add > New Scaffolded Item**.
- In the **Add Scaffold** dialog box:
  - Select **MVC controller with views, using Entity Framework**.
  - Click **Add**. The **Add MVC Controller with views, using Entity Framework** dialog box appears.

  - In **Model class** select **Student**.
  - In **Data context class** select **SchoolContext**.
  - Accept the default **StudentsController** as the name.
  - Click **Add**.

  When you click **Add**, the Visual Studio scaffolding engine creates a *StudentsController.cs* file and a set of views (*.cshtml* files) that work with the controller.

(The scaffolding engine can also create the database context for you if you don't create it manually first as you did earlier for this tutorial. You can specify a new context class in the **Add Controller** box by clicking the plus sign to the right of **Data context class**. Visual Studio will then create your `DbContext` class as well as the controller and views.)

You'll notice that the controller takes a `SchoolContext` as a constructor parameter.

```
namespace ContosoUniversity.Controllers
{
    public class StudentsController : Controller
    {
        private readonly SchoolContext _context;

        public StudentsController(SchoolContext context)
        {
            _context = context;
        }
```

ASP.NET Core dependency injection takes care of passing an instance of `SchoolContext` into the controller. You configured that in the *Startup.cs* file earlier.

The controller contains an `Index` action method, which displays all students in the database. The method gets a list of students from the Students entity set by reading the `Students` property of the database context instance:

```
public async Task<IActionResult> Index()
{
    return View(await _context.Students.ToListAsync());
}
```

You'll learn about the asynchronous programming elements in this code later in the tutorial.

The *Views/Students/Index.cshtml* view displays this list in a table:

```
@model IEnumerable<ContosoUniversity.Models.Student>

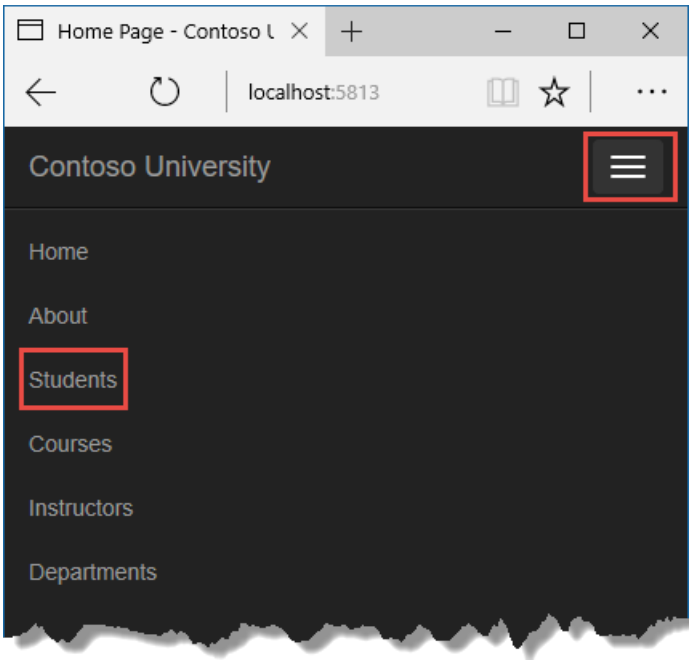
@{
    ViewData["Title"] = "Index";
}

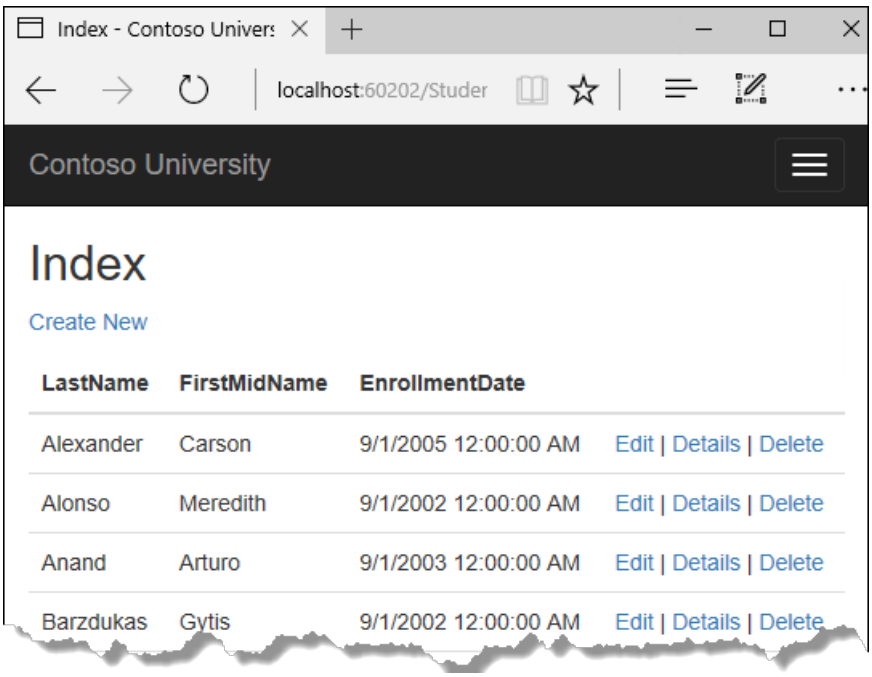
<h2>Index</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
                <th>
                    @Html.DisplayNameFor(model => model.LastName)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.FirstMidName)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.EnrollmentDate)
                </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.LastName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.FirstMidName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-action="Details" asp-route-id="@item.ID">Details</a> |
                <a asp-action="Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Press CTRL+F5 to run the project or choose **Debug > Start Without Debugging** from the menu.

Click the Students tab to see the test data that the `DbInitializer.Initialize` method inserted. Depending on how narrow your browser window is, you'll see the `Students` tab link at the top of the page or you'll have to click the navigation icon in the upper right corner to see the link.





View the database

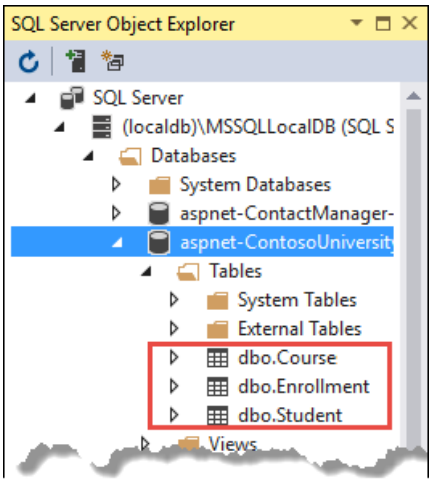
When you started the application, the `DbInitializer.Initialize` method calls `EnsureCreated`. EF saw that there was no database and so it created one, then the remainder of the `Initialize` method code populated the database with data. You can use **SQL Server Object Explorer** (SSOX) to view the database in Visual Studio.

Close the browser.

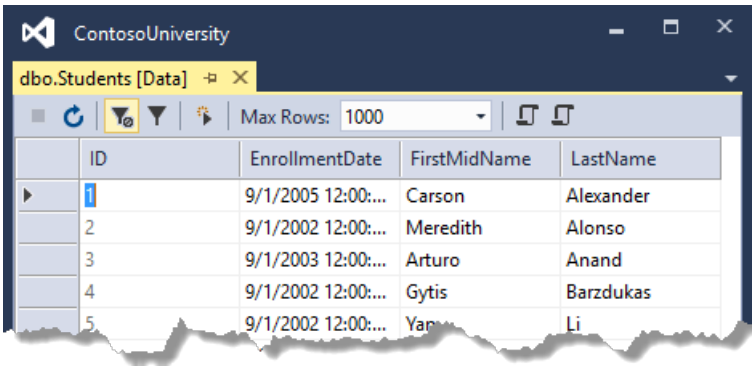
If the SSOX window isn't already open, select it from the **View** menu in Visual Studio.

In SSOX, click **(localdb)\MSSQLLocalDB > Databases**, and then click the entry for the database name that's in the connection string in your *appsettings.json* file.

Expand the **Tables** node to see the tables in your database.



Right-click the **Student** table and click **View Data** to see the columns that were created and the rows that were inserted into the table.



The *.mdf* and *.ldf* database files are in the *C:\Users\<yourusername>* folder.

Because you're calling `EnsureCreated` in the initializer method that runs on app start, you could now make a change to the `Student` class, delete the database, run the application again, and the database would automatically be re-created to match your change. For example, if you add an `EmailAddress` property to the `Student` class, you'll see a new `EmailAddress` column in the re-created table.

Conventions

The amount of code you had to write in order for the Entity Framework to be able to create a complete database for you is minimal because of the use of conventions, or assumptions that the Entity Framework makes.

- The names of `DbSet` properties are used as table names. For entities not referenced by a `DbSet` property, entity class names are used as table names.
- Entity property names are used for column names.
- Entity properties that are named ID or classnameID are recognized as primary key properties.
- A property is interpreted as a foreign key property if it's named *<navigation property name><primary key property name>* (for example, `StudentID` for the `Student` navigation property since the `Student` entity's primary key is `ID`). Foreign key properties can also be named simply *<primary key property name>* (for example, `EnrollmentID` since the `Enrollment` entity's primary key is `EnrollmentID`).

Conventional behavior can be overridden. For example, you can explicitly specify table names, as you saw earlier in this tutorial. And you can set column names and set any property as primary key or foreign key, as you'll see in a later tutorial in this series.

Asynchronous code

Asynchronous programming is the default mode for ASP.NET Core and EF Core.

A web server has a limited number of threads available, and in high load situations all of the available threads might be in use. When that happens, the server can't process new requests until the threads are freed up. With synchronous code, many threads may be tied up while they aren't actually doing any work because they're waiting for I/O to complete. With asynchronous code, when a process is waiting for I/O to complete, its thread is freed up for the server to use for processing other requests. As a result, asynchronous code enables server resources to be used more efficiently, and the server is enabled to handle more traffic without delays.

Asynchronous code does introduce a small amount of overhead at run time, but for low traffic situations the performance hit is negligible, while for high traffic situations, the potential performance improvement is substantial.

In the following code, the `async` keyword, `Task<T>` return value, `await` keyword, and `ToListAsync` method make the code execute asynchronously.

```
public async Task<IActionResult> Index()
{
    return View(await _context.Students.ToListAsync());
}
```

- The `async` keyword tells the compiler to generate callbacks for parts of the method body and to automatically create the `Task<IActionResult>` object that's returned.
- The return type `Task<IActionResult>` represents ongoing work with a result of type `IActionResult`.
- The `await` keyword causes the compiler to split the method into two parts. The first part ends with the operation that's started asynchronously. The second part is put into a callback method that's called when the operation completes.
- `ToListAsync` is the asynchronous version of the `ToList` extension method.

Some things to be aware of when you are writing asynchronous code that uses the Entity Framework:

- Only statements that cause queries or commands to be sent to the database are executed asynchronously. That includes, for example, `ToListAsync`, `SingleOrDefaultAsync`, and `SaveChangesAsync`. It doesn't include, for example, statements that just change an `IQueryable`, such as `var students = context.Students.Where(s => s.LastName == "Davolio")`.
- An EF context isn't thread safe: don't try to do multiple operations in parallel. When you call any async EF method, always use the `await` keyword.
- If you want to take advantage of the performance benefits of async code, make sure that any library packages that you're using (such as for paging), also use async if they call any Entity Framework methods that cause queries to be sent to the database.

For more information about asynchronous programming in .NET, see Async Overview.

Download or view the completed application.

Next steps

In this tutorial, you:

- Created ASP.NET Core MVC web app

- Set up the site style
- Learned about EF Core NuGet packages
- Created the data model
- Created the database context
- Registered the SchoolContext
- Initialized DB with test data
- Created controller and views
- Viewed the database

In the following tutorial, you'll learn how to perform basic CRUD (create, read, update, delete) operations.

Advance to the next tutorial to learn how to perform basic CRUD (create, read, update, delete) operations.

Implement basic CRUD functionality

Tutorial: Implement CRUD Functionality - ASP.NET MVC with EF Core

9/22/2020 • 19 minutes to read • Edit Online

In the previous tutorial, you created an MVC application that stores and displays data using the Entity Framework and SQL Server LocalDB. In this tutorial, you'll review and customize the CRUD (create, read, update, delete) code that the MVC scaffolding automatically creates for you in controllers and views.

> **NOTE**
>
> It's a common practice to implement the repository pattern in order to create an abstraction layer between your controller and the data access layer. To keep these tutorials simple and focused on teaching how to use the Entity Framework itself, they don't use repositories. For information about repositories with EF, see the last tutorial in this series.

In this tutorial, you:

- Customize the Details page
- Update the Create page
- Update the Edit page
- Update the Delete page
- Close database connections

Prerequisites

- Get started with EF Core and ASP.NET Core MVC

Customize the Details page

The scaffolded code for the Students Index page left out the `Enrollments` property, because that property holds a collection. In the **Details** page, you'll display the contents of the collection in an HTML table.

In *Controllers/StudentsController.cs*, the action method for the Details view uses the `SingleOrDefaultAsync` method to retrieve a single `Student` entity. Add code that calls `Include`. `ThenInclude`, and `AsNoTracking` methods, as shown in the following highlighted code.

```
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var student = await _context.Students
        .Include(s => s.Enrollments)
            .ThenInclude(e => e.Course)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);

    if (student == null)
    {
        return NotFound();
    }

    return View(student);
}
```

The `Include` and `ThenInclude` methods cause the context to load the `Student.Enrollments` navigation property, and within each enrollment the `Enrollment.Course` navigation property. You'll learn more about these methods in the read related data tutorial.

The `AsNoTracking` method improves performance in scenarios where the entities returned won't be updated in the current context's lifetime. You'll learn more about `AsNoTracking` at the end of this tutorial.

Route data

The key value that's passed to the `Details` method comes from *route data*. Route data is data that the model binder found in a segment of the URL. For example, the default route specifies controller, action, and id segments:

```
app.UseMvc(routes =>
{
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");
});
```

In the following URL, the default route maps Instructor as the controller, Index as the action, and 1 as the id; these are route data values.

```
http://localhost:1230/Instructor/Index/1?courseID=2021
```

The last part of the URL ("?courseID=2021") is a query string value. The model binder will also pass the ID value to the `Index` method `id` parameter if you pass it as a query string value:

```
http://localhost:1230/Instructor/Index?id=1&CourseID=2021
```

In the Index page, hyperlink URLs are created by tag helper statements in the Razor view. In the following Razor code, the `id` parameter matches the default route, so `id` is added to the route data.

```
<a asp-action="Edit" asp-route-id="@item.ID">Edit</a>
```

This generates the following HTML when `item.ID` is 6:

```
<a href="/Students/Edit/6">Edit</a>
```

In the following Razor code, `studentID` doesn't match a parameter in the default route, so it's added as a query string.

```
<a asp-action="Edit" asp-route-studentID="@item.ID">Edit</a>
```

This generates the following HTML when `item.ID` is 6:

```
<a href="/Students/Edit?studentID=6">Edit</a>
```

For more information about tag helpers, see Tag Helpers in ASP.NET Core.

Add enrollments to the Details view

Open *Views/Students/Details.cshtml*. Each field is displayed using `DisplayNameFor` and `DisplayFor` helpers, as shown in the following example:

```
<dt class="col-sm-2">
    @Html.DisplayNameFor(model => model.LastName)
</dt>
<dd class="col-sm-10">
    @Html.DisplayFor(model => model.LastName)
</dd>
```

After the last field and immediately before the closing `</dl>` tag, add the following code to display a list of enrollments:

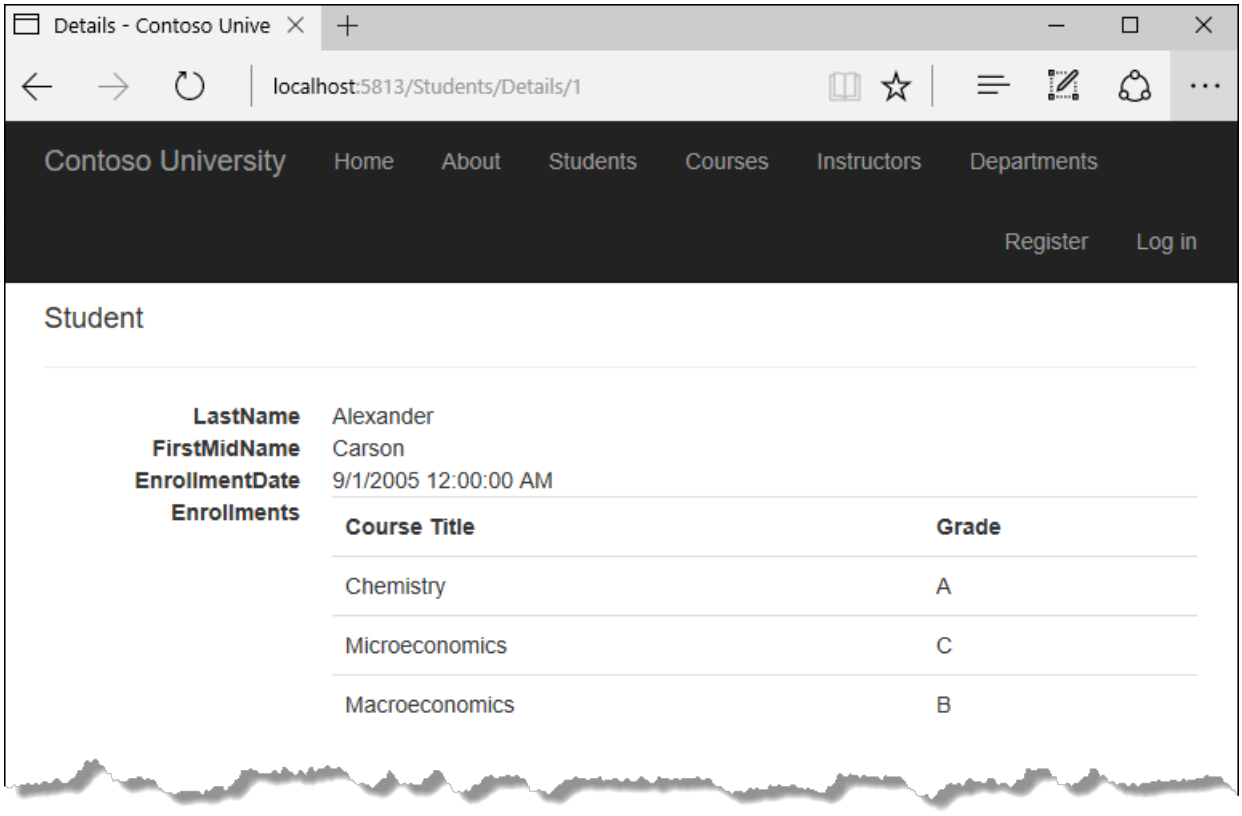
```
<dt class="col-sm-2">
    @Html.DisplayNameFor(model => model.Enrollments)
</dt>
<dd class="col-sm-10">
    <table class="table">
        <tr>
            <th>Course Title</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.Enrollments)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Course.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
</dd>
```

If code indentation is wrong after you paste the code, press CTRL-K-D to correct it.

This code loops through the entities in the `Enrollments` navigation property. For each enrollment, it displays the course title and the grade. The course title is retrieved from the Course entity that's stored in the `Course` navigation property of the Enrollments entity.

Run the app, select the **Students** tab, and click the **Details** link for a student. You see the list of courses and

grades for the selected student:



Update the Create page

In *StudentsController.cs*, modify the HttpPost `Create` method by adding a try-catch block and removing ID from the `Bind` attribute.

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Create(
    [Bind("EnrollmentDate,FirstMidName,LastName")] Student student)
{
    try
    {
        if (ModelState.IsValid)
        {
            _context.Add(student);
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
    }
    catch (DbUpdateException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.
        ModelState.AddModelError("", "Unable to save changes. " +
            "Try again, and if the problem persists " +
            "see your system administrator.");
    }
    return View(student);
}
```

This code adds the Student entity created by the ASP.NET Core MVC model binder to the Students entity set and then saves the changes to the database. (Model binder refers to the ASP.NET Core MVC functionality that makes it easier for you to work with data submitted by a form; a model binder converts posted form values to CLR types and passes them to the action method in parameters. In this case, the model binder instantiates a Student entity for you using property values from the Form collection.)

You removed `ID` from the `Bind` attribute because ID is the primary key value which SQL Server will set automatically when the row is inserted. Input from the user doesn't set the ID value.

Other than the `Bind` attribute, the try-catch block is the only change you've made to the scaffolded code. If an exception that derives from `DbUpdateException` is caught while the changes are being saved, a generic error message is displayed. `DbUpdateException` exceptions are sometimes caused by something external to the application rather than a programming error, so the user is advised to try again. Although not implemented in this sample, a production quality application would log the exception. For more information, see the **Log for insight** section in Monitoring and Telemetry (Building Real-World Cloud Apps with Azure).

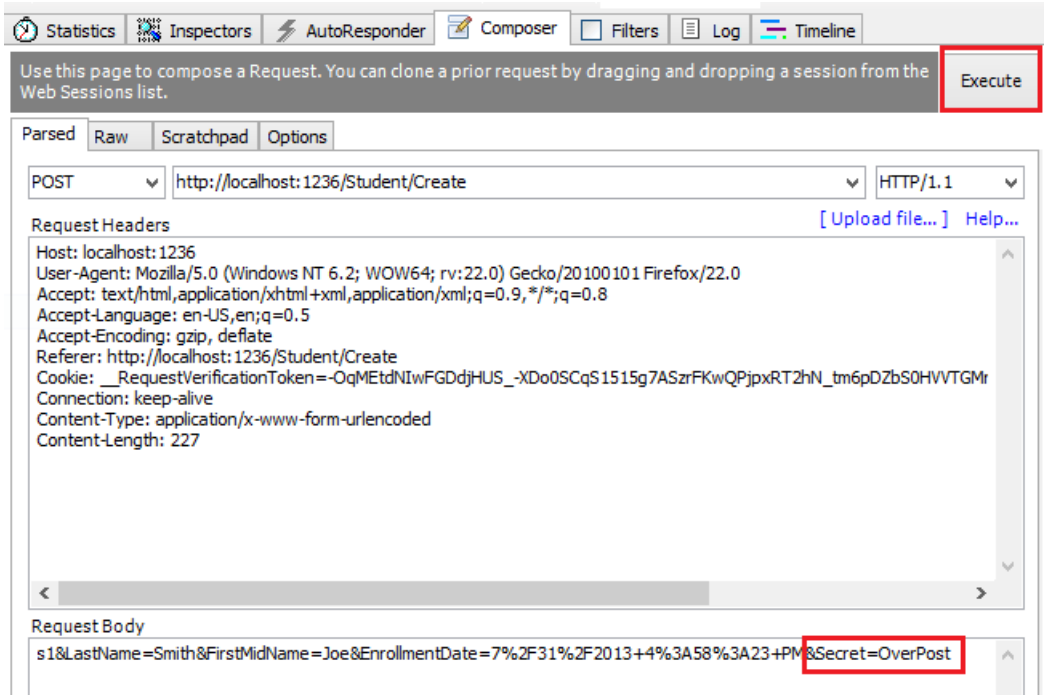
The `ValidateAntiForgeryToken` attribute helps prevent cross-site request forgery (CSRF) attacks. The token is automatically injected into the view by the FormTagHelper and is included when the form is submitted by the user. The token is validated by the `ValidateAntiForgeryToken` attribute. For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

Security note about overposting

The `Bind` attribute that the scaffolded code includes on the `Create` method is one way to protect against overposting in create scenarios. For example, suppose the Student entity includes a `Secret` property that you don't want this web page to set.

```
public class Student
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstMidName { get; set; }
    public DateTime EnrollmentDate { get; set; }
    public string Secret { get; set; }
}
```

Even if you don't have a `Secret` field on the web page, a hacker could use a tool such as Fiddler, or write some JavaScript, to post a `Secret` form value. Without the `Bind` attribute limiting the fields that the model binder uses when it creates a Student instance, the model binder would pick up that `Secret` form value and use it to create the Student entity instance. Then whatever value the hacker specified for the `Secret` form field would be updated in your database. The following image shows the Fiddler tool adding the `Secret` field (with the value "OverPost") to the posted form values.



The value "OverPost" would then be successfully added to the `Secret` property of the inserted row, although you never intended that the web page be able to set that property.

You can prevent overposting in edit scenarios by reading the entity from the database first and then calling `TryUpdateModel`, passing in an explicit allowed properties list. That's the method used in these tutorials.

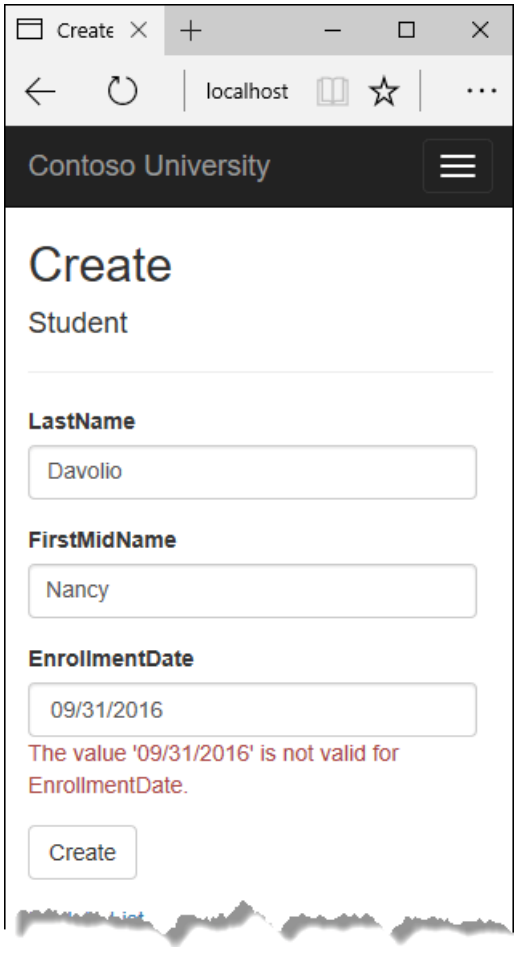
An alternative way to prevent overposting that's preferred by many developers is to use view models rather than entity classes with model binding. Include only the properties you want to update in the view model. Once the MVC model binder has finished, copy the view model properties to the entity instance, optionally using a tool such as AutoMapper. Use `_context.Entry` on the entity instance to set its state to `Unchanged`, and then set `Property("PropertyName").IsModified` to true on each entity property that's included in the view model. This method works in both edit and create scenarios.

Test the Create page

The code in *Views/Students/Create.cshtml* uses `label`, `input`, and `span` (for validation messages) tag helpers for each field.

Run the app, select the **Students** tab, and click **Create New**.

Enter names and a date. Try entering an invalid date if your browser lets you do that. (Some browsers force you to use a date picker.) Then click **Create** to see the error message.



This is server-side validation that you get by default; in a later tutorial you'll see how to add attributes that will generate code for client-side validation also. The following highlighted code shows the model validation check in the `Create` method.

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Create(
    [Bind("EnrollmentDate,FirstMidName,LastName")] Student student)
{
    try
    {
        if (ModelState.IsValid)
        {
            _context.Add(student);
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
    }
    catch (DbUpdateException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.
        ModelState.AddModelError("", "Unable to save changes. " +
            "Try again, and if the problem persists " +
            "see your system administrator.");
    }
    return View(student);
}
```

Change the date to a valid value and click **Create** to see the new student appear in the **Index** page.

Update the Edit page

In *StudentController.cs*, the HttpGet `Edit` method (the one without the `HttpPost` attribute) uses the `SingleOrDefaultAsync` method to retrieve the selected Student entity, as you saw in the `Details` method. You don't need to change this method.

Recommended HttpPost Edit code: Read and update

Replace the HttpPost Edit action method with the following code.

```
[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> EditPost(int? id)
{
    if (id == null)
    {
        return NotFound();
    }
    var studentToUpdate = await _context.Students.FirstOrDefaultAsync(s => s.ID == id);
    if (await TryUpdateModelAsync<Student>(
        studentToUpdate,
        "",
        s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
    {
        try
        {
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
    }
    return View(studentToUpdate);
}
```

These changes implement a security best practice to prevent overposting. The scaffolder generated a `Bind` attribute and added the entity created by the model binder to the entity set with a `Modified` flag. That code isn't recommended for many scenarios because the `Bind` attribute clears out any pre-existing data in fields not listed in the `Include` parameter.

The new code reads the existing entity and calls `TryUpdateModel` to update fields in the retrieved entity based on user input in the posted form data. The Entity Framework's automatic change tracking sets the `Modified` flag on the fields that are changed by form input. When the `SaveChanges` method is called, the Entity Framework creates SQL statements to update the database row. Concurrency conflicts are ignored, and only the table columns that were updated by the user are updated in the database. (A later tutorial shows how to handle concurrency conflicts.)

As a best practice to prevent overposting, the fields that you want to be updateable by the **Edit** page are declared in the `TryUpdateModel` parameters. (The empty string preceding the list of fields in the parameter list is for a prefix to use with the form fields names.) Currently there are no extra fields that you're protecting, but listing the fields that you want the model binder to bind ensures that if you add fields to the data model in the future, they're automatically protected until you explicitly add them here.

As a result of these changes, the method signature of the HttpPost `Edit` method is the same as the HttpGet `Edit` method; therefore you've renamed the method `EditPost`.

Alternative HttpPost Edit code: Create and attach

The recommended HttpPost edit code ensures that only changed columns get updated and preserves data in properties that you don't want included for model binding. However, the read-first approach requires an extra database read, and can result in more complex code for handling concurrency conflicts. An alternative is to attach an entity created by the model binder to the EF context and mark it as modified. (Don't update your project with this code, it's only shown to illustrate an optional approach.)

```
public async Task<IActionResult> Edit(int id, [Bind("ID,EnrollmentDate,FirstMidName,LastName")] Student
student)
{
    if (id != student.ID)
    {
        return NotFound();
    }
    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(student);
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
    }
    return View(student);
}
```

You can use this approach when the web page UI includes all of the fields in the entity and can update any of them.

The scaffolded code uses the create-and-attach approach but only catches `DbUpdateConcurrencyException` exceptions and returns 404 error codes. The example shown catches any database update exception and displays an error message.

Entity States

The database context keeps track of whether entities in memory are in sync with their corresponding rows in the database, and this information determines what happens when you call the `SaveChanges` method. For example, when you pass a new entity to the `Add` method, that entity's state is set to `Added`. Then when you call the `SaveChanges` method, the database context issues a SQL INSERT command.

An entity may be in one of the following states:

- `Added`. The entity doesn't yet exist in the database. The `SaveChanges` method issues an INSERT statement.
- `Unchanged`. Nothing needs to be done with this entity by the `SaveChanges` method. When you read an entity from the database, the entity starts out with this status.
- `Modified`. Some or all of the entity's property values have been modified. The `SaveChanges` method issues an UPDATE statement.
- `Deleted`. The entity has been marked for deletion. The `SaveChanges` method issues a DELETE statement.
- `Detached`. The entity isn't being tracked by the database context.

In a desktop application, state changes are typically set automatically. You read an entity and make changes to some of its property values. This causes its entity state to automatically be changed to `Modified`. Then when you call `SaveChanges`, the Entity Framework generates a SQL UPDATE statement that updates only the actual properties that you changed.

In a web app, the `DbContext` that initially reads an entity and displays its data to be edited is disposed after a page is rendered. When the HttpPost `Edit` action method is called, a new web request is made and you have a

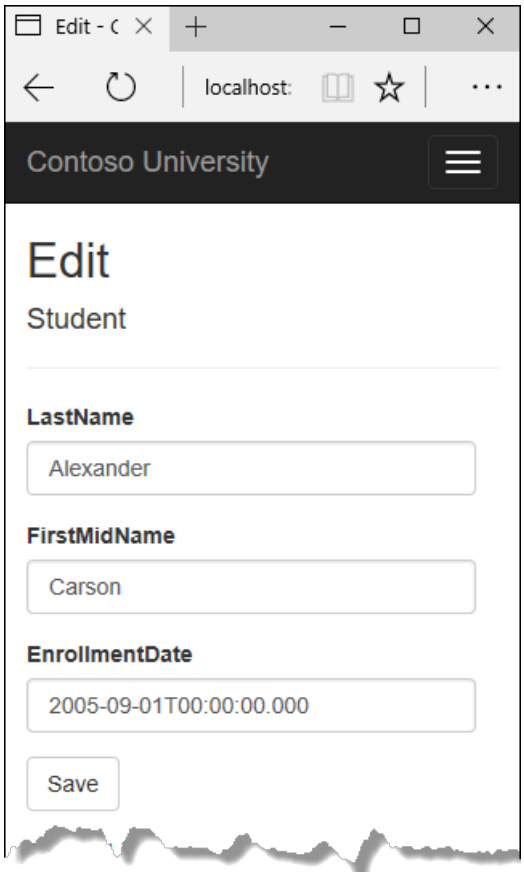
new instance of the `DbContext`. If you re-read the entity in that new context, you simulate desktop processing.

But if you don't want to do the extra read operation, you have to use the entity object created by the model binder. The simplest way to do this is to set the entity state to Modified as is done in the alternative HttpPost Edit code shown earlier. Then when you call `SaveChanges`, the Entity Framework updates all columns of the database row, because the context has no way to know which properties you changed.

If you want to avoid the read-first approach, but you also want the SQL UPDATE statement to update only the fields that the user actually changed, the code is more complex. You have to save the original values in some way (such as by using hidden fields) so that they're available when the HttpPost `Edit` method is called. Then you can create a Student entity using the original values, call the `Attach` method with that original version of the entity, update the entity's values to the new values, and then call `SaveChanges`.

Test the Edit page

Run the app, select the **Students** tab, then click an **Edit** hyperlink.



Change some of the data and click **Save**. The **Index** page opens and you see the changed data.

Update the Delete page

In *StudentController.cs*, the template code for the HttpGet `Delete` method uses the `SingleOrDefaultAsync` method to retrieve the selected Student entity, as you saw in the Details and Edit methods. However, to implement a custom error message when the call to `SaveChanges` fails, you'll add some functionality to this method and its corresponding view.

As you saw for update and create operations, delete operations require two action methods. The method that's called in response to a GET request displays a view that gives the user a chance to approve or cancel the delete operation. If the user approves it, a POST request is created. When that happens, the HttpPost `Delete` method is called and then that method actually performs the delete operation.

You'll add a try-catch block to the HttpPost `Delete` method to handle any errors that might occur when the database is updated. If an error occurs, the HttpPost Delete method calls the HttpGet Delete method, passing it a

parameter that indicates that an error has occurred. The HttpGet Delete method then redisplays the confirmation page along with the error message, giving the user an opportunity to cancel or try again.

Replace the HttpGet `Delete` action method with the following code, which manages error reporting.

```
public async Task<IActionResult> Delete(int? id, bool? saveChangesError = false)
{
    if (id == null)
    {
        return NotFound();
    }

    var student = await _context.Students
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);
    if (student == null)
    {
        return NotFound();
    }

    if (saveChangesError.GetValueOrDefault())
    {
        ViewData["ErrorMessage"] =
            "Delete failed. Try again, and if the problem persists " +
            "see your system administrator.";
    }

    return View(student);
}
```

This code accepts an optional parameter that indicates whether the method was called after a failure to save changes. This parameter is false when the HttpGet `Delete` method is called without a previous failure. When it's called by the HttpPost `Delete` method in response to a database update error, the parameter is true and an error message is passed to the view.

The read-first approach to HttpPost Delete

Replace the HttpPost `Delete` action method (named `DeleteConfirmed`) with the following code, which performs the actual delete operation and catches any database update errors.

```
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    var student = await _context.Students.FindAsync(id);
    if (student == null)
    {
        return RedirectToAction(nameof(Index));
    }

    try
    {
        _context.Students.Remove(student);
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    catch (DbUpdateException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.)
        return RedirectToAction(nameof(Delete), new { id = id, saveChangesError = true });
    }
}
```

This code retrieves the selected entity, then calls the `Remove` method to set the entity's status to `Deleted`. When `SaveChanges` is called, a SQL DELETE command is generated.

The create-and-attach approach to HttpPost Delete

If improving performance in a high-volume application is a priority, you could avoid an unnecessary SQL query by instantiating a Student entity using only the primary key value and then setting the entity state to `Deleted`. That's all that the Entity Framework needs in order to delete the entity. (Don't put this code in your project; it's here just to illustrate an alternative.)

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    try
    {
        Student studentToDelete = new Student() { ID = id };
        _context.Entry(studentToDelete).State = EntityState.Deleted;
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    catch (DbUpdateException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.)
        return RedirectToAction(nameof(Delete), new { id = id, saveChangesError = true });
    }
}
```

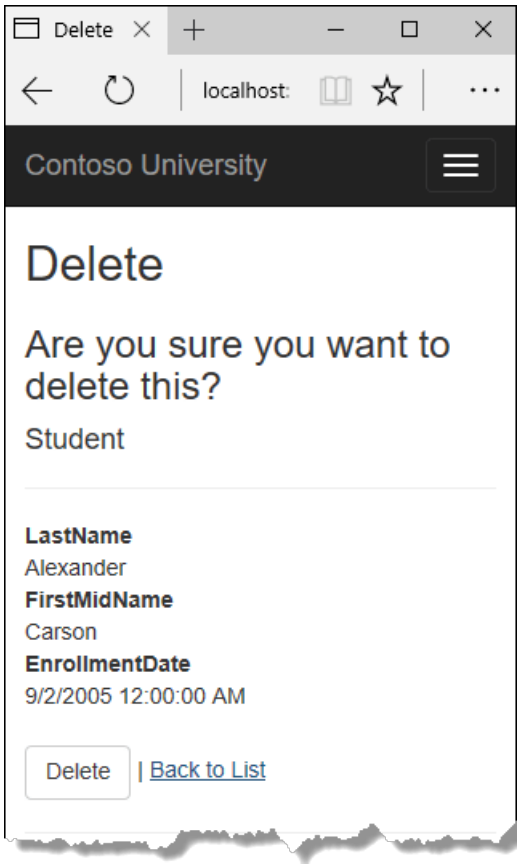
If the entity has related data that should also be deleted, make sure that cascade delete is configured in the database. With this approach to entity deletion, EF might not realize there are related entities to be deleted.

Update the Delete view

In *Views/Student/Delete.cshtml*, add an error message between the h2 heading and the h3 heading, as shown in the following example:

```
<h2>Delete</h2>
<p class="text-danger">@ViewData["ErrorMessage"]</p>
<h3>Are you sure you want to delete this?</h3>
```

Run the app, select the **Students** tab, and click a **Delete** hyperlink:



Click **Delete**. The Index page is displayed without the deleted student. (You'll see an example of the error handling code in action in the concurrency tutorial.)

Close database connections

To free up the resources that a database connection holds, the context instance must be disposed as soon as possible when you are done with it. The ASP.NET Core built-in dependency injection takes care of that task for you.

In *Startup.cs*, you call the AddDbContext extension method to provision the `DbContext` class in the ASP.NET Core DI container. That method sets the service lifetime to `Scoped` by default. `Scoped` means the context object lifetime coincides with the web request life time, and the `Dispose` method will be called automatically at the end of the web request.

Handle transactions

By default the Entity Framework implicitly implements transactions. In scenarios where you make changes to multiple rows or tables and then call `SaveChanges`, the Entity Framework automatically makes sure that either all of your changes succeed or they all fail. If some changes are done first and then an error happens, those changes are automatically rolled back. For scenarios where you need more control -- for example, if you want to include operations done outside of Entity Framework in a transaction -- see Transactions.

No-tracking queries

When a database context retrieves table rows and creates entity objects that represent them, by default it keeps track of whether the entities in memory are in sync with what's in the database. The data in memory acts as a cache and is used when you update an entity. This caching is often unnecessary in a web application because context instances are typically short-lived (a new one is created and disposed for each request) and the context that reads an entity is typically disposed before that entity is used again.

You can disable tracking of entity objects in memory by calling the `AsNoTracking` method. Typical scenarios in

which you might want to do that include the following:

- During the context lifetime you don't need to update any entities, and you don't need EF to automatically load navigation properties with entities retrieved by separate queries. Frequently these conditions are met in a controller's HttpGet action methods.
- You are running a query that retrieves a large volume of data, and only a small portion of the returned data will be updated. It may be more efficient to turn off tracking for the large query, and run a query later for the few entities that need to be updated.
- You want to attach an entity in order to update it, but earlier you retrieved the same entity for a different purpose. Because the entity is already being tracked by the database context, you can't attach the entity that you want to change. One way to handle this situation is to call `AsNoTracking` on the earlier query.

For more information, see Tracking vs. No-Tracking.

Get the code

Download or view the completed application.

Next steps

In this tutorial, you:

- Customized the Details page
- Updated the Create page
- Updated the Edit page
- Updated the Delete page
- Closed database connections

Advance to the next tutorial to learn how to expand the functionality of the **Index** page by adding sorting, filtering, and paging.

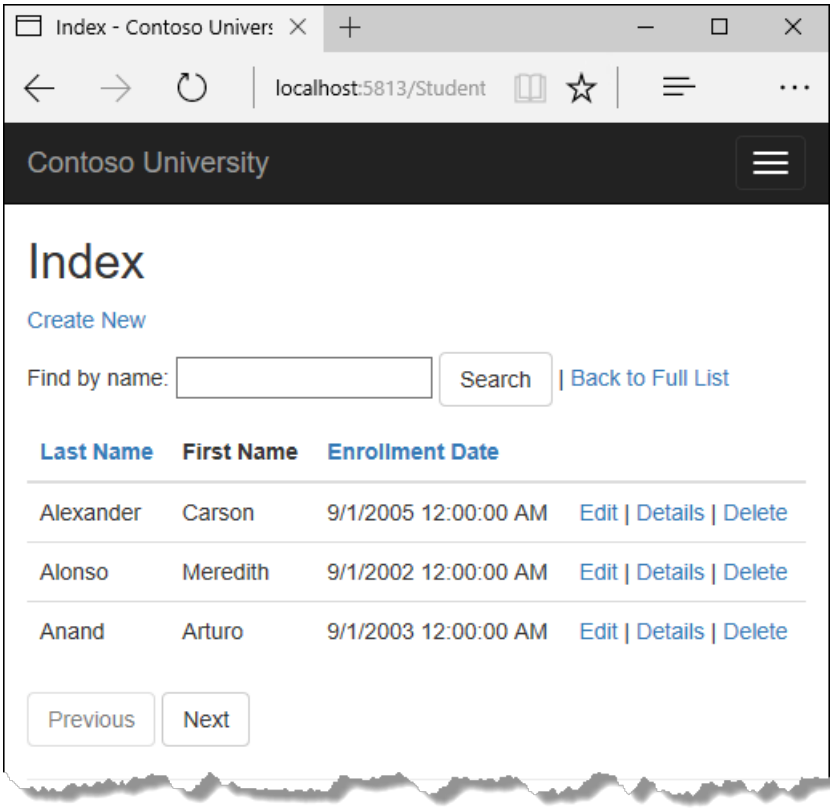
Next: Sorting, filtering, and paging

Tutorial: Add sorting, filtering, and paging - ASP.NET MVC with EF Core

9/22/2020 • 14 minutes to read • Edit Online

In the previous tutorial, you implemented a set of web pages for basic CRUD operations for Student entities. In this tutorial you'll add sorting, filtering, and paging functionality to the Students Index page. You'll also create a page that does simple grouping.

The following illustration shows what the page will look like when you're done. The column headings are links that the user can click to sort by that column. Clicking a column heading repeatedly toggles between ascending and descending sort order.



In this tutorial, you:

- Add column sort links
- Add a Search box
- Add paging to Students Index
- Add paging to Index method
- Add paging links
- Create an About page

Prerequisites

- Implement CRUD Functionality

Add column sort links

To add sorting to the Student Index page, you'll change the `Index` method of the Students controller and add

code to the Student Index view.

Add sorting Functionality to the Index method

In *StudentsController.cs*, replace the `Index` method with the following code:

```
public async Task<IActionResult> Index(string sortOrder)
{
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";
    var students = from s in _context.Students
                   select s;
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }
    return View(await students.AsNoTracking().ToListAsync());
}
```

This code receives a `sortOrder` parameter from the query string in the URL. The query string value is provided by ASP.NET Core MVC as a parameter to the action method. The parameter will be a string that's either "Name" or "Date", optionally followed by an underscore and the string "desc" to specify descending order. The default sort order is ascending.

The first time the Index page is requested, there's no query string. The students are displayed in ascending order by last name, which is the default as established by the fall-through case in the `switch` statement. When the user clicks a column heading hyperlink, the appropriate `sortOrder` value is provided in the query string.

The two `ViewData` elements (NameSortParm and DateSortParm) are used by the view to configure the column heading hyperlinks with the appropriate query string values.

```
public async Task<IActionResult> Index(string sortOrder)
{
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";
    var students = from s in _context.Students
                   select s;
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }
    return View(await students.AsNoTracking().ToListAsync());
}
```

These are ternary statements. The first one specifies that if the `sortOrder` parameter is null or empty, NameSortParm should be set to "name_desc"; otherwise, it should be set to an empty string. These two statements enable the view to set the column heading hyperlinks as follows:

CURRENT SORT ORDER	LAST NAME HYPERLINK	DATE HYPERLINK
Last Name ascending	descending	ascending
Last Name descending	ascending	ascending
Date ascending	ascending	descending
Date descending	ascending	ascending

The method uses LINQ to Entities to specify the column to sort by. The code creates an `IQueryable` variable before the switch statement, modifies it in the switch statement, and calls the `ToListAsync` method after the `switch` statement. When you create and modify `IQueryable` variables, no query is sent to the database. The query isn't executed until you convert the `IQueryable` object into a collection by calling a method such as `ToListAsync`. Therefore, this code results in a single query that's not executed until the `return View` statement.

This code could get verbose with a large number of columns. The last tutorial in this series shows how to write code that lets you pass the name of the `OrderBy` column in a string variable.

Add column heading hyperlinks to the Student Index view

Replace the code in *Views/Students/Index.cshtml*, with the following code to add column heading hyperlinks. The changed lines are highlighted.

```
@model IEnumerable<ContosoUniversity.Models.Student>

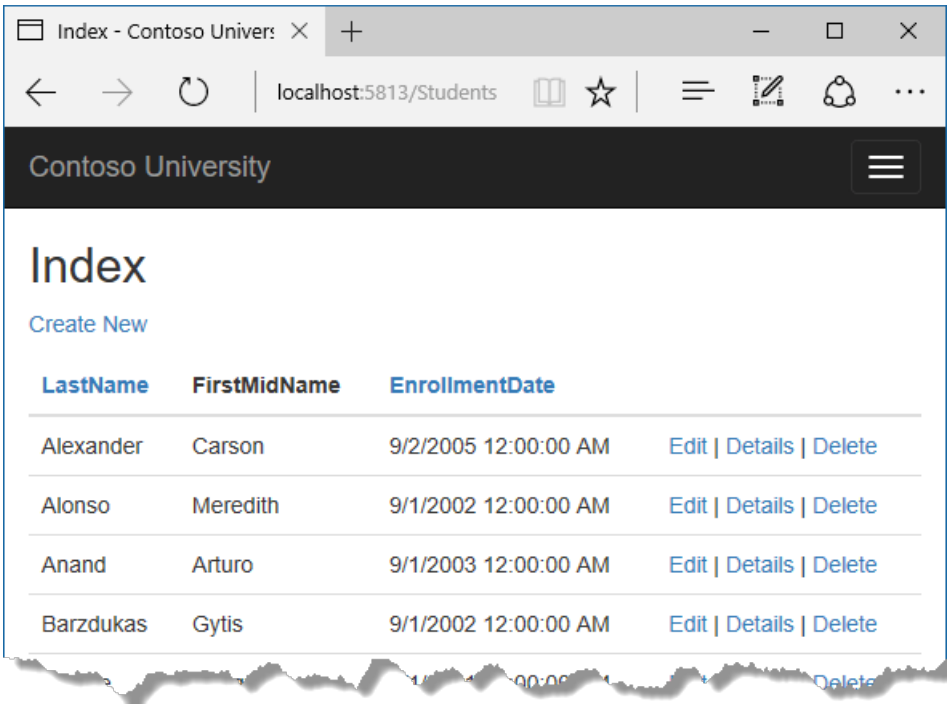
@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
                <th>
                    <a asp-action="Index" asp-route-
sortOrder="@ViewData["NameSortParm"]">@Html.DisplayNameFor(model => model.LastName)</a>
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.FirstMidName)
                </th>
                <th>
                    <a asp-action="Index" asp-route-
sortOrder="@ViewData["DateSortParm"]">@Html.DisplayNameFor(model => model.EnrollmentDate)</a>
                </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.LastName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.FirstMidName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-action="Details" asp-route-id="@item.ID">Details</a> |
                <a asp-action="Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

This code uses the information in `ViewData` properties to set up hyperlinks with the appropriate query string values.

Run the app, select the **Students** tab, and click the **Last Name** and **Enrollment Date** column headings to verify that sorting works.



Add a Search box

To add filtering to the Students Index page, you'll add a text box and a submit button to the view and make corresponding changes in the `Index` method. The text box will let you enter a string to search for in the first name and last name fields.

Add filtering functionality to the Index method

In *StudentsController.cs*, replace the `Index` method with the following code (the changes are highlighted).

```
public async Task<IActionResult> Index(string sortOrder, string searchString)
{
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";
    ViewData["CurrentFilter"] = searchString;

    var students = from s in _context.Students
                   select s;
    if (!String.IsNullOrEmpty(searchString))
    {
        students = students.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }
    return View(await students.AsNoTracking().ToListAsync());
}
```

You've added a `searchString` parameter to the `Index` method. The search string value is received from a text box that you'll add to the Index view. You've also added to the LINQ statement a where clause that selects only students whose first name or last name contains the search string. The statement that adds the where clause is executed only if there's a value to search for.

> **NOTE**
>
> Here you are calling the `Where` method on an `IQueryable` object, and the filter will be processed on the server. In some scenarios you might be calling the `Where` method as an extension method on an in-memory collection. (For example, suppose you change the reference to `_context.Students` so that instead of an EF `DbSet` it references a repository method that returns an `IEnumerable` collection.) The result would normally be the same but in some cases may be different.
>
> For example, the .NET Framework implementation of the `Contains` method performs a case-sensitive comparison by default, but in SQL Server this is determined by the collation setting of the SQL Server instance. That setting defaults to case-insensitive. You could call the `ToUpper` method to make the test explicitly case-insensitive: *Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())*. That would ensure that results stay the same if you change the code later to use a repository which returns an `IEnumerable` collection instead of an `IQueryable` object. (When you call the `Contains` method on an `IEnumerable` collection, you get the .NET Framework implementation; when you call it on an `IQueryable` object, you get the database provider implementation.) However, there's a performance penalty for this solution. The `ToUpper` code would put a function in the WHERE clause of the TSQL SELECT statement. That would prevent the optimizer from using an index. Given that SQL is mostly installed as case-insensitive, it's best to avoid the `ToUpper` code until you migrate to a case-sensitive data store.

Add a Search Box to the Student Index View

In *Views/Student/Index.cshtml*, add the highlighted code immediately before the opening table tag in order to create a caption, a text box, and a **Search** button.

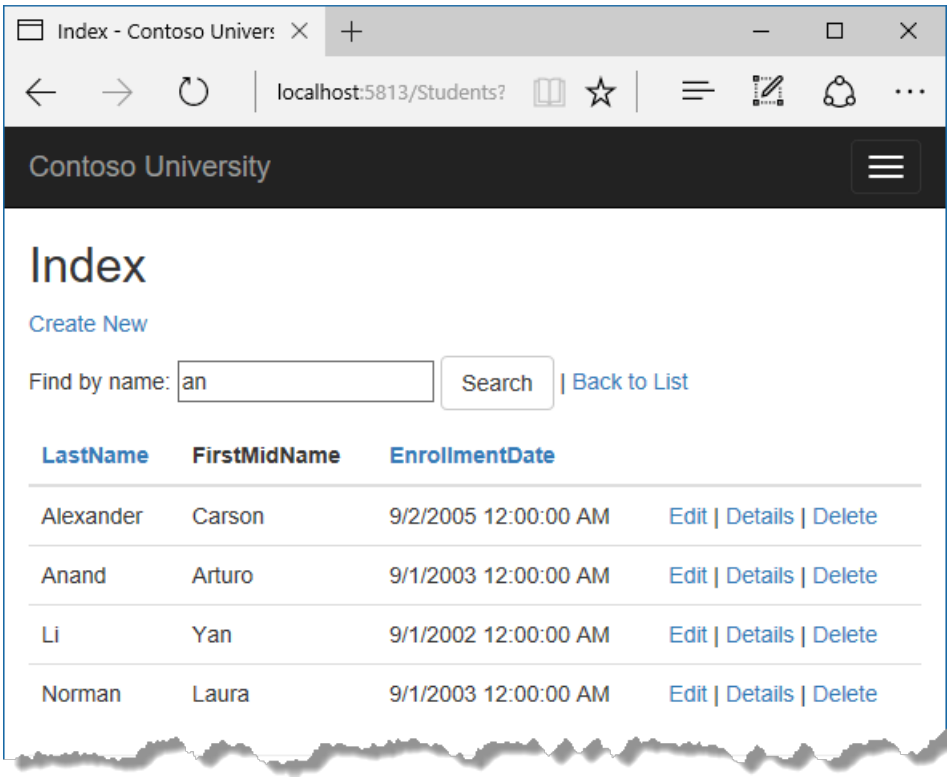
```
<p>
    <a asp-action="Create">Create New</a>
</p>

<form asp-action="Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name: <input type="text" name="SearchString" value="@ViewData["CurrentFilter"]" />
            <input type="submit" value="Search" class="btn btn-default" /> |
            <a asp-action="Index">Back to Full List</a>
        </p>
    </div>
</form>

<table class="table">
```

This code uses the `<form>` tag helper to add the search text box and button. By default, the `<form>` tag helper submits form data with a POST, which means that parameters are passed in the HTTP message body and not in the URL as query strings. When you specify HTTP GET, the form data is passed in the URL as query strings, which enables users to bookmark the URL. The W3C guidelines recommend that you should use GET when the action doesn't result in an update.

Run the app, select the **Students** tab, enter a search string, and click Search to verify that filtering is working.



Notice that the URL contains the search string.

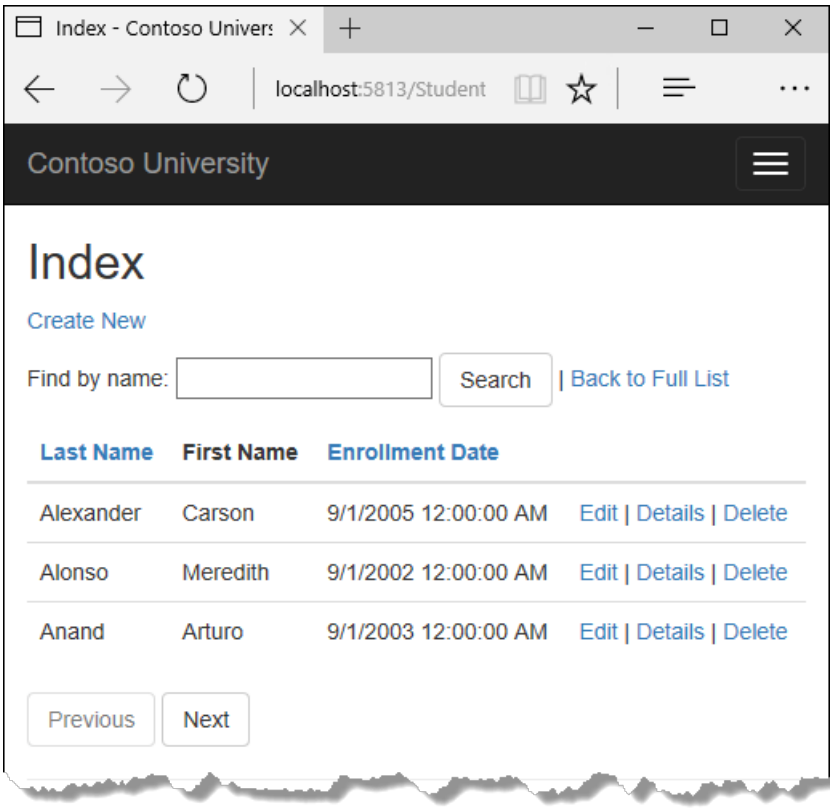
```
http://localhost:5813/Students?SearchString=an
```

If you bookmark this page, you'll get the filtered list when you use the bookmark. Adding `method="get"` to the `form` tag is what caused the query string to be generated.

At this stage, if you click a column heading sort link you'll lose the filter value that you entered in the **Search** box. You'll fix that in the next section.

Add paging to Students Index

To add paging to the Students Index page, you'll create a `PaginatedList` class that uses `Skip` and `Take` statements to filter data on the server instead of always retrieving all rows of the table. Then you'll make additional changes in the `Index` method and add paging buttons to the `Index` view. The following illustration shows the paging buttons.



In the project folder, create `PaginatedList.cs`, and then replace the template code with the following code.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity
{
    public class PaginatedList<T> : List<T>
    {
        public int PageIndex { get; private set; }
        public int TotalPages { get; private set; }

        public PaginatedList(List<T> items, int count, int pageIndex, int pageSize)
        {
            PageIndex = pageIndex;
            TotalPages = (int)Math.Ceiling(count / (double)pageSize);

            this.AddRange(items);
        }

        public bool HasPreviousPage
        {
            get
            {
                return (PageIndex > 1);
            }
        }

        public bool HasNextPage
        {
            get
            {
                return (PageIndex < TotalPages);
            }
        }

        public static async Task<PaginatedList<T>> CreateAsync(IQueryable<T> source, int pageIndex, int
pageSize)
        {
            var count = await source.CountAsync();
            var items = await source.Skip((pageIndex - 1) * pageSize).Take(pageSize).ToListAsync();
            return new PaginatedList<T>(items, count, pageIndex, pageSize);
        }
    }
}
```

The `CreateAsync` method in this code takes page size and page number and applies the appropriate `Skip` and `Take` statements to the `IQueryable`. When `ToListAsync` is called on the `IQueryable`, it will return a List containing only the requested page. The properties `HasPreviousPage` and `HasNextPage` can be used to enable or disable **Previous** and **Next** paging buttons.

A `CreateAsync` method is used instead of a constructor to create the `PaginatedList<T>` object because constructors can't run asynchronous code.

Add paging to Index method

In *StudentsController.cs*, replace the `Index` method with the following code.

```
public async Task<IActionResult> Index(
    string sortOrder,
    string currentFilter,
    string searchString,
    int? pageNumber)
{
    ViewData["CurrentSort"] = sortOrder;
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";

    if (searchString != null)
    {
        pageNumber = 1;
    }
    else
    {
        searchString = currentFilter;
    }

    ViewData["CurrentFilter"] = searchString;

    var students = from s in _context.Students
                   select s;
    if (!String.IsNullOrEmpty(searchString))
    {
        students = students.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }

    int pageSize = 3;
    return View(await PaginatedList<Student>.CreateAsync(students.AsNoTracking(), pageNumber ?? 1,
pageSize));
}
```

This code adds a page number parameter, a current sort order parameter, and a current filter parameter to the method signature.

```
public async Task<IActionResult> Index(
    string sortOrder,
    string currentFilter,
    string searchString,
    int? pageNumber)
```

The first time the page is displayed, or if the user hasn't clicked a paging or sorting link, all the parameters will be null. If a paging link is clicked, the page variable will contain the page number to display.

The `ViewData` element named CurrentSort provides the view with the current sort order, because this must be included in the paging links in order to keep the sort order the same while paging.

The `ViewData` element named CurrentFilter provides the view with the current filter string. This value must be included in the paging links in order to maintain the filter settings during paging, and it must be restored to the text box when the page is redisplayed.

If the search string is changed during paging, the page has to be reset to 1, because the new filter can result in different data to display. The search string is changed when a value is entered in the text box and the Submit button is pressed. In that case, the `searchString` parameter isn't null.

```
if (searchString != null)
{
    pageNumber = 1;
}
else
{
    searchString = currentFilter;
}
```

At the end of the `Index` method, the `PaginatedList.CreateAsync` method converts the student query to a single page of students in a collection type that supports paging. That single page of students is then passed to the view.

```
return View(await PaginatedList<Student>.CreateAsync(students.AsNoTracking(), pageNumber ?? 1, pageSize));
```

The `PaginatedList.CreateAsync` method takes a page number. The two question marks represent the null-coalescing operator. The null-coalescing operator defines a default value for a nullable type; the expression `(pageNumber ?? 1)` means return the value of `pageNumber` if it has a value, or return 1 if `pageNumber` is null.

Add paging links

In *Views/Students/Index.cshtml*, replace the existing code with the following code. The changes are highlighted.

```
@model PaginatedList<ContosoUniversity.Models.Student>

@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>

<form asp-action="Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name: <input type="text" name="SearchString" value="@ViewData["CurrentFilter"]" />
            <input type="submit" value="Search" class="btn btn-default" /> |
            <a asp-action="Index">Back to Full List</a>
        </p>
    </div>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-action="Index" asp-route-sortOrder="@ViewData["NameSortParm"]" asp-route-
currentFilter="@ViewData["CurrentFilter"]">Last Name</a>
            </th>
            <th>
                First Name
```

```
            </th>
            <th>
                <a asp-action="Index" asp-route-sortOrder="@ViewData["DateSortParm"]" asp-route-
currentFilter="@ViewData["CurrentFilter"]">Enrollment Date</a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-action="Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-action="Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>

@{
    var prevDisabled = !Model.HasPreviousPage ? "disabled" : "";
    var nextDisabled = !Model.HasNextPage ? "disabled" : "";
}

<a asp-action="Index"
   asp-route-sortOrder="@ViewData["CurrentSort"]"
   asp-route-pageNumber="@(Model.PageIndex - 1)"
   asp-route-currentFilter="@ViewData["CurrentFilter"]"
   class="btn btn-default @prevDisabled">
    Previous
</a>
<a asp-action="Index"
   asp-route-sortOrder="@ViewData["CurrentSort"]"
   asp-route-pageNumber="@(Model.PageIndex + 1)"
   asp-route-currentFilter="@ViewData["CurrentFilter"]"
   class="btn btn-default @nextDisabled">
    Next
</a>
```

The `@model` statement at the top of the page specifies that the view now gets a `PaginatedList<T>` object instead of a `List<T>` object.

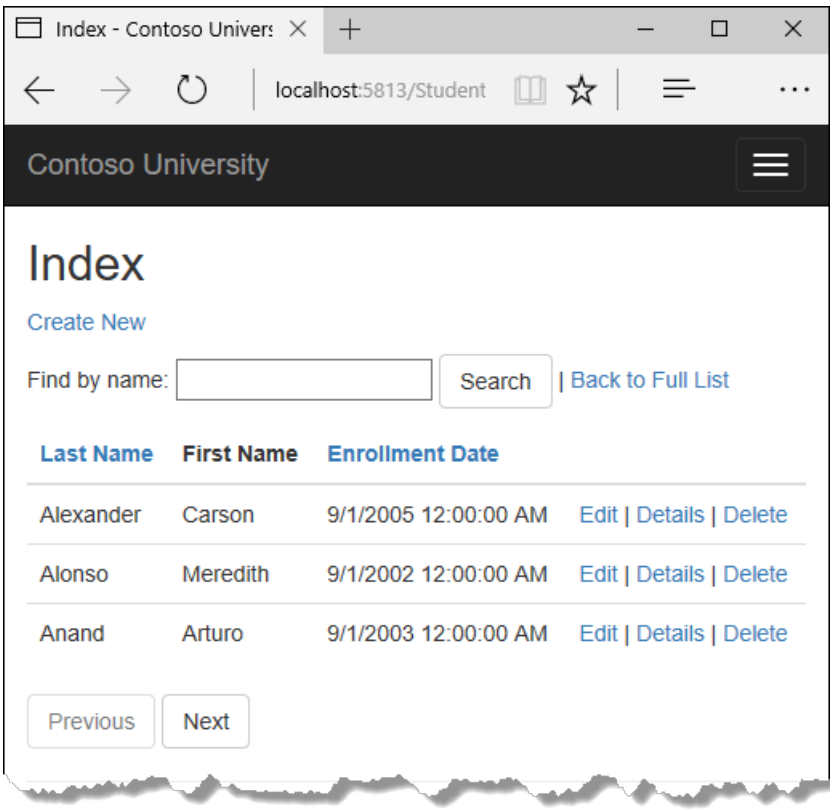
The column header links use the query string to pass the current search string to the controller so that the user can sort within filter results:

```
<a asp-action="Index" asp-route-sortOrder="@ViewData["DateSortParm"]" asp-route-currentFilter
="@ViewData["CurrentFilter"]">Enrollment Date</a>
```

The paging buttons are displayed by tag helpers:

```
<a asp-action="Index"
   asp-route-sortOrder="@ViewData["CurrentSort"]"
   asp-route-pageNumber="@(Model.PageIndex - 1)"
   asp-route-currentFilter="@ViewData["CurrentFilter"]"
   class="btn btn-default @prevDisabled">
   Previous
</a>
```

Run the app and go to the Students page.



Click the paging links in different sort orders to make sure paging works. Then enter a search string and try paging again to verify that paging also works correctly with sorting and filtering.

Create an About page

For the Contoso University website's **About** page, you'll display how many students have enrolled for each enrollment date. This requires grouping and simple calculations on the groups. To accomplish this, you'll do the following:

- Create a view model class for the data that you need to pass to the view.
- Create the About method in the Home controller.
- Create the About view.

Create the view model

Create a *SchoolViewModels* folder in the *Models* folder.

In the new folder, add a class file *EnrollmentDateGroup.cs* and replace the template code with the following code:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class EnrollmentDateGroup
    {
        [DataType(DataType.Date)]
        public DateTime? EnrollmentDate { get; set; }

        public int StudentCount { get; set; }
    }
}
```

Modify the Home Controller

In *HomeController.cs*, add the following using statements at the top of the file:

```
using Microsoft.EntityFrameworkCore;
using ContosoUniversity.Data;
using ContosoUniversity.Models.SchoolViewModels;
```

Add a class variable for the database context immediately after the opening curly brace for the class, and get an instance of the context from ASP.NET Core DI:

```
public class HomeController : Controller
{
    private readonly SchoolContext _context;

    public HomeController(SchoolContext context)
    {
        _context = context;
    }
```

Add an `About` method with the following code:

```
public async Task<ActionResult> About()
{
    IQueryable<EnrollmentDateGroup> data =
        from student in _context.Students
        group student by student.EnrollmentDate into dateGroup
        select new EnrollmentDateGroup()
        {
            EnrollmentDate = dateGroup.Key,
            StudentCount = dateGroup.Count()
        };
    return View(await data.AsNoTracking().ToListAsync());
}
```

The LINQ statement groups the student entities by enrollment date, calculates the number of entities in each group, and stores the results in a collection of `EnrollmentDateGroup` view model objects.

Create the About View

Add a *Views/Home/About.cshtml* file with the following code:

```
@model IEnumerable<ContosoUniversity.Models.SchoolViewModels.EnrollmentDateGroup>

@{
    ViewData["Title"] = "Student Body Statistics";
}

<h2>Student Body Statistics</h2>

<table>
    <tr>
        <th>
            Enrollment Date
        </th>
        <th>
            Students
        </th>
    </tr>

    @foreach (var item in Model)
    {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                @item.StudentCount
            </td>
        </tr>
    }
</table>
```

Run the app and go to the About page. The count of students for each enrollment date is displayed in a table.

Download or view the completed application.

Next steps

In this tutorial, you:

- Added column sort links
- Added a Search box
- Added paging to Students Index
- Added paging to Index method
- Added paging links
- Created an About page

Advance to the next tutorial to learn how to handle data model changes by using migrations.

Next: Handle data model changes

Tutorial: Using the migrations feature - ASP.NET MVC with EF Core

9/22/2020 • 7 minutes to read • Edit Online

In this tutorial, you start using the EF Core migrations feature for managing data model changes. In later tutorials, you'll add more migrations as you change the data model.

In this tutorial, you:

- Learn about migrations
- Change the connection string
- Create an initial migration
- Examine Up and Down methods
- Learn about the data model snapshot
- Apply the migration

Prerequisites

- Sorting, filtering, and paging

About migrations

When you develop a new application, your data model changes frequently, and each time the model changes, it gets out of sync with the database. You started these tutorials by configuring the Entity Framework to create the database if it doesn't exist. Then each time you change the data model -- add, remove, or change entity classes or change your DbContext class -- you can delete the database and EF creates a new one that matches the model, and seeds it with test data.

This method of keeping the database in sync with the data model works well until you deploy the application to production. When the application is running in production it's usually storing data that you want to keep, and you don't want to lose everything each time you make a change such as adding a new column. The EF Core Migrations feature solves this problem by enabling EF to update the database schema instead of creating a new database.

To work with migrations, you can use the **Package Manager Console** (PMC) or the CLI. These tutorials show how to use CLI commands. Information about the PMC is at the end of this tutorial.

Change the connection string

In the *appsettings.json* file, change the name of the database in the connection string to ContosoUniversity2 or some other name that you haven't used on the computer you're using.

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=
(localdb)\\mssqllocaldb;Database=ContosoUniversity2;Trusted_Connection=True;MultipleActiveResultSets=true"
  },
```

This change sets up the project so that the first migration will create a new database. This isn't required to get started with migrations, but you'll see later why it's a good idea.

NOTE

As an alternative to changing the database name, you can delete the database. Use **SQL Server Object Explorer** (SSOX) or the `database drop` CLI command:

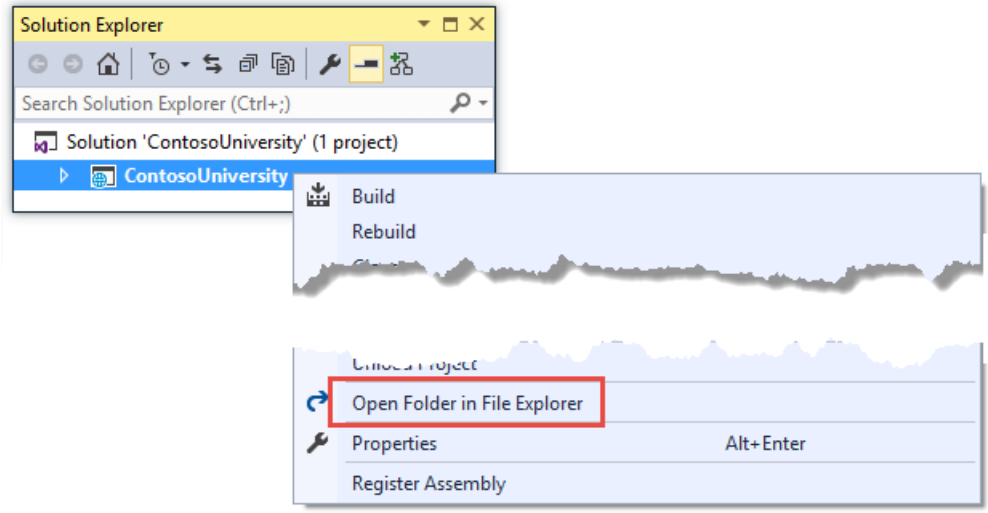
```
dotnet ef database drop
```

The following section explains how to run CLI commands.

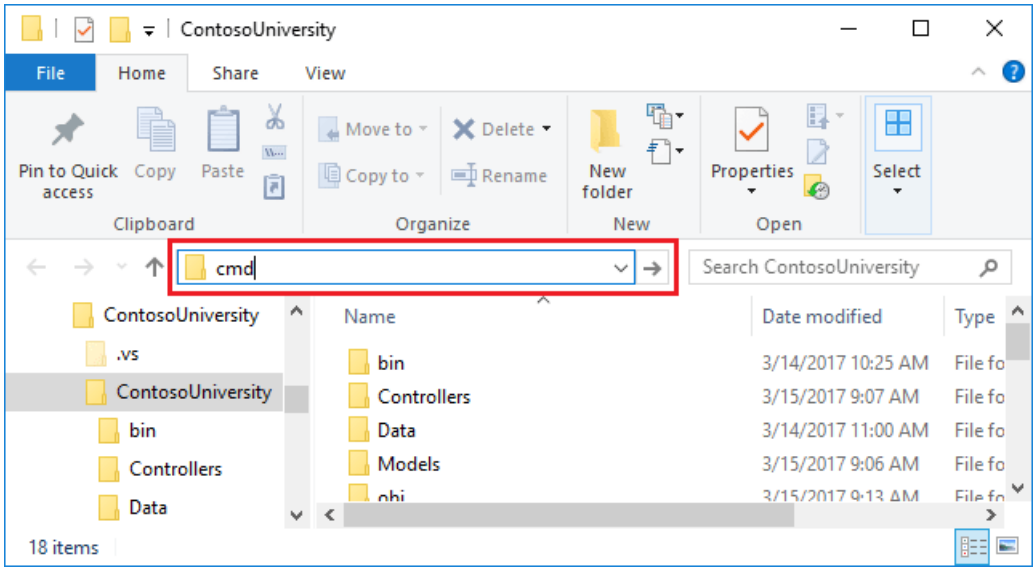
Create an initial migration

Save your changes and build the project. Then open a command window and navigate to the project folder. Here's a quick way to do that:

- In **Solution Explorer**, right-click the project and choose **Open Folder in File Explorer** from the context menu.



- Enter "cmd" in the address bar and press Enter.



Enter the following command in the command window:

```
dotnet tool install --global dotnet-ef
dotnet ef migrations add InitialCreate
```

`dotnet tool install --global dotnet-ef` installs `dotnet ef` as a global tool.

In the preceding commands, output similar to the following is displayed:

```
info: Microsoft.EntityFrameworkCore.Infrastructure[10403]
      Entity Framework Core 2.2.0-rtm-35687 initialized 'SchoolContext' using provider
'Microsoft.EntityFrameworkCore.SqlServer' with options: None
Done. To undo this action, use 'ef migrations remove'
```

If you see an error message "*cannot access the file ... ContosoUniversity.dll because it is being used by another process.*", find the IIS Express icon in the Windows System Tray, and right-click it, then click **ContosoUniversity > Stop Site**.

Examine Up and Down methods

When you executed the `migrations add` command, EF generated the code that will create the database from scratch. This code is in the *Migrations* folder, in the file named *<timestamp>_InitialCreate.cs*. The `Up` method of the `InitialCreate` class creates the database tables that correspond to the data model entity sets, and the `Down` method deletes them, as shown in the following example.

```
public partial class InitialCreate : Migration
{
    protected override void Up(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.CreateTable(
            name: "Course",
            columns: table => new
            {
                CourseID = table.Column<int>(nullable: false),
                Credits = table.Column<int>(nullable: false),
                Title = table.Column<string>(nullable: true)
            },
            constraints: table =>
            {
                table.PrimaryKey("PK_Course", x => x.CourseID);
            });

        // Additional code not shown
    }

    protected override void Down(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.DropTable(
            name: "Enrollment");
        // Additional code not shown
    }
}
```

Migrations calls the `Up` method to implement the data model changes for a migration. When you enter a command to roll back the update, Migrations calls the `Down` method.

This code is for the initial migration that was created when you entered the `migrations add InitialCreate` command. The migration name parameter ("InitialCreate" in the example) is used for the file name and can be whatever you want. It's best to choose a word or phrase that summarizes what is being done in the migration. For example, you might name a later migration "AddDepartmentTable".

If you created the initial migration when the database already exists, the database creation code is generated but it doesn't have to run because the database already matches the data model. When you deploy the app to another environment where the database doesn't exist yet, this code will run to create your database, so it's a

good idea to test it first. That's why you changed the name of the database in the connection string earlier -- so that migrations can create a new one from scratch.

The data model snapshot

Migrations creates a *snapshot* of the current database schema in *Migrations/SchoolContextModelSnapshot.cs*. When you add a migration, EF determines what changed by comparing the data model to the snapshot file.

Use the dotnet ef migrations remove command to remove a migration. `dotnet ef migrations remove` deletes the migration and ensures the snapshot is correctly reset. If `dotnet ef migrations remove` fails, use `dotnet ef migrations remove -v` to get more information on the failure.

See EF Core Migrations in Team Environments for more information about how the snapshot file is used.

Apply the migration

In the command window, enter the following command to create the database and tables in it.

```
dotnet ef database update
```

The output from the command is similar to the `migrations add` command, except that you see logs for the SQL commands that set up the database. Most of the logs are omitted in the following sample output. If you prefer not to see this level of detail in log messages, you can change the log level in the *appsettings.Development.json* file. For more information, see Logging in .NET Core and ASP.NET Core.

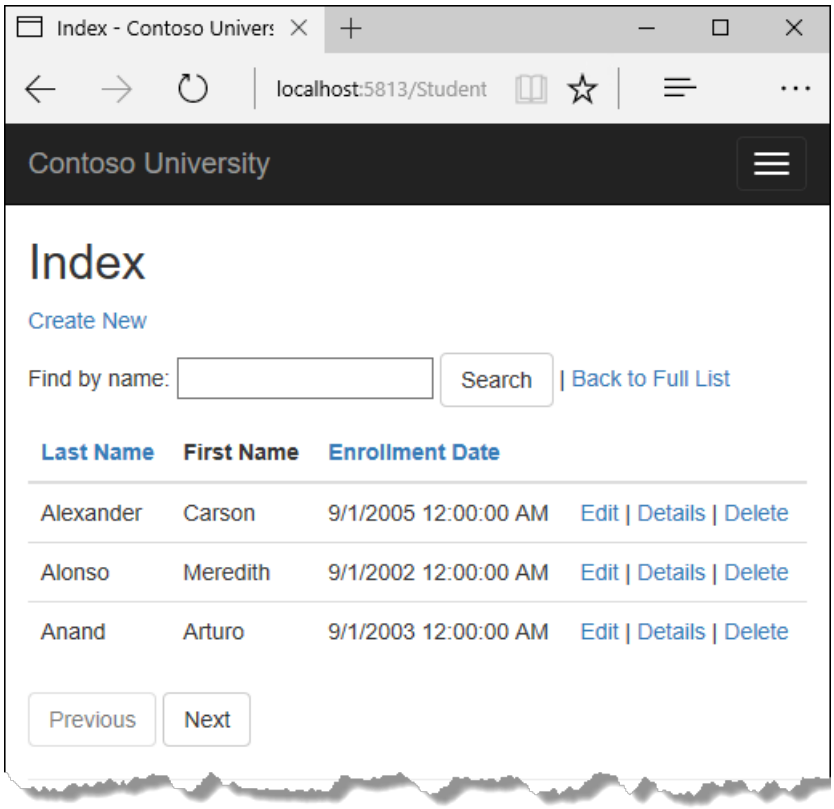
```
info: Microsoft.EntityFrameworkCore.Infrastructure[10403]
      Entity Framework Core 2.2.0-rtm-35687 initialized 'SchoolContext' using provider
'Microsoft.EntityFrameworkCore.SqlServer' with options: None
info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (274ms) [Parameters=[], CommandType='Text', CommandTimeout='60']
      CREATE DATABASE [ContosoUniversity2];
info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (60ms) [Parameters=[], CommandType='Text', CommandTimeout='60']
      IF SERVERPROPERTY('EngineEdition') <> 5
      BEGIN
          ALTER DATABASE [ContosoUniversity2] SET READ_COMMITTED_SNAPSHOT ON;
      END;
info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (15ms) [Parameters=[], CommandType='Text', CommandTimeout='30']
      CREATE TABLE [__EFMigrationsHistory] (
          [MigrationId] nvarchar(150) NOT NULL,
          [ProductVersion] nvarchar(32) NOT NULL,
          CONSTRAINT [PK___EFMigrationsHistory] PRIMARY KEY ([MigrationId])
      );

<logs omitted for brevity>

info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (3ms) [Parameters=[], CommandType='Text', CommandTimeout='30']
      INSERT INTO [__EFMigrationsHistory] ([MigrationId], [ProductVersion])
      VALUES (N'20190327172701_InitialCreate', N'2.2.0-rtm-35687');
Done.
```

Use **SQL Server Object Explorer** to inspect the database as you did in the first tutorial. You'll notice the addition of an __EFMigrationsHistory table that keeps track of which migrations have been applied to the database. View the data in that table and you'll see one row for the first migration. (The last log in the preceding CLI output example shows the INSERT statement that creates this row.)

Run the application to verify that everything still works the same as before.



Compare CLI and PMC

The EF tooling for managing migrations is available from .NET Core CLI commands or from PowerShell cmdlets in the Visual Studio **Package Manager Console** (PMC) window. This tutorial shows how to use the CLI, but you can use the PMC if you prefer.

The EF commands for the PMC commands are in the Microsoft.EntityFrameworkCore.Tools package. This package is included in the Microsoft.AspNetCore.App metapackage, so you don't need to add a package reference if your app has a package reference for `Microsoft.AspNetCore.App`.

Important: This isn't the same package as the one you install for the CLI by editing the *.csproj* file. The name of this one ends in `Tools`, unlike the CLI package name which ends in `Tools.DotNet`.

For more information about the CLI commands, see .NET Core CLI.

For more information about the PMC commands, see Package Manager Console (Visual Studio).

Next step

In this tutorial, you:

- Learned about migrations
- Learned about NuGet migration packages
- Changed the connection string
- Created an initial migration
- Examined Up and Down methods
- Learned about the data model snapshot
- Applied the migration

Advance to the next tutorial to begin looking at more advanced topics about expanding the data model. Along the way you'll create and apply additional migrations.

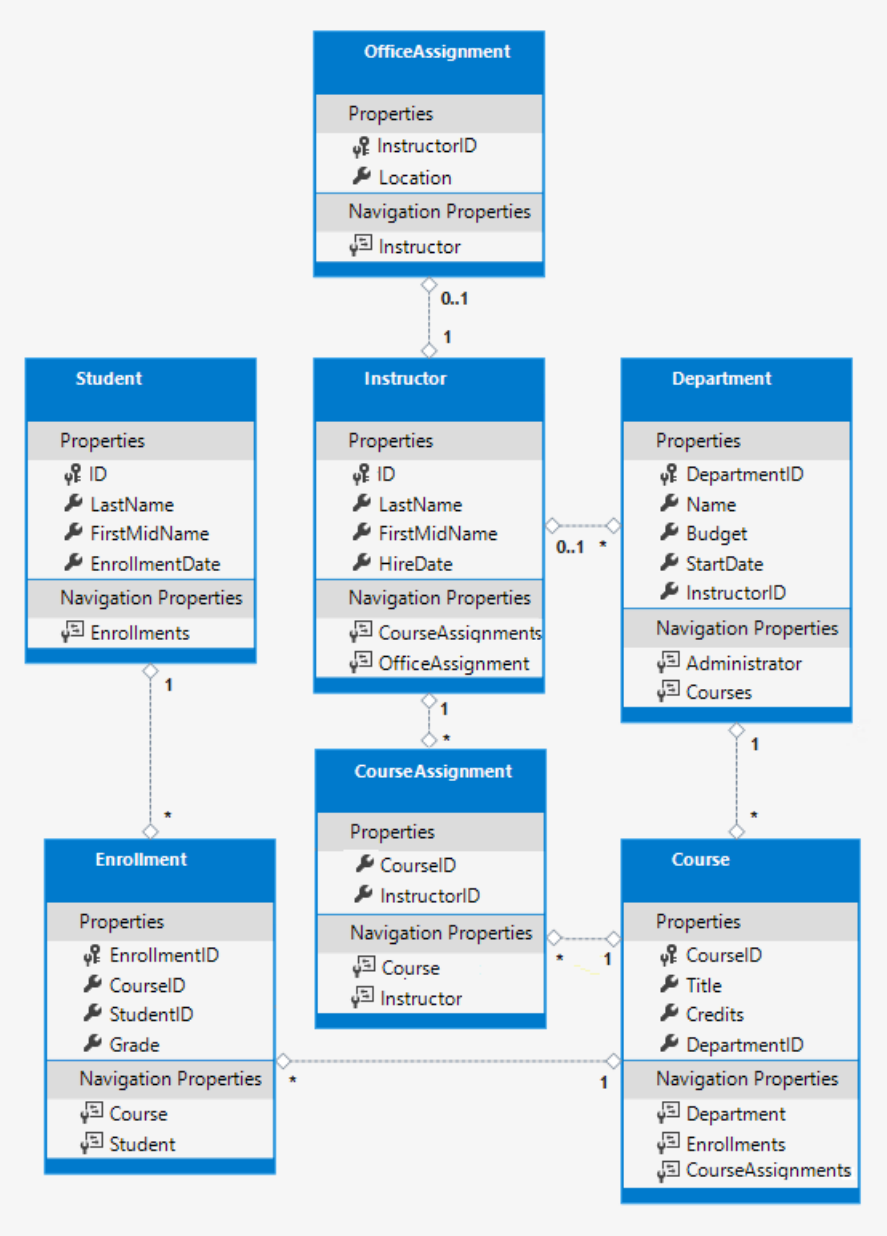
Create and apply additional migrations

Tutorial: Create a complex data model - ASP.NET MVC with EF Core

9/22/2020 • 30 minutes to read • Edit Online

In the previous tutorials, you worked with a simple data model that was composed of three entities. In this tutorial, you'll add more entities and relationships and you'll customize the data model by specifying formatting, validation, and database mapping rules.

When you're finished, the entity classes will make up the completed data model that's shown in the following illustration:



In this tutorial, you:

- Customize the Data model
- Make changes to Student entity
- Create Instructor entity
- Create OfficeAssignment entity

- Modify Course entity
- Create Department entity
- Modify Enrollment entity
- Update the database context
- Seed database with test data
- Add a migration
- Change the connection string
- Update the database

Prerequisites

- Using EF Core migrations

Customize the Data model

In this section you'll see how to customize the data model by using attributes that specify formatting, validation, and database mapping rules. Then in several of the following sections you'll create the complete School data model by adding attributes to the classes you already created and creating new classes for the remaining entity types in the model.

The DataType attribute

For student enrollment dates, all of the web pages currently display the time along with the date, although all you care about for this field is the date. By using data annotation attributes, you can make one code change that will fix the display format in every view that shows the data. To see an example of how to do that, you'll add an attribute to the `EnrollmentDate` property in the `Student` class.

In *Models/Student.cs*, add a `using` statement for the `System.ComponentModel.DataAnnotations` namespace and add `DataType` and `DisplayFormat` attributes to the `EnrollmentDate` property, as shown in the following example:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `DataType` attribute is used to specify a data type that's more specific than the database intrinsic type. In this case we only want to keep track of the date, not the date and time. The `DataType` Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress, and more. The `DataType` attribute can also enable the application to automatically provide type-specific features. For example, a `mailto:` link can be created for `DataType.EmailAddress`, and a date selector can be provided for `DataType.Date` in browsers that support HTML5. The `DataType` attribute emits HTML 5 `data-` (pronounced data dash) attributes that HTML 5 browsers can understand. The `DataType` attributes don't provide any validation.

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the data field is displayed according to the default formats based on the server's CultureInfo.

The `DisplayFormat` attribute is used to explicitly specify the date format:

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
```

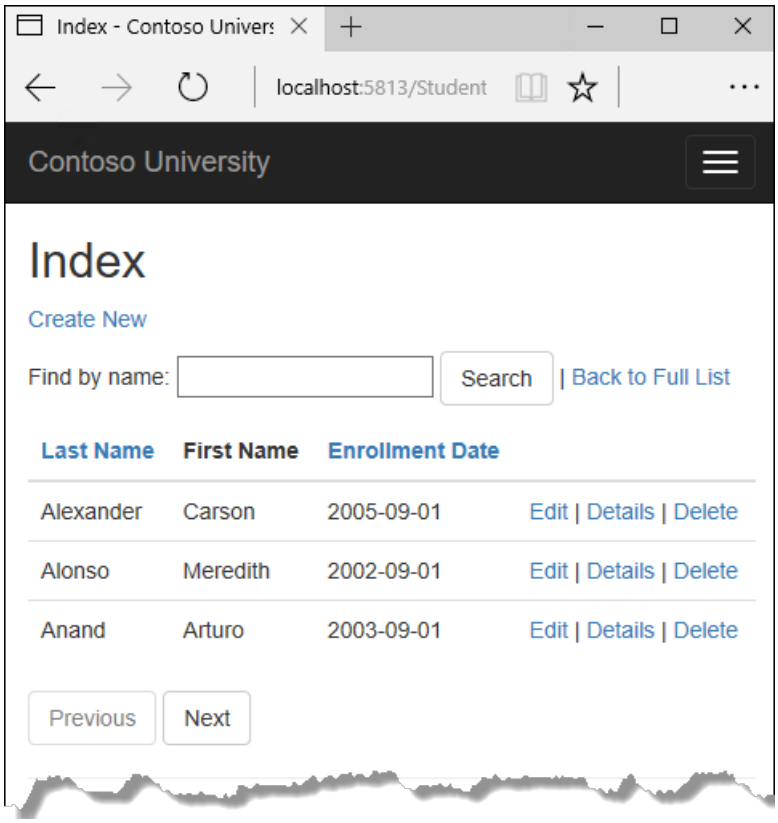
The `ApplyFormatInEditMode` setting specifies that the formatting should also be applied when the value is displayed in a text box for editing. (You might not want that for some fields -- for example, for currency values, you might not want the currency symbol in the text box for editing.)

You can use the `DisplayFormat` attribute by itself, but it's generally a good idea to use the `DataType` attribute also. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen, and provides the following benefits that you don't get with `DisplayFormat`:

- The browser can enable HTML5 features (for example to show a calendar control, the locale-appropriate currency symbol, email links, some client-side input validation, etc.).
- By default, the browser will render data using the correct format based on your locale.

For more information, see the <input> tag helper documentation.

Run the app, go to the Students Index page and notice that times are no longer displayed for the enrollment dates. The same will be true for any view that uses the Student model.



The StringLength attribute

You can also specify data validation rules and validation error messages using attributes. The `StringLength` attribute sets the maximum length in the database and provides client side and server side validation for ASP.NET Core MVC. You can also specify the minimum string length in this attribute, but the minimum value has no impact on the database schema.

Suppose you want to ensure that users don't enter more than 50 characters for a name. To add this limitation, add `StringLength` attributes to the `LastName` and `FirstMidName` properties, as shown in the following example:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50)]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `StringLength` attribute won't prevent a user from entering white space for a name. You can use the `RegularExpression` attribute to apply restrictions to the input. For example, the following code requires the first character to be upper case and the remaining characters to be alphabetical:

```
[RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
```

The `MaxLength` attribute provides functionality similar to the `StringLength` attribute but doesn't provide client side validation.

The database model has now changed in a way that requires a change in the database schema. You'll use migrations to update the schema without losing any data that you may have added to the database by using the application UI.

Save your changes and build the project. Then open the command window in the project folder and enter the following commands:

```
dotnet ef migrations add MaxLengthOnNames
```

```
dotnet ef database update
```

The `migrations add` command warns that data loss may occur, because the change makes the maximum length shorter for two columns. Migrations creates a file named *<timeStamp>_MaxLengthOnNames.cs*. This file contains code in the `Up` method that will update the database to match the current data model. The `database update` command ran that code.

The timestamp prefixed to the migrations file name is used by Entity Framework to order the migrations. You can create multiple migrations before running the update-database command, and then all of the migrations are applied in the order in which they were created.

Run the app, select the **Students** tab, click **Create New**, and try to enter either name longer than 50 characters. The application should prevent you from doing this.

The Column attribute

You can also use attributes to control how your classes and properties are mapped to the database. Suppose you had used the name `FirstMidName` for the first-name field because the field might also contain a middle name.

But you want the database column to be named `FirstName`, because users who will be writing ad-hoc queries against the database are accustomed to that name. To make this mapping, you can use the `Column` attribute.

The `Column` attribute specifies that when the database is created, the column of the `Student` table that maps to the `FirstMidName` property will be named `FirstName`. In other words, when your code refers to `Student.FirstMidName`, the data will come from or be updated in the `FirstName` column of the `Student` table. If you don't specify column names, they're given the same name as the property name.

In the *Student.cs* file, add a `using` statement for `System.ComponentModel.DataAnnotations.Schema` and add the column name attribute to the `FirstMidName` property, as shown in the following highlighted code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50)]
        [Column("FirstName")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

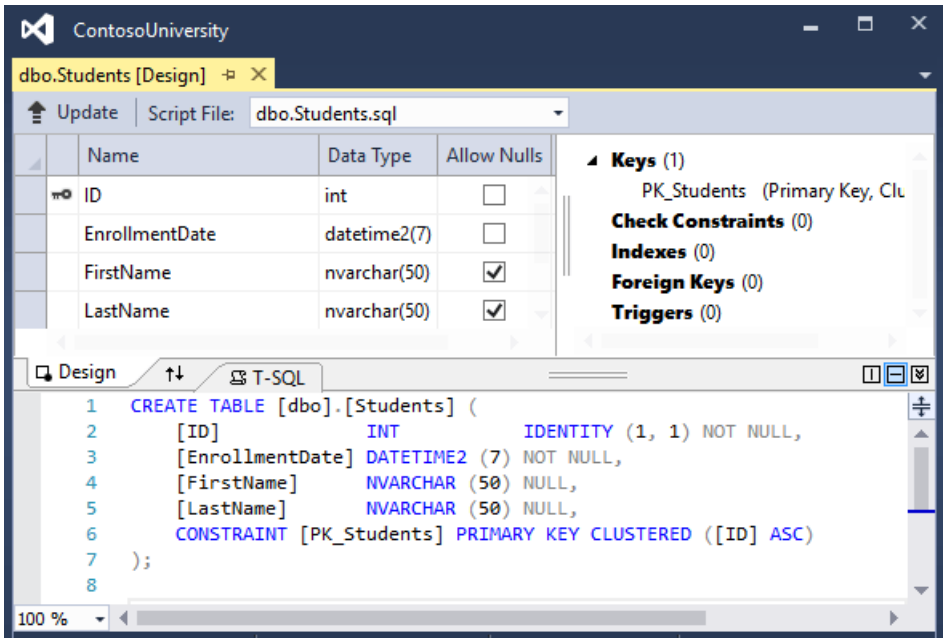
The addition of the `Column` attribute changes the model backing the `SchoolContext`, so it won't match the database.

Save your changes and build the project. Then open the command window in the project folder and enter the following commands to create another migration:

```
dotnet ef migrations add ColumnFirstName
```

```
dotnet ef database update
```

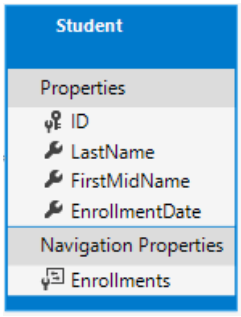
In **SQL Server Object Explorer**, open the Student table designer by double-clicking the **Student** table.



Before you applied the first two migrations, the name columns were of type nvarchar(MAX). They're now nvarchar(50) and the column name has changed from FirstMidName to FirstName.

> **NOTE**
> If you try to compile before you finish creating all of the entity classes in the following sections, you might get compiler errors.

Changes to Student entity



In *Models/Student.cs*, replace the code you added earlier with the following code. The changes are highlighted.

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [Required]
        [StringLength(50)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50)]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }
        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The Required attribute

The `Required` attribute makes the name properties required fields. The `Required` attribute isn't needed for non-nullable types such as value types (DateTime, int, double, float, etc.). Types that can't be null are automatically treated as required fields.

The `Required` attribute must be used with `MinimumLength` for the `MinimumLength` to be enforced.

```
[Display(Name = "Last Name")]
[Required]
[StringLength(50, MinimumLength=2)]
public string LastName { get; set; }
```

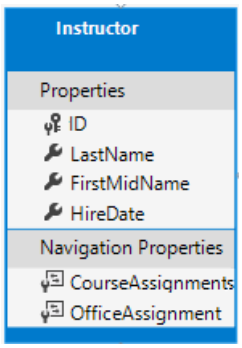
The Display attribute

The `Display` attribute specifies that the caption for the text boxes should be "First Name", "Last Name", "Full Name", and "Enrollment Date" instead of the property name in each instance (which has no space dividing the words).

The FullName calculated property

`FullName` is a calculated property that returns a value that's created by concatenating two other properties. Therefore it has only a get accessor, and no `FullName` column will be generated in the database.

Create Instructor entity



Create *Models/Instructor.cs*, replacing the template code with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor
    {
        public int ID { get; set; }

        [Required]
        [Display(Name = "Last Name")]
        [StringLength(50)]
        public string LastName { get; set; }

        [Required]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        [StringLength(50)]
        public string FirstMidName { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get { return LastName + ", " + FirstMidName; }
        }

        public ICollection<CourseAssignment> CourseAssignments { get; set; }
        public OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Notice that several properties are the same in the Student and Instructor entities. In the Implementing Inheritance tutorial later in this series, you'll refactor this code to eliminate the redundancy.

You can put multiple attributes on one line, so you could also write the `HireDate` attributes as follows:

```
[DataType(DataType.Date),Display(Name = "Hire Date"),DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
```

The CourseAssignments and OfficeAssignment navigation properties

The `CourseAssignments` and `OfficeAssignment` properties are navigation properties.

An instructor can teach any number of courses, so `CourseAssignments` is defined as a collection.

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

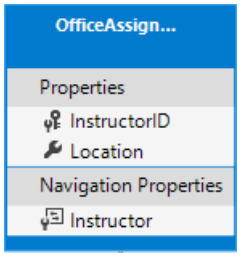
If a navigation property can hold multiple entities, its type must be a list in which entries can be added, deleted, and updated. You can specify `ICollection<T>` or a type such as `List<T>` or `HashSet<T>`. If you specify `ICollection<T>`, EF creates a `HashSet<T>` collection by default.

The reason why these are `CourseAssignment` entities is explained below in the section about many-to-many relationships.

Contoso University business rules state that an instructor can only have at most one office, so the `OfficeAssignment` property holds a single OfficeAssignment entity (which may be null if no office is assigned).

```
public OfficeAssignment OfficeAssignment { get; set; }
```

Create OfficeAssignment entity



Create *Models/OfficeAssignment.cs* with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class OfficeAssignment
    {
        [Key]
        public int InstructorID { get; set; }
        [StringLength(50)]
        [Display(Name = "Office Location")]
        public string Location { get; set; }

        public Instructor Instructor { get; set; }
    }
}
```

The Key attribute

There's a one-to-zero-or-one relationship between the Instructor and the OfficeAssignment entities. An office assignment only exists in relation to the instructor it's assigned to, and therefore its primary key is also its foreign key to the Instructor entity. But the Entity Framework can't automatically recognize InstructorID as the primary key of this entity because its name doesn't follow the ID or classnameID naming convention. Therefore, the `Key` attribute is used to identify it as the key:

```
[Key]
public int InstructorID { get; set; }
```

You can also use the `Key` attribute if the entity does have its own primary key but you want to name the property something other than classnameID or ID.

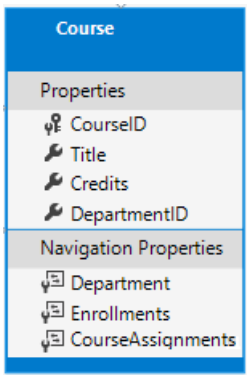
By default, EF treats the key as non-database-generated because the column is for an identifying relationship.

The Instructor navigation property

The Instructor entity has a nullable `OfficeAssignment` navigation property (because an instructor might not have an office assignment), and the OfficeAssignment entity has a non-nullable `Instructor` navigation property (because an office assignment can't exist without an instructor -- `InstructorID` is non-nullable). When an Instructor entity has a related OfficeAssignment entity, each entity will have a reference to the other one in its navigation property.

You could put a `[Required]` attribute on the Instructor navigation property to specify that there must be a related instructor, but you don't have to do that because the `InstructorID` foreign key (which is also the key to this table) is non-nullable.

Modify Course entity



In *Models/Course.cs*, replace the code you added earlier with the following code. The changes are highlighted.

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        [Display(Name = "Number")]
        public int CourseID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Title { get; set; }

        [Range(0, 5)]
        public int Credits { get; set; }

        public int DepartmentID { get; set; }

        public Department Department { get; set; }
        public ICollection<Enrollment> Enrollments { get; set; }
        public ICollection<CourseAssignment> CourseAssignments { get; set; }
    }
}
```

The course entity has a foreign key property `DepartmentID` which points to the related Department entity and it has a `Department` navigation property.

The Entity Framework doesn't require you to add a foreign key property to your data model when you have a navigation property for a related entity. EF automatically creates foreign keys in the database wherever they're needed and creates shadow properties for them. But having the foreign key in the data model can make updates simpler and more efficient. For example, when you fetch a course entity to edit, the Department entity is null if you don't load it, so when you update the course entity, you would have to first fetch the Department entity. When the foreign key property `DepartmentID` is included in the data model, you don't need to fetch the Department entity before you update.

The DatabaseGenerated attribute

The `DatabaseGenerated` attribute with the `None` parameter on the `CourseID` property specifies that primary key values are provided by the user rather than generated by the database.

```
[DatabaseGenerated(DatabaseGeneratedOption.None)]
[Display(Name = "Number")]
public int CourseID { get; set; }
```

By default, Entity Framework assumes that primary key values are generated by the database. That's what you want in most scenarios. However, for Course entities, you'll use a user-specified course number such as a 1000 series for one department, a 2000 series for another department, and so on.

The `DatabaseGenerated` attribute can also be used to generate default values, as in the case of database columns used to record the date a row was created or updated. For more information, see Generated Properties.

Foreign key and navigation properties

The foreign key properties and navigation properties in the Course entity reflect the following relationships:

A course is assigned to one department, so there's a `DepartmentID` foreign key and a `Department` navigation property for the reasons mentioned above.

```
public int DepartmentID { get; set; }
public Department Department { get; set; }
```

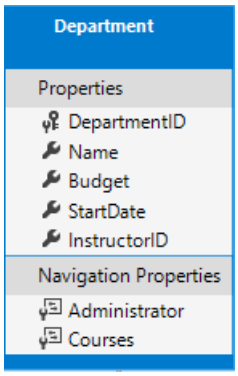
A course can have any number of students enrolled in it, so the `Enrollments` navigation property is a collection:

```
public ICollection<Enrollment> Enrollments { get; set; }
```

A course may be taught by multiple instructors, so the `CourseAssignments` navigation property is a collection (the type `CourseAssignment` is explained later):

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

Create Department entity



Create *Models/Department.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The Column attribute

Earlier you used the `Column` attribute to change column name mapping. In the code for the Department entity, the `Column` attribute is being used to change SQL data type mapping so that the column will be defined using the SQL Server money type in the database:

```
[Column(TypeName="money")]
public decimal Budget { get; set; }
```

Column mapping is generally not required, because the Entity Framework chooses the appropriate SQL Server data type based on the CLR type that you define for the property. The CLR `decimal` type maps to a SQL Server `decimal` type. But in this case you know that the column will be holding currency amounts, and the money data type is more appropriate for that.

Foreign key and navigation properties

The foreign key and navigation properties reflect the following relationships:

A department may or may not have an administrator, and an administrator is always an instructor. Therefore the `InstructorID` property is included as the foreign key to the Instructor entity, and a question mark is added after the `int` type designation to mark the property as nullable. The navigation property is named `Administrator` but holds an Instructor entity:

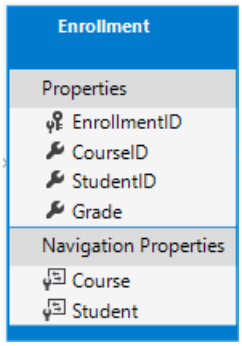
```
public int? InstructorID { get; set; }
public Instructor Administrator { get; set; }
```

A department may have many courses, so there's a Courses navigation property:

```
public ICollection<Course> Courses { get; set; }
```

> **NOTE**
> By convention, the Entity Framework enables cascade delete for non-nullable foreign keys and for many-to-many relationships. This can result in circular cascade delete rules, which will cause an exception when you try to add a migration. For example, if you didn't define the Department.InstructorID property as nullable, EF would configure a cascade delete rule to delete the department when you delete the instructor, which isn't what you want to have happen. If your business rules required the `InstructorID` property to be non-nullable, you would have to use the following fluent API statement to disable cascade delete on the relationship:
>
> ```
> modelBuilder.Entity<Department>()
>    .HasOne(d => d.Administrator)
>    .WithMany()
>    .OnDelete(DeleteBehavior.Restrict)
> ```

Modify Enrollment entity



In *Models/Enrollment.cs*, replace the code you added earlier with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        [DisplayFormat(NullDisplayText = "No grade")]
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

Foreign key and navigation properties

The foreign key properties and navigation properties reflect the following relationships:

An enrollment record is for a single course, so there's a `CourseID` foreign key property and a `Course` navigation property:

```
public int CourseID { get; set; }
public Course Course { get; set; }
```

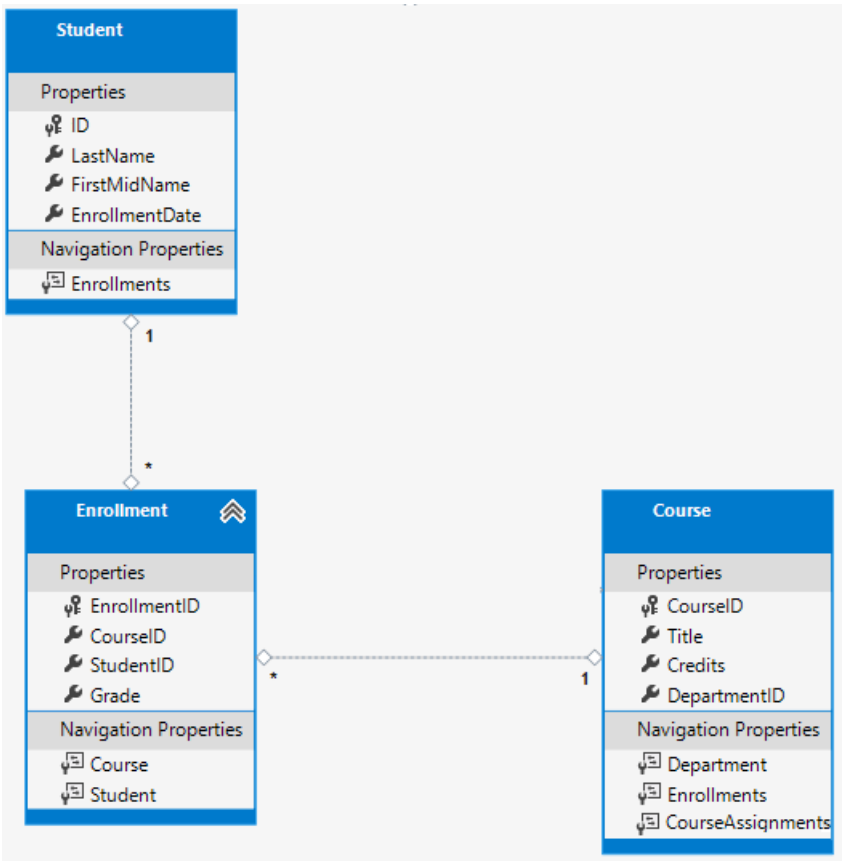
An enrollment record is for a single student, so there's a `StudentID` foreign key property and a `Student` navigation property:

```
public int StudentID { get; set; }
public Student Student { get; set; }
```

Many-to-Many relationships

There's a many-to-many relationship between the Student and Course entities, and the Enrollment entity functions as a many-to-many join table *with payload* in the database. "With payload" means that the Enrollment table contains additional data besides foreign keys for the joined tables (in this case, a primary key and a Grade property).

The following illustration shows what these relationships look like in an entity diagram. (This diagram was generated using the Entity Framework Power Tools for EF 6.x; creating the diagram isn't part of the tutorial, it's just being used here as an illustration.)

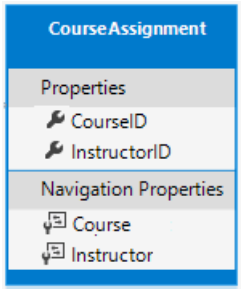


Each relationship line has a 1 at one end and an asterisk (*) at the other, indicating a one-to-many relationship.

If the Enrollment table didn't include grade information, it would only need to contain the two foreign keys CourseID and StudentID. In that case, it would be a many-to-many join table without payload (or a pure join table) in the database. The Instructor and Course entities have that kind of many-to-many relationship, and your next step is to create an entity class to function as a join table without payload.

(EF 6.x supports implicit join tables for many-to-many relationships, but EF Core doesn't. For more information, see the discussion in the EF Core GitHub repository.)

The CourseAssignment entity



Create *Models/CourseAssignment.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class CourseAssignment
    {
        public int InstructorID { get; set; }
        public int CourseID { get; set; }
        public Instructor Instructor { get; set; }
        public Course Course { get; set; }
    }
}
```

Join entity names

A join table is required in the database for the Instructor-to-Courses many-to-many relationship, and it has to be represented by an entity set. It's common to name a join entity `EntityName1EntityName2`, which in this case would be `CourseInstructor`. However, we recommend that you choose a name that describes the relationship. Data models start out simple and grow, with no-payload joins frequently getting payloads later. If you start with a descriptive entity name, you won't have to change the name later. Ideally, the join entity would have its own natural (possibly single word) name in the business domain. For example, Books and Customers could be linked through Ratings. For this relationship, `CourseAssignment` is a better choice than `CourseInstructor`.

Composite key

Since the foreign keys are not nullable and together uniquely identify each row of the table, there's no need for a separate primary key. The *InstructorID* and *CourseID* properties should function as a composite primary key. The only way to identify composite primary keys to EF is by using the *fluent API* (it can't be done by using attributes). You'll see how to configure the composite primary key in the next section.

The composite key ensures that while you can have multiple rows for one course, and multiple rows for one instructor, you can't have multiple rows for the same instructor and course. The `Enrollment` join entity defines its own primary key, so duplicates of this sort are possible. To prevent such duplicates, you could add a unique index on the foreign key fields, or configure `Enrollment` with a primary composite key similar to `CourseAssignment`. For more information, see Indexes.

Update the database context

Add the following highlighted code to the *Data/SchoolContext.cs* file:

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) : base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
        public DbSet<Department> Departments { get; set; }
        public DbSet<Instructor> Instructors { get; set; }
        public DbSet<OfficeAssignment> OfficeAssignments { get; set; }
        public DbSet<CourseAssignment> CourseAssignments { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
            modelBuilder.Entity<Department>().ToTable("Department");
            modelBuilder.Entity<Instructor>().ToTable("Instructor");
            modelBuilder.Entity<OfficeAssignment>().ToTable("OfficeAssignment");
            modelBuilder.Entity<CourseAssignment>().ToTable("CourseAssignment");

            modelBuilder.Entity<CourseAssignment>()
                .HasKey(c => new { c.CourseID, c.InstructorID });
        }
    }
}
```

This code adds the new entities and configures the CourseAssignment entity's composite primary key.

About a fluent API alternative

The code in the `OnModelCreating` method of the `DbContext` class uses the *fluent API* to configure EF behavior. The API is called "fluent" because it's often used by stringing a series of method calls together into a single statement, as in this example from the EF Core documentation:

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    modelBuilder.Entity<Blog>()
        .Property(b => b.Url)
        .IsRequired();
}
```

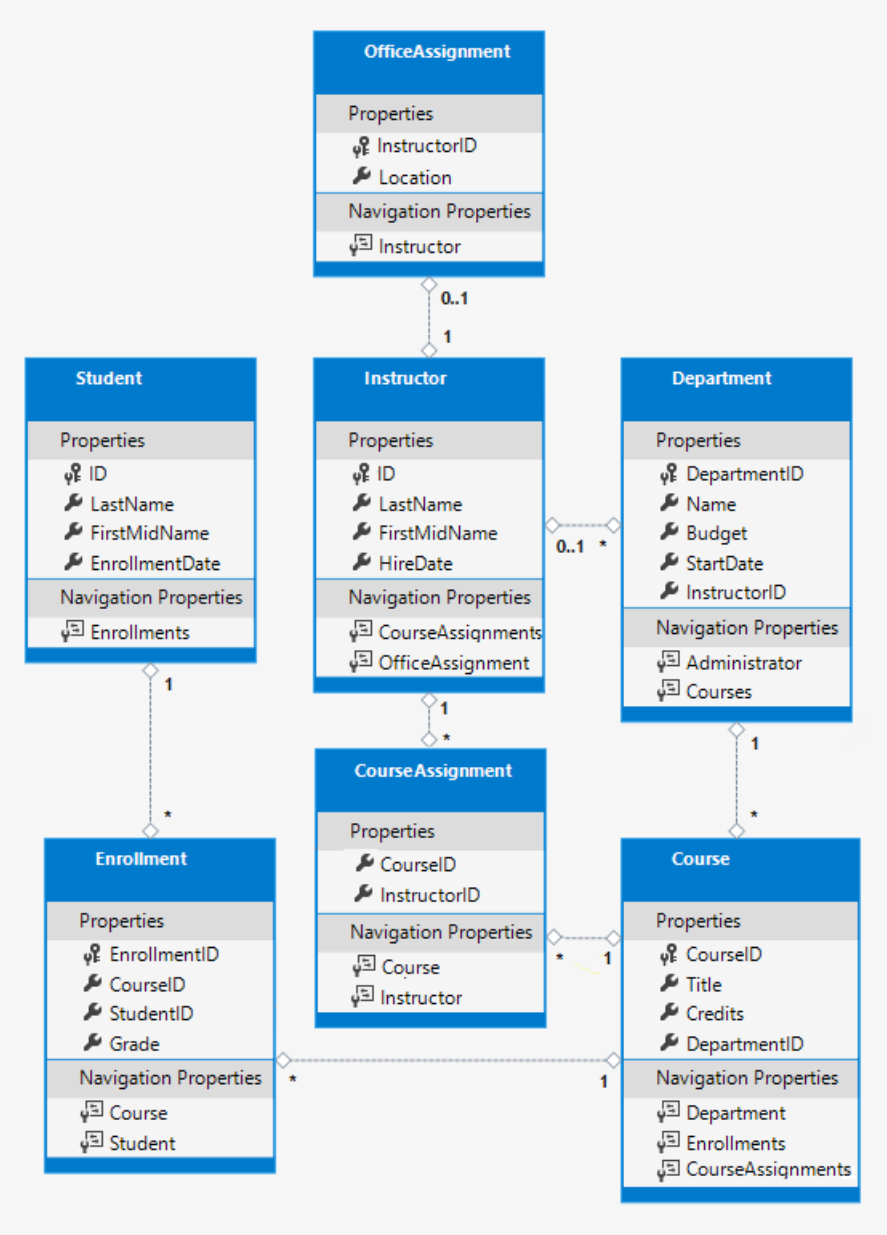
In this tutorial, you're using the fluent API only for database mapping that you can't do with attributes. However, you can also use the fluent API to specify most of the formatting, validation, and mapping rules that you can do by using attributes. Some attributes such as `MinimumLength` can't be applied with the fluent API. As mentioned previously, `MinimumLength` doesn't change the schema, it only applies a client and server side validation rule.

Some developers prefer to use the fluent API exclusively so that they can keep their entity classes "clean." You can mix attributes and fluent API if you want, and there are a few customizations that can only be done by using fluent API, but in general the recommended practice is to choose one of these two approaches and use that consistently as much as possible. If you do use both, note that wherever there's a conflict, Fluent API overrides attributes.

For more information about attributes vs. fluent API, see Methods of configuration.

Entity Diagram Showing Relationships

The following illustration shows the diagram that the Entity Framework Power Tools create for the completed School model.



Besides the one-to-many relationship lines (1 to *), you can see here the one-to-zero-or-one relationship line (1 to 0..1) between the Instructor and OfficeAssignment entities and the zero-or-one-to-many relationship line (0..1 to *) between the Instructor and Department entities.

Seed database with test data

Replace the code in the *Data/DbInitializer.cs* file with the following code in order to provide seed data for the new entities you've created.

```
using System;
using System.Linq;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
```

```
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            //context.Database.EnsureCreated();

            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
                new Student { FirstMidName = "Carson",   LastName = "Alexander",
                    EnrollmentDate = DateTime.Parse("2010-09-01") },
                new Student { FirstMidName = "Meredith", LastName = "Alonso",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Arturo",   LastName = "Anand",
                    EnrollmentDate = DateTime.Parse("2013-09-01") },
                new Student { FirstMidName = "Gytis",    LastName = "Barzdukas",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Yan",      LastName = "Li",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Peggy",    LastName = "Justice",
                    EnrollmentDate = DateTime.Parse("2011-09-01") },
                new Student { FirstMidName = "Laura",    LastName = "Norman",
                    EnrollmentDate = DateTime.Parse("2013-09-01") },
                new Student { FirstMidName = "Nino",     LastName = "Olivetto",
                    EnrollmentDate = DateTime.Parse("2005-09-01") }
            };

            foreach (Student s in students)
            {
                context.Students.Add(s);
            }
            context.SaveChanges();

            var instructors = new Instructor[]
            {
                new Instructor { FirstMidName = "Kim",     LastName = "Abercrombie",
                    HireDate = DateTime.Parse("1995-03-11") },
                new Instructor { FirstMidName = "Fadi",    LastName = "Fakhouri",
                    HireDate = DateTime.Parse("2002-07-06") },
                new Instructor { FirstMidName = "Roger",   LastName = "Harui",
                    HireDate = DateTime.Parse("1998-07-01") },
                new Instructor { FirstMidName = "Candace", LastName = "Kapoor",
                    HireDate = DateTime.Parse("2001-01-15") },
                new Instructor { FirstMidName = "Roger",   LastName = "Zheng",
                    HireDate = DateTime.Parse("2004-02-12") }
            };

            foreach (Instructor i in instructors)
            {
                context.Instructors.Add(i);
            }
            context.SaveChanges();

            var departments = new Department[]
            {
                new Department { Name = "English",     Budget = 350000,
                    StartDate = DateTime.Parse("2007-09-01"),

                InstructorID = instructors.Single(i => i.LastName == "Abercrombie").ID
                },
            new CourseAssignment {
                CourseID = courses.Single(c => c.Title == "Literature" ).CourseID,
                InstructorID = instructors.Single(i => i.LastName == "Abercrombie").ID
                },
        };

        foreach (CourseAssignment ci in courseInstructors)
        {
            context.CourseAssignments.Add(ci);
        }
        context.SaveChanges();

        var enrollments = new Enrollment[]
        {
            new Enrollment {
                StudentID = students.Single(s => s.LastName == "Alexander").ID,
                CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID,
                Grade = Grade.A
            },
                new Enrollment {
                StudentID = students.Single(s => s.LastName == "Alexander").ID,
                CourseID = courses.Single(c => c.Title == "Microeconomics" ).CourseID,
                Grade = Grade.C
                },
                new Enrollment {
                StudentID = students.Single(s => s.LastName == "Alexander").ID,
                CourseID = courses.Single(c => c.Title == "Macroeconomics" ).CourseID,
                Grade = Grade.B
                },
                new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Alonso").ID,
                CourseID = courses.Single(c => c.Title == "Calculus" ).CourseID,
                Grade = Grade.B
                },
                new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Alonso").ID,
                CourseID = courses.Single(c => c.Title == "Trigonometry" ).CourseID,
                Grade = Grade.B
                },
                new Enrollment {
                StudentID = students.Single(s => s.LastName == "Alonso").ID,
                CourseID = courses.Single(c => c.Title == "Composition" ).CourseID,
                Grade = Grade.B
                },
                new Enrollment {
```

```
                    StudentID = students.Single(s => s.LastName == "Anand").ID,
                    CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Anand").ID,
                    CourseID = courses.Single(c => c.Title == "Microeconomics").CourseID,
                    Grade = Grade.B
                    },
                new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Barzdukas").ID,
                    CourseID = courses.Single(c => c.Title == "Chemistry").CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Li").ID,
                    CourseID = courses.Single(c => c.Title == "Composition").CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Justice").ID,
                    CourseID = courses.Single(c => c.Title == "Literature").CourseID,
                    Grade = Grade.B
                    }
            };

            foreach (Enrollment e in enrollments)
            {
                var enrollmentInDataBase = context.Enrollments.Where(
                    s =>
                            s.Student.ID == e.StudentID &&
                            s.Course.CourseID == e.CourseID).SingleOrDefault();
                if (enrollmentInDataBase == null)
                {
                    context.Enrollments.Add(e);
                }
            }
            context.SaveChanges();
        }
    }
}
```

As you saw in the first tutorial, most of this code simply creates new entity objects and loads sample data into properties as required for testing. Notice how the many-to-many relationships are handled: the code creates relationships by creating entities in the `Enrollments` and `CourseAssignment` join entity sets.

Add a migration

Save your changes and build the project. Then open the command window in the project folder and enter the `migrations add` command (don't do the update-database command yet):

```
dotnet ef migrations add ComplexDataModel
```

You get a warning about possible data loss.

```
An operation was scaffolded that may result in the loss of data. Please review the migration for accuracy.
Done. To undo this action, use 'ef migrations remove'
```

If you tried to run the `database update` command at this point (don't do it yet), you would get the following error:

> The ALTER TABLE statement conflicted with the FOREIGN KEY constraint

> "FK_dbo.Course_dbo.Department_DepartmentID". The conflict occurred in database "ContosoUniversity", table "dbo.Department", column 'DepartmentID'.

Sometimes when you execute migrations with existing data, you need to insert stub data into the database to satisfy foreign key constraints. The generated code in the `Up` method adds a non-nullable DepartmentID foreign key to the Course table. If there are already rows in the Course table when the code runs, the `AddColumn` operation fails because SQL Server doesn't know what value to put in the column that can't be null. For this tutorial you'll run the migration on a new database, but in a production application you'd have to make the migration handle existing data, so the following directions show an example of how to do that.

To make this migration work with existing data you have to change the code to give the new column a default value, and create a stub department named "Temp" to act as the default department. As a result, existing Course rows will all be related to the "Temp" department after the `Up` method runs.

- Open the *{timestamp}_ComplexDataModel.cs* file.
- Comment out the line of code that adds the DepartmentID column to the Course table.

```
migrationBuilder.AlterColumn<string>(
    name: "Title",
    table: "Course",
    maxLength: 50,
    nullable: true,
    oldClrType: typeof(string),
    oldNullable: true);

//migrationBuilder.AddColumn<int>(
//    name: "DepartmentID",
//    table: "Course",
//    nullable: false,
//    defaultValue: 0);
```

- Add the following highlighted code after the code that creates the Department table:

```
migrationBuilder.CreateTable(
    name: "Department",
    columns: table => new
    {
        DepartmentID = table.Column<int>(nullable: false)
            .Annotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn),
        Budget = table.Column<decimal>(type: "money", nullable: false),
        InstructorID = table.Column<int>(nullable: true),
        Name = table.Column<string>(maxLength: 50, nullable: true),
        StartDate = table.Column<DateTime>(nullable: false)
    },
    constraints: table =>
    {
        table.PrimaryKey("PK_Department", x => x.DepartmentID);
        table.ForeignKey(
            name: "FK_Department_Instructor_InstructorID",
            column: x => x.InstructorID,
            principalTable: "Instructor",
            principalColumn: "ID",
            onDelete: ReferentialAction.Restrict);
    });

migrationBuilder.Sql("INSERT INTO dbo.Department (Name, Budget, StartDate) VALUES ('Temp', 0.00,
GETDATE())");
// Default value for FK points to department created above, with
// defaultValue changed to 1 in following AddColumn statement.

migrationBuilder.AddColumn<int>(
    name: "DepartmentID",
    table: "Course",
    nullable: false,
    defaultValue: 1);
```

In a production application, you would write code or scripts to add Department rows and relate Course rows to the new Department rows. You would then no longer need the "Temp" department or the default value on the Course.DepartmentID column.

Save your changes and build the project.

Change the connection string

You now have new code in the `DbInitializer` class that adds seed data for the new entities to an empty database. To make EF create a new empty database, change the name of the database in the connection string in *appsettings.json* to ContosoUniversity3 or some other name that you haven't used on the computer you're using.

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=
(localdb)\\mssqllocaldb;Database=ContosoUniversity3;Trusted_Connection=True;MultipleActiveResultSets=true"
  },
```

Save your change to *appsettings.json*.

NOTE

As an alternative to changing the database name, you can delete the database. Use **SQL Server Object Explorer** (SSOX) or the `database drop` CLI command:

```
dotnet ef database drop
```

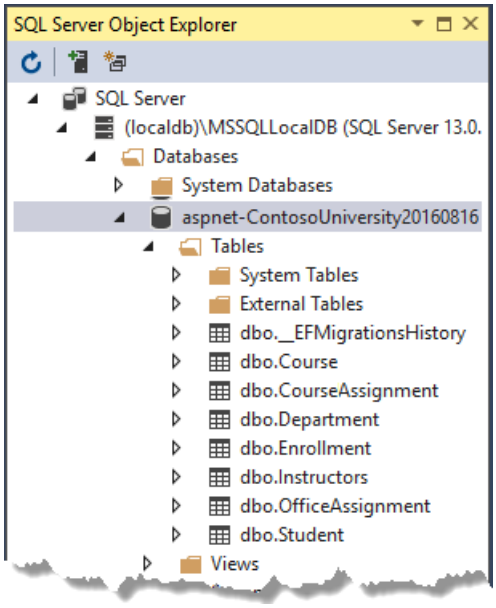
Update the database

After you have changed the database name or deleted the database, run the `database update` command in the command window to execute the migrations.

```
dotnet ef database update
```

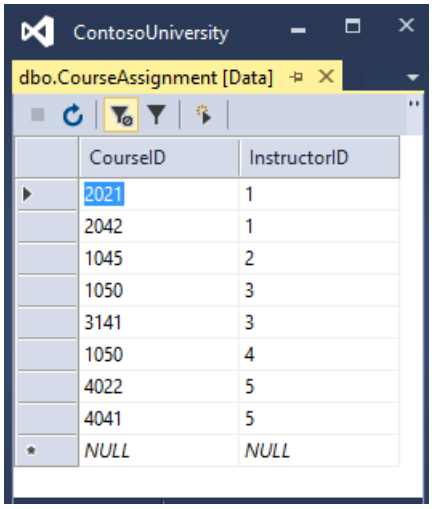
Run the app to cause the `DbInitializer.Initialize` method to run and populate the new database.

Open the database in SSOX as you did earlier, and expand the **Tables** node to see that all of the tables have been created. (If you still have SSOX open from the earlier time, click the **Refresh** button.)



Run the app to trigger the initializer code that seeds the database.

Right-click the **CourseAssignment** table and select **View Data** to verify that it has data in it.



Get the code

Download or view the completed application.

Next steps

In this tutorial, you:

- Customized the Data model
- Made changes to Student entity
- Created Instructor entity
- Created OfficeAssignment entity
- Modified Course entity
- Created Department entity
- Modified Enrollment entity
- Updated the database context
- Seeded database with test data
- Added a migration
- Changed the connection string
- Updated the database

Advance to the next tutorial to learn more about how to access related data.

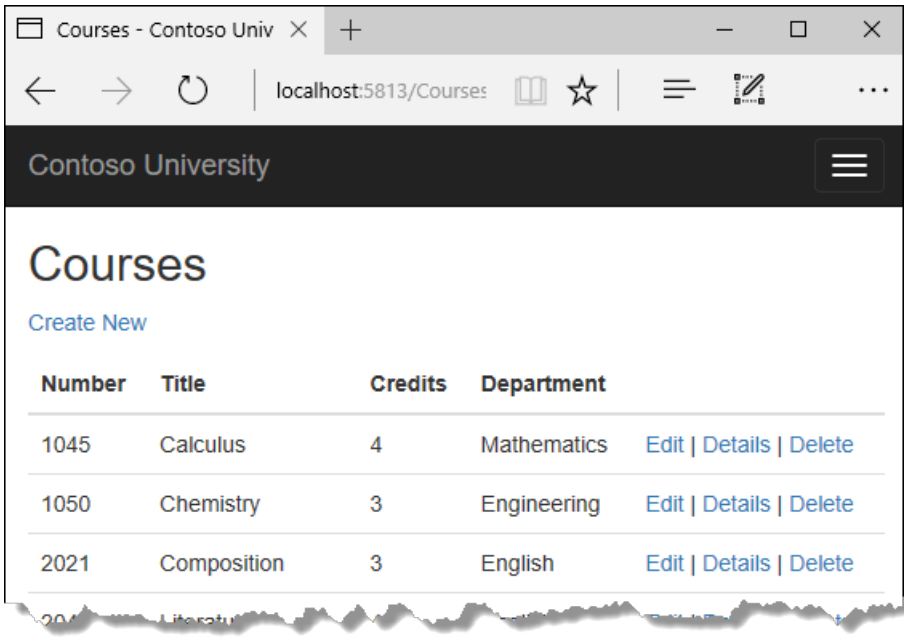
Next: Access related data

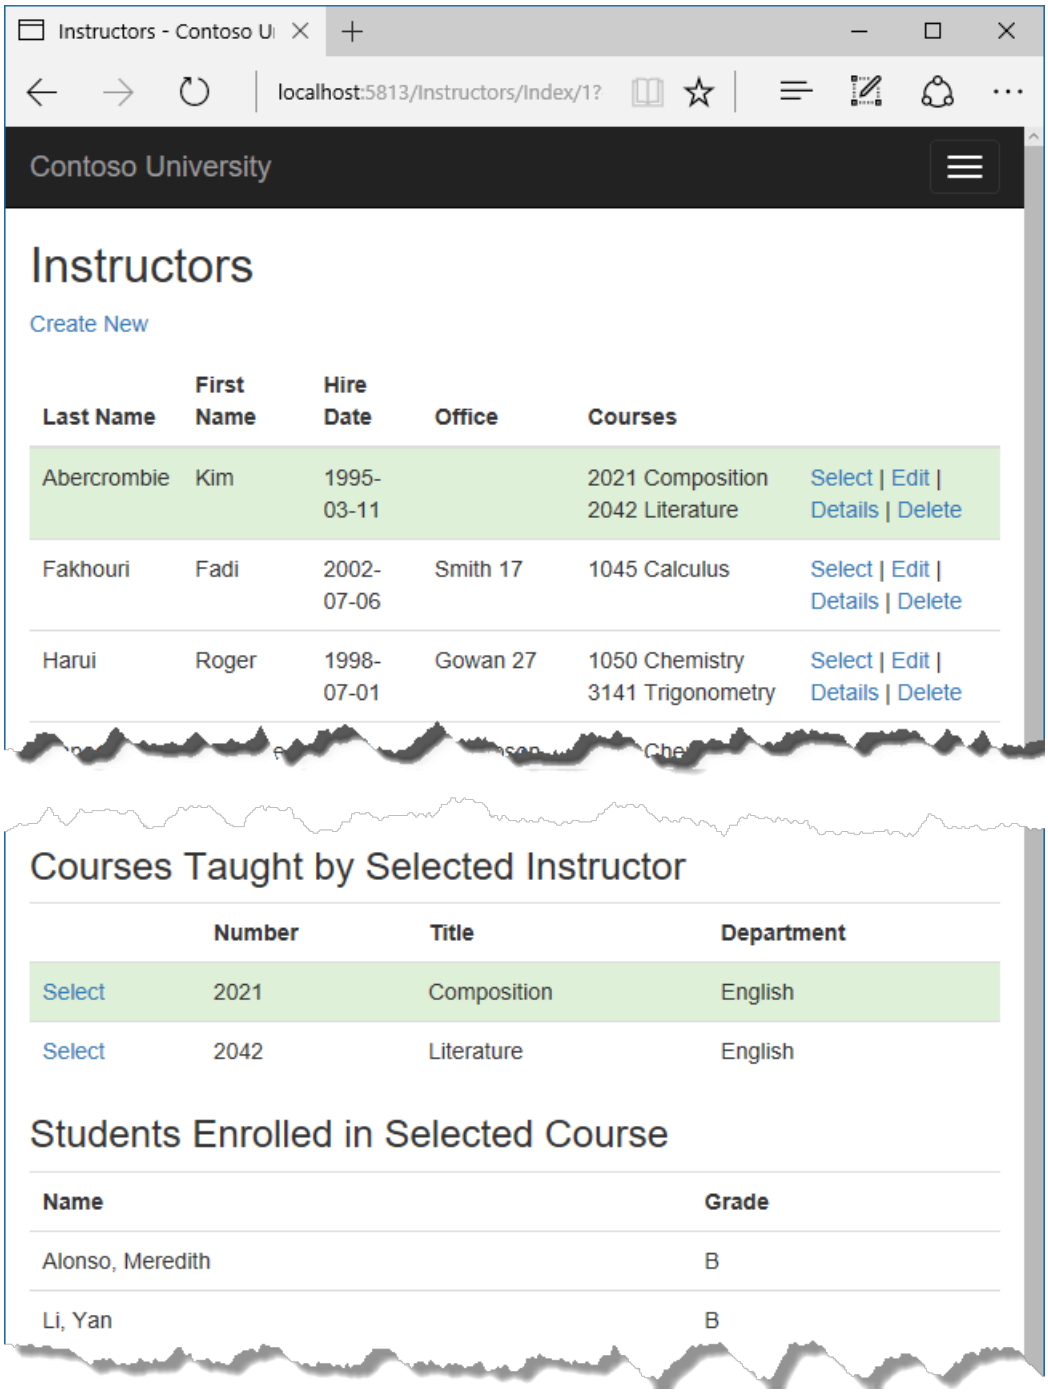
Tutorial: Read related data - ASP.NET MVC with EF Core

9/22/2020 • 14 minutes to read • Edit Online

In the previous tutorial, you completed the School data model. In this tutorial, you'll read and display related data -- that is, data that the Entity Framework loads into navigation properties.

The following illustrations show the pages that you'll work with.





In this tutorial, you:

- Learn how to load related data
- Create a Courses page
- Create an Instructors page
- Learn about explicit loading

Prerequisites

- Create a complex data model

Learn how to load related data

There are several ways that Object-Relational Mapping (ORM) software such as Entity Framework can load related data into the navigation properties of an entity:

- Eager loading. When the entity is read, related data is retrieved along with it. This typically results in a

single join query that retrieves all of the data that's needed. You specify eager loading in Entity Framework Core by using the `Include` and `ThenInclude` methods.

```
var departments = _context.Departments.Include(d => d.Courses);
foreach (Department d in departments)
{
    foreach(Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department entities and related Course entities

You can retrieve some of the data in separate queries, and EF "fixes up" the navigation properties. That is, EF automatically adds the separately retrieved entities where they belong in navigation properties of previously retrieved entities. For the query that retrieves related data, you can use the `Load` method instead of a method that returns a list or object, such as `ToList` or `Single`.

```
var departments = _context.Departments;
foreach (Department d in departments)
{
    _context.Courses.Where(c => c.DepartmentID == d.DepartmentID).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows

Query: Course rows related to Department d

- Explicit loading. When the entity is first read, related data isn't retrieved. You write code that retrieves the related data if it's needed. As in the case of eager loading with separate queries, explicit loading results in multiple queries sent to the database. The difference is that with explicit loading, the code specifies the navigation properties to be loaded. In Entity Framework Core 1.1 you can use the `Load` method to do explicit loading. For example:

```
var departments = _context.Departments;
foreach (Department d in departments)
{
    _context.Entry(d).Collection(p => p.Courses).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows

Query: Course rows related to Department d

- Lazy loading. When the entity is first read, related data isn't retrieved. However, the first time you attempt to access a navigation property, the data required for that navigation property is automatically retrieved. A query is sent to the database each time you try to get data from a navigation property for the first time. Entity Framework Core 1.0 doesn't support lazy loading.

Performance considerations

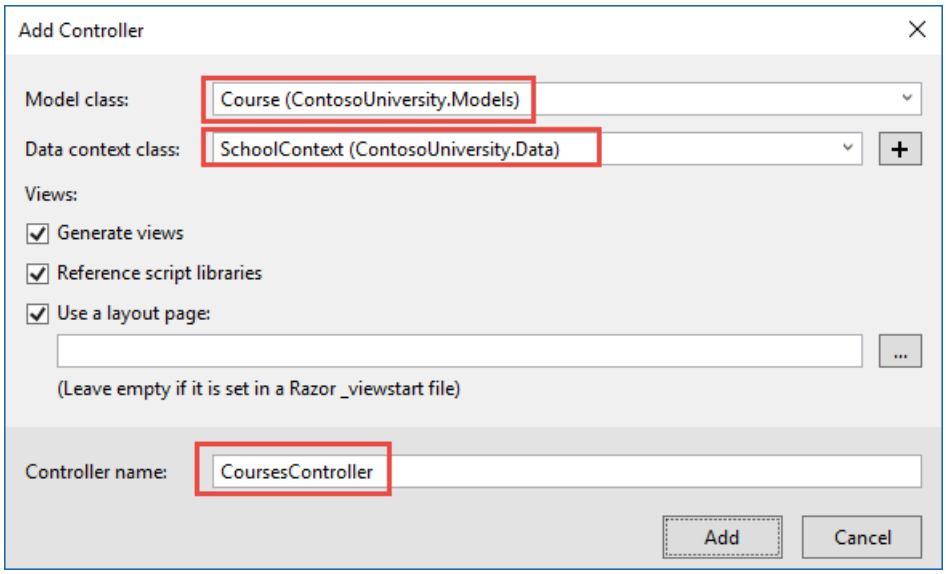
If you know you need related data for every entity retrieved, eager loading often offers the best performance, because a single query sent to the database is typically more efficient than separate queries for each entity retrieved. For example, suppose that each department has ten related courses. Eager loading of all related data would result in just a single (join) query and a single round trip to the database. A separate query for courses for each department would result in eleven round trips to the database. The extra round trips to the database are especially detrimental to performance when latency is high.

On the other hand, in some scenarios separate queries is more efficient. Eager loading of all related data in one query might cause a very complex join to be generated, which SQL Server can't process efficiently. Or if you need to access an entity's navigation properties only for a subset of a set of the entities you're processing, separate queries might perform better because eager loading of everything up front would retrieve more data than you need. If performance is critical, it's best to test performance both ways in order to make the best choice.

Create a Courses page

The Course entity includes a navigation property that contains the Department entity of the department that the course is assigned to. To display the name of the assigned department in a list of courses, you need to get the Name property from the Department entity that's in the `Course.Department` navigation property.

Create a controller named CoursesController for the Course entity type, using the same options for the **MVC Controller with views, using Entity Framework** scaffolder that you did earlier for the Students controller, as shown in the following illustration:



Open *CoursesController.cs* and examine the `Index` method. The automatic scaffolding has specified eager loading for the `Department` navigation property by using the `Include` method.

Replace the `Index` method with the following code that uses a more appropriate name for the `IQueryable` that returns Course entities (`courses` instead of `schoolContext`):

```
public async Task<IActionResult> Index()
{
    var courses = _context.Courses
        .Include(c => c.Department)
        .AsNoTracking();
    return View(await courses.ToListAsync());
}
```

Open *Views/Courses/Index.cshtml* and replace the template code with the following code. The changes are highlighted:

```
@model IEnumerable<ContosoUniversity.Models.Course>

@{
    ViewData["Title"] = "Courses";
}

<h2>Courses</h2>

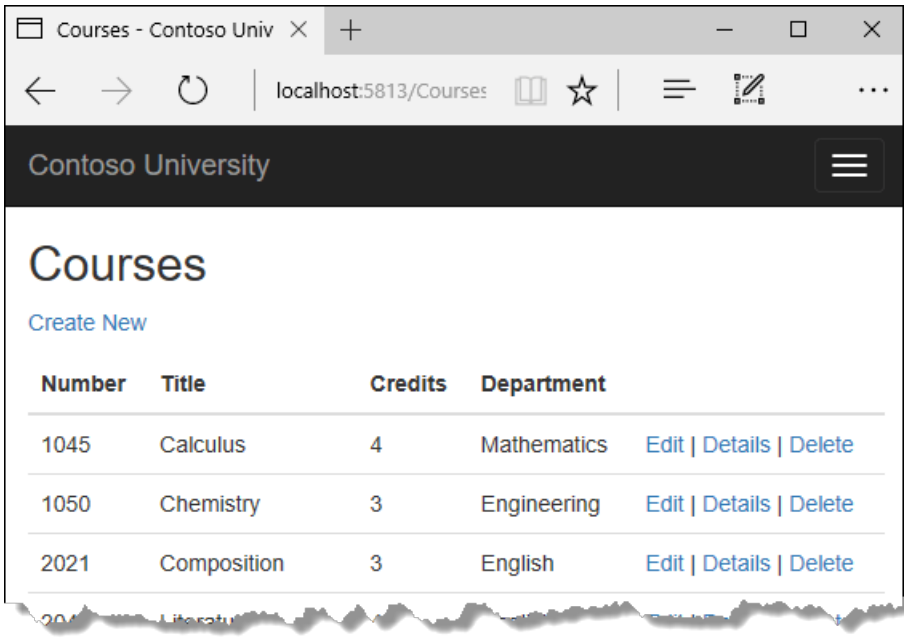
<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.CourseID)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Credits)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Department)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.CourseID)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Credits)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Department.Name)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-id="@item.CourseID">Edit</a> |
                    <a asp-action="Details" asp-route-id="@item.CourseID">Details</a> |
                    <a asp-action="Delete" asp-route-id="@item.CourseID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

You've made the following changes to the scaffolded code:

- Changed the heading from Index to Courses.
- Added a **Number** column that shows the `CourseID` property value. By default, primary keys aren't scaffolded because normally they're meaningless to end users. However, in this case the primary key is meaningful and you want to show it.
- Changed the **Department** column to display the department name. The code displays the `Name` property of the Department entity that's loaded into the `Department` navigation property:

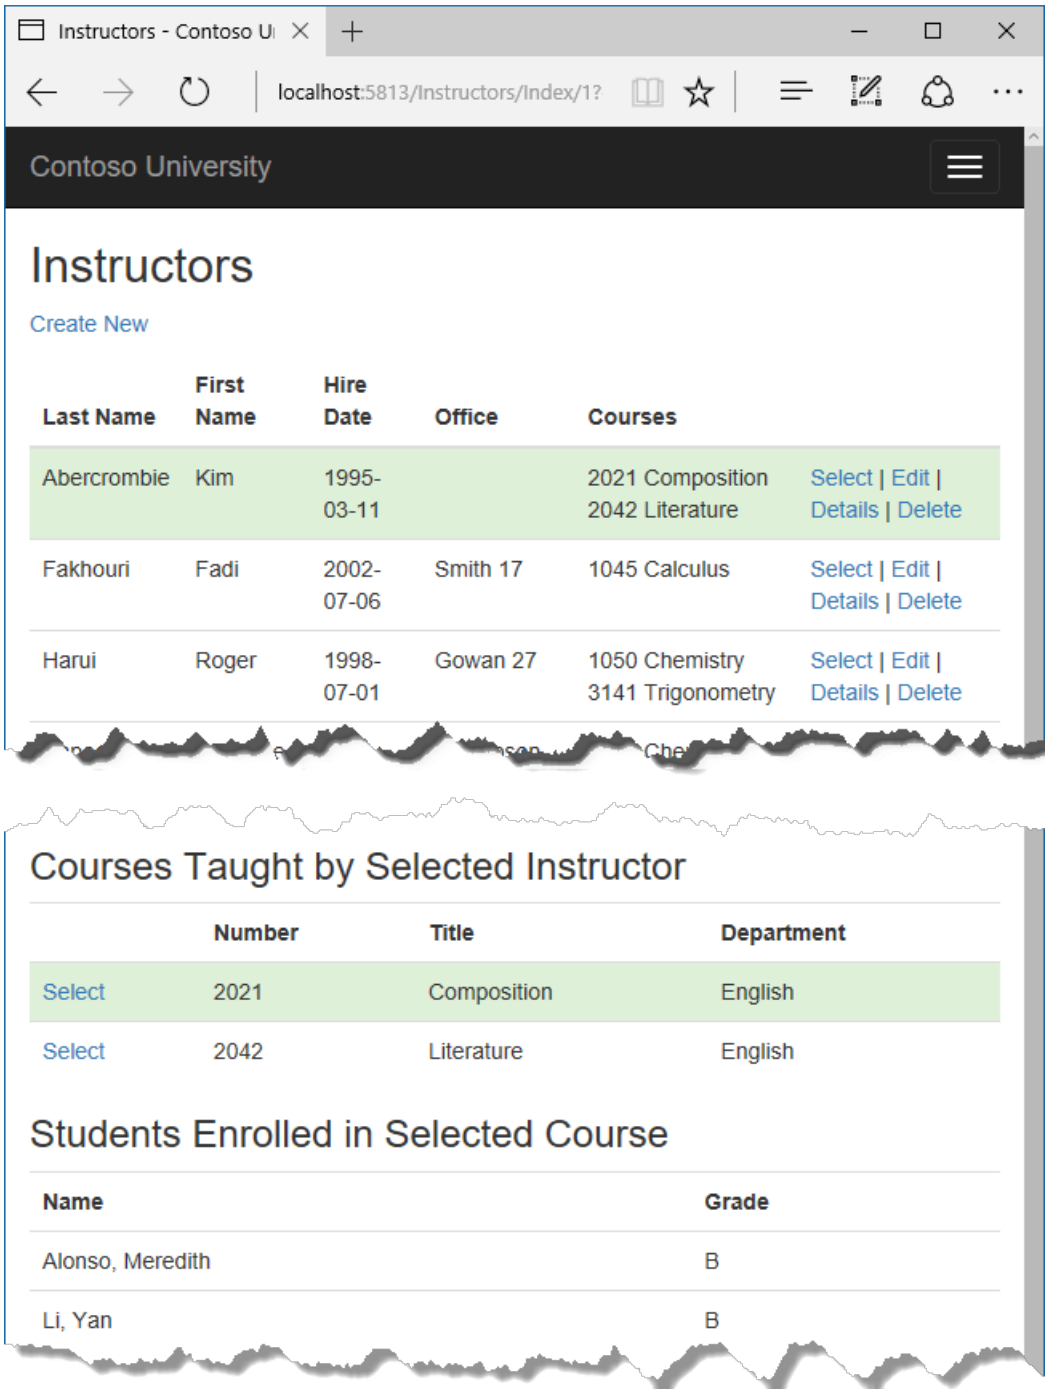
```
@Html.DisplayFor(modelItem => item.Department.Name)
```

Run the app and select the **Courses** tab to see the list with department names.



Create an Instructors page

In this section, you'll create a controller and view for the Instructor entity in order to display the Instructors page:



This page reads and displays related data in the following ways:

- The list of instructors displays related data from the OfficeAssignment entity. The Instructor and OfficeAssignment entities are in a one-to-zero-or-one relationship. You'll use eager loading for the OfficeAssignment entities. As explained earlier, eager loading is typically more efficient when you need the related data for all retrieved rows of the primary table. In this case, you want to display office assignments for all displayed instructors.
- When the user selects an instructor, related Course entities are displayed. The Instructor and Course entities are in a many-to-many relationship. You'll use eager loading for the Course entities and their related Department entities. In this case, separate queries might be more efficient because you need courses only for the selected instructor. However, this example shows how to use eager loading for navigation properties within entities that are themselves in navigation properties.
- When the user selects a course, related data from the Enrollments entity set is displayed. The Course and Enrollment entities are in a one-to-many relationship. You'll use separate queries for Enrollment entities and their related Student entities.

Create a view model for the Instructor Index view

The Instructors page shows data from three different tables. Therefore, you'll create a view model that includes three properties, each holding the data for one of the tables.

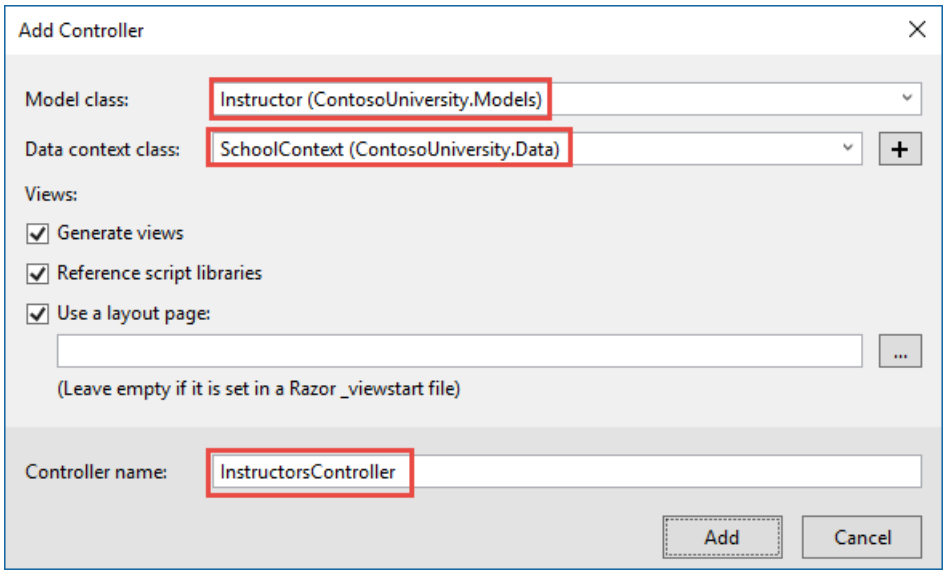
In the *SchoolViewModels* folder, create *InstructorIndexData.cs* and replace the existing code with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class InstructorIndexData
    {
        public IEnumerable<Instructor> Instructors { get; set; }
        public IEnumerable<Course> Courses { get; set; }
        public IEnumerable<Enrollment> Enrollments { get; set; }
    }
}
```

Create the Instructor controller and views

Create an Instructors controller with EF read/write actions as shown in the following illustration:



Open *InstructorsController.cs* and add a using statement for the ViewModels namespace:

```
using ContosoUniversity.Models.SchoolViewModels;
```

Replace the Index method with the following code to do eager loading of related data and put it in the view model.

```
public async Task<IActionResult> Index(int? id, int? courseID)
{
    var viewModel = new InstructorIndexData();
    viewModel.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Enrollments)
                    .ThenInclude(i => i.Student)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
          .AsNoTracking()
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        ViewData["InstructorID"] = id.Value;
        Instructor instructor = viewModel.Instructors.Where(
            i => i.ID == id.Value).Single();
        viewModel.Courses = instructor.CourseAssignments.Select(s => s.Course);
    }

    if (courseID != null)
    {
        ViewData["CourseID"] = courseID.Value;
        viewModel.Enrollments = viewModel.Courses.Where(
            x => x.CourseID == courseID).Single().Enrollments;
    }

    return View(viewModel);
}
```

The method accepts optional route data (`id`) and a query string parameter (`courseID`) that provide the ID values of the selected instructor and selected course. The parameters are provided by the **Select** hyperlinks on the page.

The code begins by creating an instance of the view model and putting in it the list of instructors. The code specifies eager loading for the `Instructor.OfficeAssignment` and the `Instructor.CourseAssignments` navigation properties. Within the `CourseAssignments` property, the `Course` property is loaded, and within that, the `Enrollments` and `Department` properties are loaded, and within each `Enrollment` entity the `Student` property is loaded.

```
viewModel.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

Since the view always requires the OfficeAssignment entity, it's more efficient to fetch that in the same query. Course entities are required when an instructor is selected in the web page, so a single query is better than multiple queries only if the page is displayed more often with a course selected than without.

The code repeats `CourseAssignments` and `Course` because you need two properties from `Course`. The first string

of `ThenInclude` calls gets `CourseAssignment.Course`, `Course.Enrollments`, and `Enrollment.Student`.

```
viewModel.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

At that point in the code, another `ThenInclude` would be for navigation properties of `Student`, which you don't need. But calling `Include` starts over with `Instructor` properties, so you have to go through the chain again, this time specifying `Course.Department` instead of `Course.Enrollments`.

```
viewModel.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

The following code executes when an instructor was selected. The selected instructor is retrieved from the list of instructors in the view model. The view model's `Courses` property is then loaded with the Course entities from that instructor's `CourseAssignments` navigation property.

```
if (id != null)
{
    ViewData["InstructorID"] = id.Value;
    Instructor instructor = viewModel.Instructors.Where(
        i => i.ID == id.Value).Single();
    viewModel.Courses = instructor.CourseAssignments.Select(s => s.Course);
}
```

The `Where` method returns a collection, but in this case the criteria passed to that method result in only a single Instructor entity being returned. The `Single` method converts the collection into a single Instructor entity, which gives you access to that entity's `CourseAssignments` property. The `CourseAssignments` property contains `CourseAssignment` entities, from which you want only the related `Course` entities.

You use the `Single` method on a collection when you know the collection will have only one item. The Single method throws an exception if the collection passed to it's empty or if there's more than one item. An alternative is `SingleOrDefault`, which returns a default value (null in this case) if the collection is empty. However, in this case that would still result in an exception (from trying to find a `Courses` property on a null reference), and the exception message would less clearly indicate the cause of the problem. When you call the `Single` method, you can also pass in the Where condition instead of calling the `Where` method separately:

```
.Single(i => i.ID == id.Value)
```

Instead of:

```
.Where(i => i.ID == id.Value).Single()
```

Next, if a course was selected, the selected course is retrieved from the list of courses in the view model. Then the view model's `Enrollments` property is loaded with the Enrollment entities from that course's `Enrollments` navigation property.

```
if (courseID != null)
{
    ViewData["CourseID"] = courseID.Value;
    viewModel.Enrollments = viewModel.Courses.Where(
        x => x.CourseID == courseID).Single().Enrollments;
}
```

Modify the Instructor Index view

In *Views/Instructors/Index.cshtml*, replace the template code with the following code. The changes are highlighted.

```
@model ContosoUniversity.Models.SchoolViewModels.InstructorIndexData

@{
    ViewData["Title"] = "Instructors";
}

<h2>Instructors</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>Last Name</th>
            <th>First Name</th>
            <th>Hire Date</th>
            <th>Office</th>
            <th>Courses</th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Instructors)
        {
            string selectedRow = "";
            if (item.ID == (int?)ViewData["InstructorID"])
            {
                selectedRow = "success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.HireDate)
                </td>
                <td>
                    @if (item.OfficeAssignment != null)
                    {
                        @item.OfficeAssignment.Location
                    }
                </td>
                <td>
                    @{
                        foreach (var course in item.CourseAssignments)
                        {
                            @course.Course.CourseID @:  @course.Course.Title <br />
                        }
                    }
                </td>
                <td>
                    <a asp-action="Index" asp-route-id="@item.ID">Select</a> |
                    <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-action="Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-action="Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
          }
    </tbody>
</table>
```

You've made the following changes to the existing code:

- Changed the model class to `InstructorIndexData`.
- Changed the page title from **Index** to **Instructors**.
- Added an **Office** column that displays `item.OfficeAssignment.Location` only if `item.OfficeAssignment` isn't null. (Because this is a one-to-zero-or-one relationship, there might not be a related OfficeAssignment entity.)

```
@if (item.OfficeAssignment != null)
{
    @item.OfficeAssignment.Location
}
```

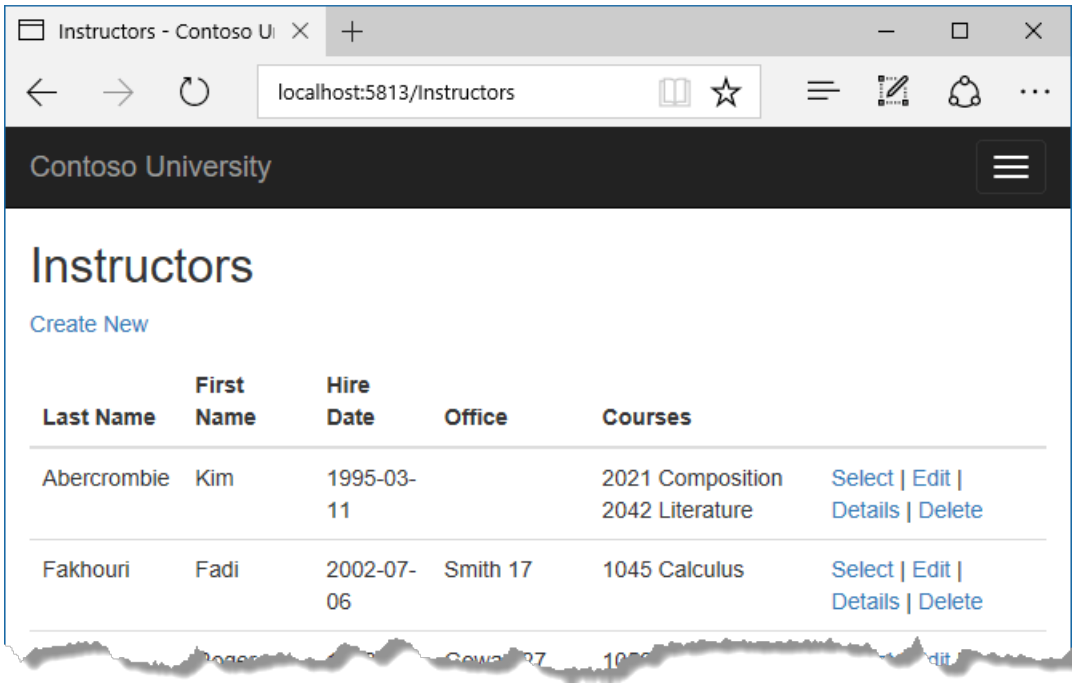
- Added a **Courses** column that displays courses taught by each instructor. For more information, see the Explicit line transition section of the Razor syntax article.
- Added code that dynamically adds `class="success"` to the `tr` element of the selected instructor. This sets a background color for the selected row using a Bootstrap class.

```
string selectedRow = "";
if (item.ID == (int?)ViewData["InstructorID"])
{
    selectedRow = "success";
}
<tr class="@selectedRow">
```

- Added a new hyperlink labeled **Select** immediately before the other links in each row, which causes the selected instructor's ID to be sent to the `Index` method.

```
<a asp-action="Index" asp-route-id="@item.ID">Select</a> |
```

Run the app and select the **Instructors** tab. The page displays the Location property of related OfficeAssignment entities and an empty table cell when there's no related OfficeAssignment entity.



In the *Views/Instructors/Index.cshtml* file, after the closing table element (at the end of the file), add the following code. This code displays a list of courses related to an instructor when an instructor is selected.

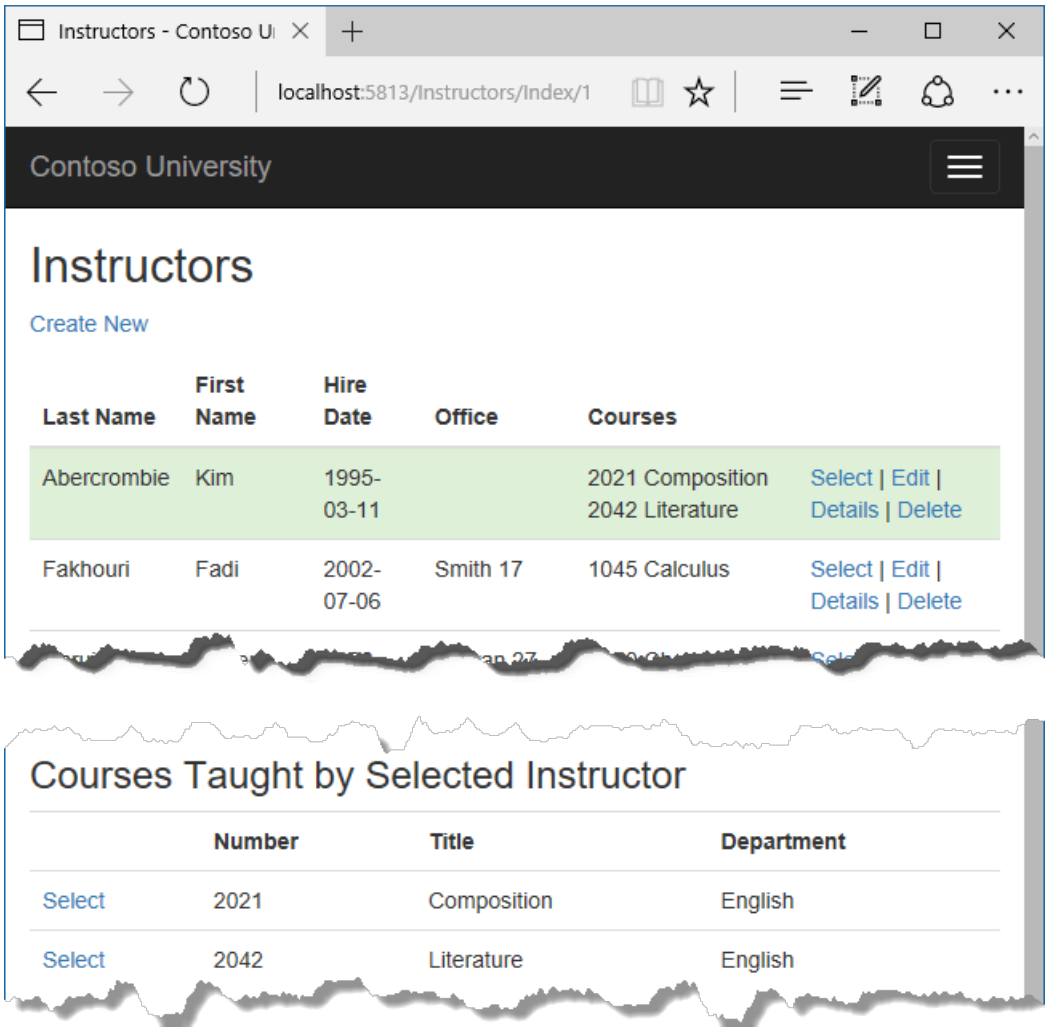
```
@if (Model.Courses != null)
{
    <h3>Courses Taught by Selected Instructor</h3>
    <table class="table">
        <tr>
            <th></th>
            <th>Number</th>
            <th>Title</th>
            <th>Department</th>
        </tr>

        @foreach (var item in Model.Courses)
        {
            string selectedRow = "";
            if (item.CourseID == (int?)ViewData["CourseID"])
            {
                selectedRow = "success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.ActionLink("Select", "Index", new { courseID = item.CourseID })
                </td>
                <td>
                    @item.CourseID
                </td>
                <td>
                    @item.Title
                </td>
                <td>
                    @item.Department.Name
                </td>
            </tr>
        }

    </table>
}
```

This code reads the `Courses` property of the view model to display a list of courses. It also provides a **Select** hyperlink that sends the ID of the selected course to the `Index` action method.

Refresh the page and select an instructor. Now you see a grid that displays courses assigned to the selected instructor, and for each course you see the name of the assigned department.



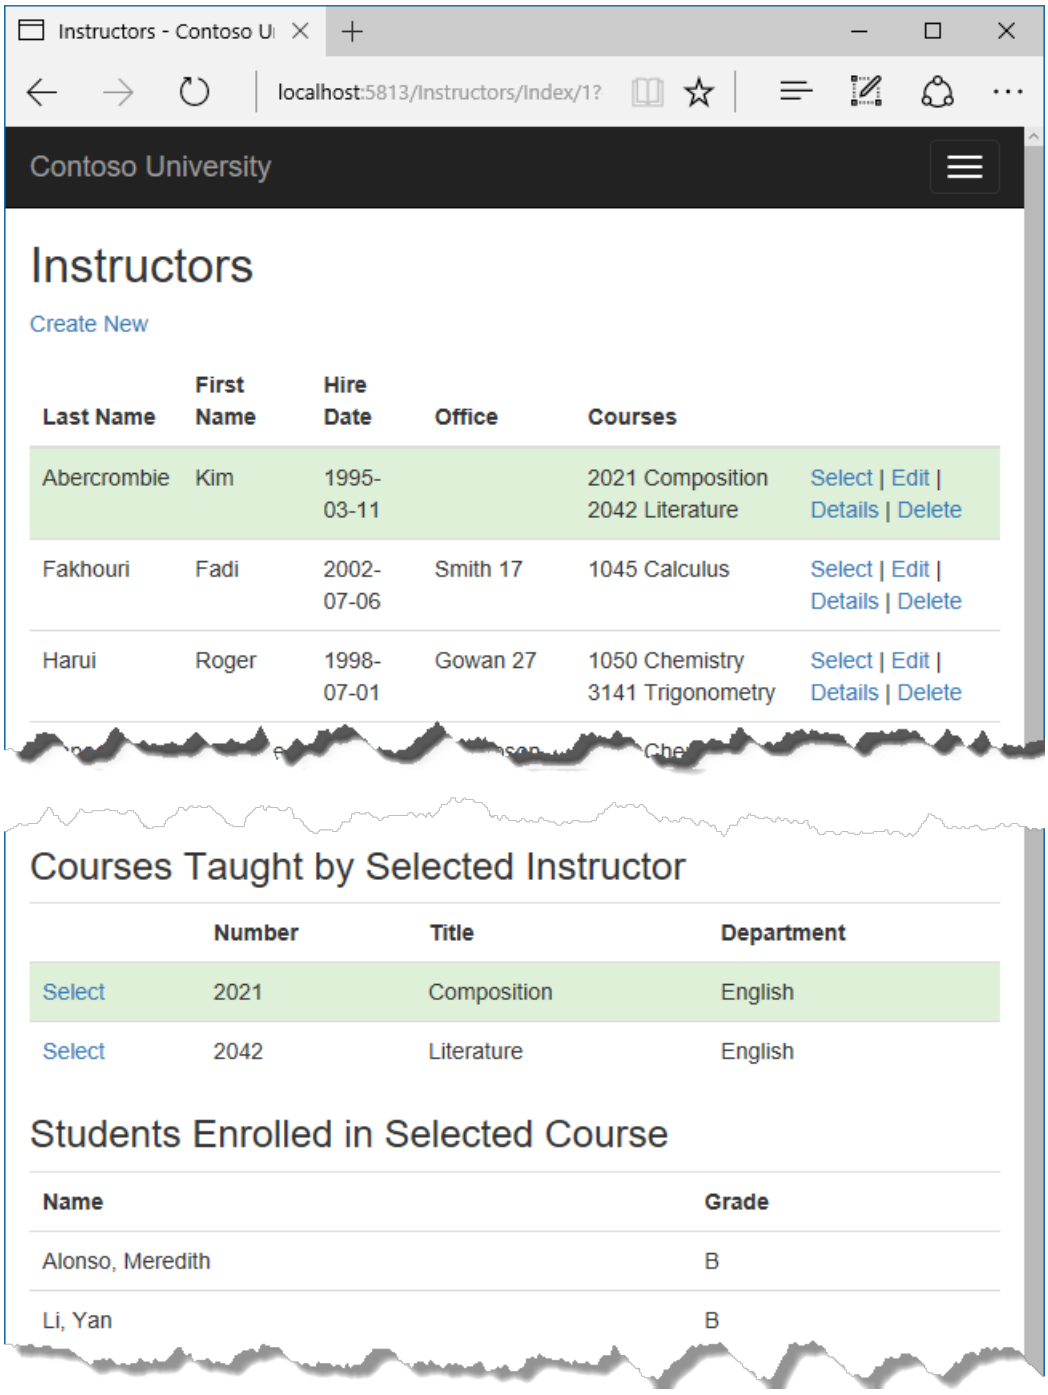
After the code block you just added, add the following code. This displays a list of the students who are enrolled in a course when that course is selected.

```
@if (Model.Enrollments != null)
{
    <h3>
        Students Enrolled in Selected Course
    </h3>
    <table class="table">
        <tr>
            <th>Name</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.Enrollments)
        {
            <tr>
                <td>
                    @item.Student.FullName
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
}
```

This code reads the Enrollments property of the view model in order to display a list of students enrolled in the course.

Refresh the page again and select an instructor. Then select a course to see the list of enrolled students and their

grades.



About explicit loading

When you retrieved the list of instructors in *InstructorsController.cs*, you specified eager loading for the `CourseAssignments` navigation property.

Suppose you expected users to only rarely want to see enrollments in a selected instructor and course. In that case, you might want to load the enrollment data only if it's requested. To see an example of how to do explicit loading, replace the `Index` method with the following code, which removes eager loading for Enrollments and loads that property explicitly. The code changes are highlighted.

```
public async Task<IActionResult> Index(int? id, int? courseID)
{
    var viewModel = new InstructorIndexData();
    viewModel.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        ViewData["InstructorID"] = id.Value;
        Instructor instructor = viewModel.Instructors.Where(
            i => i.ID == id.Value).Single();
        viewModel.Courses = instructor.CourseAssignments.Select(s => s.Course);
    }

    if (courseID != null)
    {
        ViewData["CourseID"] = courseID.Value;
        var selectedCourse = viewModel.Courses.Where(x => x.CourseID == courseID).Single();
        await _context.Entry(selectedCourse).Collection(x => x.Enrollments).LoadAsync();
        foreach (Enrollment enrollment in selectedCourse.Enrollments)
        {
            await _context.Entry(enrollment).Reference(x => x.Student).LoadAsync();
        }
        viewModel.Enrollments = selectedCourse.Enrollments;
    }

    return View(viewModel);
}
```

The new code drops the *ThenInclude* method calls for enrollment data from the code that retrieves instructor entities. It also drops `AsNoTracking`. If an instructor and course are selected, the highlighted code retrieves Enrollment entities for the selected course, and Student entities for each Enrollment.

Run the app, go to the Instructors Index page now and you'll see no difference in what's displayed on the page, although you've changed how the data is retrieved.

Get the code

Download or view the completed application.

Next steps

In this tutorial, you:

- Learned how to load related data
- Created a Courses page
- Created an Instructors page
- Learned about explicit loading

Advance to the next tutorial to learn how to update related data.

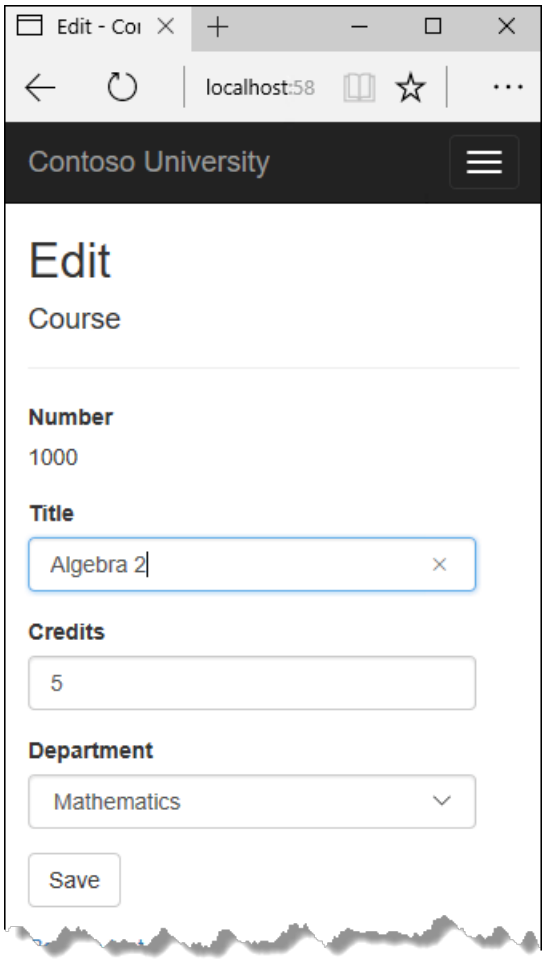
Update related data

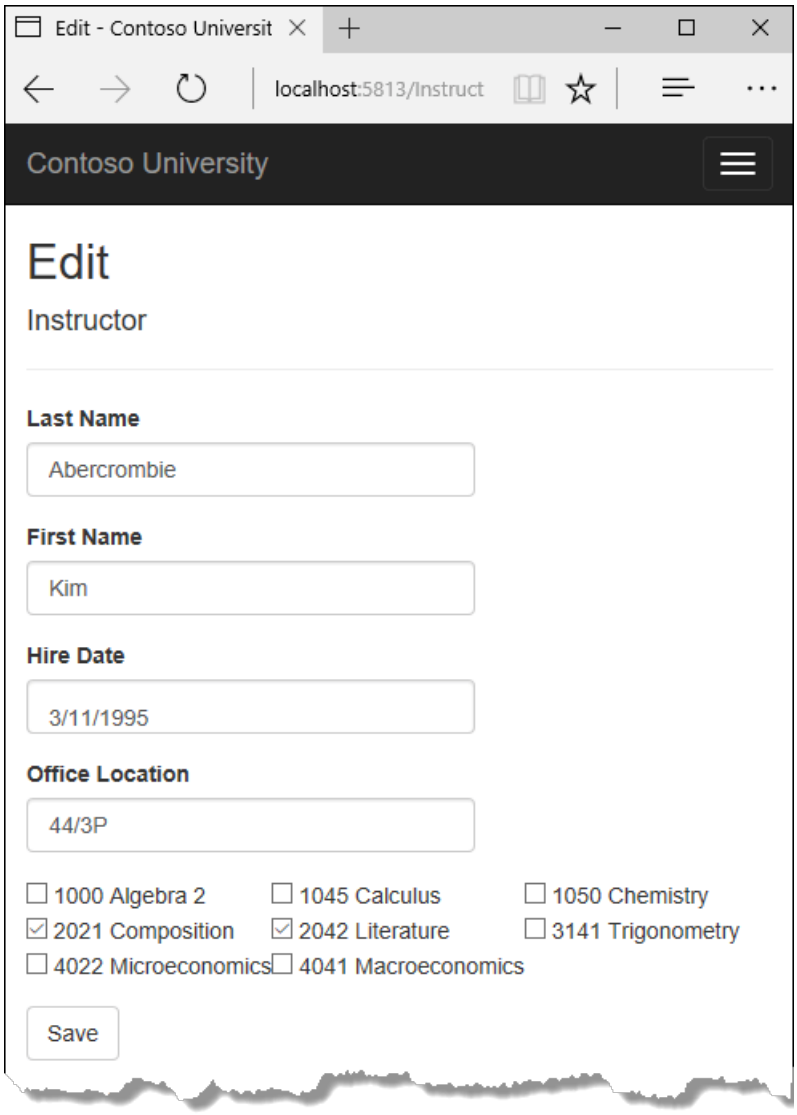
Tutorial: Update related data - ASP.NET MVC with EF Core

9/22/2020 • 18 minutes to read • Edit Online

In the previous tutorial you displayed related data; in this tutorial you'll update related data by updating foreign key fields and navigation properties.

The following illustrations show some of the pages that you'll work with.





In this tutorial, you:

- Customize Courses pages
- Add Instructors Edit page
- Add courses to Edit page
- Update Delete page
- Add office location and courses to Create page

Prerequisites

- Read related data

Customize Courses pages

When a new course entity is created, it must have a relationship to an existing department. To facilitate this, the scaffolded code includes controller methods and Create and Edit views that include a drop-down list for selecting the department. The drop-down list sets the `Course.DepartmentID` foreign key property, and that's all the Entity Framework needs in order to load the `Department` navigation property with the appropriate Department entity. You'll use the scaffolded code, but change it slightly to add error handling and sort the drop-down list.

In *CoursesController.cs*, delete the four Create and Edit methods and replace them with the following code:

```
public IActionResult Create()
{
    PopulateDepartmentsDropDownList();
    return View();
}
```

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Create([Bind("CourseID,Credits,DepartmentID,Title")] Course course)
{
    if (ModelState.IsValid)
    {
        _context.Add(course);
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}
```

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var course = await _context.Courses
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
    if (course == null)
    {
        return NotFound();
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}
```

```
[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> EditPost(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var courseToUpdate = await _context.Courses
        .FirstOrDefaultAsync(c => c.CourseID == id);

    if (await TryUpdateModelAsync<Course>(courseToUpdate,
        "",
        c => c.Credits, c => c.DepartmentID, c => c.Title))
    {
        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
        return RedirectToAction(nameof(Index));
    }
    PopulateDepartmentsDropDownList(courseToUpdate.DepartmentID);
    return View(courseToUpdate);
}
```

After the `Edit` HttpPost method, create a new method that loads department info for the drop-down list.

```
private void PopulateDepartmentsDropDownList(object selectedDepartment = null)
{
    var departmentsQuery = from d in _context.Departments
                           orderby d.Name
                           select d;
    ViewBag.DepartmentID = new SelectList(departmentsQuery.AsNoTracking(), "DepartmentID", "Name",
selectedDepartment);
}
```

The `PopulateDepartmentsDropDownList` method gets a list of all departments sorted by name, creates a `SelectList` collection for a drop-down list, and passes the collection to the view in `ViewBag`. The method accepts the optional `selectedDepartment` parameter that allows the calling code to specify the item that will be selected when the drop-down list is rendered. The view will pass the name "DepartmentID" to the `<select>` tag helper, and the helper then knows to look in the `ViewBag` object for a `SelectList` named "DepartmentID".

The HttpGet `Create` method calls the `PopulateDepartmentsDropDownList` method without setting the selected item, because for a new course the department isn't established yet:

```
public IActionResult Create()
{
    PopulateDepartmentsDropDownList();
    return View();
}
```

The HttpGet `Edit` method sets the selected item, based on the ID of the department that's already assigned to

the course being edited:

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var course = await _context.Courses
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
    if (course == null)
    {
        return NotFound();
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}
```

The HttpPost methods for both `Create` and `Edit` also include code that sets the selected item when they redisplay the page after an error. This ensures that when the page is redisplayed to show the error message, whatever department was selected stays selected.

Add .AsNoTracking to Details and Delete methods

To optimize performance of the Course Details and Delete pages, add `AsNoTracking` calls in the `Details` and HttpGet `Delete` methods.

```
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var course = await _context.Courses
        .Include(c => c.Department)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
    if (course == null)
    {
        return NotFound();
    }

    return View(course);
}
```

```
public async Task<IActionResult> Delete(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var course = await _context.Courses
        .Include(c => c.Department)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
    if (course == null)
    {
        return NotFound();
    }

    return View(course);
}
```

Modify the Course views

In *Views/Courses/Create.cshtml*, add a "Select Department" option to the **Department** drop-down list, change the caption from **DepartmentID** to **Department**, and add a validation message.

```
<div class="form-group">
    <label asp-for="Department" class="control-label"></label>
    <select asp-for="DepartmentID" class="form-control" asp-items="ViewBag.DepartmentID">
        <option value="">-- Select Department --</option>
    </select>
    <span asp-validation-for="DepartmentID" class="text-danger" />
```

In *Views/Courses/Edit.cshtml*, make the same change for the Department field that you just did in *Create.cshtml*.

Also in *Views/Courses/Edit.cshtml*, add a course number field before the **Title** field. Because the course number is the primary key, it's displayed, but it can't be changed.

```
<div class="form-group">
    <label asp-for="CourseID" class="control-label"></label>
    <div>@Html.DisplayFor(model => model.CourseID)</div>
</div>
```

There's already a hidden field (`<input type="hidden">`) for the course number in the Edit view. Adding a `<label>` tag helper doesn't eliminate the need for the hidden field because it doesn't cause the course number to be included in the posted data when the user clicks **Save** on the **Edit** page.

In *Views/Courses/Delete.cshtml*, add a course number field at the top and change department ID to department name.

```
@model ContosoUniversity.Models.Course

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

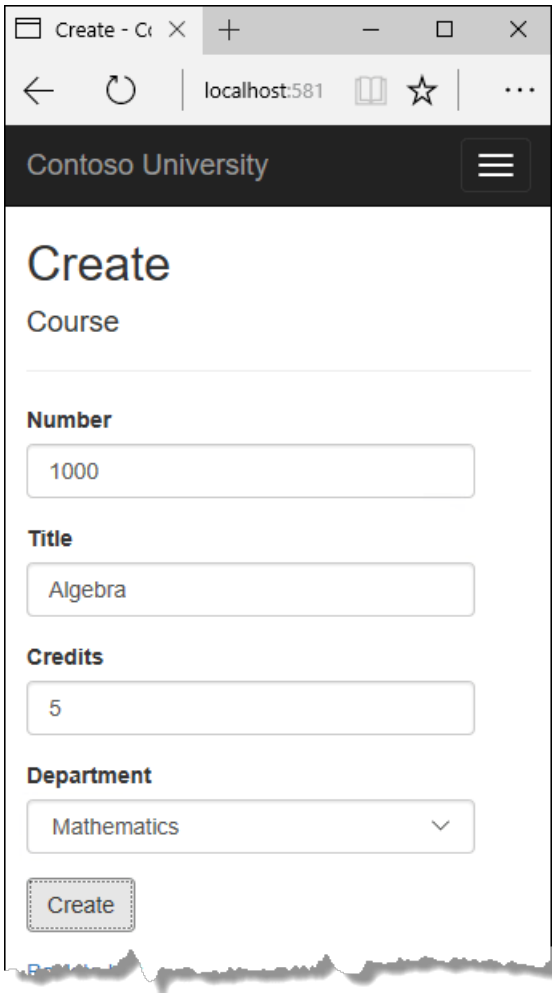
<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Course</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.CourseID)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.CourseID)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Credits)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Credits)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Department)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Department.Name)
        </dd>
    </dl>

    <form asp-action="Delete">
        <div class="form-actions no-color">
            <input type="submit" value="Delete" class="btn btn-default" /> |
            <a asp-action="Index">Back to List</a>
        </div>
    </form>
</div>
```

In *Views/Courses/Details.cshtml*, make the same change that you just did for *Delete.cshtml*.

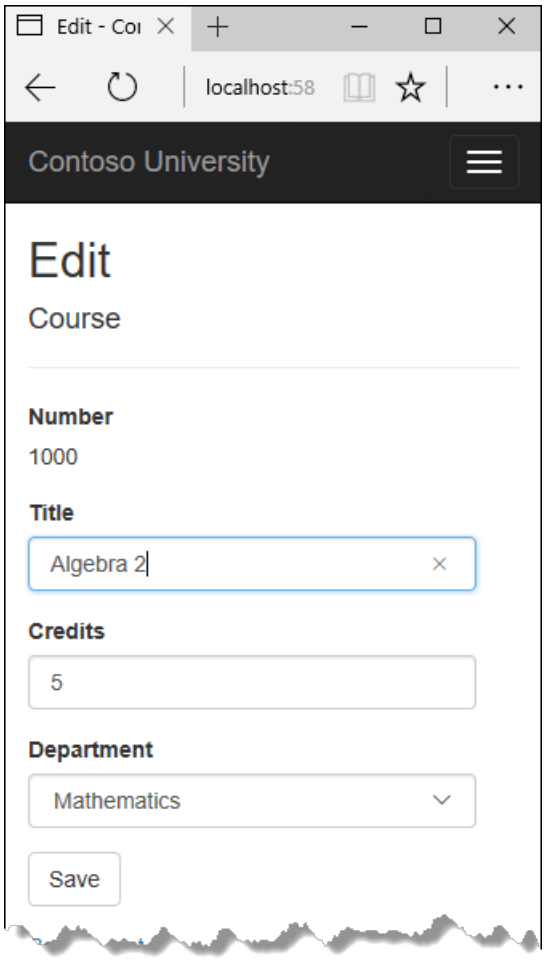
Test the Course pages

Run the app, select the **Courses** tab, click **Create New**, and enter data for a new course:



Click **Create**. The Courses Index page is displayed with the new course added to the list. The department name in the Index page list comes from the navigation property, showing that the relationship was established correctly.

Click **Edit** on a course in the Courses Index page.



Change data on the page and click **Save**. The Courses Index page is displayed with the updated course data.

Add Instructors Edit page

When you edit an instructor record, you want to be able to update the instructor's office assignment. The Instructor entity has a one-to-zero-or-one relationship with the OfficeAssignment entity, which means your code has to handle the following situations:

- If the user clears the office assignment and it originally had a value, delete the OfficeAssignment entity.
- If the user enters an office assignment value and it originally was empty, create a new OfficeAssignment entity.
- If the user changes the value of an office assignment, change the value in an existing OfficeAssignment entity.

Update the Instructors controller

In *InstructorsController.cs*, change the code in the HttpGet `Edit` method so that it loads the Instructor entity's `OfficeAssignment` navigation property and calls `AsNoTracking`:

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructor = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);
    if (instructor == null)
    {
        return NotFound();
    }
    return View(instructor);
}
```

Replace the HttpPost `Edit` method with the following code to handle office assignment updates:

```
[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> EditPost(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructorToUpdate = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .FirstOrDefaultAsync(s => s.ID == id);

    if (await TryUpdateModelAsync<Instructor>(
        instructorToUpdate,
        "",
        i => i.FirstMidName, i => i.LastName, i => i.HireDate, i => i.OfficeAssignment))
    {
        if (String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment?.Location))
        {
            instructorToUpdate.OfficeAssignment = null;
        }
        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
        return RedirectToAction(nameof(Index));
    }
    return View(instructorToUpdate);
}
```

The code does the following:

- Changes the method name to `EditPost` because the signature is now the same as the HttpGet `Edit` method (the `ActionName` attribute specifies that the `/Edit/` URL is still used).
- Gets the current Instructor entity from the database using eager loading for the `OfficeAssignment`

navigation property. This is the same as what you did in the HttpGet `Edit` method.

- Updates the retrieved Instructor entity with values from the model binder. The `TryUpdateModel` overload enables you to declare the properties you want to include. This prevents over-posting, as explained in the second tutorial.

```
if (await TryUpdateModelAsync<Instructor>(
    instructorToUpdate,
    "",
    i => i.FirstMidName, i => i.LastName, i => i.HireDate, i => i.OfficeAssignment))
```

- If the office location is blank, sets the Instructor.OfficeAssignment property to null so that the related row in the OfficeAssignment table will be deleted.

```
if (String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment?.Location))
{
    instructorToUpdate.OfficeAssignment = null;
}
```

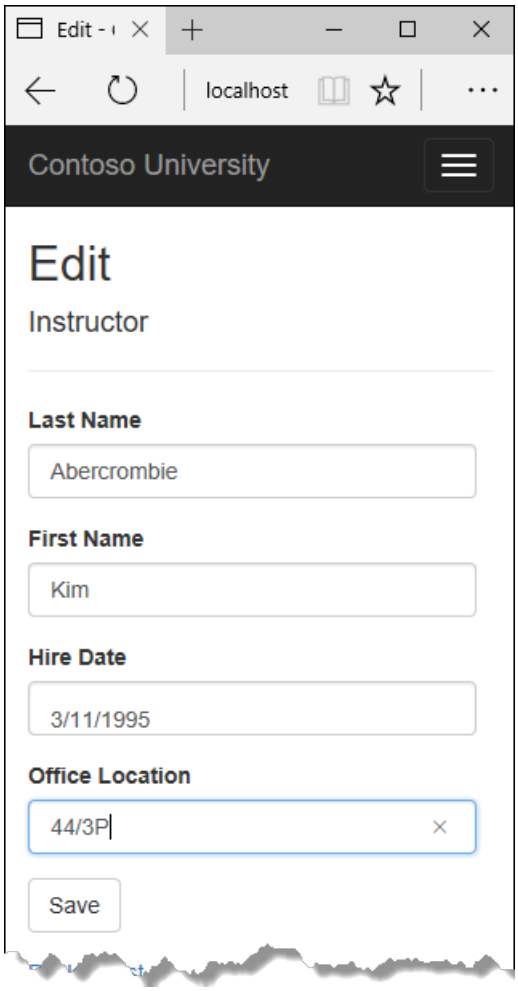
- Saves the changes to the database.

Update the Instructor Edit view

In *Views/Instructors/Edit.cshtml*, add a new field for editing the office location, at the end before the **Save** button:

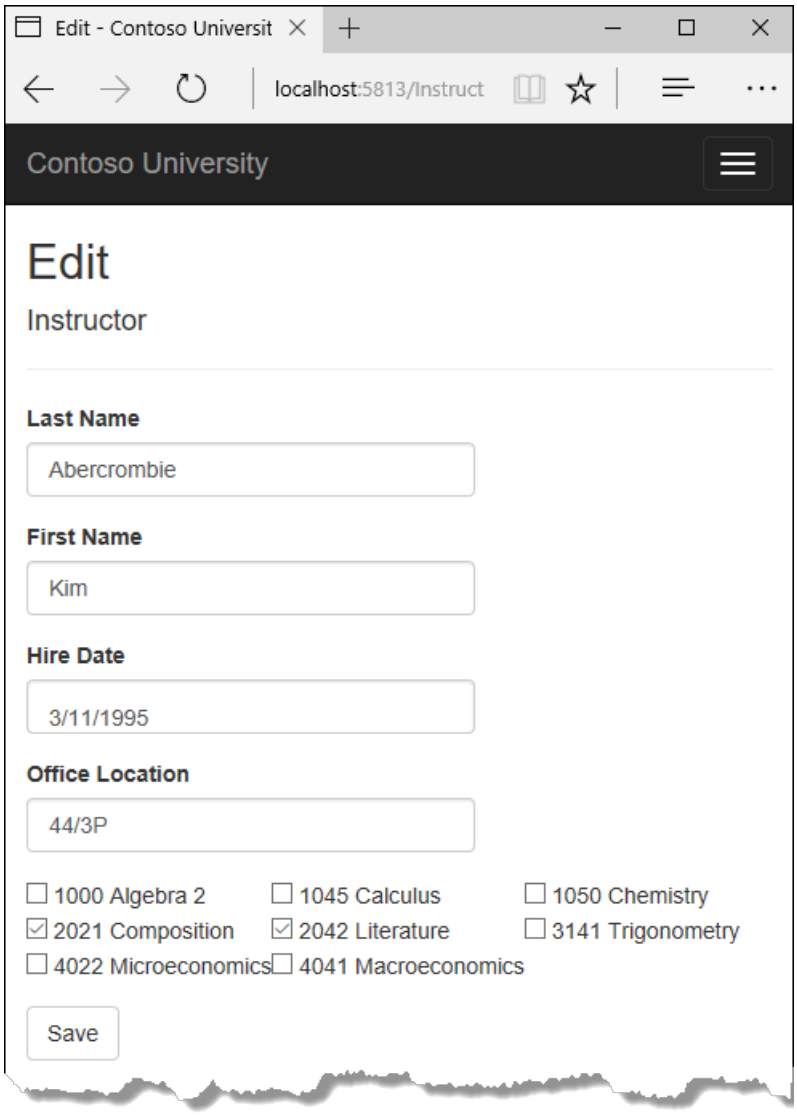
```
<div class="form-group">
    <label asp-for="OfficeAssignment.Location" class="control-label"></label>
    <input asp-for="OfficeAssignment.Location" class="form-control" />
    <span asp-validation-for="OfficeAssignment.Location" class="text-danger" />
</div>
```

Run the app, select the **Instructors** tab, and then click **Edit** on an instructor. Change the **Office Location** and click **Save**.



Add courses to Edit page

Instructors may teach any number of courses. Now you'll enhance the Instructor Edit page by adding the ability to change course assignments using a group of check boxes, as shown in the following screen shot:



The relationship between the Course and Instructor entities is many-to-many. To add and remove relationships, you add and remove entities to and from the CourseAssignments join entity set.

The UI that enables you to change which courses an instructor is assigned to is a group of check boxes. A check box for every course in the database is displayed, and the ones that the instructor is currently assigned to are selected. The user can select or clear check boxes to change course assignments. If the number of courses were much greater, you would probably want to use a different method of presenting the data in the view, but you'd use the same method of manipulating a join entity to create or delete relationships.

Update the Instructors controller

To provide data to the view for the list of check boxes, you'll use a view model class.

Create *AssignedCourseData.cs* in the *SchoolViewModels* folder and replace the existing code with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class AssignedCourseData
    {
        public int CourseID { get; set; }
        public string Title { get; set; }
        public bool Assigned { get; set; }
    }
}
```

In *InstructorsController.cs*, replace the HttpGet `Edit` method with the following code. The changes are highlighted.

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructor = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.CourseAssignments).ThenInclude(i => i.Course)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);
    if (instructor == null)
    {
        return NotFound();
    }
    PopulateAssignedCourseData(instructor);
    return View(instructor);
}

private void PopulateAssignedCourseData(Instructor instructor)
{
    var allCourses = _context.Courses;
    var instructorCourses = new HashSet<int>(instructor.CourseAssignments.Select(c => c.CourseID));
    var viewModel = new List<AssignedCourseData>();
    foreach (var course in allCourses)
    {
        viewModel.Add(new AssignedCourseData
        {
            CourseID = course.CourseID,
            Title = course.Title,
            Assigned = instructorCourses.Contains(course.CourseID)
        });
    }
    ViewData["Courses"] = viewModel;
}
```

The code adds eager loading for the `Courses` navigation property and calls the new `PopulateAssignedCourseData` method to provide information for the check box array using the `AssignedCourseData` view model class.

The code in the `PopulateAssignedCourseData` method reads through all Course entities in order to load a list of courses using the view model class. For each course, the code checks whether the course exists in the instructor's `Courses` navigation property. To create efficient lookup when checking whether a course is assigned to the instructor, the courses assigned to the instructor are put into a `HashSet` collection. The `Assigned` property is set

to true for courses the instructor is assigned to. The view will use this property to determine which check boxes must be displayed as selected. Finally, the list is passed to the view in `ViewData`.

Next, add the code that's executed when the user clicks **Save**. Replace the `EditPost` method with the following code, and add a new method that updates the `Courses` navigation property of the Instructor entity.

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int? id, string[] selectedCourses)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructorToUpdate = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
        .FirstOrDefaultAsync(m => m.ID == id);

    if (await TryUpdateModelAsync<Instructor>(
        instructorToUpdate,
        "",
        i => i.FirstMidName, i => i.LastName, i => i.HireDate, i => i.OfficeAssignment))
    {
        if (String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment?.Location))
        {
            instructorToUpdate.OfficeAssignment = null;
        }
        UpdateInstructorCourses(selectedCourses, instructorToUpdate);
        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
        return RedirectToAction(nameof(Index));
    }
    UpdateInstructorCourses(selectedCourses, instructorToUpdate);
    PopulateAssignedCourseData(instructorToUpdate);
    return View(instructorToUpdate);
}
```

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor instructorToUpdate)
{
    if (selectedCourses == null)
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c => c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new CourseAssignment { InstructorID =
instructorToUpdate.ID, CourseID = course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove = instructorToUpdate.CourseAssignments.FirstOrDefault(i =>
i.CourseID == course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

The method signature is now different from the HttpGet `Edit` method, so the method name changes from `EditPost` back to `Edit`.

Since the view doesn't have a collection of Course entities, the model binder can't automatically update the `CourseAssignments` navigation property. Instead of using the model binder to update the `CourseAssignments` navigation property, you do that in the new `UpdateInstructorCourses` method. Therefore, you need to exclude the `CourseAssignments` property from model binding. This doesn't require any change to the code that calls `TryUpdateModel` because you're using the overload that requires explicit approval and `CourseAssignments` isn't in the include list.

If no check boxes were selected, the code in `UpdateInstructorCourses` initializes the `CourseAssignments` navigation property with an empty collection and returns:

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor instructorToUpdate)
{
    if (selectedCourses == null)
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c => c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new CourseAssignment { InstructorID =
instructorToUpdate.ID, CourseID = course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove = instructorToUpdate.CourseAssignments.FirstOrDefault(i =>
i.CourseID == course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

The code then loops through all courses in the database and checks each course against the ones currently assigned to the instructor versus the ones that were selected in the view. To facilitate efficient lookups, the latter two collections are stored in `HashSet` objects.

If the check box for a course was selected but the course isn't in the `Instructor.CourseAssignments` navigation property, the course is added to the collection in the navigation property.

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor instructorToUpdate)
{
    if (selectedCourses == null)
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c => c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new CourseAssignment { InstructorID =
instructorToUpdate.ID, CourseID = course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove = instructorToUpdate.CourseAssignments.FirstOrDefault(i =>
i.CourseID == course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

If the check box for a course wasn't selected, but the course is in the `Instructor.CourseAssignments` navigation property, the course is removed from the navigation property.

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor instructorToUpdate)
{
    if (selectedCourses == null)
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c => c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new CourseAssignment { InstructorID =
instructorToUpdate.ID, CourseID = course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove = instructorToUpdate.CourseAssignments.FirstOrDefault(i =>
i.CourseID == course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

Update the Instructor views

In *Views/Instructors/Edit.cshtml*, add a **Courses** field with an array of check boxes by adding the following code immediately after the `div` elements for the **Office** field and before the `div` element for the **Save** button.

> **NOTE**
>
> When you paste the code in Visual Studio, line breaks might be changed in a way that breaks the code. If the code looks different after pasting, press Ctrl+Z one time to undo the automatic formatting. This will fix the line breaks so that they look like what you see here. The indentation doesn't have to be perfect, but the `@:</tr><tr>`, `@:<td>`, `@:</td>`, and `@:</tr>` lines must each be on a single line as shown or you'll get a runtime error. With the block of new code selected, press Tab three times to line up the new code with the existing code. This problem is fixed in Visual Studio 2019.

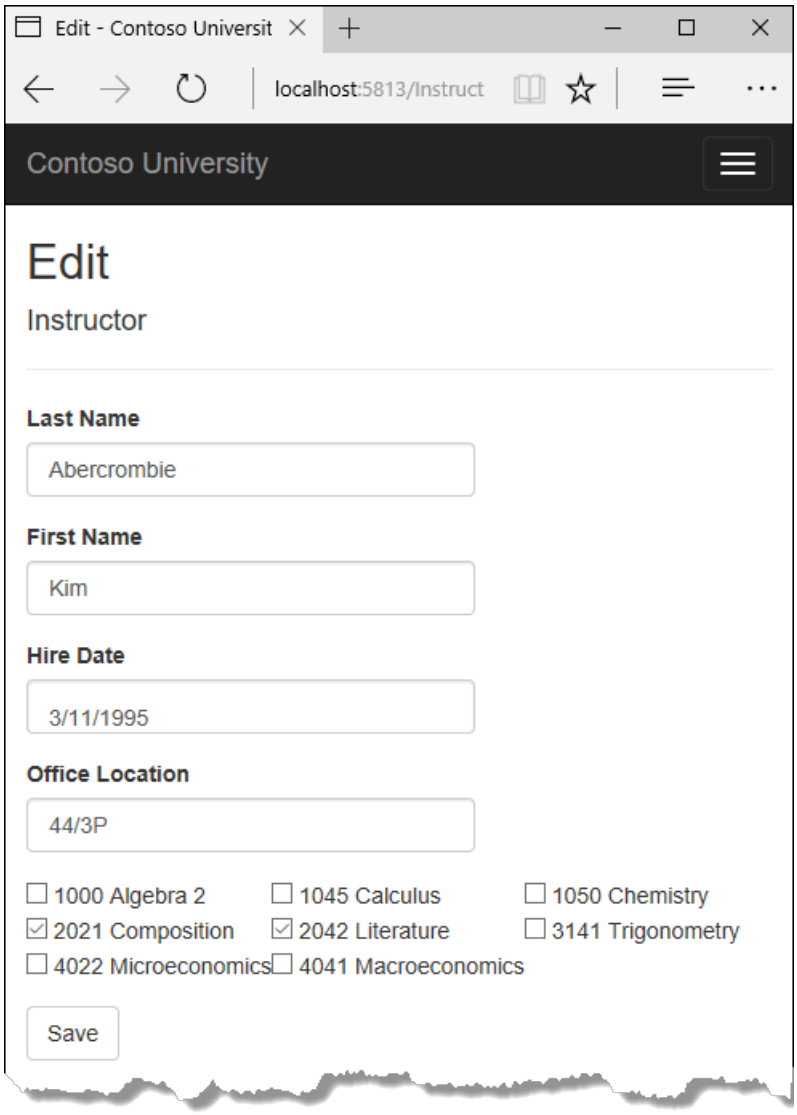
```
<div class="form-group">
    <div class="col-md-offset-2 col-md-10">
        <table>
            <tr>
                @{
                    int cnt = 0;
                    List<ContosoUniversity.Models.SchoolViewModels.AssignedCourseData> courses =
ViewBag.Courses;

                    foreach (var course in courses)
                    {
                        if (cnt++ % 3 == 0)
                        {
                            @:</tr><tr>
                        }
                        @:<td>
                            <input type="checkbox"
                                   name="selectedCourses"
                                   value="@course.CourseID"
                                   @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                                   @course.CourseID @:  @course.Title
                        @:</td>
                    }
                    @:</tr>
                }
        </table>
    </div>
</div>
```

This code creates an HTML table that has three columns. In each column is a check box followed by a caption that consists of the course number and title. The check boxes all have the same name ("selectedCourses"), which informs the model binder that they're to be treated as a group. The value attribute of each check box is set to the value of `CourseID`. When the page is posted, the model binder passes an array to the controller that consists of the `CourseID` values for only the check boxes which are selected.

When the check boxes are initially rendered, those that are for courses assigned to the instructor have checked attributes, which selects them (displays them checked).

Run the app, select the **Instructors** tab, and click **Edit** on an instructor to see the **Edit** page.



Change some course assignments and click Save. The changes you make are reflected on the Index page.

> **NOTE**
> The approach taken here to edit instructor course data works well when there's a limited number of courses. For collections that are much larger, a different UI and a different updating method would be required.

Update Delete page

In *InstructorsController.cs*, delete the `DeleteConfirmed` method and insert the following code in its place.

```
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    Instructor instructor = await _context.Instructors
        .Include(i => i.CourseAssignments)
        .SingleAsync(i => i.ID == id);

    var departments = await _context.Departments
        .Where(d => d.InstructorID == id)
        .ToListAsync();
    departments.ForEach(d => d.InstructorID = null);

    _context.Instructors.Remove(instructor);

    await _context.SaveChangesAsync();
    return RedirectToAction(nameof(Index));
}
```

This code makes the following changes:

- Does eager loading for the `CourseAssignments` navigation property. You have to include this or EF won't know about related `CourseAssignment` entities and won't delete them. To avoid needing to read them here you could configure cascade delete in the database.
- If the instructor to be deleted is assigned as administrator of any departments, removes the instructor assignment from those departments.

Add office location and courses to Create page

In *InstructorsController.cs*, delete the HttpGet and HttpPost `Create` methods, and then add the following code in their place:

```
public IActionResult Create()
{
    var instructor = new Instructor();
    instructor.CourseAssignments = new List<CourseAssignment>();
    PopulateAssignedCourseData(instructor);
    return View();
}

// POST: Instructors/Create
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Create([Bind("FirstMidName,HireDate,LastName,OfficeAssignment")] Instructor
instructor, string[] selectedCourses)
{
    if (selectedCourses != null)
    {
        instructor.CourseAssignments = new List<CourseAssignment>();
        foreach (var course in selectedCourses)
        {
            var courseToAdd = new CourseAssignment { InstructorID = instructor.ID, CourseID =
int.Parse(course) };
            instructor.CourseAssignments.Add(courseToAdd);
        }
    }
    if (ModelState.IsValid)
    {
        _context.Add(instructor);
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    PopulateAssignedCourseData(instructor);
    return View(instructor);
}
```

This code is similar to what you saw for the `Edit` methods except that initially no courses are selected. The HttpGet `Create` method calls the `PopulateAssignedCourseData` method not because there might be courses selected but in order to provide an empty collection for the `foreach` loop in the view (otherwise the view code would throw a null reference exception).

The HttpPost `Create` method adds each selected course to the `CourseAssignments` navigation property before it checks for validation errors and adds the new instructor to the database. Courses are added even if there are model errors so that when there are model errors (for an example, the user keyed an invalid date), and the page is redisplayed with an error message, any course selections that were made are automatically restored.

Notice that in order to be able to add courses to the `CourseAssignments` navigation property you have to initialize the property as an empty collection:

```
instructor.CourseAssignments = new List<CourseAssignment>();
```

As an alternative to doing this in controller code, you could do it in the Instructor model by changing the property getter to automatically create the collection if it doesn't exist, as shown in the following example:

```
private ICollection<CourseAssignment> _courseAssignments;
public ICollection<CourseAssignment> CourseAssignments
{
    get
    {
        return _courseAssignments ?? (_courseAssignments = new List<CourseAssignment>());
    }
    set
    {
        _courseAssignments = value;
    }
}
```

If you modify the `CourseAssignments` property in this way, you can remove the explicit property initialization code in the controller.

In *Views/Instructor/Create.cshtml*, add an office location text box and check boxes for courses before the Submit button. As in the case of the Edit page, fix the formatting if Visual Studio reformats the code when you paste it.

```
<div class="form-group">
    <label asp-for="OfficeAssignment.Location" class="control-label"></label>
    <input asp-for="OfficeAssignment.Location" class="form-control" />
    <span asp-validation-for="OfficeAssignment.Location" class="text-danger" />
</div>

<div class="form-group">
    <div class="col-md-offset-2 col-md-10">
        <table>
            <tr>
                @{
                    int cnt = 0;
                    List<ContosoUniversity.Models.SchoolViewModels.AssignedCourseData> courses =
ViewBag.Courses;

                    foreach (var course in courses)
                    {
                        if (cnt++ % 3 == 0)
                        {
                            @:</tr><tr>
                        }
                        @:<td>
                            <input type="checkbox"
                                   name="selectedCourses"
                                   value="@course.CourseID"
                                   @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                                   @course.CourseID @:  @course.Title
                            @:</td>
                    }
                    @:</tr>
                }
        </table>
    </div>
</div>
```

Test by running the app and creating an instructor.

Handling Transactions

As explained in the CRUD tutorial, the Entity Framework implicitly implements transactions. For scenarios where you need more control -- for example, if you want to include operations done outside of Entity Framework in a transaction -- see Transactions.

Get the code

Download or view the completed application.

Next steps

In this tutorial, you:

- Customized Courses pages
- Added Instructors Edit page
- Added courses to Edit page
- Updated Delete page
- Added office location and courses to Create page

Advance to the next tutorial to learn how to handle concurrency conflicts.

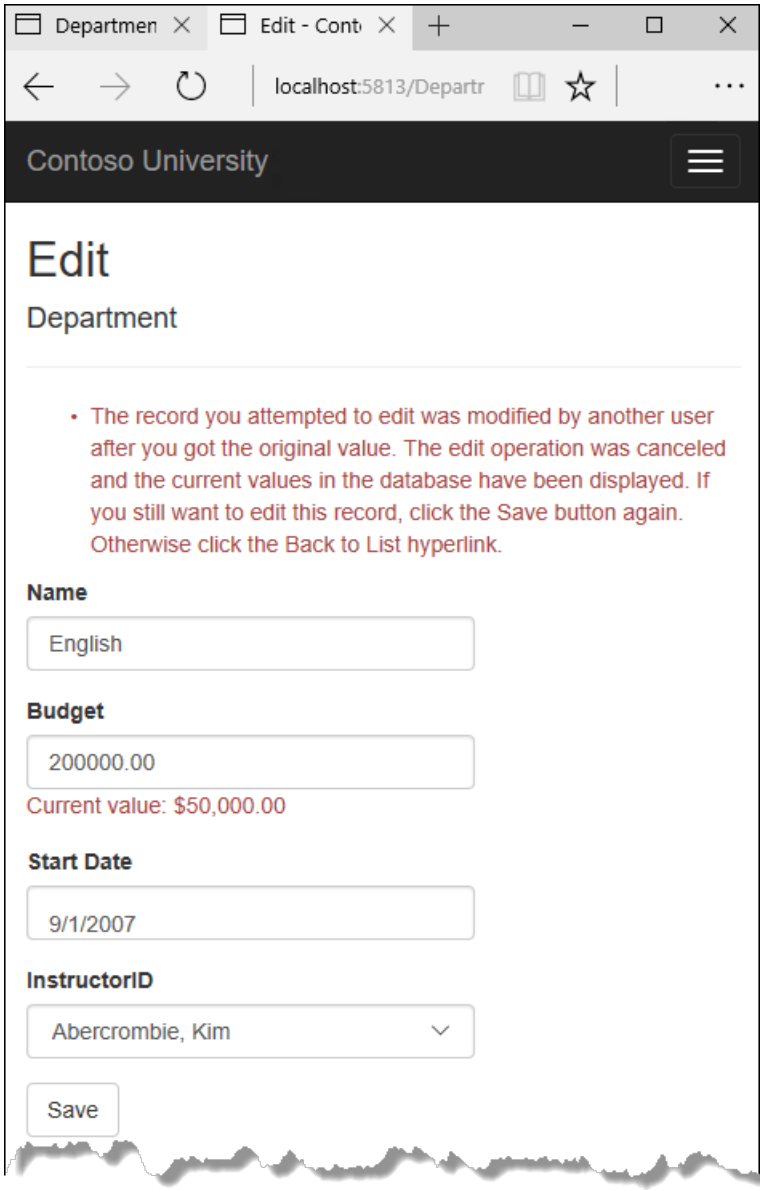
Handle concurrency conflicts

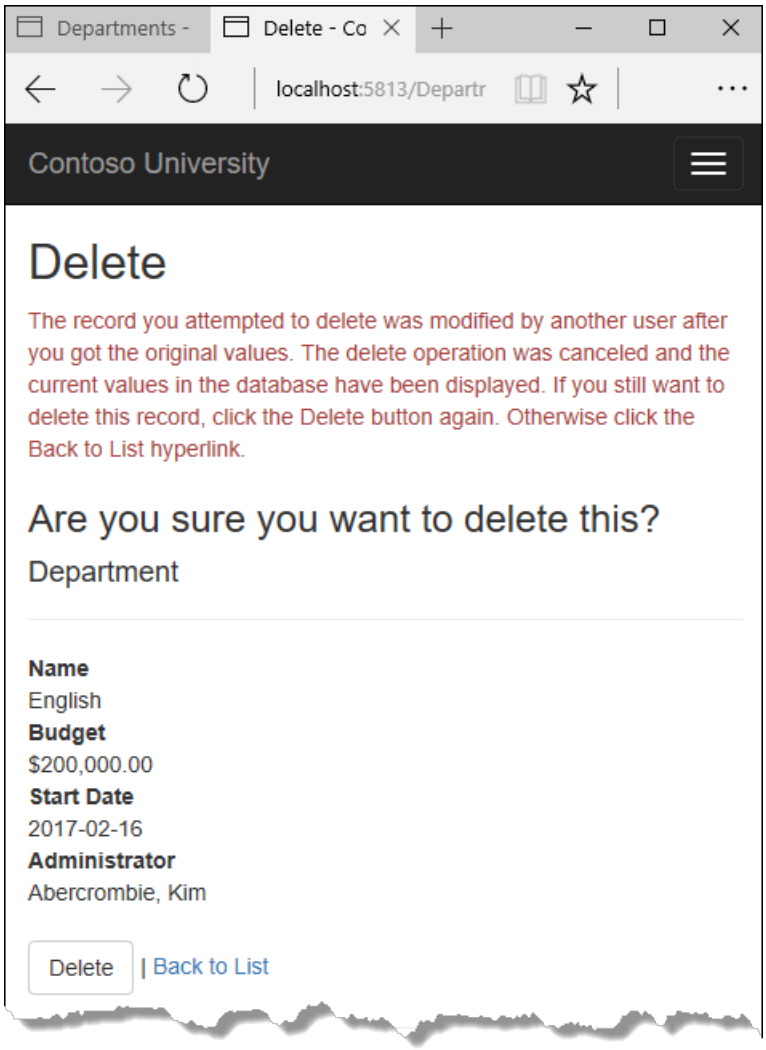
Tutorial: Handle concurrency - ASP.NET MVC with EF Core

9/22/2020 • 18 minutes to read • Edit Online

In earlier tutorials, you learned how to update data. This tutorial shows how to handle conflicts when multiple users update the same entity at the same time.

You'll create web pages that work with the Department entity and handle concurrency errors. The following illustrations show the Edit and Delete pages, including some messages that are displayed if a concurrency conflict occurs.





In this tutorial, you:

- Learn about concurrency conflicts
- Add a tracking property
- Create Departments controller and views
- Update Index view
- Update Edit methods
- Update Edit view
- Test concurrency conflicts
- Update the Delete page
- Update Details and Create views

Prerequisites

- Update related data

Concurrency conflicts

A concurrency conflict occurs when one user displays an entity's data in order to edit it, and then another user updates the same entity's data before the first user's change is written to the database. If you don't enable the detection of such conflicts, whoever updates the database last overwrites the other user's changes. In many applications, this risk is acceptable: if there are few users, or few updates, or if isn't really critical if some changes are overwritten, the cost of programming for concurrency might outweigh the benefit. In that case, you don't have to configure the application to handle concurrency conflicts.

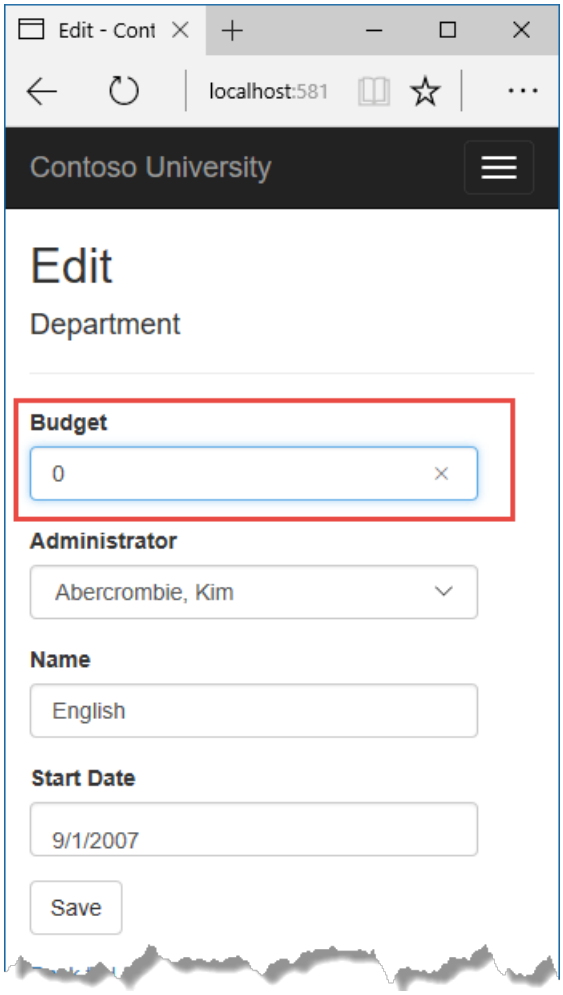
Pessimistic concurrency (locking)

If your application does need to prevent accidental data loss in concurrency scenarios, one way to do that is to use database locks. This is called pessimistic concurrency. For example, before you read a row from a database, you request a lock for read-only or for update access. If you lock a row for update access, no other users are allowed to lock the row either for read-only or update access, because they would get a copy of data that's in the process of being changed. If you lock a row for read-only access, others can also lock it for read-only access but not for update.

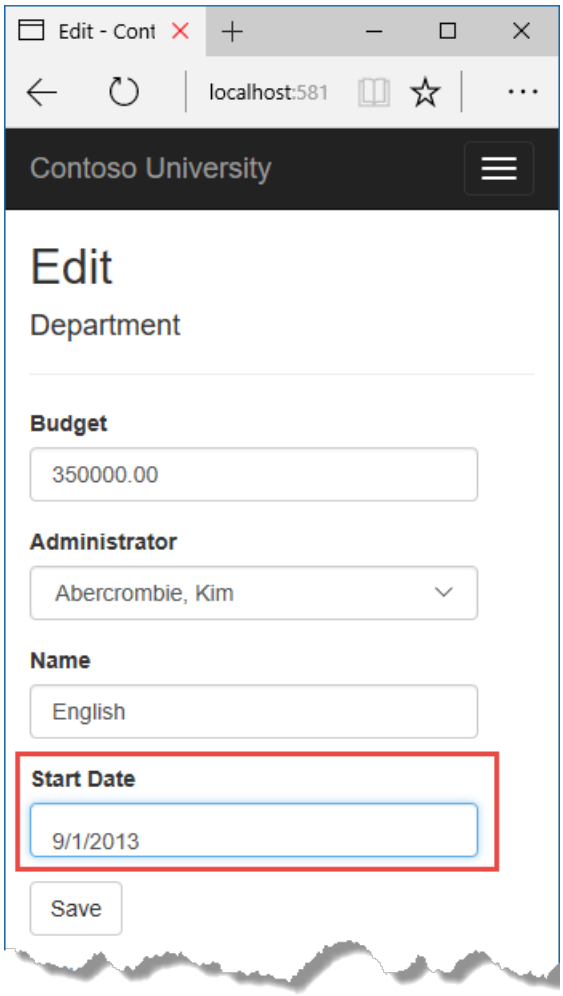
Managing locks has disadvantages. It can be complex to program. It requires significant database management resources, and it can cause performance problems as the number of users of an application increases. For these reasons, not all database management systems support pessimistic concurrency. Entity Framework Core provides no built-in support for it, and this tutorial doesn't show you how to implement it.

Optimistic Concurrency

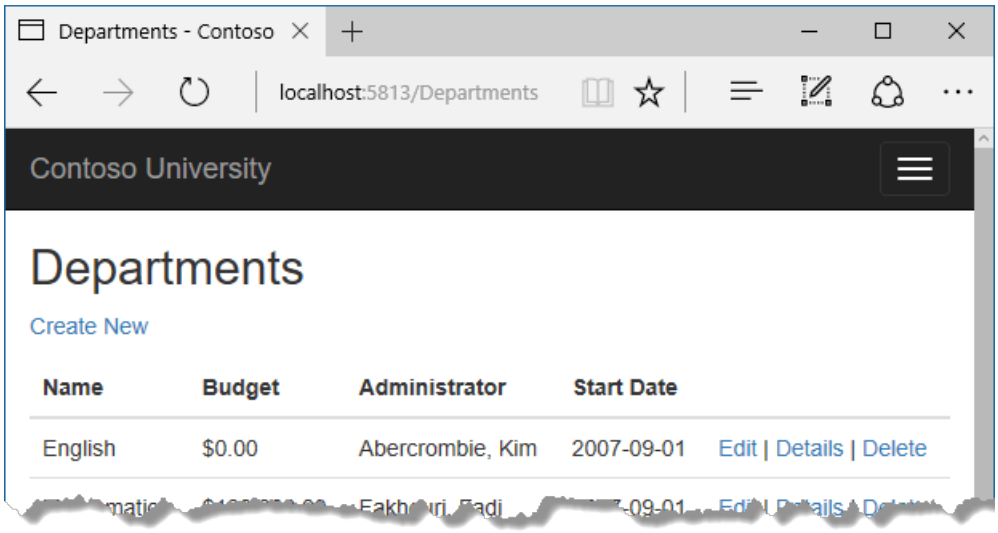
The alternative to pessimistic concurrency is optimistic concurrency. Optimistic concurrency means allowing concurrency conflicts to happen, and then reacting appropriately if they do. For example, Jane visits the Department Edit page and changes the Budget amount for the English department from $350,000.00 to $0.00.



Before Jane clicks **Save**, John visits the same page and changes the Start Date field from 9/1/2007 to 9/1/2013.



Jane clicks **Save** first and sees her change when the browser returns to the Index page.



Then John clicks **Save** on an Edit page that still shows a budget of $350,000.00. What happens next is determined by how you handle concurrency conflicts.

Some of the options include the following:

- You can keep track of which property a user has modified and update only the corresponding columns in the database.

  In the example scenario, no data would be lost, because different properties were updated by the two users. The next time someone browses the English department, they will see both Jane's and John's changes -- a start date of 9/1/2013 and a budget of zero dollars. This method of updating can reduce the number of conflicts that could result in data loss, but it can't avoid data loss if competing changes are

made to the same property of an entity. Whether the Entity Framework works this way depends on how you implement your update code. It's often not practical in a web application, because it can require that you maintain large amounts of state in order to keep track of all original property values for an entity as well as new values. Maintaining large amounts of state can affect application performance because it either requires server resources or must be included in the web page itself (for example, in hidden fields) or in a cookie.

- You can let John's change overwrite Jane's change.

  The next time someone browses the English department, they will see 9/1/2013 and the restored $350,000.00 value. This is called a *Client Wins* or *Last in Wins* scenario. (All values from the client take precedence over what's in the data store.) As noted in the introduction to this section, if you don't do any coding for concurrency handling, this will happen automatically.

- You can prevent John's change from being updated in the database.

  Typically, you would display an error message, show him the current state of the data, and allow him to reapply his changes if he still wants to make them. This is called a *Store Wins* scenario. (The data-store values take precedence over the values submitted by the client.) You'll implement the Store Wins scenario in this tutorial. This method ensures that no changes are overwritten without a user being alerted to what's happening.

Detecting concurrency conflicts

You can resolve conflicts by handling `DbConcurrencyException` exceptions that the Entity Framework throws. In order to know when to throw these exceptions, the Entity Framework must be able to detect conflicts. Therefore, you must configure the database and the data model appropriately. Some options for enabling conflict detection include the following:

- In the database table, include a tracking column that can be used to determine when a row has been changed. You can then configure the Entity Framework to include that column in the Where clause of SQL Update or Delete commands.

  The data type of the tracking column is typically `rowversion`. The `rowversion` value is a sequential number that's incremented each time the row is updated. In an Update or Delete command, the Where clause includes the original value of the tracking column (the original row version) . If the row being updated has been changed by another user, the value in the `rowversion` column is different than the original value, so the Update or Delete statement can't find the row to update because of the Where clause. When the Entity Framework finds that no rows have been updated by the Update or Delete command (that is, when the number of affected rows is zero), it interprets that as a concurrency conflict.

- Configure the Entity Framework to include the original values of every column in the table in the Where clause of Update and Delete commands.

  As in the first option, if anything in the row has changed since the row was first read, the Where clause won't return a row to update, which the Entity Framework interprets as a concurrency conflict. For database tables that have many columns, this approach can result in very large Where clauses, and can require that you maintain large amounts of state. As noted earlier, maintaining large amounts of state can affect application performance. Therefore this approach is generally not recommended, and it isn't the method used in this tutorial.

  If you do want to implement this approach to concurrency, you have to mark all non-primary-key properties in the entity you want to track concurrency for by adding the `ConcurrencyCheck` attribute to them. That change enables the Entity Framework to include all columns in the SQL Where clause of Update and Delete statements.

In the remainder of this tutorial you'll add a `rowversion` tracking property to the Department entity, create a

controller and views, and test to verify that everything works correctly.

Add a tracking property

In *Models/Department.cs*, add a tracking property named RowVersion:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        [Timestamp]
        public byte[] RowVersion { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The `Timestamp` attribute specifies that this column will be included in the Where clause of Update and Delete commands sent to the database. The attribute is called `Timestamp` because previous versions of SQL Server used a SQL `timestamp` data type before the SQL `rowversion` replaced it. The .NET type for `rowversion` is a byte array.

If you prefer to use the fluent API, you can use the `IsConcurrencyToken` method (in *Data/SchoolContext.cs*) to specify the tracking property, as shown in the following example:

```
modelBuilder.Entity<Department>()
    .Property(p => p.RowVersion).IsConcurrencyToken();
```

By adding a property you changed the database model, so you need to do another migration.

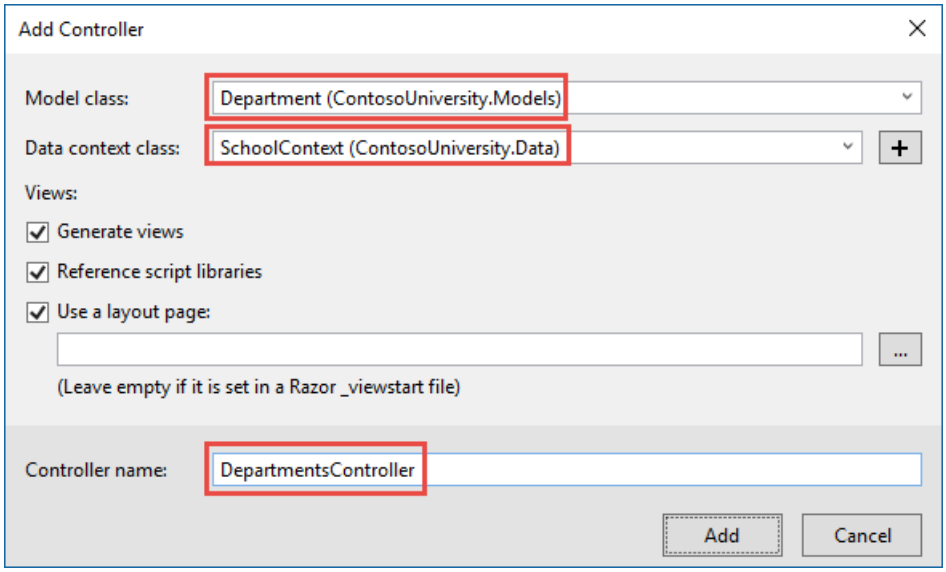
Save your changes and build the project, and then enter the following commands in the command window:

```
dotnet ef migrations add RowVersion
```

```
dotnet ef database update
```

Create Departments controller and views

Scaffold a Departments controller and views as you did earlier for Students, Courses, and Instructors.



In the *DepartmentsController.cs* file, change all four occurrences of "FirstMidName" to "FullName" so that the department administrator drop-down lists will contain the full name of the instructor rather than just the last name.

```
ViewData["InstructorID"] = new SelectList(_context.Instructors, "ID", "FullName", department.InstructorID);
```

Update Index view

The scaffolding engine created a RowVersion column in the Index view, but that field shouldn't be displayed.

Replace the code in *Views/Departments/Index.cshtml* with the following code.

```
@model IEnumerable<ContosoUniversity.Models.Department>

@{
    ViewData["Title"] = "Departments";
}

<h2>Departments</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Name)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Budget)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.StartDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Administrator)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Name)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Budget)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.StartDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Administrator.FullName)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-id="@item.DepartmentID">Edit</a> |
                    <a asp-action="Details" asp-route-id="@item.DepartmentID">Details</a> |
                    <a asp-action="Delete" asp-route-id="@item.DepartmentID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

This changes the heading to "Departments", deletes the RowVersion column, and shows full name instead of first name for the administrator.

Update Edit methods

In both the HttpGet `Edit` method and the `Details` method, add `AsNoTracking`. In the HttpGet `Edit` method, add eager loading for the Administrator.

```
var department = await _context.Departments
    .Include(i => i.Administrator)
    .AsNoTracking()
    .FirstOrDefaultAsync(m => m.DepartmentID == id);
```

Replace the existing code for the HttpPost `Edit` method with the following code:

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int? id, byte[] rowVersion)
{
    if (id == null)
    {
        return NotFound();
    }

    var departmentToUpdate = await _context.Departments.Include(i => i.Administrator).FirstOrDefaultAsync(m
=> m.DepartmentID == id);

    if (departmentToUpdate == null)
    {
        Department deletedDepartment = new Department();
        await TryUpdateModelAsync(deletedDepartment);
        ModelState.AddModelError(string.Empty,
            "Unable to save changes. The department was deleted by another user.");
        ViewData["InstructorID"] = new SelectList(_context.Instructors, "ID", "FullName",
deletedDepartment.InstructorID);
        return View(deletedDepartment);
    }

    _context.Entry(departmentToUpdate).Property("RowVersion").OriginalValue = rowVersion;

    if (await TryUpdateModelAsync<Department>(
        departmentToUpdate,
        "",
        s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
    {
        try
        {
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
        catch (DbUpdateConcurrencyException ex)
        {
            var exceptionEntry = ex.Entries.Single();
            var clientValues = (Department)exceptionEntry.Entity;
            var databaseEntry = exceptionEntry.GetDatabaseValues();
            if (databaseEntry == null)
            {
                ModelState.AddModelError(string.Empty,
                    "Unable to save changes. The department was deleted by another user.");
            }
            else
            {
                var databaseValues = (Department)databaseEntry.ToObject();

                if (databaseValues.Name != clientValues.Name)
                {
                    ModelState.AddModelError("Name", $"Current value: {databaseValues.Name}");
                }
                if (databaseValues.Budget != clientValues.Budget)
                {
                    ModelState.AddModelError("Budget", $"Current value: {databaseValues.Budget:c}");
                }
                if (databaseValues.StartDate != clientValues.StartDate)
                {
```

```
                    ModelState.AddModelError("StartDate", $"Current value: {databaseValues.StartDate:d}");
                }
                if (databaseValues.InstructorID != clientValues.InstructorID)
                {
                    Instructor databaseInstructor = await _context.Instructors.FirstOrDefaultAsync(i => i.ID
== databaseValues.InstructorID);
                    ModelState.AddModelError("InstructorID", $"Current value:
{databaseInstructor?.FullName}");
                }

                ModelState.AddModelError(string.Empty, "The record you attempted to edit "
                        + "was modified by another user after you got the original value. The "
                        + "edit operation was canceled and the current values in the database "
                        + "have been displayed. If you still want to edit this record, click "
                        + "the Save button again. Otherwise click the Back to List hyperlink.");
                departmentToUpdate.RowVersion = (byte[])databaseValues.RowVersion;
                ModelState.Remove("RowVersion");
            }
        }
    }
    ViewData["InstructorID"] = new SelectList(_context.Instructors, "ID", "FullName",
departmentToUpdate.InstructorID);
    return View(departmentToUpdate);
}
```

The code begins by trying to read the department to be updated. If the `FirstOrDefaultAsync` method returns null, the department was deleted by another user. In that case the code uses the posted form values to create a department entity so that the Edit page can be redisplayed with an error message. As an alternative, you wouldn't have to re-create the department entity if you display only an error message without redisplaying the department fields.

The view stores the original `RowVersion` value in a hidden field, and this method receives that value in the `rowVersion` parameter. Before you call `SaveChanges`, you have to put that original `RowVersion` property value in the `OriginalValues` collection for the entity.

```
_context.Entry(departmentToUpdate).Property("RowVersion").OriginalValue = rowVersion;
```

Then when the Entity Framework creates a SQL UPDATE command, that command will include a WHERE clause that looks for a row that has the original `RowVersion` value. If no rows are affected by the UPDATE command (no rows have the original `RowVersion` value), the Entity Framework throws a `DbUpdateConcurrencyException` exception.

The code in the catch block for that exception gets the affected Department entity that has the updated values from the `Entries` property on the exception object.

```
var exceptionEntry = ex.Entries.Single();
```

The `Entries` collection will have just one `EntityEntry` object. You can use that object to get the new values entered by the user and the current database values.

```
var clientValues = (Department)exceptionEntry.Entity;
var databaseEntry = exceptionEntry.GetDatabaseValues();
```

The code adds a custom error message for each column that has database values different from what the user entered on the Edit page (only one field is shown here for brevity).

```
var databaseValues = (Department)databaseEntry.ToObject();

if (databaseValues.Name != clientValues.Name)
{
    ModelState.AddModelError("Name", $"Current value: {databaseValues.Name}");
```

Finally, the code sets the `RowVersion` value of the `departmentToUpdate` to the new value retrieved from the database. This new `RowVersion` value will be stored in the hidden field when the Edit page is redisplayed, and the next time the user clicks **Save**, only concurrency errors that happen since the redisplay of the Edit page will be caught.

```
departmentToUpdate.RowVersion = (byte[])databaseValues.RowVersion;
ModelState.Remove("RowVersion");
```

The `ModelState.Remove` statement is required because `ModelState` has the old `RowVersion` value. In the view, the `ModelState` value for a field takes precedence over the model property values when both are present.

Update Edit view

In *Views/Departments/Edit.cshtml*, make the following changes:

- Add a hidden field to save the `RowVersion` property value, immediately following the hidden field for the `DepartmentID` property.
- Add a "Select Administrator" option to the drop-down list.

```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Edit";
}

<h2>Edit</h2>

<h4>Department</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Edit">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="DepartmentID" />
            <input type="hidden" asp-for="RowVersion" />
            <div class="form-group">
                <label asp-for="Name" class="control-label"></label>
                <input asp-for="Name" class="form-control" />
                <span asp-validation-for="Name" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Budget" class="control-label"></label>
                <input asp-for="Budget" class="form-control" />
                <span asp-validation-for="Budget" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="StartDate" class="control-label"></label>
                <input asp-for="StartDate" class="form-control" />
                <span asp-validation-for="StartDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="InstructorID" class="control-label"></label>
                <select asp-for="InstructorID" class="form-control" asp-items="ViewBag.InstructorID">
                    <option value="">-- Select Administrator --</option>
                </select>
                <span asp-validation-for="InstructorID" class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>

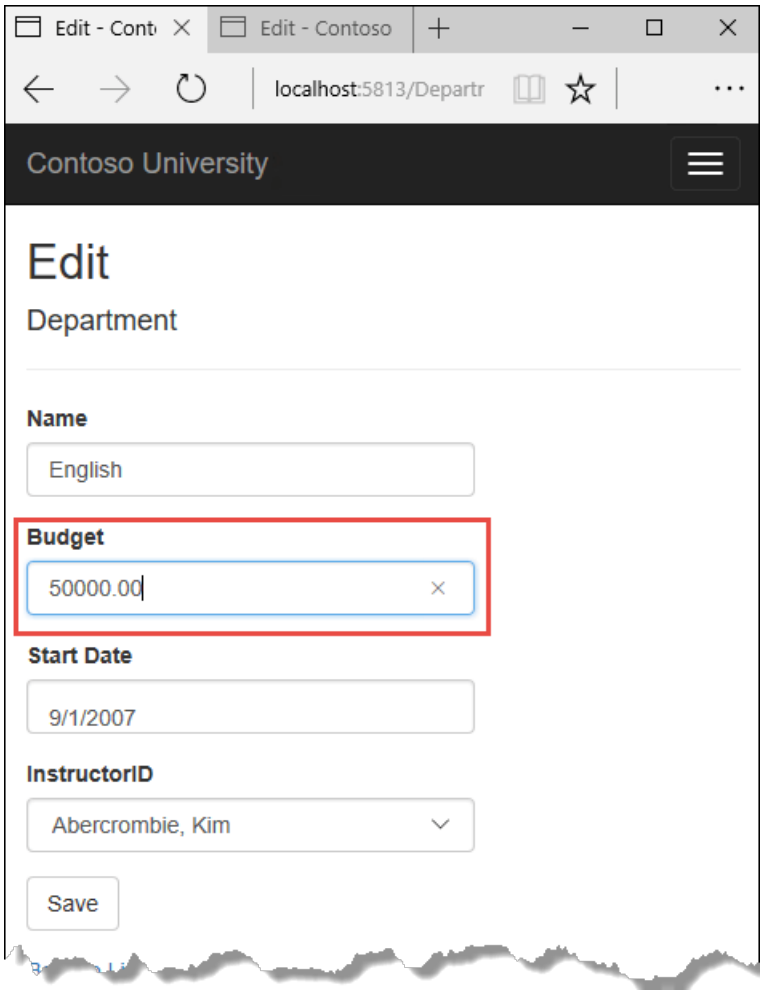
<div>
    <a asp-action="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Test concurrency conflicts

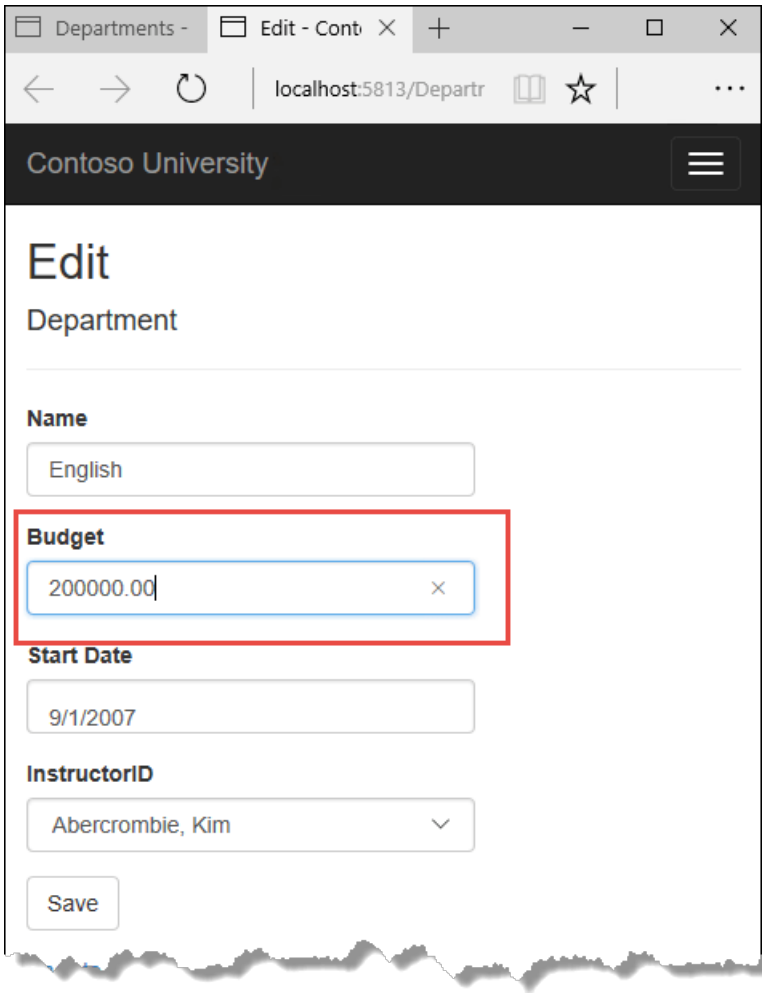
Run the app and go to the Departments Index page. Right-click the **Edit** hyperlink for the English department and select **Open in new tab**, then click the **Edit** hyperlink for the English department. The two browser tabs now display the same information.

Change a field in the first browser tab and click **Save**.

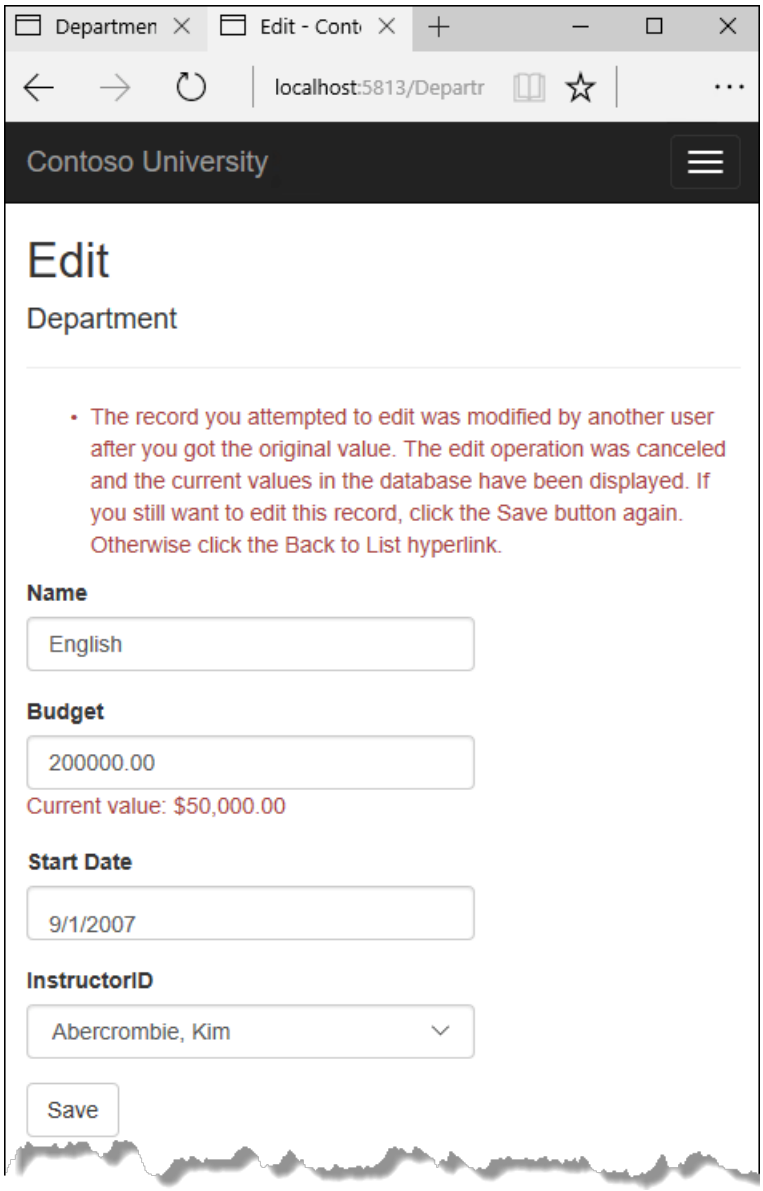


The browser shows the Index page with the changed value.

Change a field in the second browser tab.



Click **Save**. You see an error message:



Click **Save** again. The value you entered in the second browser tab is saved. You see the saved values when the Index page appears.

Update the Delete page

For the Delete page, the Entity Framework detects concurrency conflicts caused by someone else editing the department in a similar manner. When the HttpGet `Delete` method displays the confirmation view, the view includes the original `RowVersion` value in a hidden field. That value is then available to the HttpPost `Delete` method that's called when the user confirms the deletion. When the Entity Framework creates the SQL DELETE command, it includes a WHERE clause with the original `RowVersion` value. If the command results in zero rows affected (meaning the row was changed after the Delete confirmation page was displayed), a concurrency exception is thrown, and the HttpGet `Delete` method is called with an error flag set to true in order to redisplay the confirmation page with an error message. It's also possible that zero rows were affected because the row was deleted by another user, so in that case no error message is displayed.

Update the Delete methods in the Departments controller

In *DepartmentsController.cs*, replace the HttpGet `Delete` method with the following code:

```
public async Task<IActionResult> Delete(int? id, bool? concurrencyError)
{
    if (id == null)
    {
        return NotFound();
    }

    var department = await _context.Departments
        .Include(d => d.Administrator)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.DepartmentID == id);
    if (department == null)
    {
        if (concurrencyError.GetValueOrDefault())
        {
            return RedirectToAction(nameof(Index));
        }
        return NotFound();
    }

    if (concurrencyError.GetValueOrDefault())
    {
        ViewData["ConcurrencyErrorMessage"] = "The record you attempted to delete "
            + "was modified by another user after you got the original values. "
            + "The delete operation was canceled and the current values in the "
            + "database have been displayed. If you still want to delete this "
            + "record, click the Delete button again. Otherwise "
            + "click the Back to List hyperlink.";
    }

    return View(department);
}
```

The method accepts an optional parameter that indicates whether the page is being redisplayed after a concurrency error. If this flag is true and the department specified no longer exists, it was deleted by another user. In that case, the code redirects to the Index page. If this flag is true and the Department does exist, it was changed by another user. In that case, the code sends an error message to the view using `ViewData`.

Replace the code in the HttpPost `Delete` method (named `DeleteConfirmed`) with the following code:

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Delete(Department department)
{
    try
    {
        if (await _context.Departments.AnyAsync(m => m.DepartmentID == department.DepartmentID))
        {
            _context.Departments.Remove(department);
            await _context.SaveChangesAsync();
        }
        return RedirectToAction(nameof(Index));
    }
    catch (DbUpdateConcurrencyException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.)
        return RedirectToAction(nameof(Delete), new { concurrencyError = true, id = department.DepartmentID
});
    }
}
```

In the scaffolded code that you just replaced, this method accepted only a record ID:

```
public async Task<IActionResult> DeleteConfirmed(int id)
```

You've changed this parameter to a Department entity instance created by the model binder. This gives EF access to the RowVersion property value in addition to the record key.

```
public async Task<IActionResult> Delete(Department department)
```

You have also changed the action method name from `DeleteConfirmed` to `Delete`. The scaffolded code used the name `DeleteConfirmed` to give the HttpPost method a unique signature. (The CLR requires overloaded methods to have different method parameters.) Now that the signatures are unique, you can stick with the MVC convention and use the same name for the HttpPost and HttpGet delete methods.

If the department is already deleted, the `AnyAsync` method returns false and the application just goes back to the Index method.

If a concurrency error is caught, the code redisplays the Delete confirmation page and provides a flag that indicates it should display a concurrency error message.

Update the Delete view

In *Views/Departments/Delete.cshtml*, replace the scaffolded code with the following code that adds an error message field and hidden fields for the DepartmentID and RowVersion properties. The changes are highlighted.

```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

<p class="text-danger">@ViewData["ConcurrencyErrorMessage"]</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Department</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Name)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Name)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Budget)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Budget)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.StartDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.StartDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Administrator)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Administrator.FullName)
        </dd>
    </dl>

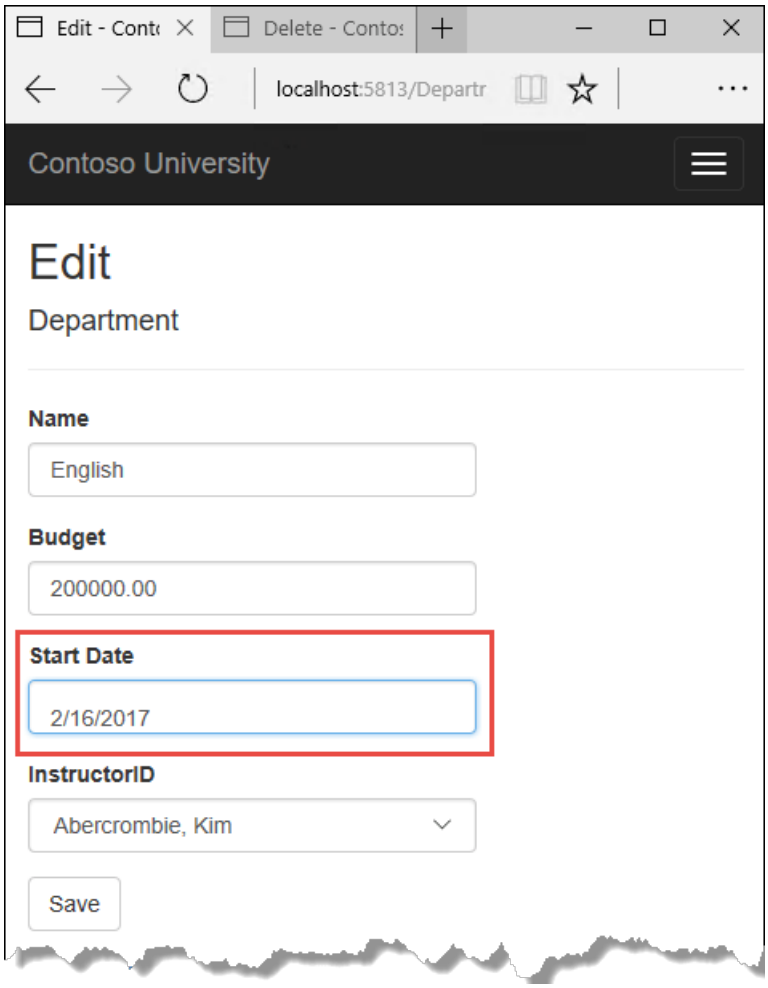
    <form asp-action="Delete">
        <input type="hidden" asp-for="DepartmentID" />
        <input type="hidden" asp-for="RowVersion" />
        <div class="form-actions no-color">
            <input type="submit" value="Delete" class="btn btn-default" /> |
            <a asp-action="Index">Back to List</a>
        </div>
    </form>
</div>
```

This makes the following changes:

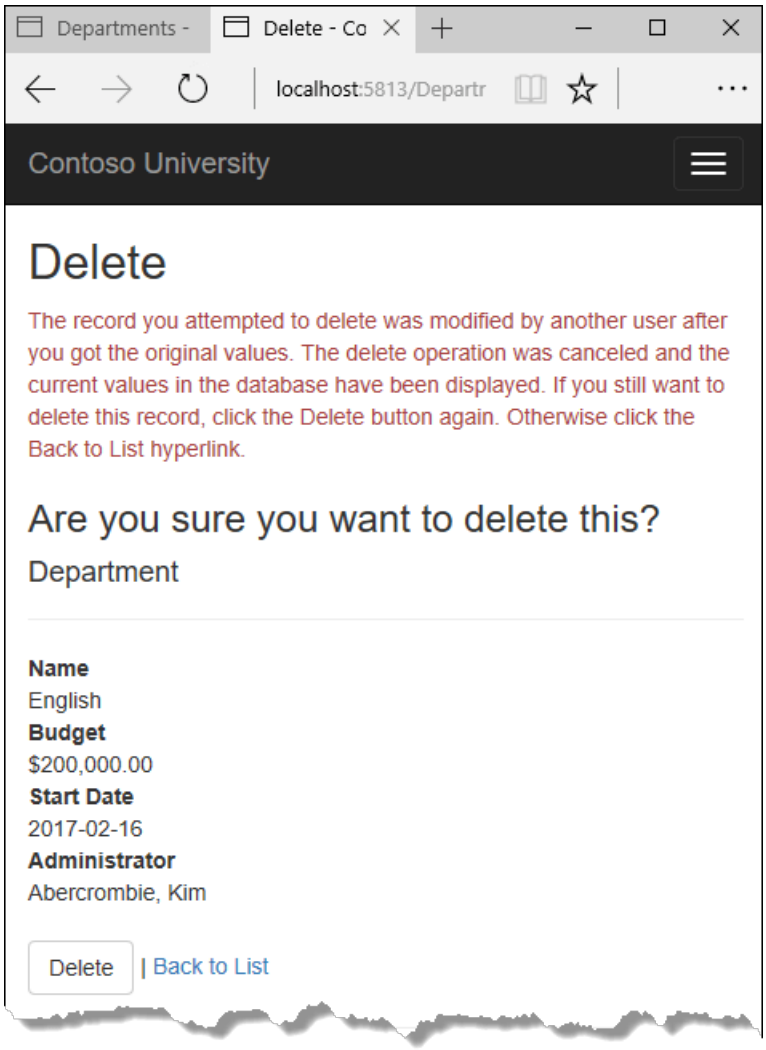
- Adds an error message between the `h2` and `h3` headings.
- Replaces FirstMidName with FullName in the **Administrator** field.
- Removes the RowVersion field.
- Adds a hidden field for the `RowVersion` property.

Run the app and go to the Departments Index page. Right-click the **Delete** hyperlink for the English department and select **Open in new tab**, then in the first tab click the **Edit** hyperlink for the English department.

In the first window, change one of the values, and click **Save**:



In the second tab, click **Delete**. You see the concurrency error message, and the Department values are refreshed with what's currently in the database.



If you click **Delete** again, you're redirected to the Index page, which shows that the department has been deleted.

Update Details and Create views

You can optionally clean up scaffolded code in the Details and Create views.

Replace the code in *Views/Departments/Details.cshtml* to delete the RowVersion column and show the full name of the Administrator.

```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Details";
}

<h2>Details</h2>

<div>
    <h4>Department</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Name)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Name)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Budget)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Budget)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.StartDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.StartDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Administrator)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Administrator.FullName)
        </dd>
    </dl>
</div>
<div>
    <a asp-action="Edit" asp-route-id="@Model.DepartmentID">Edit</a> |
    <a asp-action="Index">Back to List</a>
</div>
```

Replace the code in *Views/Departments/Create.cshtml* to add a Select option to the drop-down list.

```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Create";
}

<h2>Create</h2>

<h4>Department</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Create">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Name" class="control-label"></label>
                <input asp-for="Name" class="form-control" />
                <span asp-validation-for="Name" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Budget" class="control-label"></label>
                <input asp-for="Budget" class="form-control" />
                <span asp-validation-for="Budget" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="StartDate" class="control-label"></label>
                <input asp-for="StartDate" class="form-control" />
                <span asp-validation-for="StartDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="InstructorID" class="control-label"></label>
                <select asp-for="InstructorID" class="form-control" asp-items="ViewBag.InstructorID">
                    <option value="">-- Select Administrator --</option>
                </select>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-action="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

For more information about how to handle concurrency in EF Core, see Concurrency conflicts.

Next steps

In this tutorial, you:

- Learned about concurrency conflicts

- Added a tracking property
- Created Departments controller and views
- Updated Index view
- Updated Edit methods
- Updated Edit view
- Tested concurrency conflicts
- Updated the Delete page
- Updated Details and Create views

Advance to the next tutorial to learn how to implement table-per-hierarchy inheritance for the Instructor and Student entities.

Next: Implement table-per-hierarchy inheritance

Tutorial: Implement inheritance - ASP.NET MVC with EF Core

9/22/2020 • 8 minutes to read • Edit Online

In the previous tutorial, you handled concurrency exceptions. This tutorial will show you how to implement inheritance in the data model.

In object-oriented programming, you can use inheritance to facilitate code reuse. In this tutorial, you'll change the `Instructor` and `Student` classes so that they derive from a `Person` base class which contains properties such as `LastName` that are common to both instructors and students. You won't add or change any web pages, but you'll change some of the code and those changes will be automatically reflected in the database.

In this tutorial, you:

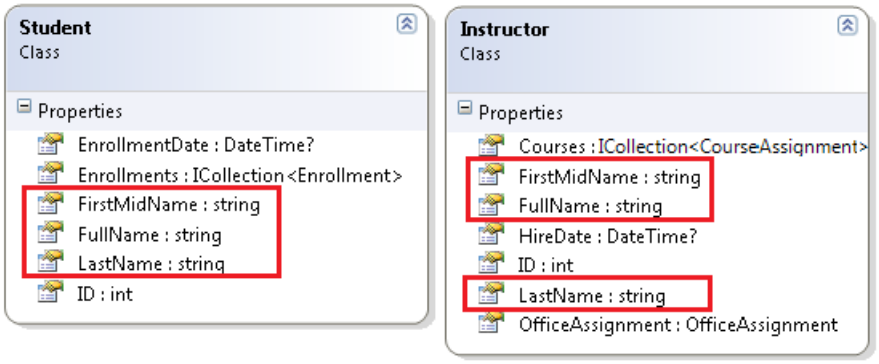
- Map inheritance to database
- Create the Person class
- Update Instructor and Student
- Add Person to the model
- Create and update migrations
- Test the implementation

Prerequisites

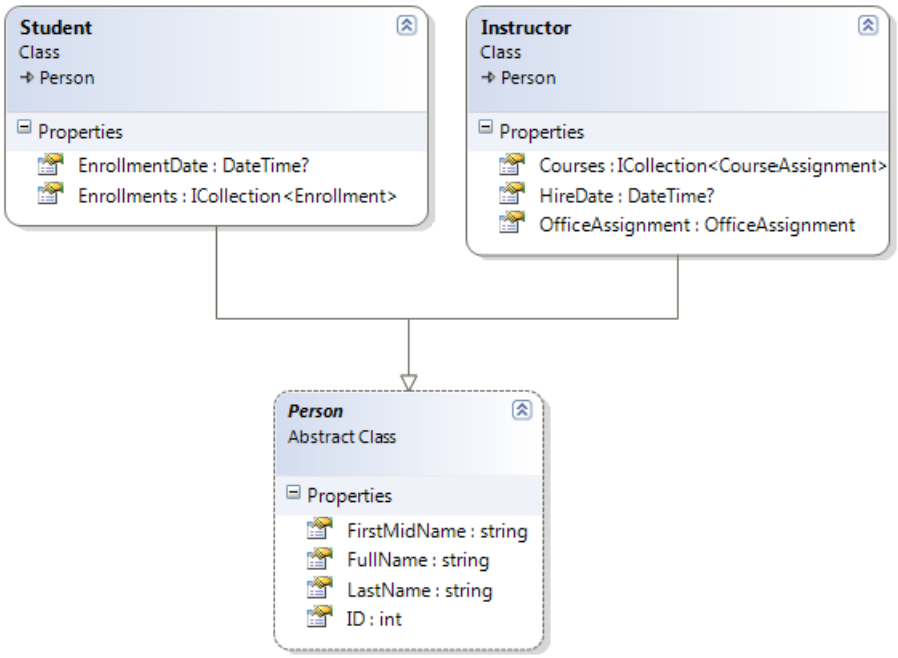
- Handle Concurrency

Map inheritance to database

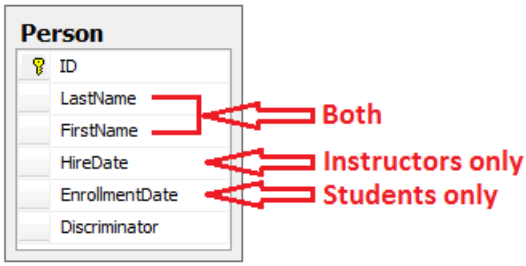
The `Instructor` and `Student` classes in the School data model have several properties that are identical:



Suppose you want to eliminate the redundant code for the properties that are shared by the `Instructor` and `Student` entities. Or you want to write a service that can format names without caring whether the name came from an instructor or a student. You could create a `Person` base class that contains only those shared properties, then make the `Instructor` and `Student` classes inherit from that base class, as shown in the following illustration:



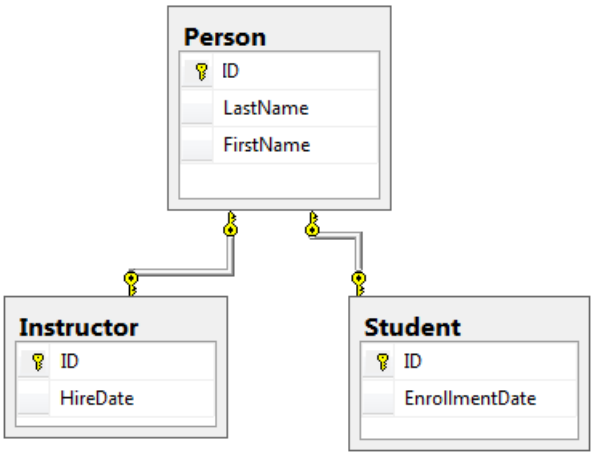
There are several ways this inheritance structure could be represented in the database. You could have a Person table that includes information about both students and instructors in a single table. Some of the columns could apply only to instructors (HireDate), some only to students (EnrollmentDate), some to both (LastName, FirstName). Typically, you'd have a discriminator column to indicate which type each row represents. For example, the discriminator column might have "Instructor" for instructors and "Student" for students.



This pattern of generating an entity inheritance structure from a single database table is called table-per-hierarchy (TPH) inheritance.

An alternative is to make the database look more like the inheritance structure. For example, you could have only the name fields in the Person table and have separate Instructor and Student tables with the date fields.

> **WARNING**
>
> Table Per Type (TPT) is not supported by EF Core 3.x, however it is has been implemented in EF Core 5.0.



This pattern of making a database table for each entity class is called table per type (TPT) inheritance.

Yet another option is to map all non-abstract types to individual tables. All properties of a class, including inherited properties, map to columns of the corresponding table. This pattern is called Table-per-Concrete Class (TPC) inheritance. If you implemented TPC inheritance for the Person, Student, and Instructor classes as shown earlier, the Student and Instructor tables would look no different after implementing inheritance than they did before.

TPC and TPH inheritance patterns generally deliver better performance than TPT inheritance patterns, because TPT patterns can result in complex join queries.

This tutorial demonstrates how to implement TPH inheritance. TPH is the only inheritance pattern that the Entity Framework Core supports. What you'll do is create a `Person` class, change the `Instructor` and `Student` classes to derive from `Person`, add the new class to the `DbContext`, and create a migration.

> **TIP**
> Consider saving a copy of the project before making the following changes. Then if you run into problems and need to start over, it will be easier to start from the saved project instead of reversing steps done for this tutorial or going back to the beginning of the whole series.

Create the Person class

In the Models folder, create Person.cs and replace the template code with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public abstract class Person
    {
        public int ID { get; set; }

        [Required]
        [StringLength(50)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }
    }
}
```

Update Instructor and Student

In *Instructor.cs*, derive the Instructor class from the Person class and remove the key and name fields. The code will look like the following example:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor : Person
    {
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        public ICollection<CourseAssignment> CourseAssignments { get; set; }
        public OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Make the same changes in *Student.cs*.

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student : Person
    {
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

Add Person to the model

Add the Person entity type to *SchoolContext.cs*. The new lines are highlighted.

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) : base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
        public DbSet<Department> Departments { get; set; }
        public DbSet<Instructor> Instructors { get; set; }
        public DbSet<OfficeAssignment> OfficeAssignments { get; set; }
        public DbSet<CourseAssignment> CourseAssignments { get; set; }
        public DbSet<Person> People { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
            modelBuilder.Entity<Department>().ToTable("Department");
            modelBuilder.Entity<Instructor>().ToTable("Instructor");
            modelBuilder.Entity<OfficeAssignment>().ToTable("OfficeAssignment");
            modelBuilder.Entity<CourseAssignment>().ToTable("CourseAssignment");
            modelBuilder.Entity<Person>().ToTable("Person");

            modelBuilder.Entity<CourseAssignment>()
                .HasKey(c => new { c.CourseID, c.InstructorID });
        }
    }
}
```

This is all that the Entity Framework needs in order to configure table-per-hierarchy inheritance. As you'll see, when the database is updated, it will have a Person table in place of the Student and Instructor tables.

Create and update migrations

Save your changes and build the project. Then open the command window in the project folder and enter the following command:

```
dotnet ef migrations add Inheritance
```

Don't run the `database update` command yet. That command will result in lost data because it will drop the Instructor table and rename the Student table to Person. You need to provide custom code to preserve existing data.

Open *Migrations/<timestamp>_Inheritance.cs* and replace the `Up` method with the following code:

```
protected override void Up(MigrationBuilder migrationBuilder)
{
    migrationBuilder.DropForeignKey(
        name: "FK_Enrollment_Student_StudentID",
        table: "Enrollment");

    migrationBuilder.DropIndex(name: "IX_Enrollment_StudentID", table: "Enrollment");

    migrationBuilder.RenameTable(name: "Instructor", newName: "Person");
    migrationBuilder.AddColumn<DateTime>(name: "EnrollmentDate", table: "Person", nullable: true);
    migrationBuilder.AddColumn<string>(name: "Discriminator", table: "Person", nullable: false, maxLength:
128, defaultValue: "Instructor");
    migrationBuilder.AlterColumn<DateTime>(name: "HireDate", table: "Person", nullable: true);
    migrationBuilder.AddColumn<int>(name: "OldId", table: "Person", nullable: true);

    // Copy existing Student data into new Person table.
    migrationBuilder.Sql("INSERT INTO dbo.Person (LastName, FirstName, HireDate, EnrollmentDate,
Discriminator, OldId) SELECT LastName, FirstName, null AS HireDate, EnrollmentDate, 'Student' AS
Discriminator, ID AS OldId FROM dbo.Student");
    // Fix up existing relationships to match new PK's.
    migrationBuilder.Sql("UPDATE dbo.Enrollment SET StudentId = (SELECT ID FROM dbo.Person WHERE OldId =
Enrollment.StudentId AND Discriminator = 'Student')");

    // Remove temporary key
    migrationBuilder.DropColumn(name: "OldID", table: "Person");

    migrationBuilder.DropTable(
        name: "Student");

    migrationBuilder.CreateIndex(
         name: "IX_Enrollment_StudentID",
         table: "Enrollment",
         column: "StudentID");

    migrationBuilder.AddForeignKey(
        name: "FK_Enrollment_Person_StudentID",
        table: "Enrollment",
        column: "StudentID",
        principalTable: "Person",
        principalColumn: "ID",
        onDelete: ReferentialAction.Cascade);
}
```

This code takes care of the following database update tasks:

- Removes foreign key constraints and indexes that point to the Student table.
- Renames the Instructor table as Person and makes changes needed for it to store Student data:
- Adds nullable EnrollmentDate for students.

- Adds Discriminator column to indicate whether a row is for a student or an instructor.
- Makes HireDate nullable since student rows won't have hire dates.
- Adds a temporary field that will be used to update foreign keys that point to students. When you copy students into the Person table they will get new primary key values.
- Copies data from the Student table into the Person table. This causes students to get assigned new primary key values.
- Fixes foreign key values that point to students.
- Re-creates foreign key constraints and indexes, now pointing them to the Person table.

(If you had used GUID instead of integer as the primary key type, the student primary key values wouldn't have to change, and several of these steps could have been omitted.)

Run the `database update` command:

```
dotnet ef database update
```

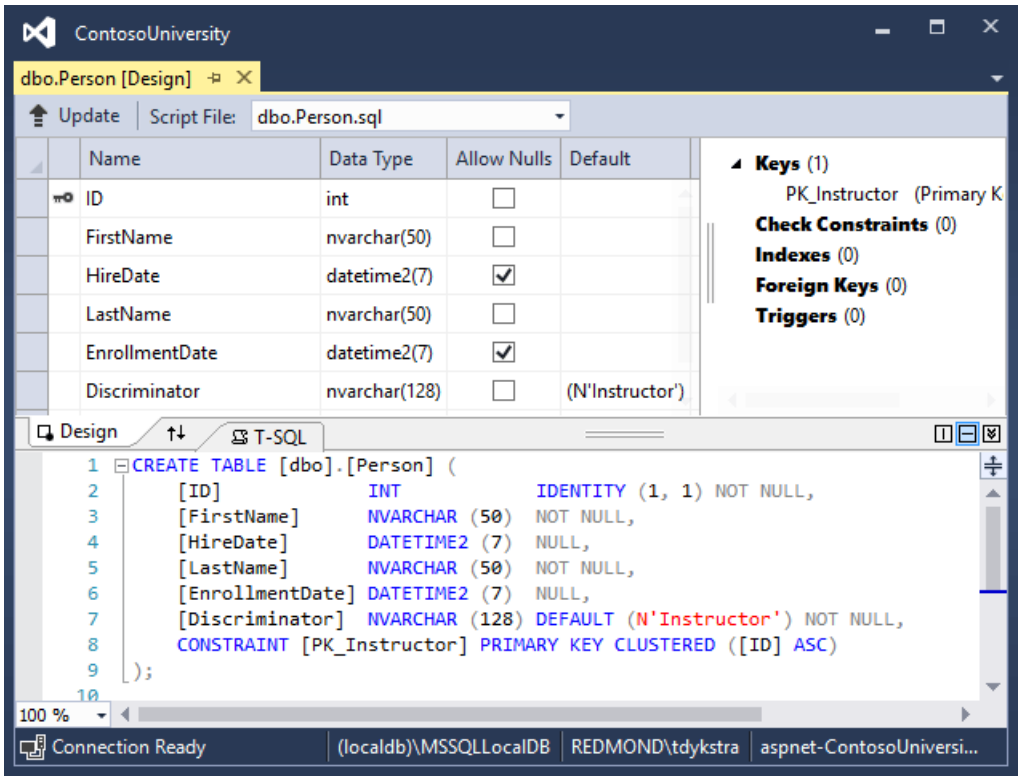
(In a production system you would make corresponding changes to the `Down` method in case you ever had to use that to go back to the previous database version. For this tutorial you won't be using the `Down` method.)

> **NOTE**
> It's possible to get other errors when making schema changes in a database that has existing data. If you get migration errors that you can't resolve, you can either change the database name in the connection string or delete the database. With a new database, there's no data to migrate, and the update-database command is more likely to complete without errors. To delete the database, use SSOX or run the `database drop` CLI command.

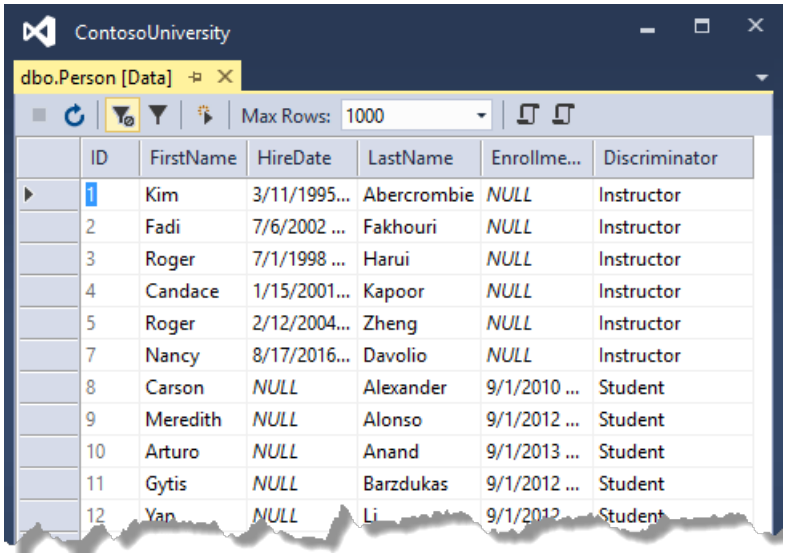
Test the implementation

Run the app and try various pages. Everything works the same as it did before.

In **SQL Server Object Explorer**, expand **Data Connections/SchoolContext** and then **Tables**, and you see that the Student and Instructor tables have been replaced by a Person table. Open the Person table designer and you see that it has all of the columns that used to be in the Student and Instructor tables.



Right-click the Person table, and then click **Show Table Data** to see the discriminator column.



Get the code

Download or view the completed application.

Additional resources

For more information about inheritance in Entity Framework Core, see Inheritance.

Next steps

In this tutorial, you:

- Mapped inheritance to database
- Created the Person class
- Updated Instructor and Student
- Added Person to the model

- Created and update migrations
- Tested the implementation

Advance to the next tutorial to learn how to handle a variety of relatively advanced Entity Framework scenarios.

Next: Advanced topics

Tutorial: Learn about advanced scenarios - ASP.NET MVC with EF Core

9/22/2020 • 13 minutes to read • Edit Online

In the previous tutorial, you implemented table-per-hierarchy inheritance. This tutorial introduces several topics that are useful to be aware of when you go beyond the basics of developing ASP.NET Core web applications that use Entity Framework Core.

In this tutorial, you:

- Perform raw SQL queries
- Call a query to return entities
- Call a query to return other types
- Call an update query
- Examine SQL queries
- Create an abstraction layer
- Learn about Automatic change detection
- Learn about EF Core source code and development plans
- Learn how to use dynamic LINQ to simplify code

Prerequisites

- Implement Inheritance

Perform raw SQL queries

One of the advantages of using the Entity Framework is that it avoids tying your code too closely to a particular method of storing data. It does this by generating SQL queries and commands for you, which also frees you from having to write them yourself. But there are exceptional scenarios when you need to run specific SQL queries that you have manually created. For these scenarios, the Entity Framework Code First API includes methods that enable you to pass SQL commands directly to the database. You have the following options in EF Core 1.0:

- Use the `DbSet.FromSql` method for queries that return entity types. The returned objects must be of the type expected by the `DbSet` object, and they're automatically tracked by the database context unless you turn tracking off.
- Use the `Database.ExecuteSqlCommand` for non-query commands.

If you need to run a query that returns types that aren't entities, you can use ADO.NET with the database connection provided by EF. The returned data isn't tracked by the database context, even if you use this method to retrieve entity types.

As is always true when you execute SQL commands in a web application, you must take precautions to protect your site against SQL injection attacks. One way to do that is to use parameterized queries to make sure that strings submitted by a web page can't be interpreted as SQL commands. In this tutorial you'll use parameterized queries when integrating user input into a query.

Call a query to return entities

The `DbSet<TEntity>` class provides a method that you can use to execute a query that returns an entity of type

`TEntity`. To see how this works you'll change the code in the `Details` method of the Department controller.

In *DepartmentsController.cs*, in the `Details` method, replace the code that retrieves a department with a `FromSql` method call, as shown in the following highlighted code:

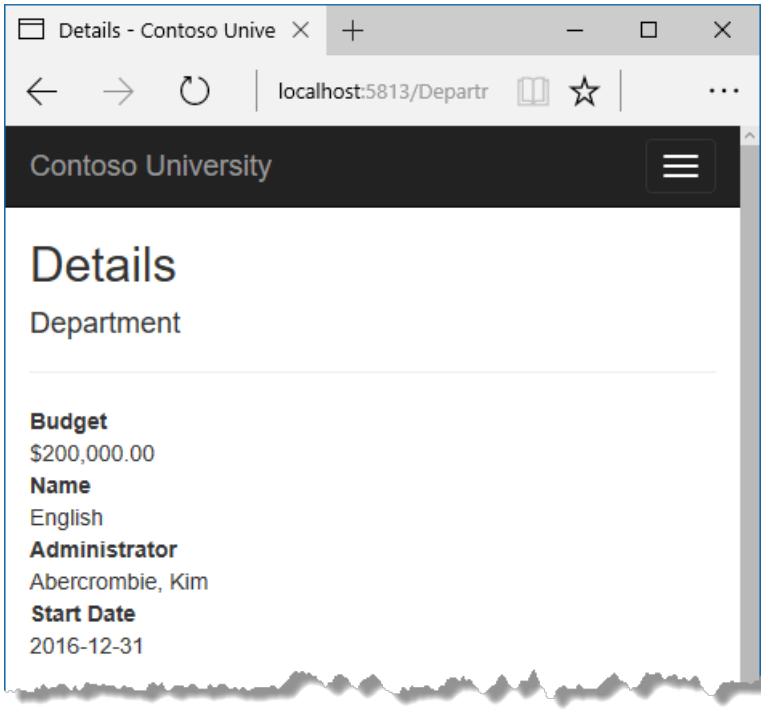
```
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    string query = "SELECT * FROM Department WHERE DepartmentID = {0}";
    var department = await _context.Departments
        .FromSql(query, id)
        .Include(d => d.Administrator)
        .AsNoTracking()
        .FirstOrDefaultAsync();

    if (department == null)
    {
        return NotFound();
    }

    return View(department);
}
```

To verify that the new code works correctly, select the **Departments** tab and then **Details** for one of the departments.



Call a query to return other types

Earlier you created a student statistics grid for the About page that showed the number of students for each enrollment date. You got the data from the Students entity set (`_context.Students`) and used LINQ to project the results into a list of `EnrollmentDateGroup` view model objects. Suppose you want to write the SQL itself rather than using LINQ. To do that you need to run a SQL query that returns something other than entity objects. In EF Core 1.0, one way to do that is write ADO.NET code and get the database connection from EF.

In *HomeController.cs*, replace the `About` method with the following code:

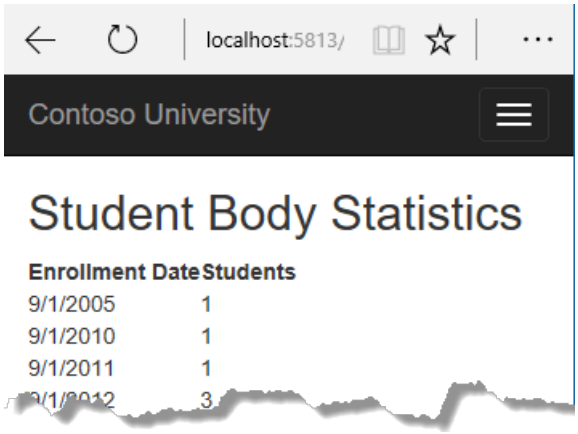
```
public async Task<ActionResult> About()
{
    List<EnrollmentDateGroup> groups = new List<EnrollmentDateGroup>();
    var conn = _context.Database.GetDbConnection();
    try
    {
        await conn.OpenAsync();
        using (var command = conn.CreateCommand())
        {
            string query = "SELECT EnrollmentDate, COUNT(*) AS StudentCount "
                + "FROM Person "
                + "WHERE Discriminator = 'Student' "
                + "GROUP BY EnrollmentDate";
            command.CommandText = query;
            DbDataReader reader = await command.ExecuteReaderAsync();

            if (reader.HasRows)
            {
                while (await reader.ReadAsync())
                {
                    var row = new EnrollmentDateGroup { EnrollmentDate = reader.GetDateTime(0), StudentCount
= reader.GetInt32(1) };
                    groups.Add(row);
                }
            }
            reader.Dispose();
        }
    }
    finally
    {
        conn.Close();
    }
    return View(groups);
}
```

Add a using statement:

```
using System.Data.Common;
```

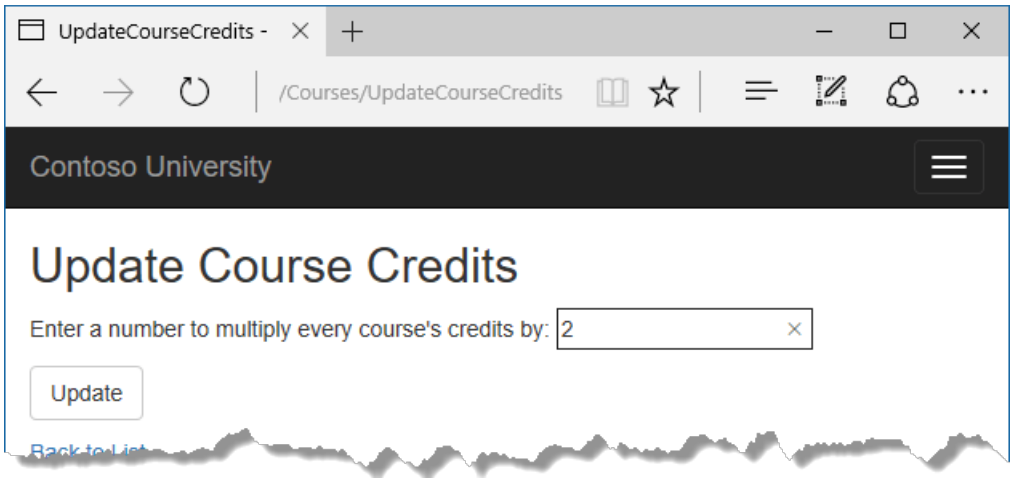
Run the app and go to the About page. It displays the same data it did before.



Call an update query

Suppose Contoso University administrators want to perform global changes in the database, such as changing the number of credits for every course. If the university has a large number of courses, it would be inefficient to retrieve them all as entities and change them individually. In this section you'll implement a web page that enables the user to specify a factor by which to change the number of credits for all courses, and you'll make the

change by executing a SQL UPDATE statement. The web page will look like the following illustration:



In *CoursesController.cs*, add UpdateCourseCredits methods for HttpGet and HttpPost:

```
public IActionResult UpdateCourseCredits()
{
    return View();
}
```

```
[HttpPost]
public async Task<IActionResult> UpdateCourseCredits(int? multiplier)
{
    if (multiplier != null)
    {
        ViewData["RowsAffected"] =
            await _context.Database.ExecuteSqlCommandAsync(
                "UPDATE Course SET Credits = Credits * {0}",
                parameters: multiplier);
    }
    return View();
}
```

When the controller processes an HttpGet request, nothing is returned in `ViewData["RowsAffected"]`, and the view displays an empty text box and a submit button, as shown in the preceding illustration.

When the **Update** button is clicked, the HttpPost method is called, and multiplier has the value entered in the text box. The code then executes the SQL that updates courses and returns the number of affected rows to the view in `ViewData`. When the view gets a `RowsAffected` value, it displays the number of rows updated.

In **Solution Explorer**, right-click the *Views/Courses* folder, and then click **Add > New Item**.

In the **Add New Item** dialog, click **ASP.NET Core** under **Installed** in the left pane, click **Razor View**, and name the new view *UpdateCourseCredits.cshtml*.

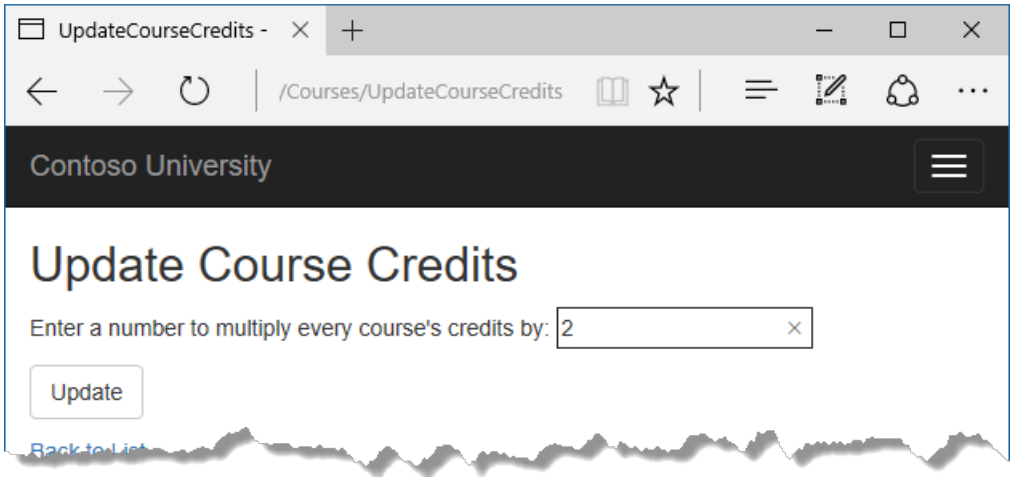
In *Views/Courses/UpdateCourseCredits.cshtml*, replace the template code with the following code:

```
@{
    ViewBag.Title = "UpdateCourseCredits";
}

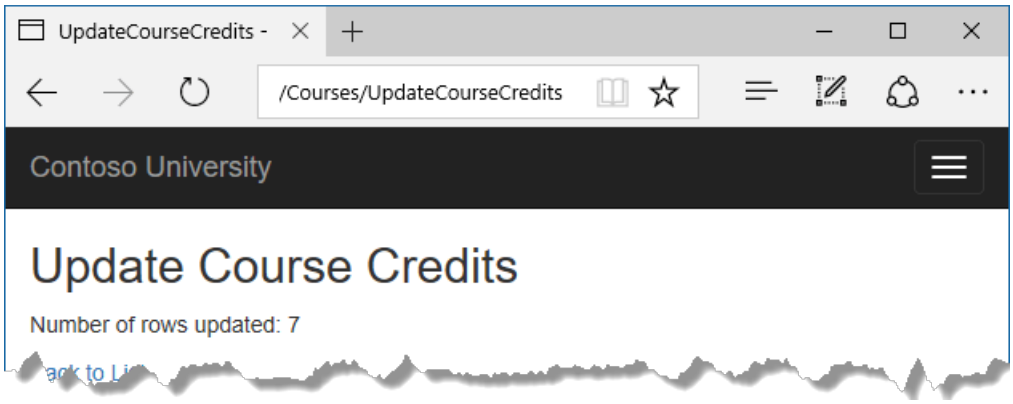
<h2>Update Course Credits</h2>

@if (ViewData["RowsAffected"] == null)
{
    <form asp-action="UpdateCourseCredits">
        <div class="form-actions no-color">
            <p>
                Enter a number to multiply every course's credits by: @Html.TextBox("multiplier")
            </p>
            <p>
                <input type="submit" value="Update" class="btn btn-default" />
            </p>
        </div>
    </form>
}
@if (ViewData["RowsAffected"] != null)
{
    <p>
        Number of rows updated: @ViewData["RowsAffected"]
    </p>
}
<div>
    @Html.ActionLink("Back to List", "Index")
</div>
```

Run the `UpdateCourseCredits` method by selecting the **Courses** tab, then adding "/UpdateCourseCredits" to the end of the URL in the browser's address bar (for example: `http://localhost:5813/Courses/UpdateCourseCredits`). Enter a number in the text box:



Click **Update**. You see the number of rows affected:



Click **Back to List** to see the list of courses with the revised number of credits.

Note that production code would ensure that updates always result in valid data. The simplified code shown here could multiply the number of credits enough to result in numbers greater than 5. (The `Credits` property has a `[Range(0, 5)]` attribute.) The update query would work but the invalid data could cause unexpected results in other parts of the system that assume the number of credits is 5 or less.

For more information about raw SQL queries, see Raw SQL Queries.

Examine SQL queries

Sometimes it's helpful to be able to see the actual SQL queries that are sent to the database. Built-in logging functionality for ASP.NET Core is automatically used by EF Core to write logs that contain the SQL for queries and updates. In this section you'll see some examples of SQL logging.

Open *StudentsController.cs* and in the `Details` method set a breakpoint on the `if (student == null)` statement.

Run the app in debug mode, and go to the Details page for a student.

Go to the **Output** window showing debug output, and you see the query:

```
Microsoft.EntityFrameworkCore.Database.Command:Information: Executed DbCommand (56ms) [Parameters=
[@__id_0='?'], CommandType='Text', CommandTimeout='30']
SELECT TOP(2) [s].[ID], [s].[Discriminator], [s].[FirstName], [s].[LastName], [s].[EnrollmentDate]
FROM [Person] AS [s]
WHERE ([s].[Discriminator] = N'Student') AND ([s].[ID] = @__id_0)
ORDER BY [s].[ID]
Microsoft.EntityFrameworkCore.Database.Command:Information: Executed DbCommand (122ms) [Parameters=
[@__id_0='?'], CommandType='Text', CommandTimeout='30']
SELECT [s.Enrollments].[EnrollmentID], [s.Enrollments].[CourseID], [s.Enrollments].[Grade], [s.Enrollments].
[StudentID], [e.Course].[CourseID], [e.Course].[Credits], [e.Course].[DepartmentID], [e.Course].[Title]
FROM [Enrollment] AS [s.Enrollments]
INNER JOIN [Course] AS [e.Course] ON [s.Enrollments].[CourseID] = [e.Course].[CourseID]
INNER JOIN (
    SELECT TOP(1) [s0].[ID]
    FROM [Person] AS [s0]
    WHERE ([s0].[Discriminator] = N'Student') AND ([s0].[ID] = @__id_0)
    ORDER BY [s0].[ID]
) AS [t] ON [s.Enrollments].[StudentID] = [t].[ID]
ORDER BY [t].[ID]
```

You'll notice something here that might surprise you: the SQL selects up to 2 rows (`TOP(2)`) from the Person table. The `SingleOrDefaultAsync` method doesn't resolve to 1 row on the server. Here's why:

- If the query would return multiple rows, the method returns null.
- To determine whether the query would return multiple rows, EF has to check if it returns at least 2.

Note that you don't have to use debug mode and stop at a breakpoint to get logging output in the **Output** window. It's just a convenient way to stop the logging at the point you want to look at the output. If you don't do that, logging continues and you have to scroll back to find the parts you're interested in.

Create an abstraction layer

Many developers write code to implement the repository and unit of work patterns as a wrapper around code that works with the Entity Framework. These patterns are intended to create an abstraction layer between the data access layer and the business logic layer of an application. Implementing these patterns can help insulate your application from changes in the data store and can facilitate automated unit testing or test-driven development (TDD). However, writing additional code to implement these patterns isn't always the best choice for applications that use EF, for several reasons:

- The EF context class itself insulates your code from data-store-specific code.
- The EF context class can act as a unit-of-work class for database updates that you do using EF.
- EF includes features for implementing TDD without writing repository code.

For information about how to implement the repository and unit of work patterns, see the Entity Framework 5 version of this tutorial series.

Entity Framework Core implements an in-memory database provider that can be used for testing. For more information, see Test with InMemory.

Automatic change detection

The Entity Framework determines how an entity has changed (and therefore which updates need to be sent to the database) by comparing the current values of an entity with the original values. The original values are stored when the entity is queried or attached. Some of the methods that cause automatic change detection are the following:

- DbContext.SaveChanges
- DbContext.Entry
- ChangeTracker.Entries

If you're tracking a large number of entities and you call one of these methods many times in a loop, you might get significant performance improvements by temporarily turning off automatic change detection using the `ChangeTracker.AutoDetectChangesEnabled` property. For example:

```
_context.ChangeTracker.AutoDetectChangesEnabled = false;
```

EF Core source code and development plans

The Entity Framework Core source is at https://github.com/dotnet/efcore. The EF Core repository contains nightly builds, issue tracking, feature specs, design meeting notes, and the roadmap for future development. You can file or find bugs, and contribute.

Although the source code is open, Entity Framework Core is fully supported as a Microsoft product. The Microsoft Entity Framework team keeps control over which contributions are accepted and tests all code changes to ensure the quality of each release.

Reverse engineer from existing database

To reverse engineer a data model including entity classes from an existing database, use the scaffold-dbcontext command. See the getting-started tutorial.

Use dynamic LINQ to simplify code

The third tutorial in this series shows how to write LINQ code by hard-coding column names in a `switch` statement. With two columns to choose from, this works fine, but if you have many columns the code could get verbose. To solve that problem, you can use the `EF.Property` method to specify the name of the property as a string. To try out this approach, replace the `Index` method in the `StudentsController` with the following code.

```
public async Task<IActionResult> Index(
    string sortOrder,
    string currentFilter,
    string searchString,
    int? pageNumber)
{
    ViewData["CurrentSort"] = sortOrder;
    ViewData["NameSortParm"] =
        String.IsNullOrEmpty(sortOrder) ? "LastName_desc" : "";
    ViewData["DateSortParm"] =
        sortOrder == "EnrollmentDate" ? "EnrollmentDate_desc" : "EnrollmentDate";

    if (searchString != null)
    {
        pageNumber = 1;
    }
    else
    {
        searchString = currentFilter;
    }

    ViewData["CurrentFilter"] = searchString;

    var students = from s in _context.Students
                   select s;

    if (!String.IsNullOrEmpty(searchString))
    {
        students = students.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }

    if (string.IsNullOrEmpty(sortOrder))
    {
        sortOrder = "LastName";
    }

    bool descending = false;
    if (sortOrder.EndsWith("_desc"))
    {
        sortOrder = sortOrder.Substring(0, sortOrder.Length - 5);
        descending = true;
    }

    if (descending)
    {
        students = students.OrderByDescending(e => EF.Property<object>(e, sortOrder));
    }
    else
    {
        students = students.OrderBy(e => EF.Property<object>(e, sortOrder));
    }

    int pageSize = 3;
    return View(await PaginatedList<Student>.CreateAsync(students.AsNoTracking(),
        pageNumber ?? 1, pageSize));
}
```

Acknowledgments

Tom Dykstra and Rick Anderson (twitter @RickAndMSFT) wrote this tutorial. Rowan Miller, Diego Vega, and other members of the Entity Framework team assisted with code reviews and helped debug issues that arose while we were writing code for the tutorials. John Parente and Paul Goldman worked on updating the tutorial for ASP.NET Core 2.2.

Troubleshoot common errors

ContosoUniversity.dll used by another process

Error message:

> Cannot open '...bin\Debug\netcoreapp1.0\ContosoUniversity.dll' for writing -- 'The process cannot access the file '...\bin\Debug\netcoreapp1.0\ContosoUniversity.dll' because it is being used by another process.

Solution:

Stop the site in IIS Express. Go to the Windows System Tray, find IIS Express and right-click its icon, select the Contoso University site, and then click **Stop Site**.

Migration scaffolded with no code in Up and Down methods

Possible cause:

The EF CLI commands don't automatically close and save code files. If you have unsaved changes when you run the `migrations add` command, EF won't find your changes.

Solution:

Run the `migrations remove` command, save your code changes and rerun the `migrations add` command.

Errors while running database update

It's possible to get other errors when making schema changes in a database that has existing data. If you get migration errors you can't resolve, you can either change the database name in the connection string or delete the database. With a new database, there's no data to migrate, and the update-database command is much more likely to complete without errors.

The simplest approach is to rename the database in *appsettings.json*. The next time you run `database update`, a new database will be created.

To delete a database in SSOX, right-click the database, click **Delete**, and then in the **Delete Database** dialog box select **Close existing connections** and click **OK**.

To delete a database by using the CLI, run the `database drop` CLI command:

```
dotnet ef database drop
```

Error locating SQL Server instance

Error Message:

> A network-related or instance-specific error occurred while establishing a connection to SQL Server. The server was not found or was not accessible. Verify that the instance name is correct and that SQL Server is configured to allow remote connections. (provider: SQL Network Interfaces, error: 26 - Error Locating Server/Instance Specified)

Solution:

Check the connection string. If you have manually deleted the database file, change the name of the database in the construction string to start over with a new database.

Get the code

Download or view the completed application.

Additional resources

For more information about EF Core, see the Entity Framework Core documentation. A book is also available: Entity Framework Core in Action.

For information on how to deploy a web app, see Host and deploy ASP.NET Core.

For information about other topics related to ASP.NET Core MVC, such as authentication and authorization, see Introduction to ASP.NET Core.

Next steps

In this tutorial, you:

- Performed raw SQL queries
- Called a query to return entities
- Called a query to return other types
- Called an update query
- Examined SQL queries
- Created an abstraction layer
- Learned about Automatic change detection
- Learned about EF Core source code and development plans
- Learned how to use dynamic LINQ to simplify code

This completes this series of tutorials on using the Entity Framework Core in an ASP.NET Core MVC application. This series worked with a new database; an alternative is to reverse engineer a model from an existing database.

Tutorial: EF Core with MVC, existing database

ASP.NET Core and Entity Framework 6

9/22/2020 • 3 minutes to read • Edit Online

By Patrick Goode

Using Entity Framework 6 with ASP.NET Core

Entity Framework Core should be used for new development. The download sample uses Entity Framework 6 (EF6), which can be used to migrate exiting apps to ASP.NET Core.

Additional resources

- Entity Framework - Code-Based Configuration

By Paweł Grudzień, Damien Pontifex, and Tom Dykstra

This article shows how to use Entity Framework 6 in an ASP.NET Core application.

Overview

To use Entity Framework 6, your project has to compile against .NET Framework, as Entity Framework 6 doesn't support .NET Core. If you need cross-platform features you will need to upgrade to Entity Framework Core.

The recommended way to use Entity Framework 6 in an ASP.NET Core application is to put the EF6 context and model classes in a class library project that targets .NET Framework. Add a reference to the class library from the ASP.NET Core project. See the sample Visual Studio solution with EF6 and ASP.NET Core projects.

You can't put an EF6 context in an ASP.NET Core project because .NET Core projects don't support all of the functionality that EF6 commands such as *Enable-Migrations* require.

Regardless of project type in which you locate your EF6 context, only EF6 command-line tools work with an EF6 context. For example, `Scaffold-DbContext` is only available in Entity Framework Core. If you need to do reverse engineering of a database into an EF6 model, see /ef/ef6/modeling/code-first/workflows/existing-database.

Reference full framework and EF6 in the ASP.NET Core project

Your ASP.NET Core project needs to target .NET Framework and reference EF6. For example, the *.csproj* file of your ASP.NET Core project will look similar to the following example (only relevant parts of the file are shown).

```
<PropertyGroup>
  <TargetFramework>net452</TargetFramework>
  <PreserveCompilationContext>true</PreserveCompilationContext>
  <AssemblyName>MVCCore</AssemblyName>
  <OutputType>Exe</OutputType>
  <PackageId>MVCCore</PackageId>
</PropertyGroup>
```

When creating a new project, use the **ASP.NET Core Web Application (.NET Framework)** template.

Handle connection strings

The EF6 command-line tools that you'll use in the EF6 class library project require a default constructor so they can instantiate the context. But you'll probably want to specify the connection string to use in the ASP.NET Core project,

in which case your context constructor must have a parameter that lets you pass in the connection string. Here's an example.

```
public class SchoolContext : DbContext
{
    public SchoolContext(string connString) : base(connString)
    {
    }
```

Since your EF6 context doesn't have a parameterless constructor, your EF6 project has to provide an implementation of /dotnet/api/system.data.entity.infrastructure.idbcontextfactory-1?view=entity-framework-6.2.0. The EF6 command-line tools will find and use that implementation so they can instantiate the context. Here's an example.

```
public class SchoolContextFactory : IDbContextFactory<SchoolContext>
{
    public SchoolContext Create()
    {
        return new EF6.SchoolContext("Server=
(localdb)\\mssqllocaldb;Database=EF6MVCCore;Trusted_Connection=True;MultipleActiveResultSets=true");
    }
}
```

In this sample code, the `IDbContextFactory` implementation passes in a hard-coded connection string. This is the connection string that the command-line tools will use. You'll want to implement a strategy to ensure that the class library uses the same connection string that the calling application uses. For example, you could get the value from an environment variable in both projects.

Set up dependency injection in the ASP.NET Core project

In the Core project's *Startup.cs* file, set up the EF6 context for dependency injection (DI) in `ConfigureServices`. EF context objects should be scoped for a per-request lifetime.

```
public void ConfigureServices(IServiceCollection services)
{
    // Add framework services.
    services.AddMvc();
    services.AddScoped<SchoolContext>(_ => new
SchoolContext(Configuration.GetConnectionString("DefaultConnection")));
}
```

You can then get an instance of the context in your controllers by using DI. The code is similar to what you'd write for an EF Core context:

```
public class StudentsController : Controller
{
    private readonly SchoolContext _context;

    public StudentsController(SchoolContext context)
    {
        _context = context;
    }
```

Sample application

For a working sample application, see the sample Visual Studio solution that accompanies this article.

This sample can be created from scratch by the following steps in Visual Studio:

- Create a solution.
- **Add** > **New Project** > **Web** > **ASP.NET Core Web Application**
  - In project template selection dialog, select API and .NET Framework in dropdown
- **Add** > **New Project** > **Windows Desktop** > **Class Library (.NET Framework)**
- In **Package Manager Console** (PMC) for both projects, run the command `Install-Package Entityframework`.
- In the class library project, create data model classes and a context class, and an implementation of `IDbContextFactory`.
- In PMC for the class library project, run the commands `Enable-Migrations` and `Add-Migration Initial`. If you have set the ASP.NET Core project as the startup project, add `-StartupProjectName EF6` to these commands.
- In the Core project, add a project reference to the class library project.
- In the Core project, in *Startup.cs*, register the context for DI.
- In the Core project, in *appsettings.json*, add the connection string.
- In the Core project, add a controller and view(s) to verify that you can read and write data. (Note that ASP.NET Core MVC scaffolding won't work with the EF6 context referenced from the class library.)

Host and deploy ASP.NET Core

9/22/2020 • 7 minutes to read • Edit Online

In general, to deploy an ASP.NET Core app to a hosting environment:

- Deploy the published app to a folder on the hosting server.
- Set up a process manager that starts the app when requests arrive and restarts the app after it crashes or the server reboots.
- For configuration of a reverse proxy, set up a reverse proxy to forward requests to the app.

Publish to a folder

The dotnet publish command compiles app code and copies the files required to run the app into a *publish* folder. When deploying from Visual Studio, the `dotnet publish` step occurs automatically before the files are copied to the deployment destination.

Folder contents

The *publish* folder contains one or more app assembly files, dependencies, and optionally the .NET runtime.

A .NET Core app can be published as *self-contained deployment* or *framework-dependent deployment*. If the app is self-contained, the assembly files that contain the .NET runtime are included in the *publish* folder. If the app is framework-dependent, the .NET runtime files aren't included because the app has a reference to a version of .NET that's installed on the server. The default deployment model is framework-dependent. For more information, see .NET Core application deployment.

In addition to *.exe* and *.dll* files, the *publish* folder for an ASP.NET Core app typically contains configuration files, static assets, and MVC views. For more information, see ASP.NET Core directory structure.

Set up a process manager

An ASP.NET Core app is a console app that must be started when a server boots and restarted if it crashes. To automate starts and restarts, a process manager is required. The most common process managers for ASP.NET Core are:

- Linux
  - Nginx
  - Apache
- Windows
  - IIS
  - Windows Service

Set up a reverse proxy

If the app uses the Kestrel server, Nginx, Apache, or IIS can be used as a reverse proxy server. A reverse proxy server receives HTTP requests from the Internet and forwards them to Kestrel.

Either configuration—with or without a reverse proxy server—is a supported hosting configuration. For more information, see When to use Kestrel with a reverse proxy.

Proxy server and load balancer scenarios

Additional configuration might be required for apps hosted behind proxy servers and load balancers. Without additional configuration, an app might not have access to the scheme (HTTP/HTTPS) and the remote IP address where a request originated. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Use Visual Studio and MSBuild to automate deployments

Deployment often requires additional tasks besides copying the output from dotnet publish to a server. For example, extra files might be required or excluded from the *publish* folder. Visual Studio uses MSBuild for web deployment, and MSBuild can be customized to do many other tasks during deployment. For more information, see Visual Studio publish profiles (.pubxml) for ASP.NET Core app deployment and the Using MSBuild and Team Foundation Build book.

By using the Publish Web feature or built-in Git support, apps can be deployed directly from Visual Studio to the Azure App Service. Azure DevOps Services supports continuous deployment to Azure App Service. For more information, see DevOps with ASP.NET Core and Azure.

Publish to Azure

See Publish an ASP.NET Core app to Azure with Visual Studio for instructions on how to publish an app to Azure using Visual Studio. An additional example is provided by Create an ASP.NET Core web app in Azure.

Publish with MSDeploy on Windows

See Visual Studio publish profiles (.pubxml) for ASP.NET Core app deployment for instructions on how to publish an app with a Visual Studio publish profile, including from a Windows command prompt using the dotnet msbuild command.

Internet Information Services (IIS)

For deployments to Internet Information Services (IIS) with configuration provided by the *web.config* file, see the articles under Host ASP.NET Core on Windows with IIS.

Host in a web farm

For information on configuration for hosting ASP.NET Core apps in a web farm environment (for example, deployment of multiple instances of your app for scalability), see Host ASP.NET Core in a web farm.

Host on Docker

For more information, see Host ASP.NET Core in Docker containers.

Perform health checks

Use Health Check Middleware to perform health checks on an app and its dependencies. For more information, see Health checks in ASP.NET Core.

Additional resources

- Troubleshoot and debug ASP.NET Core projects
- ASP.NET Hosting

In general, to deploy an ASP.NET Core app to a hosting environment:

- Deploy the published app to a folder on the hosting server.

- Set up a process manager that starts the app when requests arrive and restarts the app after it crashes or the server reboots.
- For configuration of a reverse proxy, set up a reverse proxy to forward requests to the app.

Publish to a folder

The dotnet publish command compiles app code and copies the files required to run the app into a *publish* folder. When deploying from Visual Studio, the `dotnet publish` step occurs automatically before the files are copied to the deployment destination.

Folder contents

The *publish* folder contains one or more app assembly files, dependencies, and optionally the .NET runtime.

A .NET Core app can be published as *self-contained deployment* or *framework-dependent deployment*. If the app is self-contained, the assembly files that contain the .NET runtime are included in the *publish* folder. If the app is framework-dependent, the .NET runtime files aren't included because the app has a reference to a version of .NET that's installed on the server. The default deployment model is framework-dependent. For more information, see .NET Core application deployment.

In addition to *.exe* and *.dll* files, the *publish* folder for an ASP.NET Core app typically contains configuration files, static assets, and MVC views. For more information, see ASP.NET Core directory structure.

Set up a process manager

An ASP.NET Core app is a console app that must be started when a server boots and restarted if it crashes. To automate starts and restarts, a process manager is required. The most common process managers for ASP.NET Core are:

- Linux
  - Nginx
  - Apache
- Windows
  - IIS
  - Windows Service

Set up a reverse proxy

If the app uses the Kestrel server, Nginx, Apache, or IIS can be used as a reverse proxy server. A reverse proxy server receives HTTP requests from the Internet and forwards them to Kestrel.

Either configuration—with or without a reverse proxy server—is a supported hosting configuration. For more information, see When to use Kestrel with a reverse proxy.

Proxy server and load balancer scenarios

Additional configuration might be required for apps hosted behind proxy servers and load balancers. Without additional configuration, an app might not have access to the scheme (HTTP/HTTPS) and the remote IP address where a request originated. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Use Visual Studio and MSBuild to automate deployments

Deployment often requires additional tasks besides copying the output from dotnet publish to a server. For example, extra files might be required or excluded from the *publish* folder. Visual Studio uses MSBuild for web

deployment, and MSBuild can be customized to do many other tasks during deployment. For more information, see Visual Studio publish profiles (.pubxml) for ASP.NET Core app deployment and the Using MSBuild and Team Foundation Build book.

By using the Publish Web feature or built-in Git support, apps can be deployed directly from Visual Studio to the Azure App Service. Azure DevOps Services supports continuous deployment to Azure App Service. For more information, see DevOps with ASP.NET Core and Azure.

Publish to Azure

See Publish an ASP.NET Core app to Azure with Visual Studio for instructions on how to publish an app to Azure using Visual Studio. An additional example is provided by Create an ASP.NET Core web app in Azure.

Publish with MSDeploy on Windows

See Visual Studio publish profiles (.pubxml) for ASP.NET Core app deployment for instructions on how to publish an app with a Visual Studio publish profile, including from a Windows command prompt using the dotnet msbuild command.

Internet Information Services (IIS)

For deployments to Internet Information Services (IIS) with configuration provided by the *web.config* file, see the articles under Host ASP.NET Core on Windows with IIS.

Host in a web farm

For information on configuration for hosting ASP.NET Core apps in a web farm environment (for example, deployment of multiple instances of your app for scalability), see Host ASP.NET Core in a web farm.

Host on Docker

For more information, see Host ASP.NET Core in Docker containers.

Deploy ASP.NET Core apps to Azure App Service

9/22/2020 • 13 minutes to read • Edit Online

Azure App Service is a Microsoft cloud computing platform service for hosting web apps, including ASP.NET Core.

Useful resources

App Service Documentation is the home for Azure Apps documentation, tutorials, samples, how-to guides, and other resources. Two notable tutorials that pertain to hosting ASP.NET Core apps are:

Create an ASP.NET Core web app in Azure
Use Visual Studio to create and deploy an ASP.NET Core web app to Azure App Service on Windows.

Create an ASP.NET Core app in App Service on Linux
Use the command line to create and deploy an ASP.NET Core web app to Azure App Service on Linux.

See the ASP.NET Core on App Service Dashboard for the version of ASP.NET Core available on Azure App service.

Subscribe to the App Service Announcements repository and monitor the issues. The App Service team regularly posts announcements and scenarios arriving in App Service.

The following articles are available in ASP.NET Core documentation:

Publish an ASP.NET Core app to Azure with Visual Studio
Learn how to publish an ASP.NET Core app to Azure App Service using Visual Studio.

Continuous deployment to Azure with Visual Studio and Git with ASP.NET Core
Learn how to create an ASP.NET Core web app using Visual Studio and deploy it to Azure App Service using Git for continuous deployment.

Create your first pipeline
Set up a CI build for an ASP.NET Core app, then create a continuous deployment release to Azure App Service.

Azure Web App sandbox
Discover Azure App Service runtime execution limitations enforced by the Azure Apps platform.

Troubleshoot and debug ASP.NET Core projects
Understand and troubleshoot warnings and errors with ASP.NET Core projects.

Application configuration

Platform

The platform architecture (x86/x64) of an App Services app is set in the app's settings in the Azure Portal for apps that are hosted on an A-series compute (Basic) or higher hosting tier. Confirm that the app's publish settings (for example, in the Visual Studio publish profile (.pubxml)) match the setting in the app's service configuration in the Azure Portal.

Runtimes for 64-bit (x64) and 32-bit (x86) apps are present on Azure App Service. The .NET Core SDK available on App Service is 32-bit, but you can deploy 64-bit apps built locally using the Kudu console or the publish process in Visual Studio. For more information, see the Publish and deploy the app section.

For apps with native dependencies, runtimes for 32-bit (x86) apps are present on Azure App Service. The .NET Core SDK available on App Service is 32-bit.

For more information on .NET Core framework components and distribution methods, such as information on the .NET Core runtime and the .NET Core SDK, see About .NET Core: Composition.

Packages

Include the following NuGet packages to provide automatic logging features for apps deployed to Azure App Service:

- Microsoft.AspNetCore.AzureAppServices.HostingStartup uses IHostingStartup to provide ASP.NET Core light-up integration with Azure App Service. The added logging features are provided by the `Microsoft.AspNetCore.AzureAppServicesIntegration` package.
- Microsoft.AspNetCore.AzureAppServicesIntegration executes AddAzureWebAppDiagnostics to add Azure App Service diagnostics logging providers in the `Microsoft.Extensions.Logging.AzureAppServices` package.
- Microsoft.Extensions.Logging.AzureAppServices provides logger implementations to support Azure App Service diagnostics logs and log streaming features.

The preceding packages aren't available from the Microsoft.AspNetCore.App metapackage. Apps that target .NET Framework or reference the `Microsoft.AspNetCore.App` metapackage must explicitly reference the individual packages in the app's project file.

Override app configuration using the Azure Portal

App settings in the Azure Portal permit you to set environment variables for the app. Environment variables can be consumed by the Environment Variables Configuration Provider.

When an app setting is created or modified in the Azure Portal and the **Save** button is selected, the Azure App is restarted. The environment variable is available to the app after the service restarts.

When an app uses the Generic Host, environment variables are loaded into the app's configuration when CreateDefaultBuilder is called to build the host. For more information, see .NET Generic Host and the Environment Variables Configuration Provider.

App settings in the Azure Portal permit you to set environment variables for the app. Environment variables can be consumed by the Environment Variables Configuration Provider.

When an app setting is created or modified in the Azure Portal and the **Save** button is selected, the Azure App is restarted. The environment variable is available to the app after the service restarts.

When an app uses the Web Host, environment variables are loaded into the app's configuration when CreateDefaultBuilder is called to build the host. For more information, see ASP.NET Core Web Host and the Environment Variables Configuration Provider.

Proxy server and load balancer scenarios

The IIS Integration Middleware, which configures Forwarded Headers Middleware when hosting out-of-process, and the ASP.NET Core Module are configured to forward the scheme (HTTP/HTTPS) and the remote IP address where the request originated. Additional configuration might be required for apps hosted behind additional proxy servers and load balancers. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Monitoring and logging

ASP.NET Core apps deployed to App Service automatically receive an App Service extension, **ASP.NET Core Logging Integration**. The extension enables logging integration for ASP.NET Core apps on Azure App Service.

ASP.NET Core apps deployed to App Service automatically receive an App Service extension, **ASP.NET Core Logging Extensions**. The extension enables logging integration for ASP.NET Core apps on Azure App Service.

For monitoring, logging, and troubleshooting information, see the following articles:

Monitor apps in Azure App Service
Learn how to review quotas and metrics for apps and App Service plans.

Enable diagnostics logging for apps in Azure App Service
Discover how to enable and access diagnostic logging for HTTP status codes, failed requests, and web server activity.

Handle errors in ASP.NET Core
Understand common approaches to handling errors in ASP.NET Core apps.

Troubleshoot ASP.NET Core on Azure App Service and IIS
Learn how to diagnose issues with Azure App Service deployments with ASP.NET Core apps.

Common errors reference for Azure App Service and IIS with ASP.NET Core
See the common deployment configuration errors for apps hosted by Azure App Service/IIS with troubleshooting advice.

Data Protection key ring and deployment slots

Data Protection keys are persisted to the *%HOME%\ASP.NET\DataProtection-Keys* folder. This folder is backed by network storage and is synchronized across all machines hosting the app. Keys aren't protected at rest. This folder supplies the key ring to all instances of an app in a single deployment slot. Separate deployment slots, such as Staging and Production, don't share a key ring.

When swapping between deployment slots, any system using data protection won't be able to decrypt stored data using the key ring inside the previous slot. ASP.NET Cookie Middleware uses data protection to protect its cookies. This leads to users being signed out of an app that uses the standard ASP.NET Cookie Middleware. For a slot-independent key ring solution, use an external key ring provider, such as:

- Azure Blob Storage
- Azure Key Vault
- SQL store
- Redis cache

For more information, see Key storage providers in ASP.NET Core.

Deploy an ASP.NET Core app that uses a .NET Core preview

To deploy an app that uses a preview release of .NET Core, see the following resources. These approaches are also used when the runtime is available but the SDK hasn't been installed on Azure App Service.

- Specify the .NET Core SDK Version using Azure Pipelines
- Deploy a self-contained preview app
- Use Docker with Web Apps for containers
- Install the preview site extension

See the ASP.NET Core on App Service Dashboard for the version of ASP.NET Core available on Azure App service.

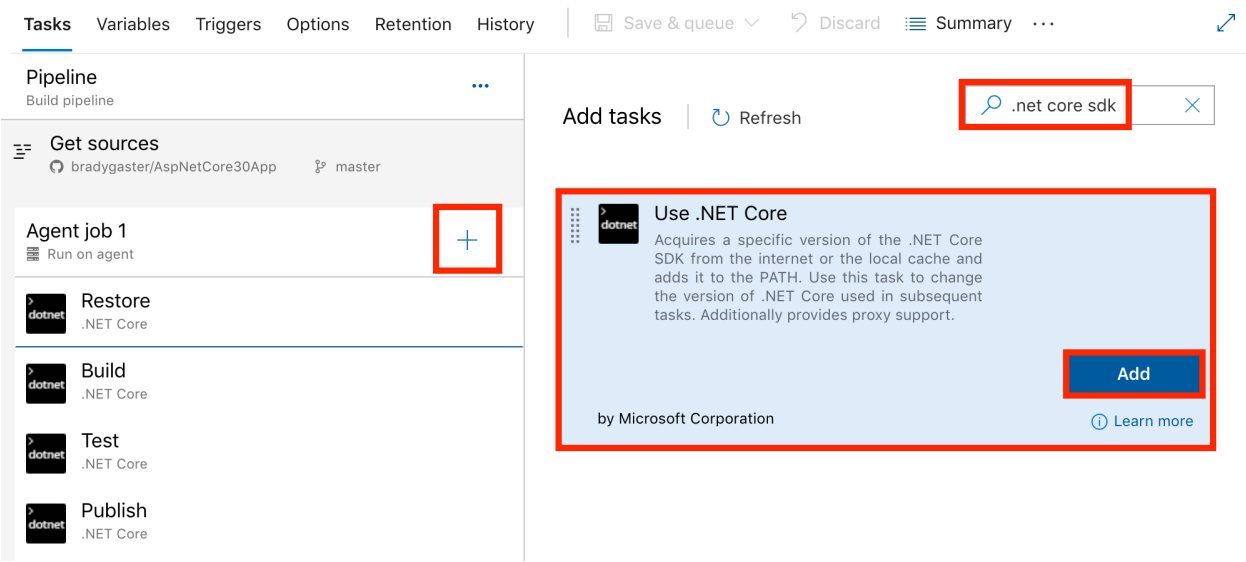
Specify the .NET Core SDK Version using Azure Pipelines

Use Azure App Service CI/CD scenarios to set up a continuous integration build with Azure DevOps. After the Azure DevOps build is created, optionally configure the build to use a specific SDK version.

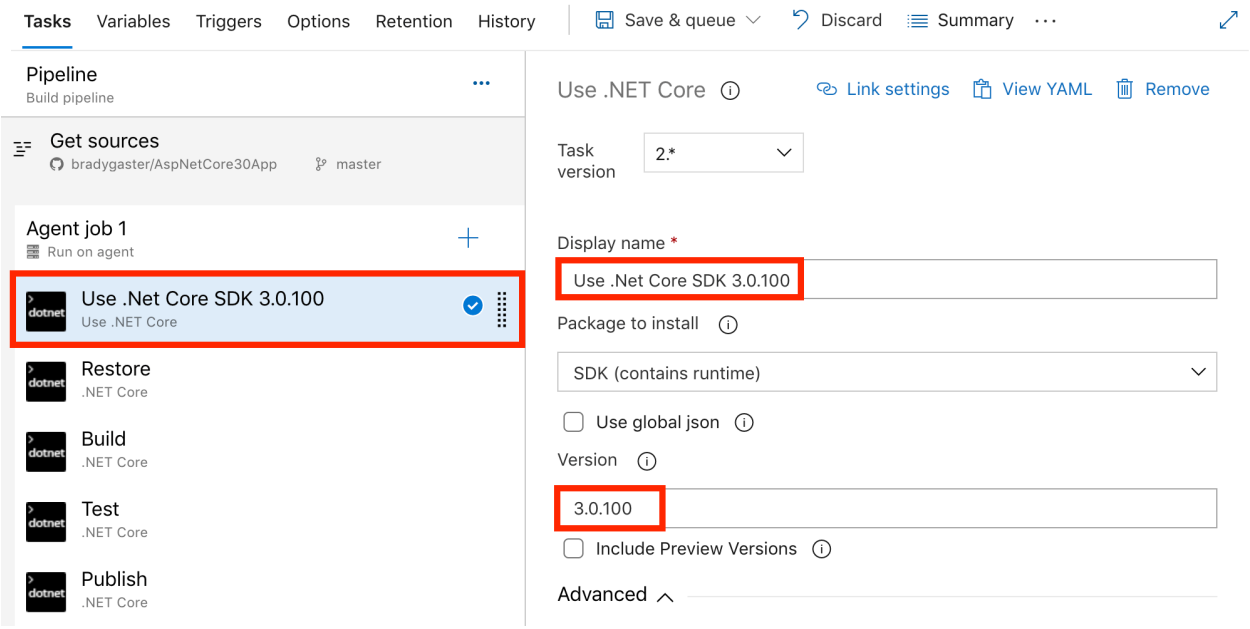
Specify the .NET Core SDK version

When using the App Service deployment center to create an Azure DevOps build, the default build pipeline includes steps for `Restore`, `Build`, `Test`, and `Publish`. To specify the SDK version, select the **Add (+)** button in

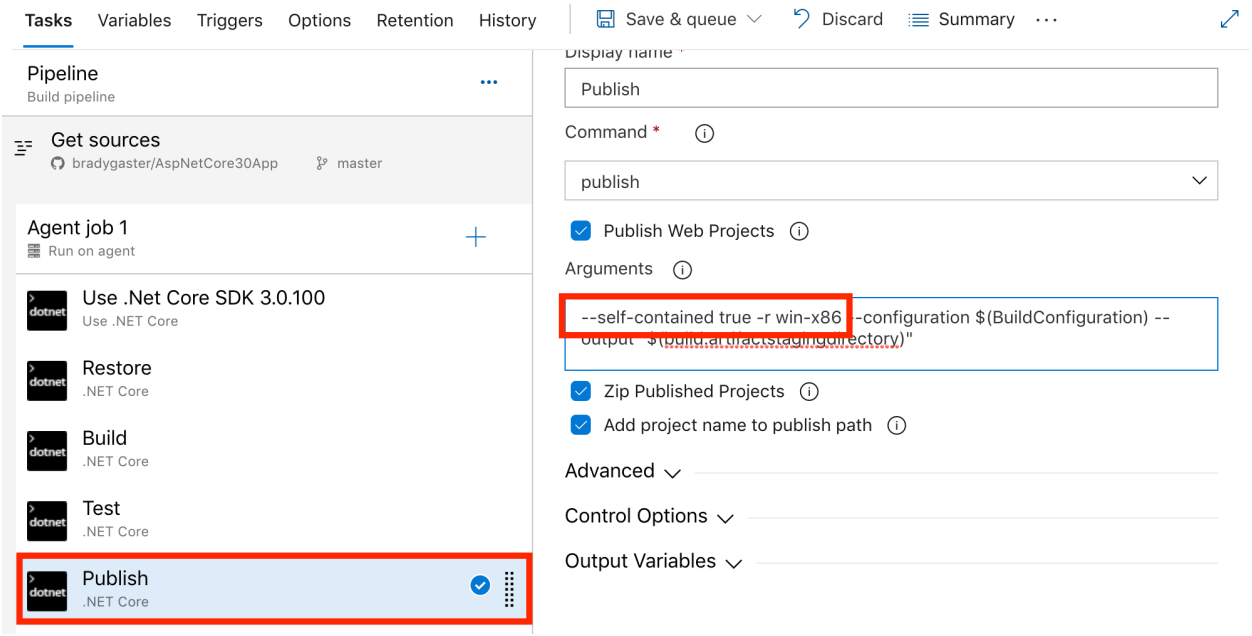
the Agent job list to add a new step. Search for **.NET Core SDK** in the search bar.



Move the step into the first position in the build so that the steps following it use the specified version of the .NET Core SDK. Specify the version of the .NET Core SDK. In this example, the SDK is set to `3.0.100`.



To publish a self-contained deployment (SCD), configure SCD in the `Publish` step and provide the Runtime Identifier (RID).



Deploy a self-contained preview app

A self-contained deployment (SCD) that targets a preview runtime carries the preview runtime in the deployment.

When deploying a self-contained app:

- The site in Azure App Service doesn't require the preview site extension.
- The app must be published following a different approach than when publishing for a framework-dependent deployment (FDD).

Follow the guidance in the Deploy the app self-contained section.

Use Docker with Web Apps for containers

The Docker Hub contains the latest preview Docker images. The images can be used as a base image. Use the image and deploy to Web Apps for Containers normally.

Install the preview site extension

If a problem occurs using the preview site extension, open an dotnet/AspNetCore issue.

1. From the Azure Portal, navigate to the App Service.
2. Select the web app.
3. Type "ex" in the search box to filter for "Extensions" or scroll down the list of management tools.
4. Select **Extensions**.
5. Select **Add**.
6. Select the **ASP.NET Core {X.Y} ({x64|x86}) Runtime** extension from the list, where `{X.Y}` is the ASP.NET Core preview version and `{x64|x86}` specifies the platform.
7. Select **OK** to accept the legal terms.
8. Select **OK** to install the extension.

When the operation completes, the latest .NET Core preview is installed. Verify the installation:

1. Select **Advanced Tools**.
2. Select **Go** in **Advanced Tools**.
3. Select the **Debug console** > **PowerShell** menu item.
4. At the PowerShell prompt, execute the following command. Substitute the ASP.NET Core runtime version for `{X.Y}` and the platform for `{PLATFORM}` in the command:

```
Test-Path D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.{PLATFORM}\
```

The command returns `True` when the x64 preview runtime is installed.

> **NOTE**
>
> The platform architecture (x86/x64) of an App Services app is set in the app's settings in the Azure Portal for apps that are hosted on an A-series compute (Basic) or higher hosting tier. Confirm that the app's publish settings (for example, in the Visual Studio publish profile (.pubxml)) match the setting in the app's service configuration in the Azure portal.
>
> If the app is run in in-process mode and the platform architecture is configured for 64-bit (x64), the ASP.NET Core Module uses the 64-bit preview runtime, if present. Install the **ASP.NET Core {X.Y} (x64) Runtime** extension using the Azure Portal.
>
> After installing the x64 preview runtime, run the following command in the Azure Kudu PowerShell command window to verify the installation. Substitute the ASP.NET Core runtime version for `{X.Y}` in the following command:
>
> ```
> Test-Path D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x64\
> ```
>
> The command returns `True` when the x64 preview runtime is installed.

> **NOTE**
>
> **ASP.NET Core Extensions** enables additional functionality for ASP.NET Core on Azure App Services, such as enabling Azure logging. The extension is installed automatically when deploying from Visual Studio. If the extension isn't installed, install it for the app.

Use the preview site extension with an ARM template

If an ARM template is used to create and deploy apps, the `siteextensions` resource type can be used to add the site extension to a web app. For example:

```
{
    "type": "siteextensions",
    "name": "AspNetCoreRuntime",
    "apiVersion": "2015-04-01",
    "location": "[resourceGroup().location]",
    "properties": {
        "version": "[parameters('aspnetcoreVersion')]"
    },
    "dependsOn": [
        "[resourceId('Microsoft.Web/Sites', parameters('siteName'))]"
    ]
}
```

Publish and deploy the app

For a 64-bit deployment:

- Use a 64-bit .NET Core SDK to build a 64-bit app.
- Set the **Platform** to **64 Bit** in the App Service's **Configuration** > **General settings**. The app must use a Basic or higher service plan to enable the choice of platform bitness.

Deploy the app framework-dependent

- Visual Studio

- .NET Core CLI

1. Select **Build** > **Publish {Application Name}** from the Visual Studio toolbar or right-click the project in **Solution Explorer** and select **Publish**.
2. In the **Pick a publish target** dialog, confirm that **App Service** is selected.
3. Select **Advanced**. The **Publish** dialog opens.
4. In the **Publish** dialog:
   - Confirm that the **Release** configuration is selected.
   - Open the **Deployment Mode** drop-down list and select **Framework-Dependent**.
   - Select **Portable** as the **Target Runtime**.
   - If you need to remove additional files upon deployment, open **File Publish Options** and select the check box to remove additional files at the destination.
   - Select **Save**.
5. Create a new site or update an existing site by following the remaining prompts of the publish wizard.

Deploy the app self-contained

Use Visual Studio or the .NET Core CLI for a self-contained deployment (SCD).

- Visual Studio
- .NET Core CLI

1. Select **Build** > **Publish {Application Name}** from the Visual Studio toolbar or right-click the project in **Solution Explorer** and select **Publish**.
2. In the **Pick a publish target** dialog, confirm that **App Service** is selected.
3. Select **Advanced**. The **Publish** dialog opens.
4. In the **Publish** dialog:
   - Confirm that the **Release** configuration is selected.
   - Open the **Deployment Mode** drop-down list and select **Self-Contained**.
   - Select the target runtime from the **Target Runtime** drop-down list. The default is `win-x86`.
   - If you need to remove additional files upon deployment, open **File Publish Options** and select the check box to remove additional files at the destination.
   - Select **Save**.
5. Create a new site or update an existing site by following the remaining prompts of the publish wizard.

Protocol settings (HTTPS)

Secure protocol bindings allow you specify a certificate to use when responding to requests over HTTPS. Binding requires a valid private certificate (*.pfx*) issued for the specific hostname. For more information, see Tutorial: Bind an existing custom SSL certificate to Azure App Service.

Transform web.config

If you need to transform *web.config* on publish (for example, set environment variables based on the configuration, profile, or environment), see Transform web.config.

- Windows Server - IT administrator content for current and previous releases

Publish an ASP.NET Core app to Azure with Visual Studio

9/22/2020 • 4 minutes to read • Edit Online

By Rick Anderson

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

See Publish a Web app to Azure App Service using Visual Studio for Mac if you are working on macOS.

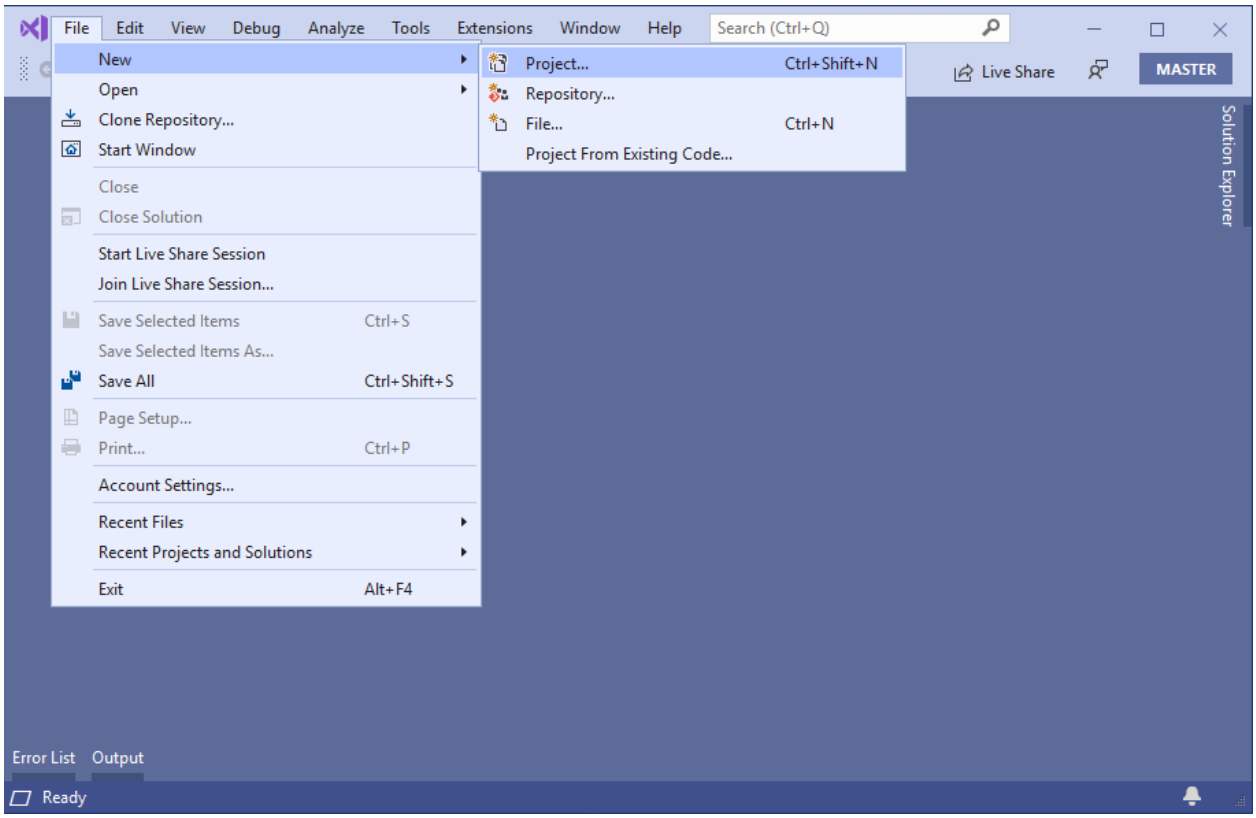
To troubleshoot an App Service deployment issue, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

Set up

- Open a free Azure account if you don't have one.

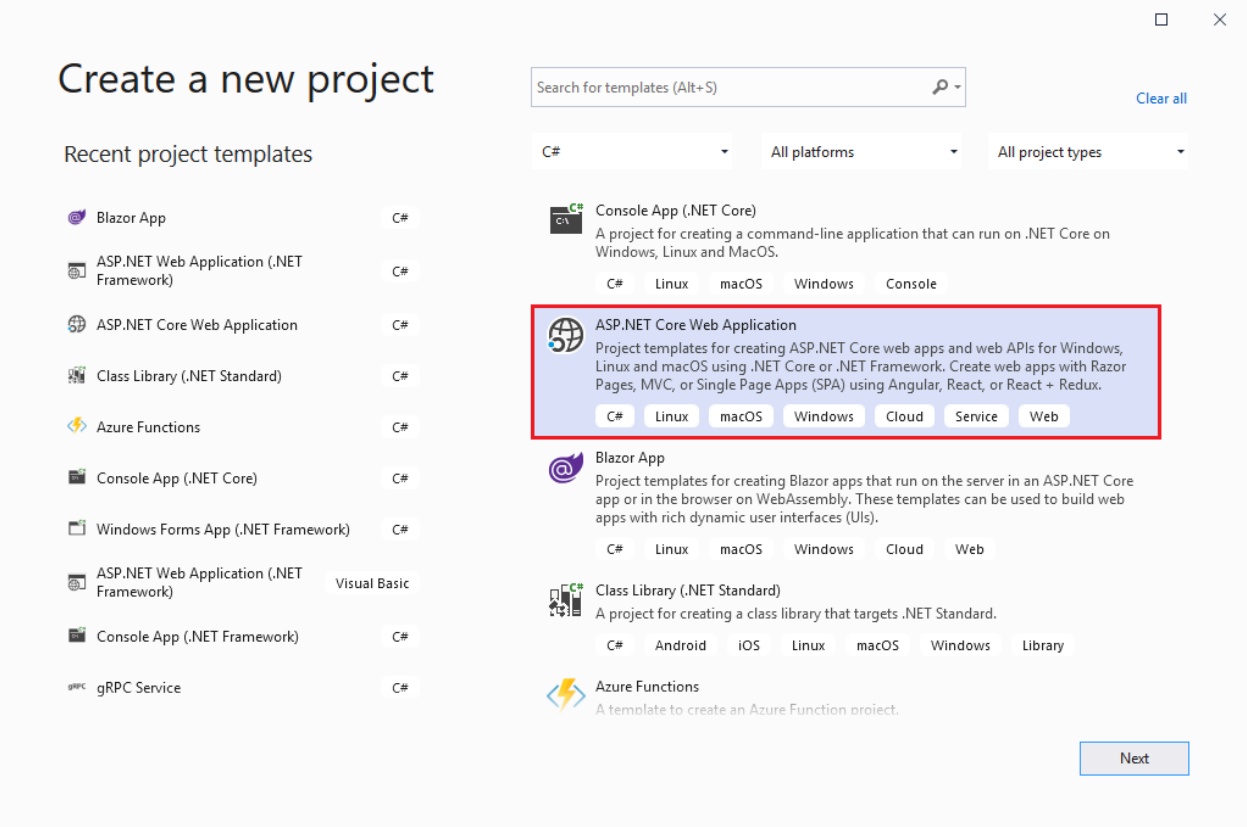
Create a web app

In the Visual Studio Start Page, select **File** > **New** > **Project...**



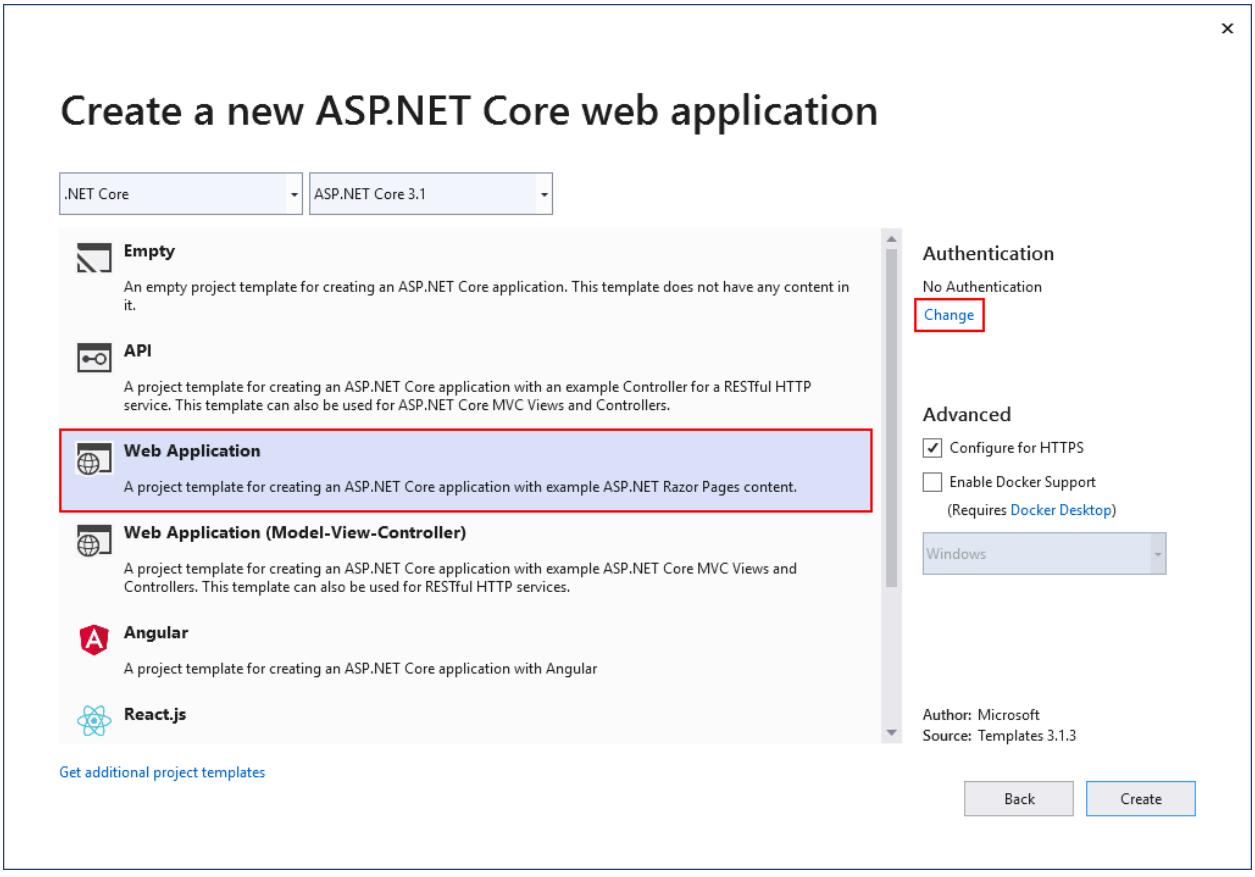
Complete the **New Project** dialog:

- Select **ASP.NET Core Web Application**.
- Select **Next**.



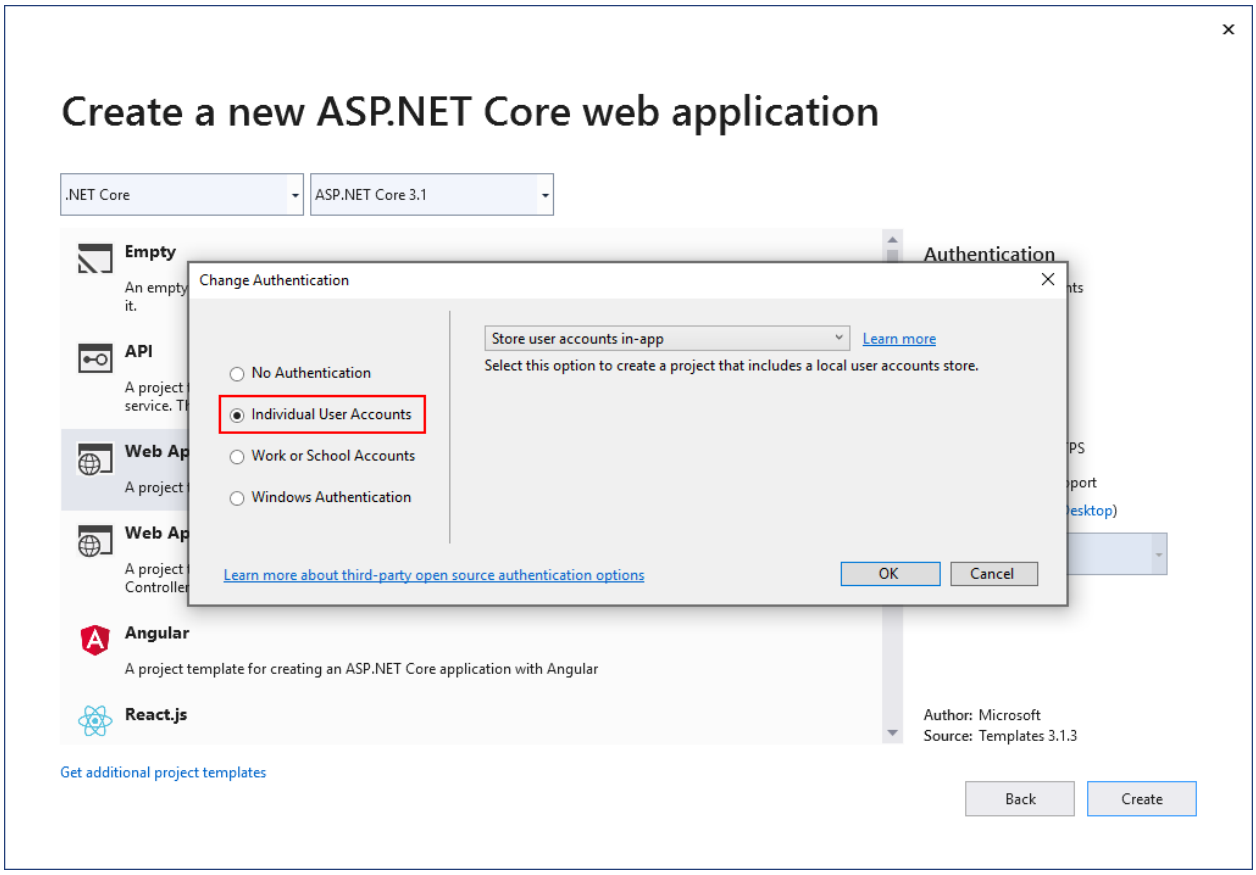
In the **New ASP.NET Core Web Application** dialog:

- Select **Web Application**.
- Select **Change** under Authentication.



The **Change Authentication** dialog appears.

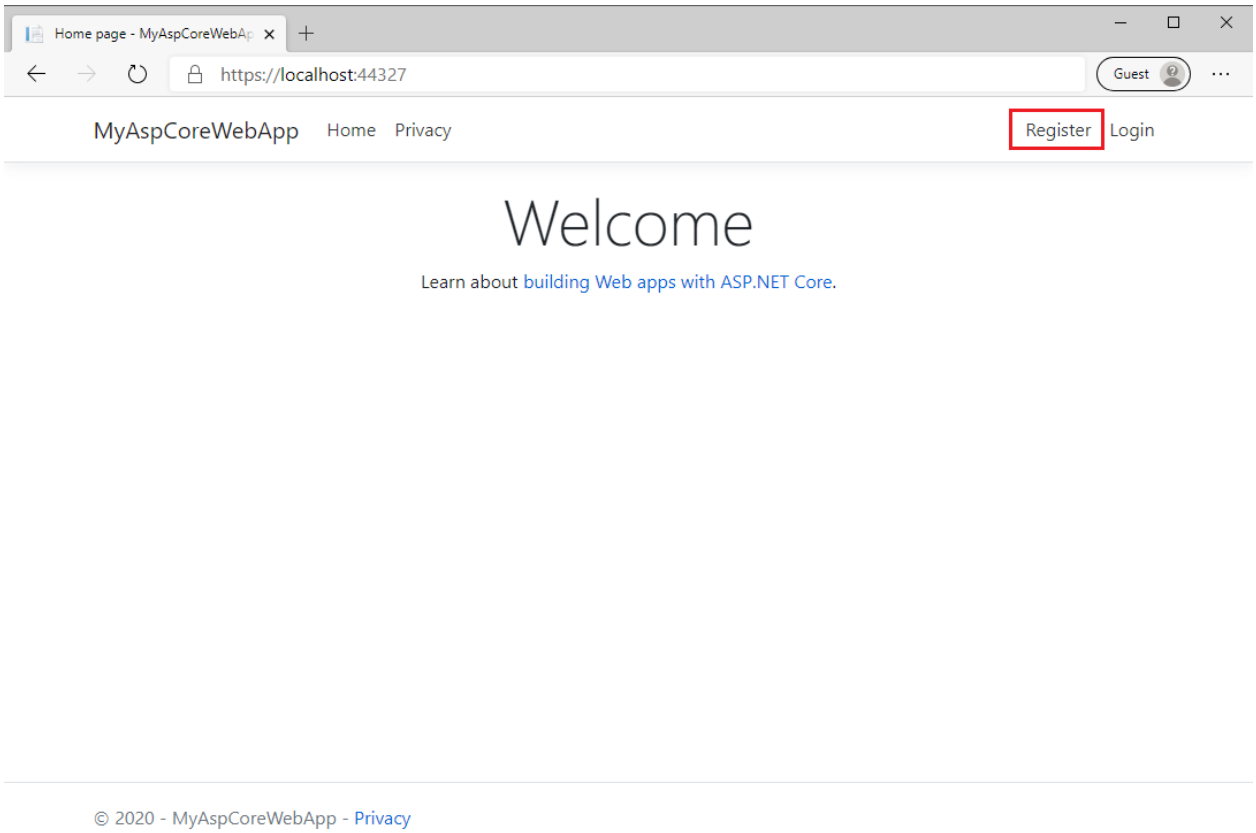
- Select **Individual User Accounts**.
- Select **OK** to return to the **New ASP.NET Core Web Application**, then select **Create**.



Visual Studio creates the solution.

Run the app

- Press CTRL+F5 to run the project.
- Test the **Privacy** link.

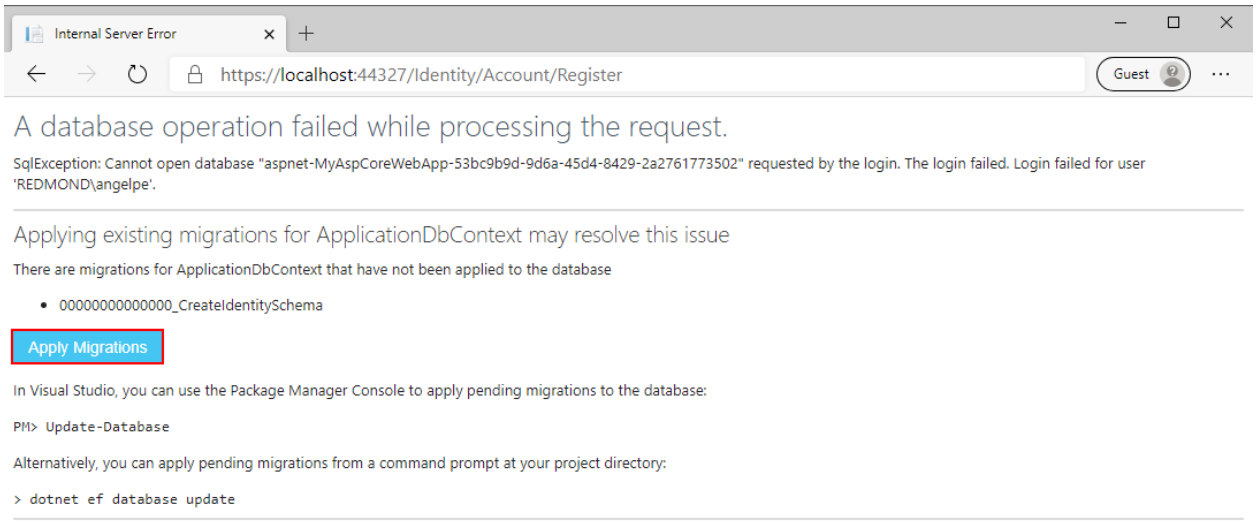


Register a user

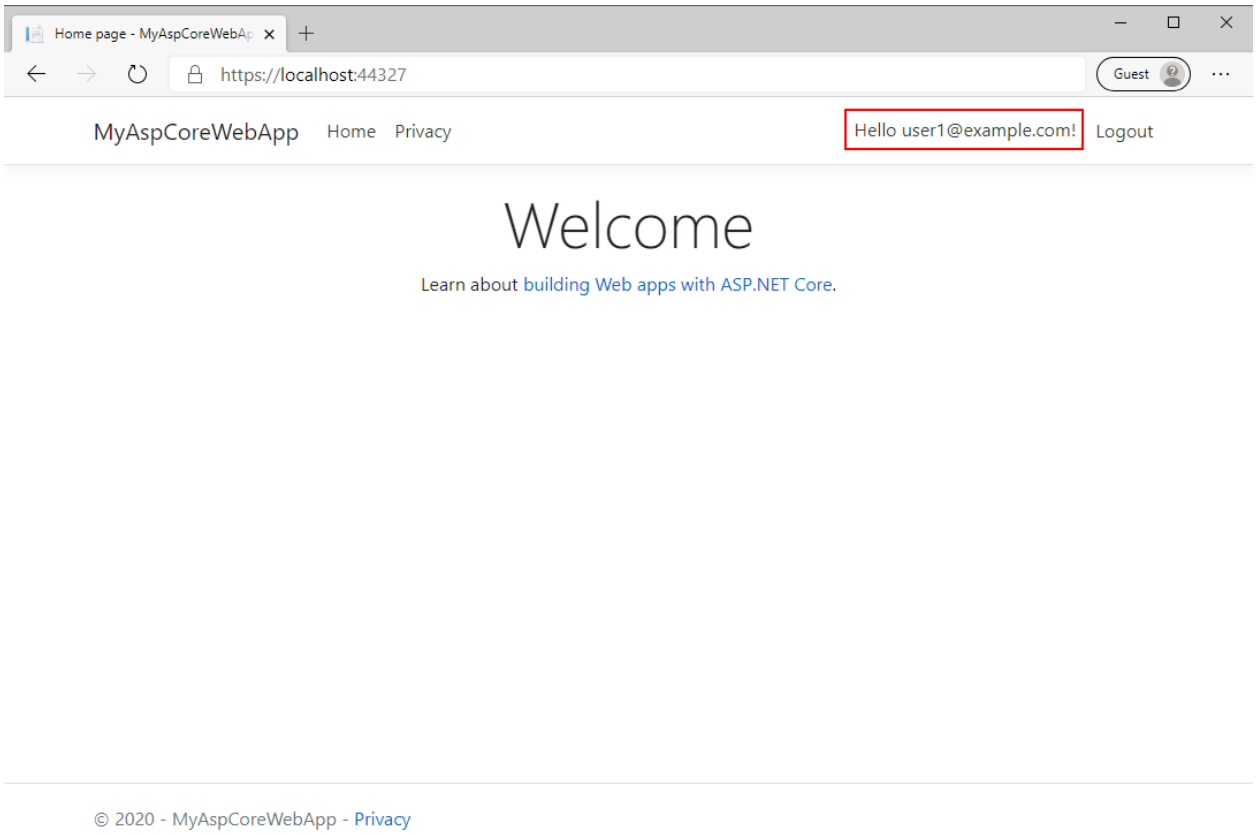
- Select **Register** and register a new user. You can use a fictitious email address. When you submit, the page displays the following error:

  "A database operation failed while processing the request. Applying existing migrations for Application DB context may resolve this issue."

- Select **Apply Migrations** and, once the page updates, refresh the page.

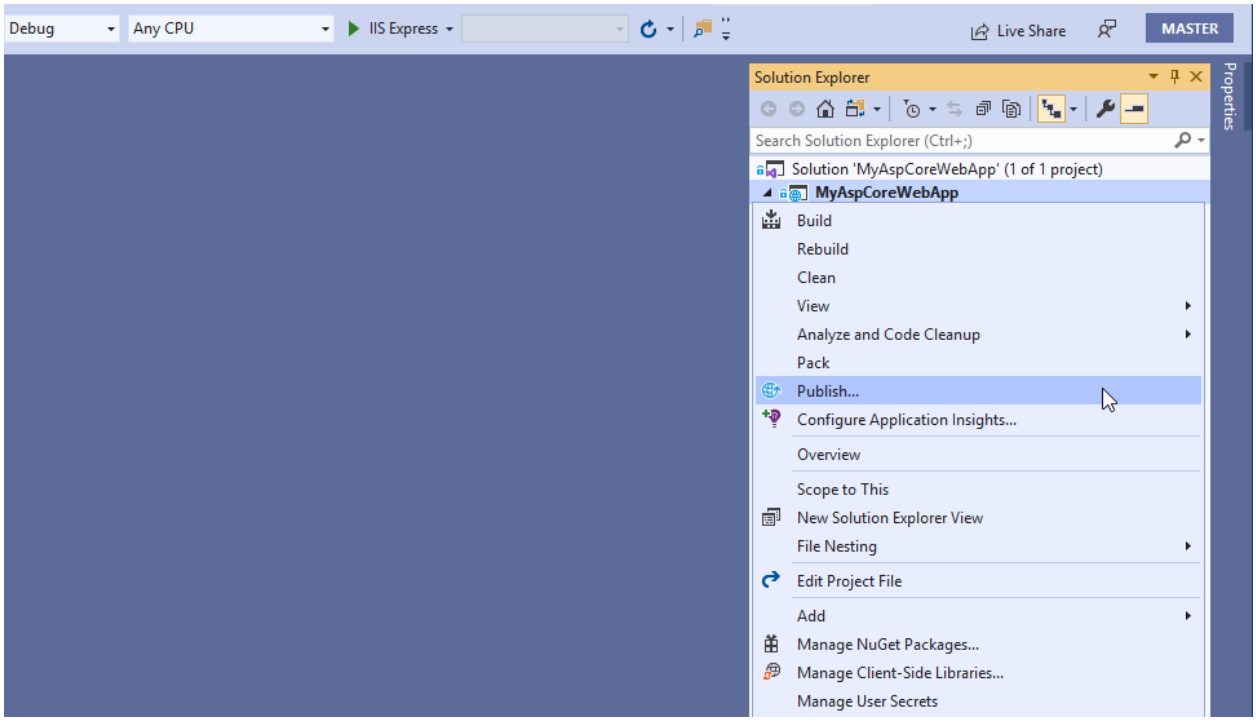


The app displays the email used to register the new user and a **Logout** link.



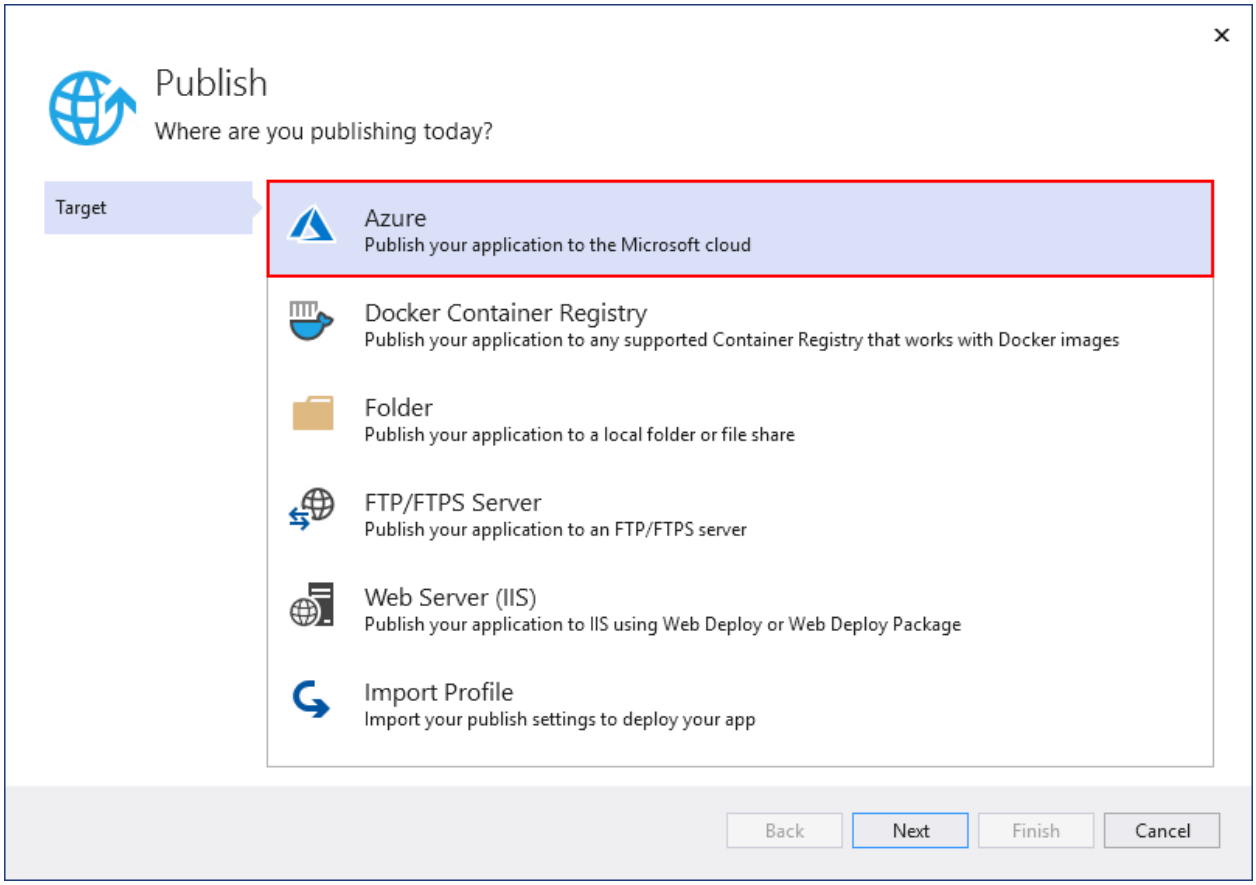
Deploy the app to Azure

Right-click on the project in Solution Explorer and select **Publish...**.



In the **Publish** dialog:

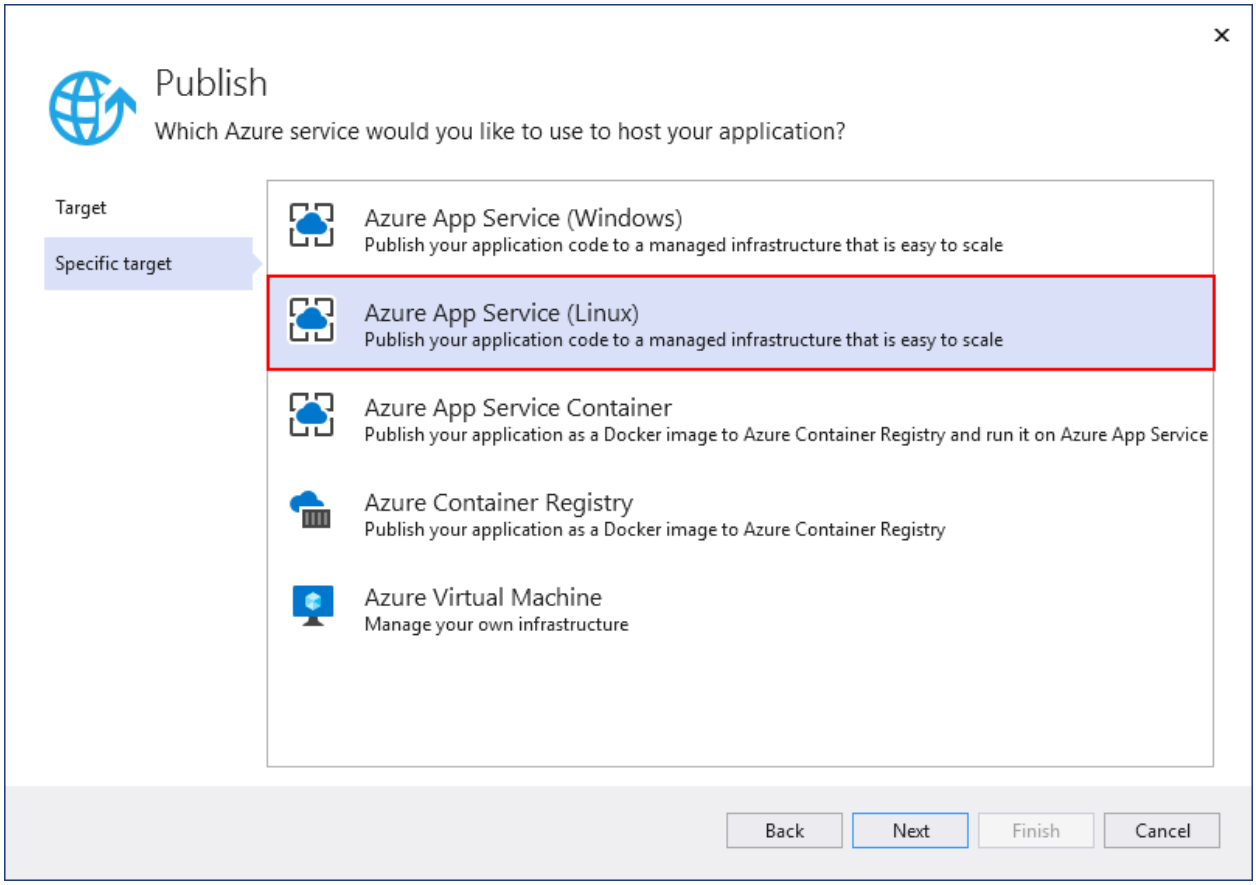
- Select **Azure**.
- Select **Next**.



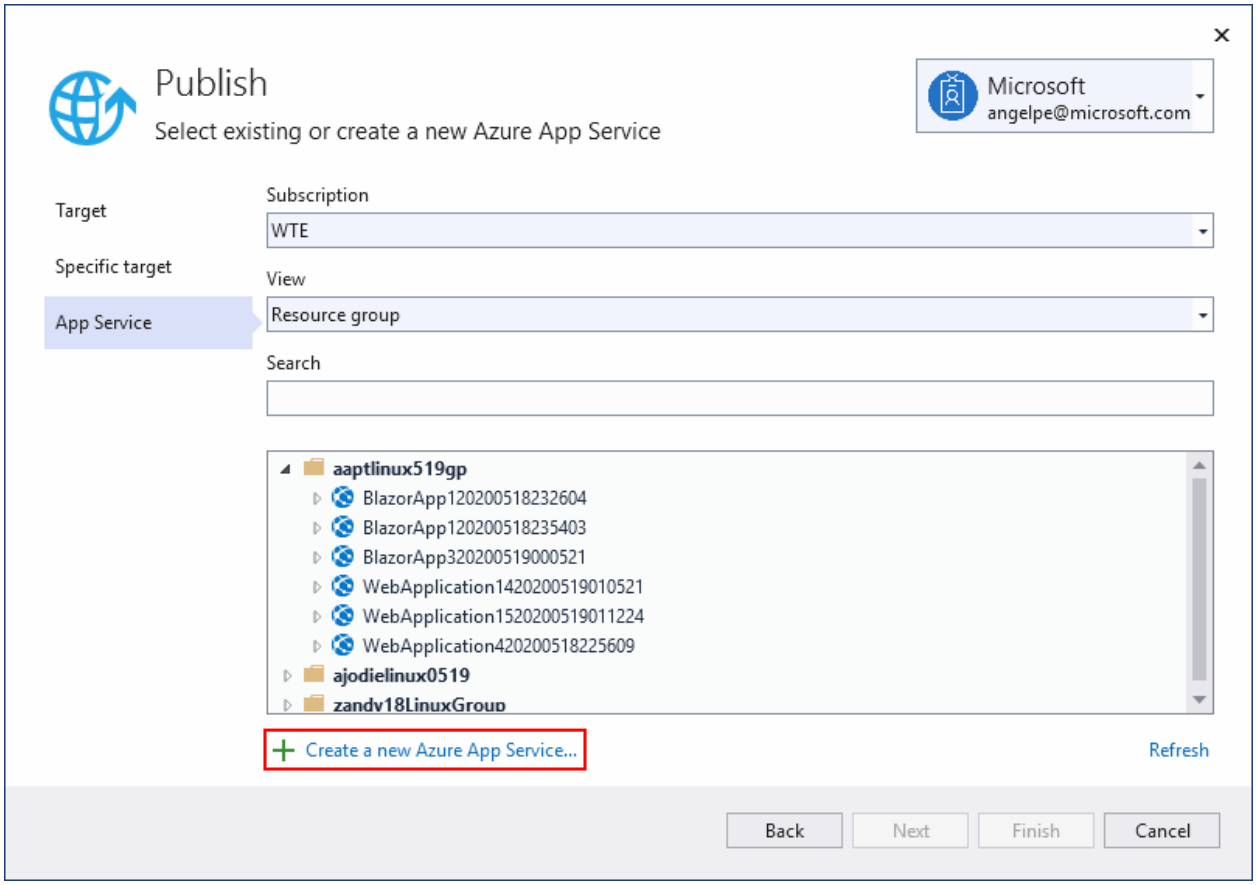
In the **Publish** dialog:

- Select **Azure App Service (Linux)**.

- Select **Next**.



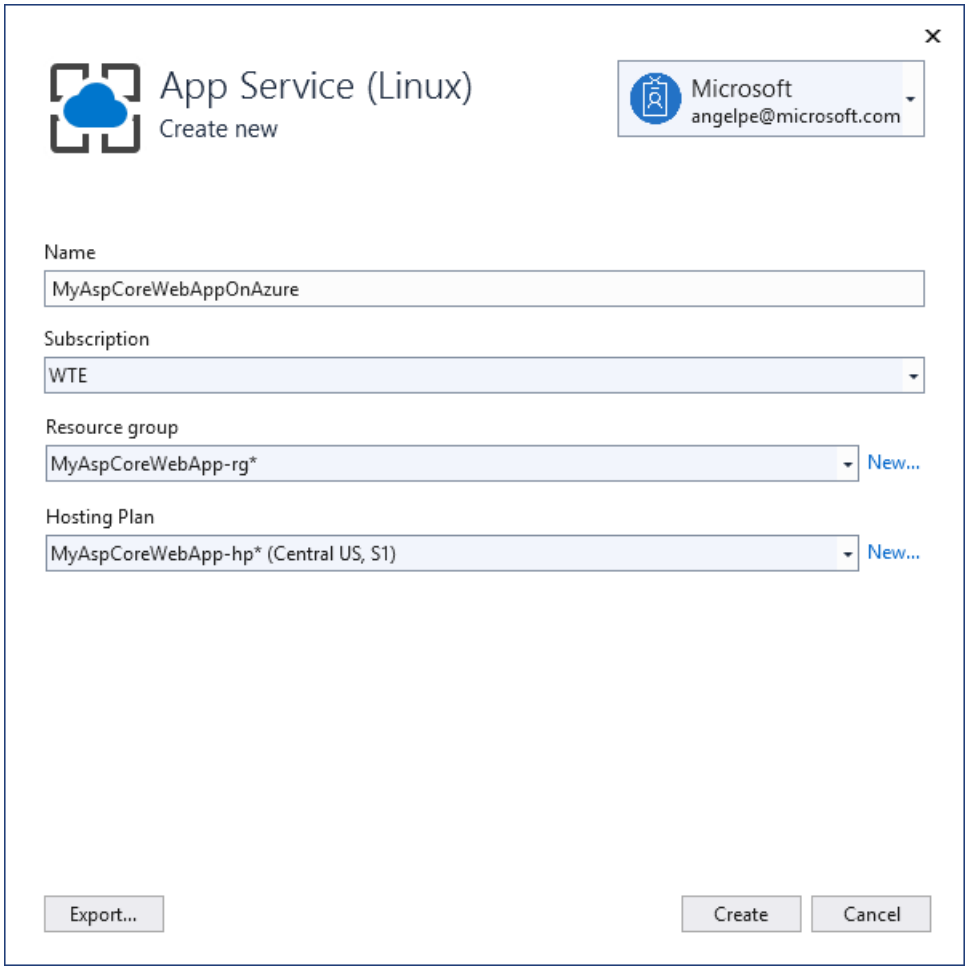
In the **Publish** dialog select **Create a new Azure App Service...**



The **Create App Service** dialog appears:

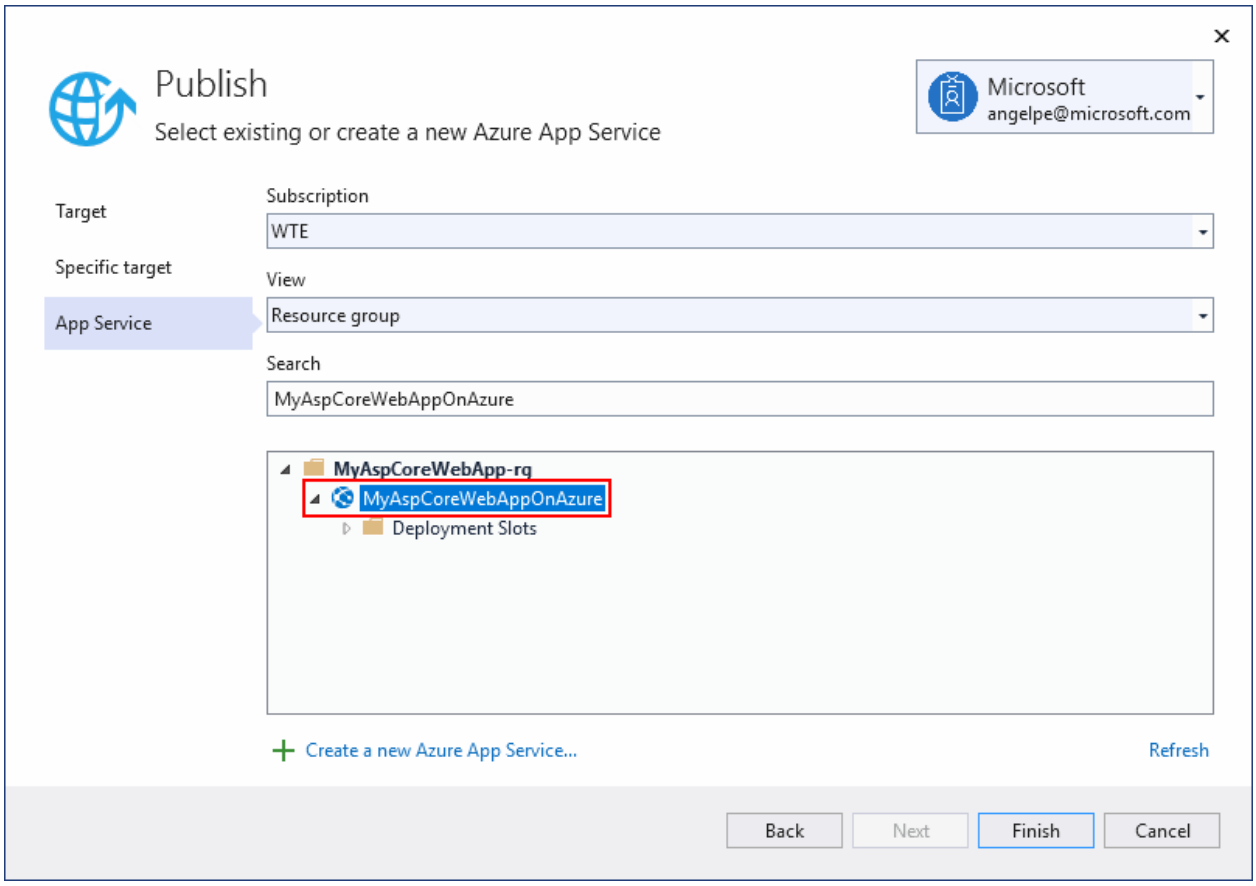
- The **App Name**, **Resource Group**, and **App Service Plan** entry fields are populated. You can keep these names or change them.

- Select **Create**.

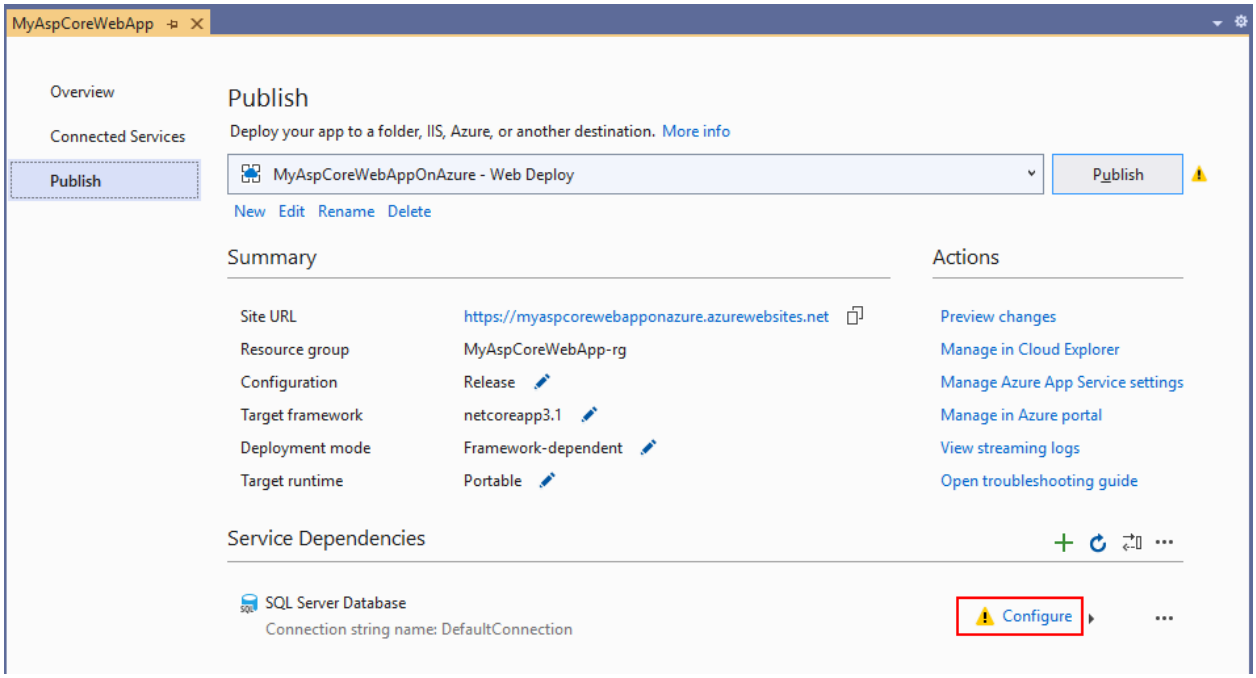


After creation is completed the dialog is automatically closed and the **Publish** dialog gets focus again:

- The new instance that was just created is automatically selected.
- Select **Finish**.

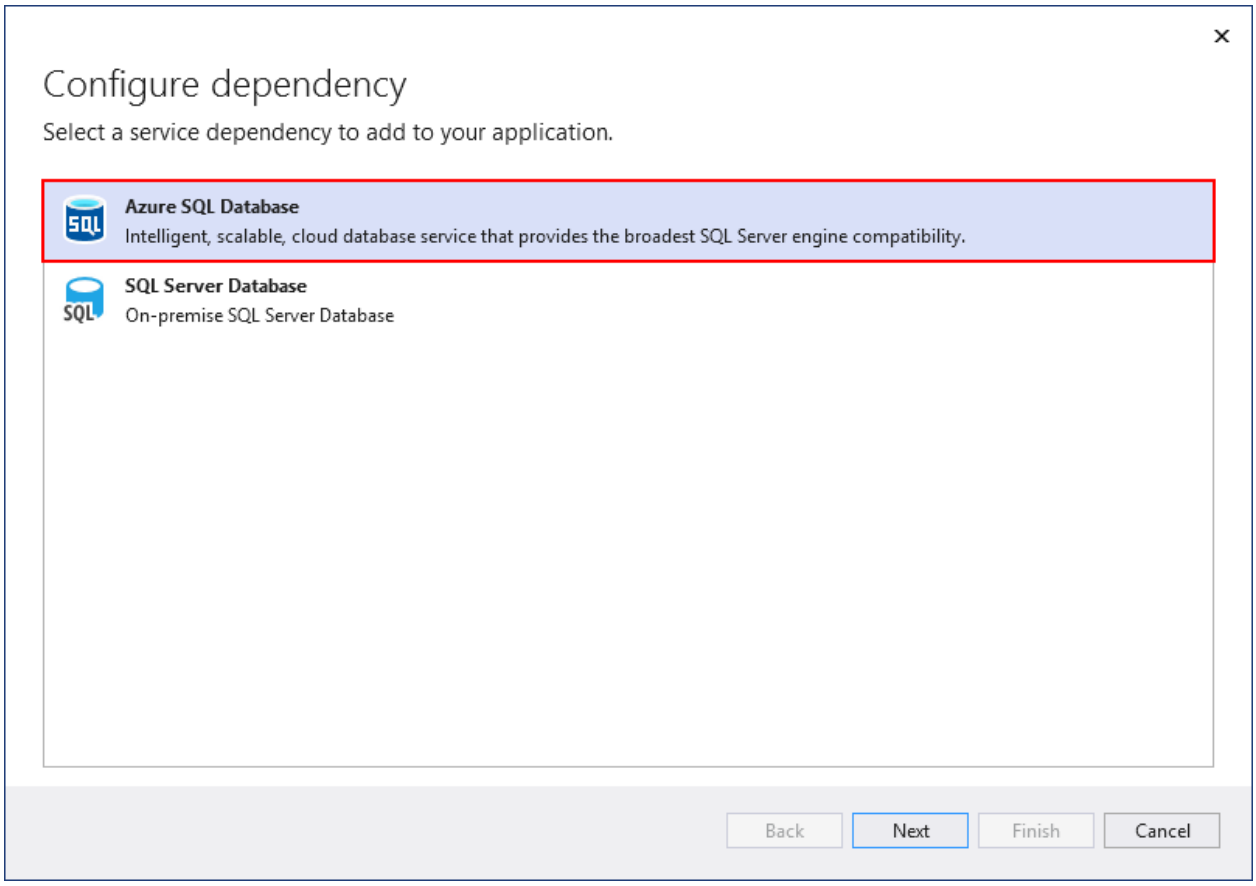


Next you see the **Publish Profile summary** page. Visual Studio has detected that this application requires a SQL Server database and it's asking you to configure it. Select **Configure**.

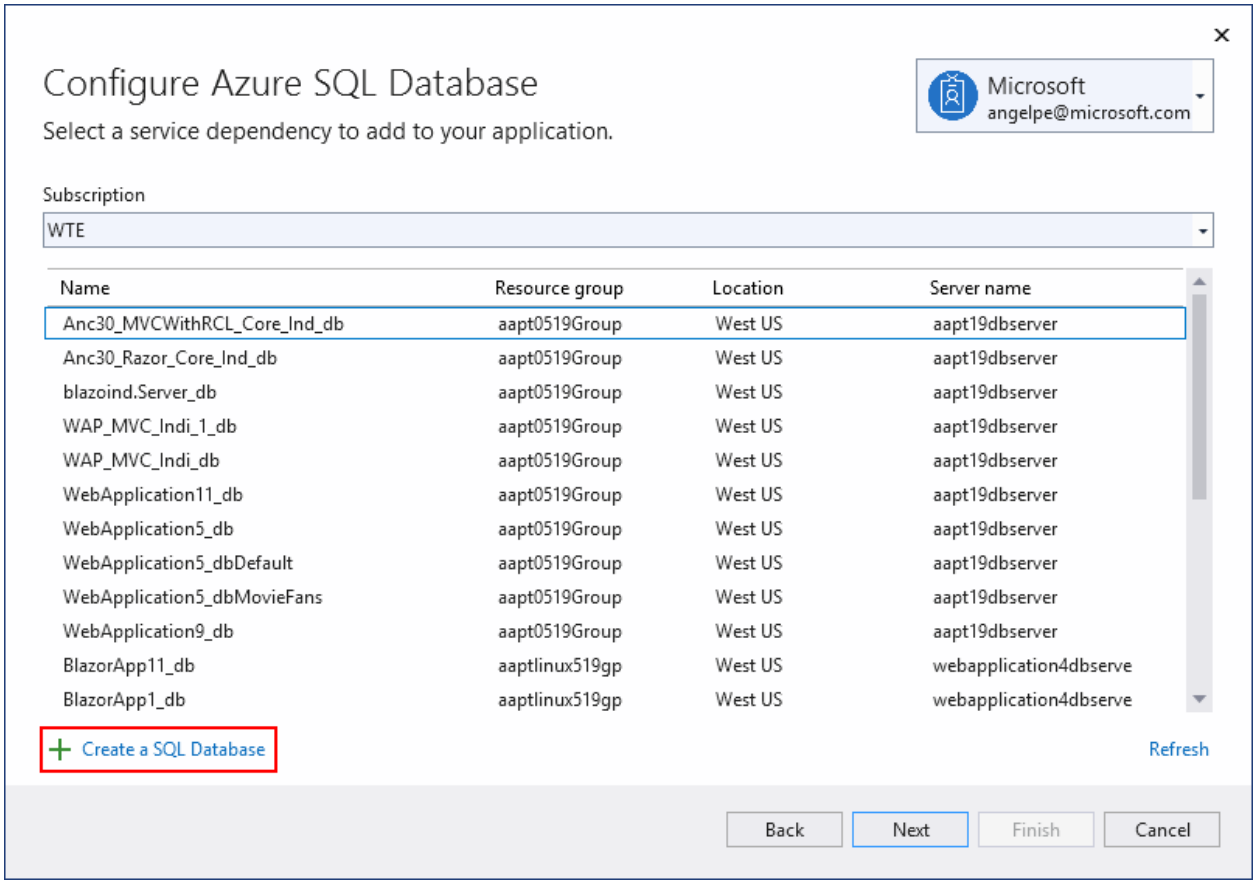


The **Configure dependency** dialog appears:

- Select **Azure SQL Database**.
- Select **Next**.



In the **Configure Azure SQL database** dialog select **Create a SQL Database**

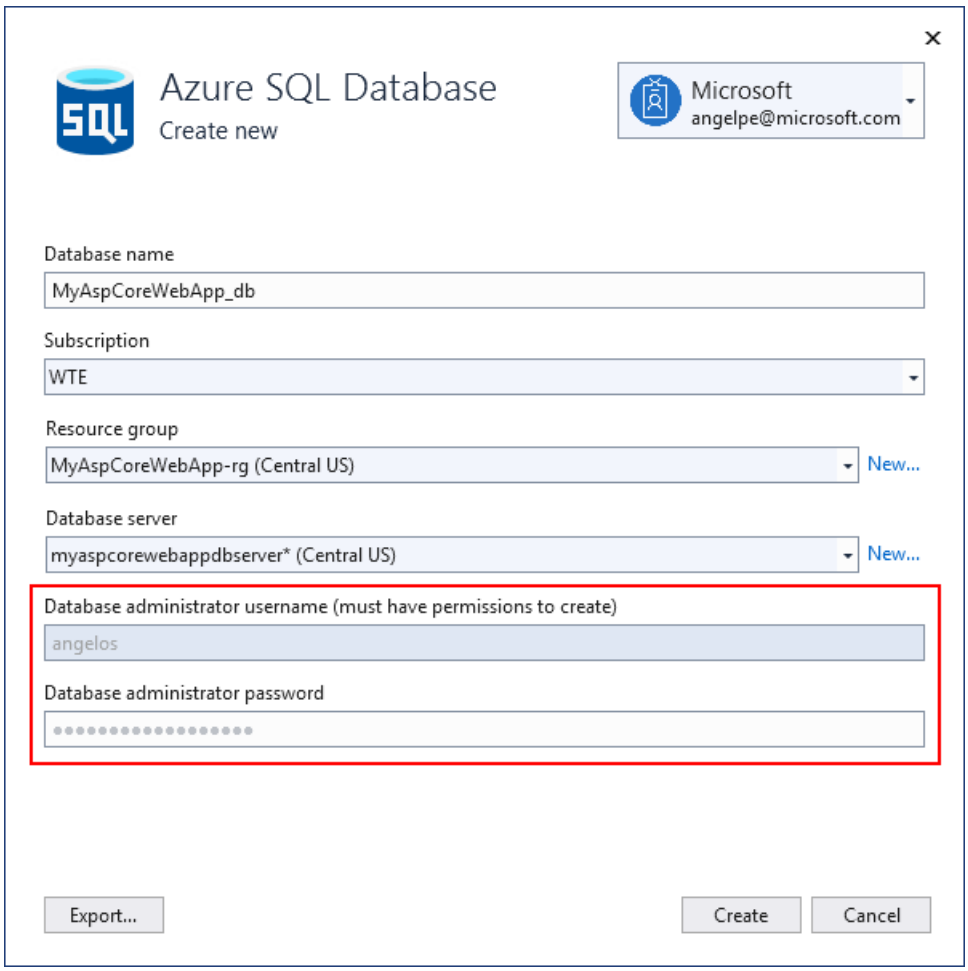


The **Create Azure SQL Database** appears:

- The **Database name**, **Resource Group**, **Database server** and **App Service Plan** entry fields are populated. You can keep these values or change them.
- Enter the **Database administrator username** and **Database administrator password** for the selected

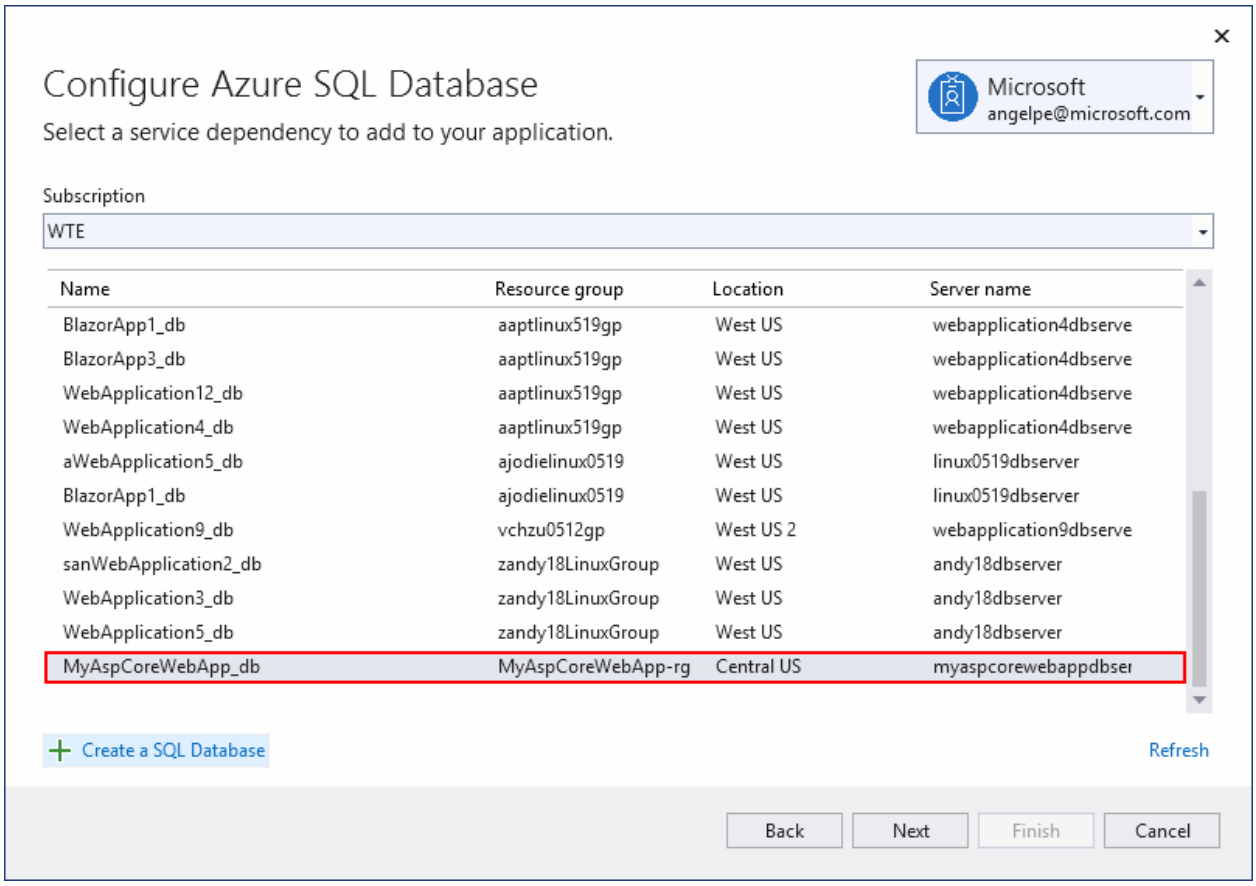
Database server (note the account you use must have the necessary permissions to create the new Azure SQL database)

- Select **Create**.



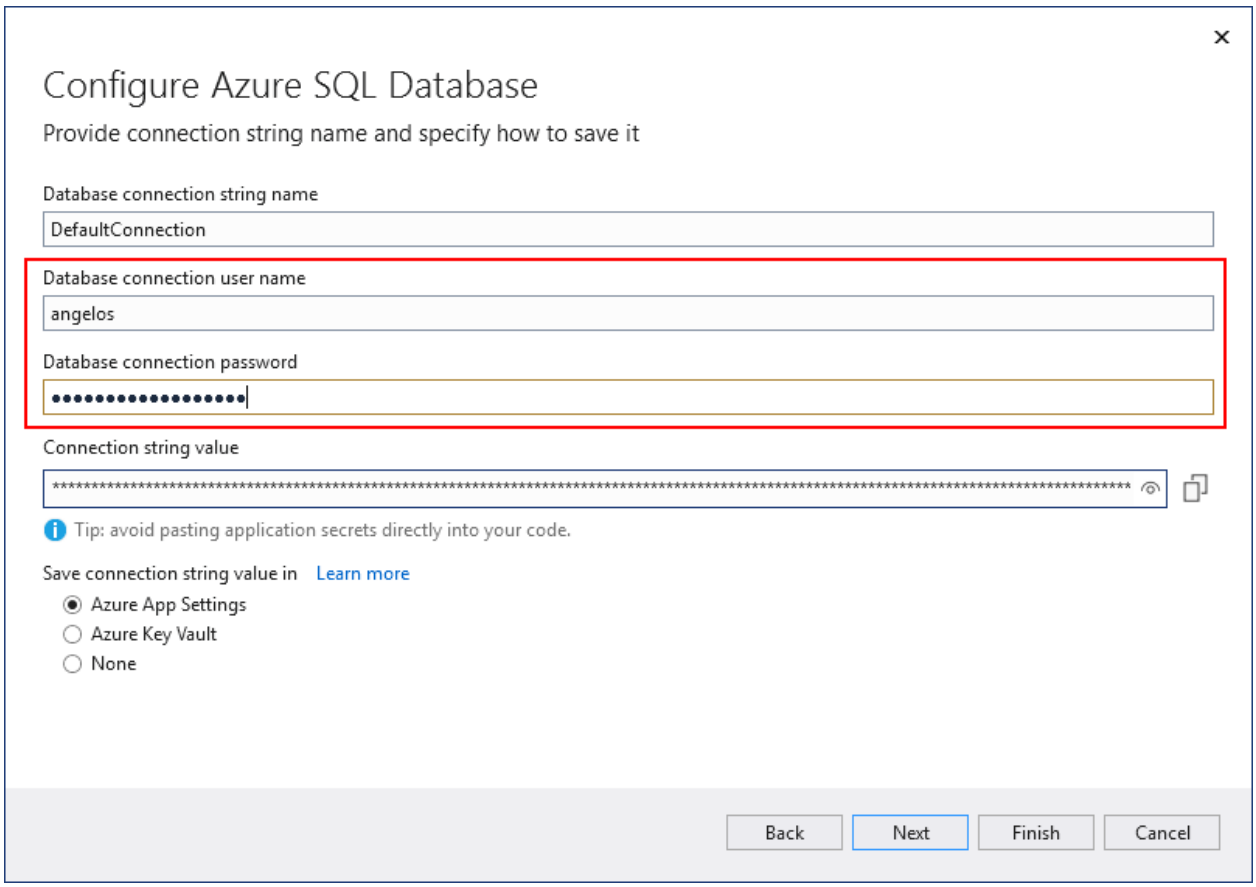
After creation is completed the dialog is automatically closed and the **Configure Azure SQL Database** dialog gets focus again:

- The new instance that was just created is automatically selected.
- Select **Next**.

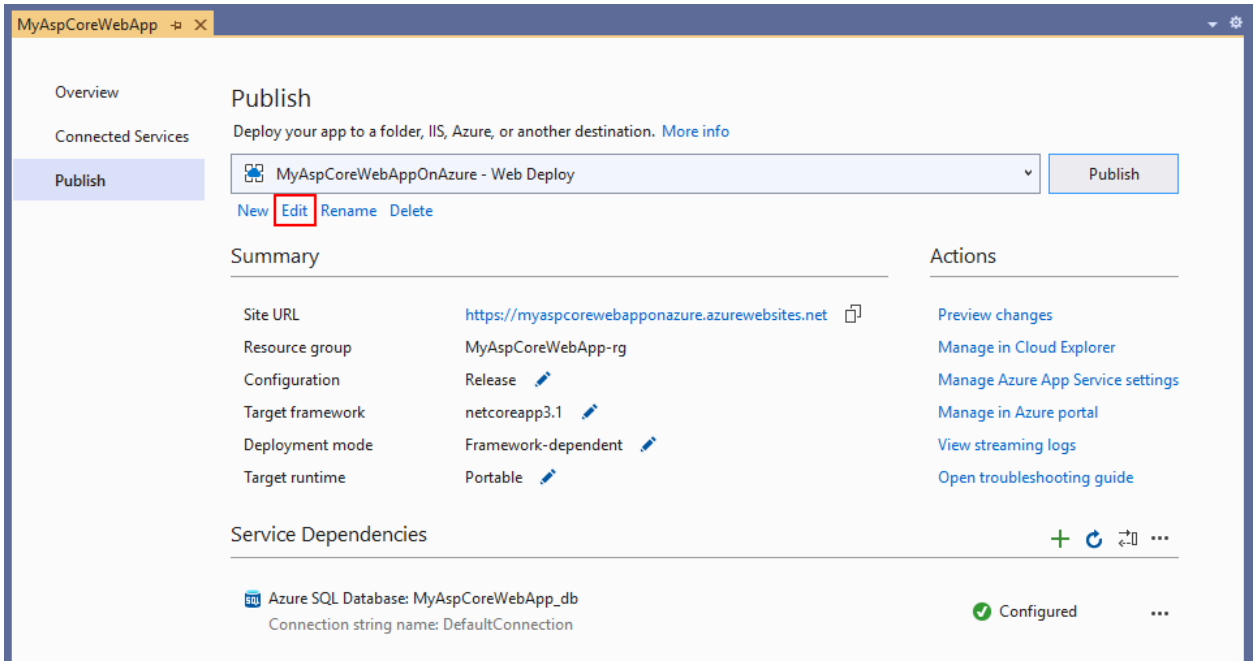


In the next step of the **Configure Azure SQL Database** dialog:

- Enter the **Database connection user name** and **Database connection password** fields. These are the details your application will use to connect to the database at runtime. Best practice is to avoid using the same details as the admin username & password used in the previous step.
- Select **Finish**.

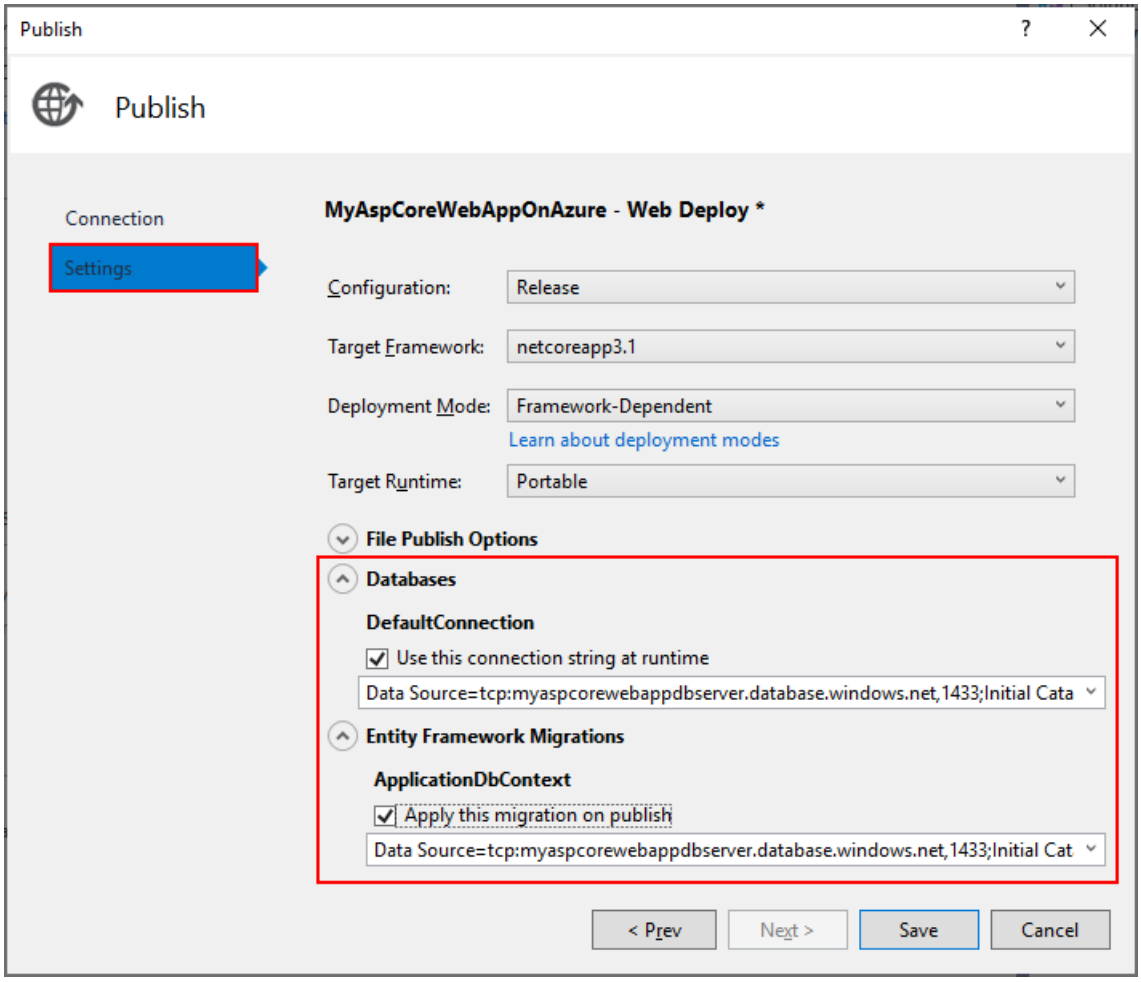


In the **Publish Profile summary** page select **Settings**:

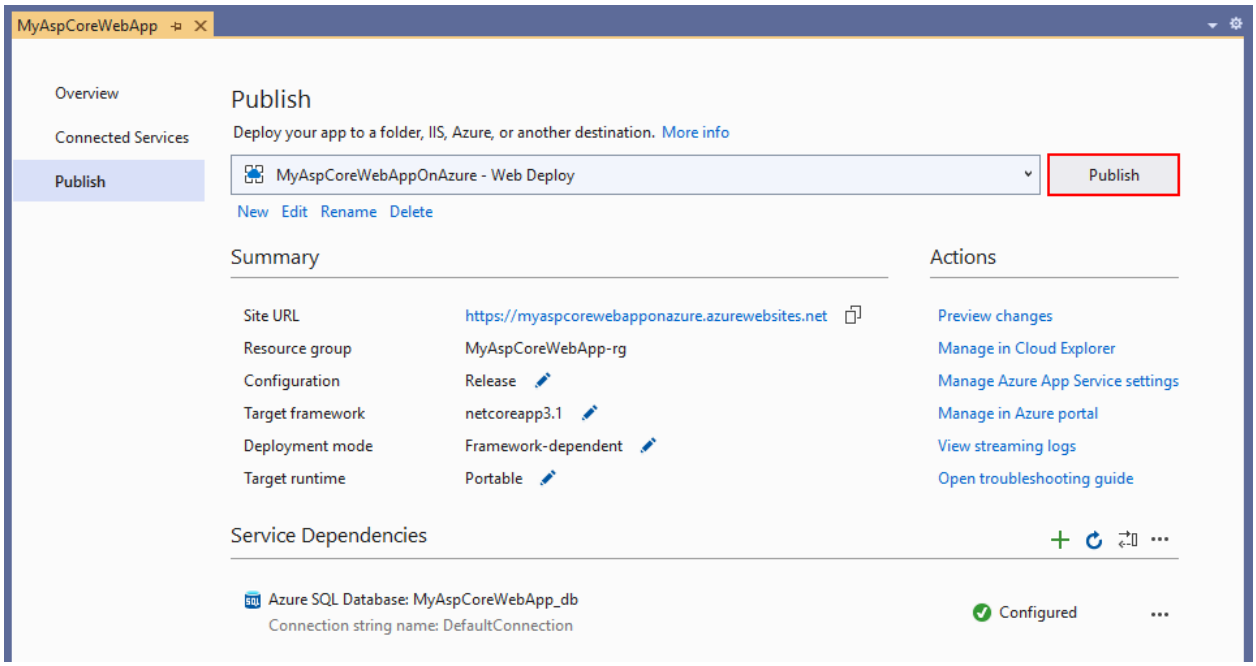


On the **Settings** page of the **Publish** dialog:

- Expand **Databases** and check **Use this connection string at runtime**.
- Expand **Entity Framework Migrations** and check **Apply this migration on publish**.
- Select **Save**. Visual Studio returns to the **Publish** dialog.



Click **Publish**. Visual Studio publishes your app to Azure. When the deployment completes, the app is opened in a browser.



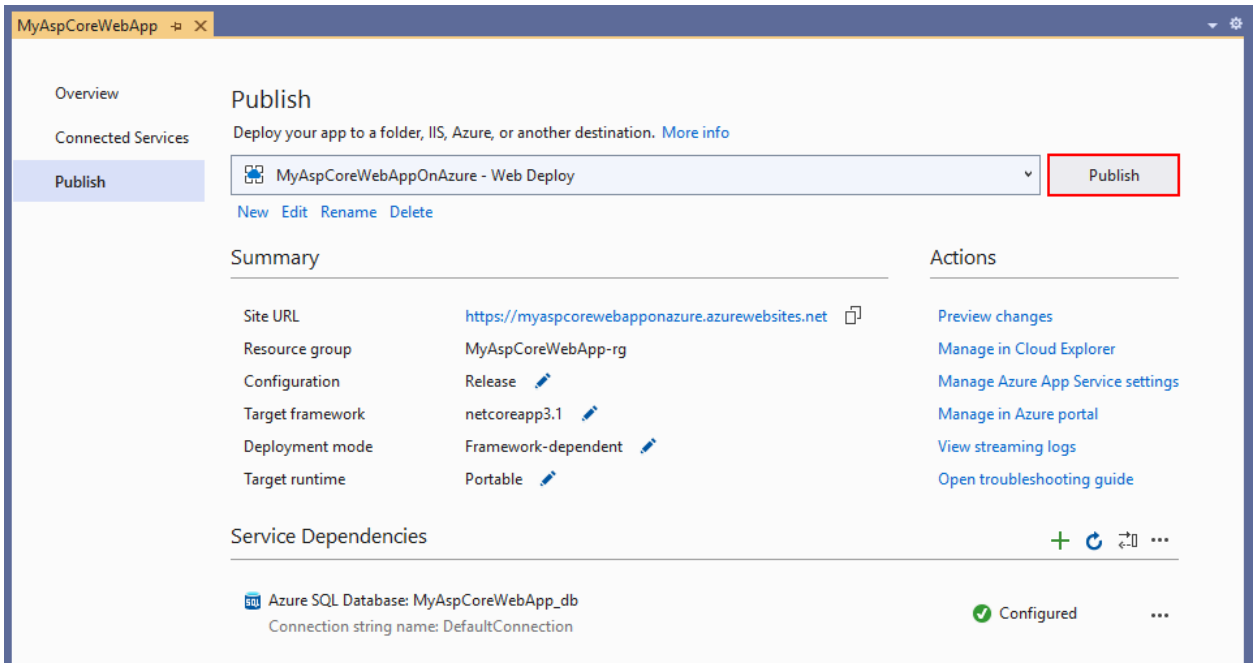
Update the app

- Edit the *Pages/Index.cshtml* Razor page and change its contents. For example, you can modify the paragraph to say "Hello ASP.NET Core!":

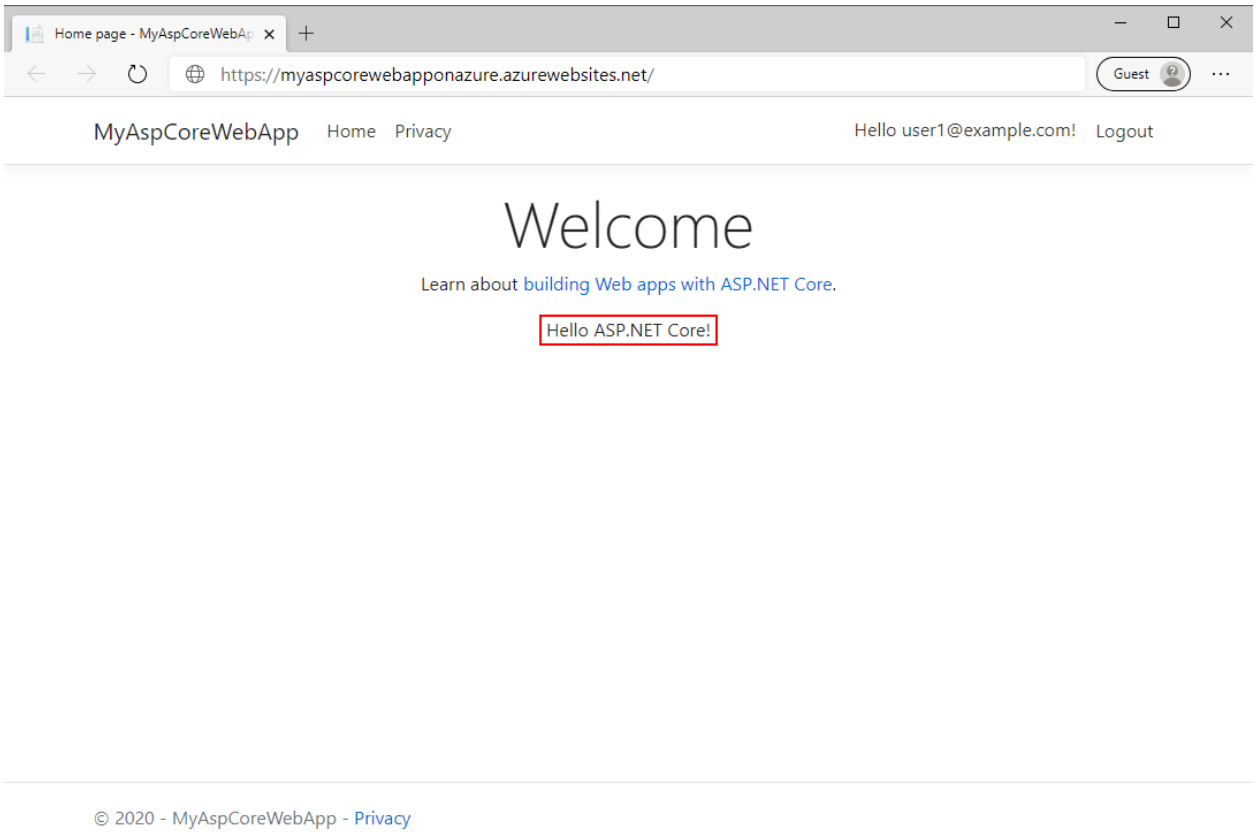
```
@page
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

<div class="text-center">
    <h1 class="display-4">Welcome</h1>
    <p>Learn about <a href="https://docs.microsoft.com/aspnet/core">building Web apps with ASP.NET
Core</a>.</p>
    <p>Hello ASP.NET Core!</p>
</div>
```

- Select **Publish** from the **Publish Profile summary** page again.



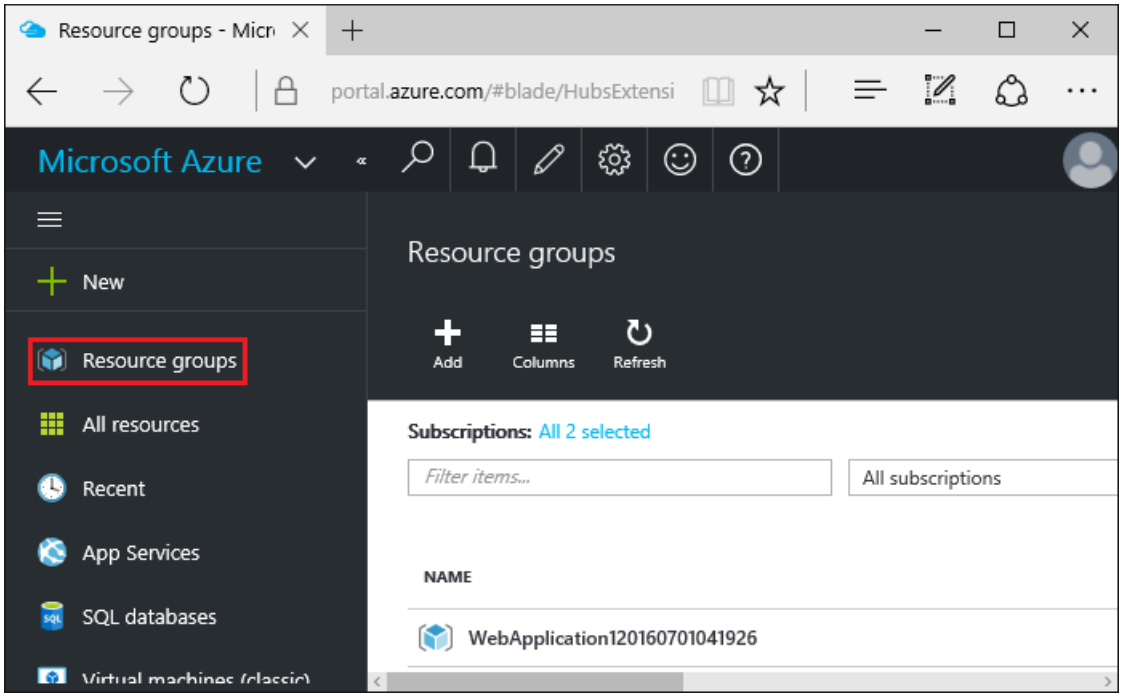
- After the app is published, verify the changes you made are available on Azure.



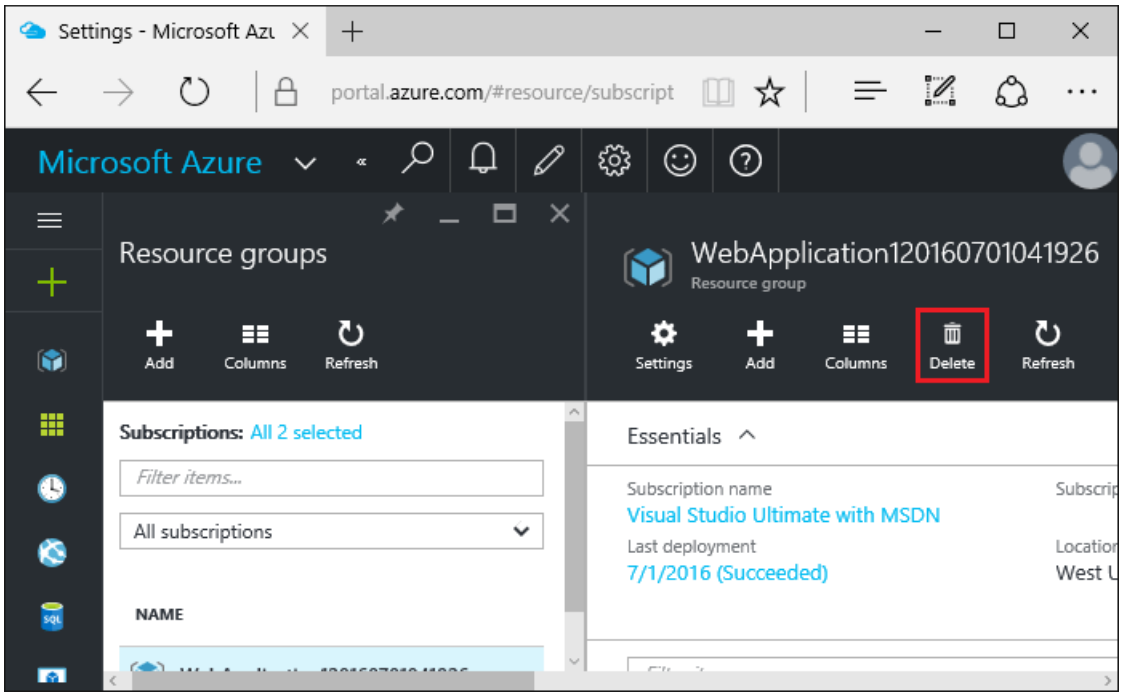
Clean up

When you have finished testing the app, go to the Azure portal and delete the app.

- Select **Resource groups**, then select the resource group you created.



- In the **Resource groups** page, select **Delete**.



- Enter the name of the resource group and select **Delete**. Your app and all other resources created in this tutorial are now deleted from Azure.

Next steps

- Continuous deployment to Azure with Visual Studio and Git with ASP.NET Core

Additional resources

- For Visual Studio Code, see Publish profiles.
- Azure App Service
- Azure resource groups
- Azure SQL Database
- Visual Studio publish profiles (.pubxml) for ASP.NET Core app deployment
- Troubleshoot ASP.NET Core on Azure App Service and IIS

Continuous deployment to Azure with Visual Studio and Git with ASP.NET Core

9/22/2020 • 6 minutes to read • Edit Online

By Erik Reitan

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

This tutorial shows how to create an ASP.NET Core web app using Visual Studio and deploy it from Visual Studio to Azure App Service using continuous deployment.

See also Create your first pipeline with Azure Pipelines, which shows how to configure a continuous delivery (CD) workflow for Azure App Service using Azure DevOps Services. Azure Pipelines (an Azure DevOps Services service) simplifies setting up a robust deployment pipeline to publish updates for apps hosted in Azure App Service. The pipeline can be configured from the Azure portal to build, run tests, deploy to a staging slot, and then deploy to production.

> **NOTE**
>
> To complete this tutorial, a Microsoft Azure account is required. To obtain an account, activate MSDN subscriber benefits or sign up for a free trial.

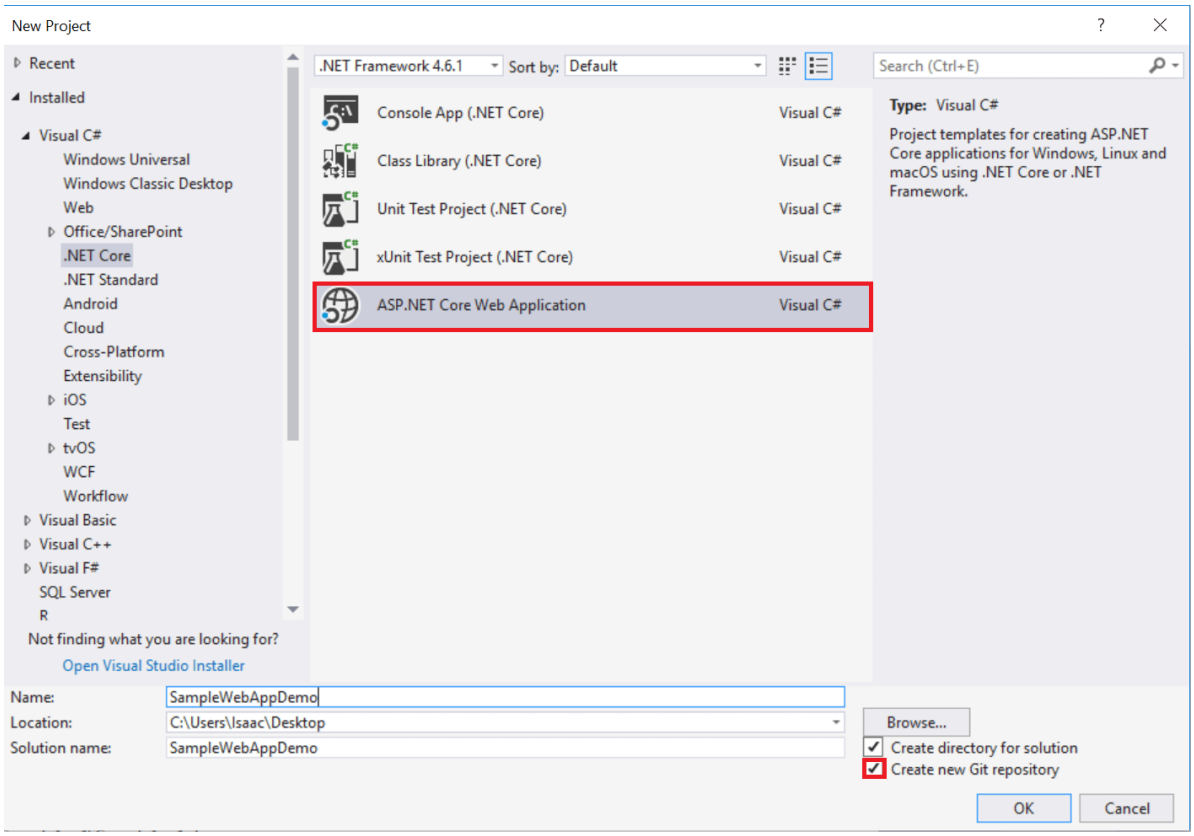
Prerequisites

This tutorial assumes the following software is installed:

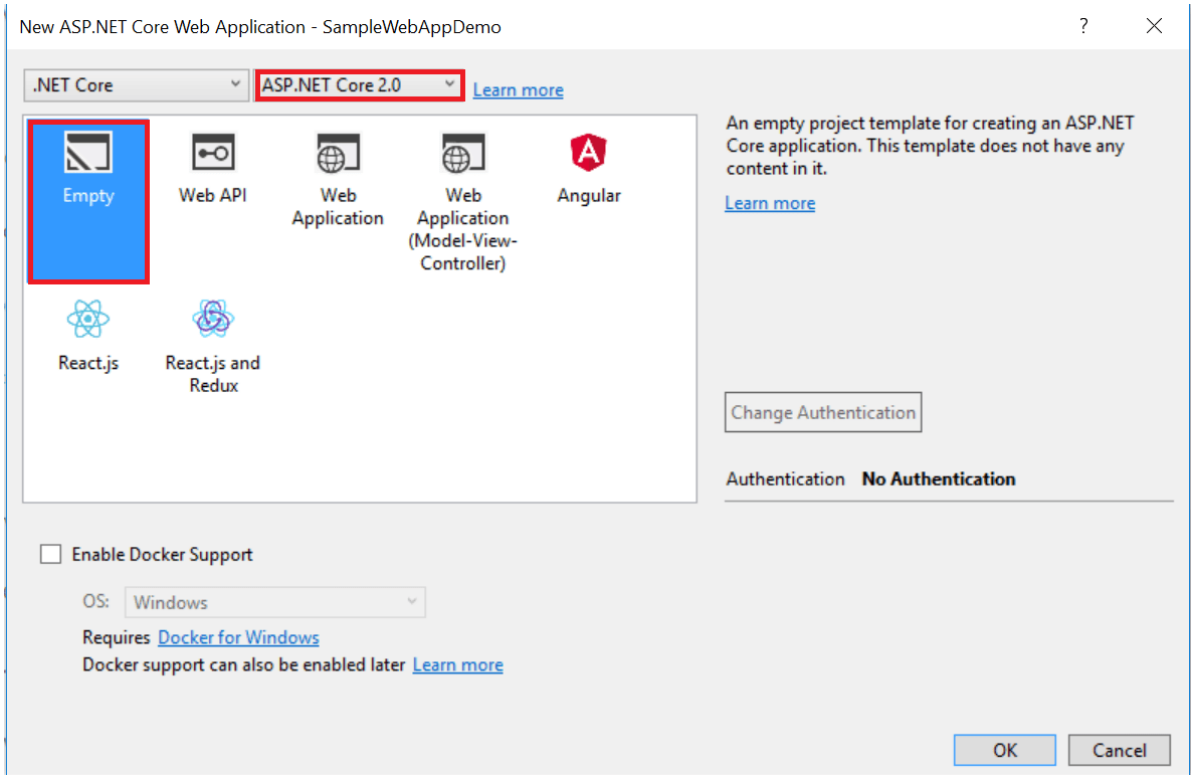
- Visual Studio
- .NET Core SDK 2.0 or later
- Git for Windows

Create an ASP.NET Core web app

1. Start Visual Studio.
2. From the **File** menu, select **New** > **Project**.
3. Select the **ASP.NET Core Web Application** project template. It appears under **Installed** > **Templates** > **Visual C#** > **.NET Core**. Name the project `SampleWebAppDemo`. Select the **Create new Git repository** option and click **OK**.



4. In the **New ASP.NET Core Project** dialog, select the ASP.NET Core **Empty** template, then click **OK**.



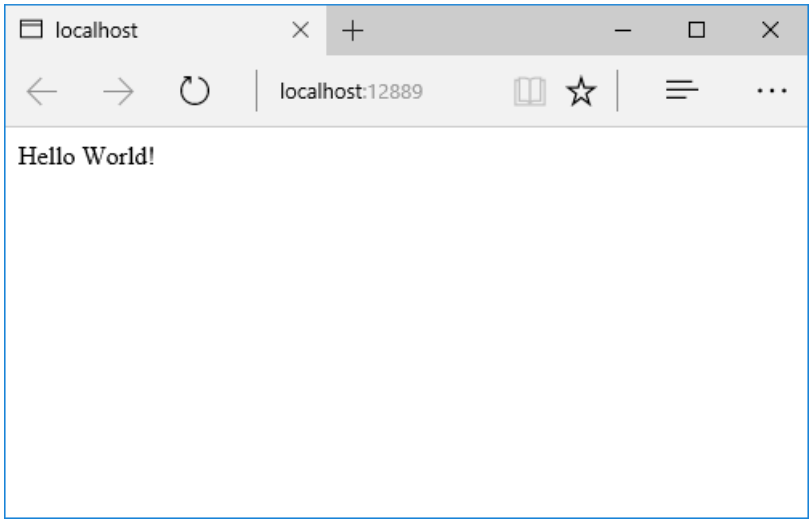
> **NOTE**
>
> The most recent release of .NET Core is 2.0.

Running the web app locally

1. Once Visual Studio finishes creating the app, run the app by selecting **Debug** > **Start Debugging**. As an alternative, press **F5**.

   It may take time to initialize Visual Studio and the new app. Once it's complete, the browser shows the

running app.

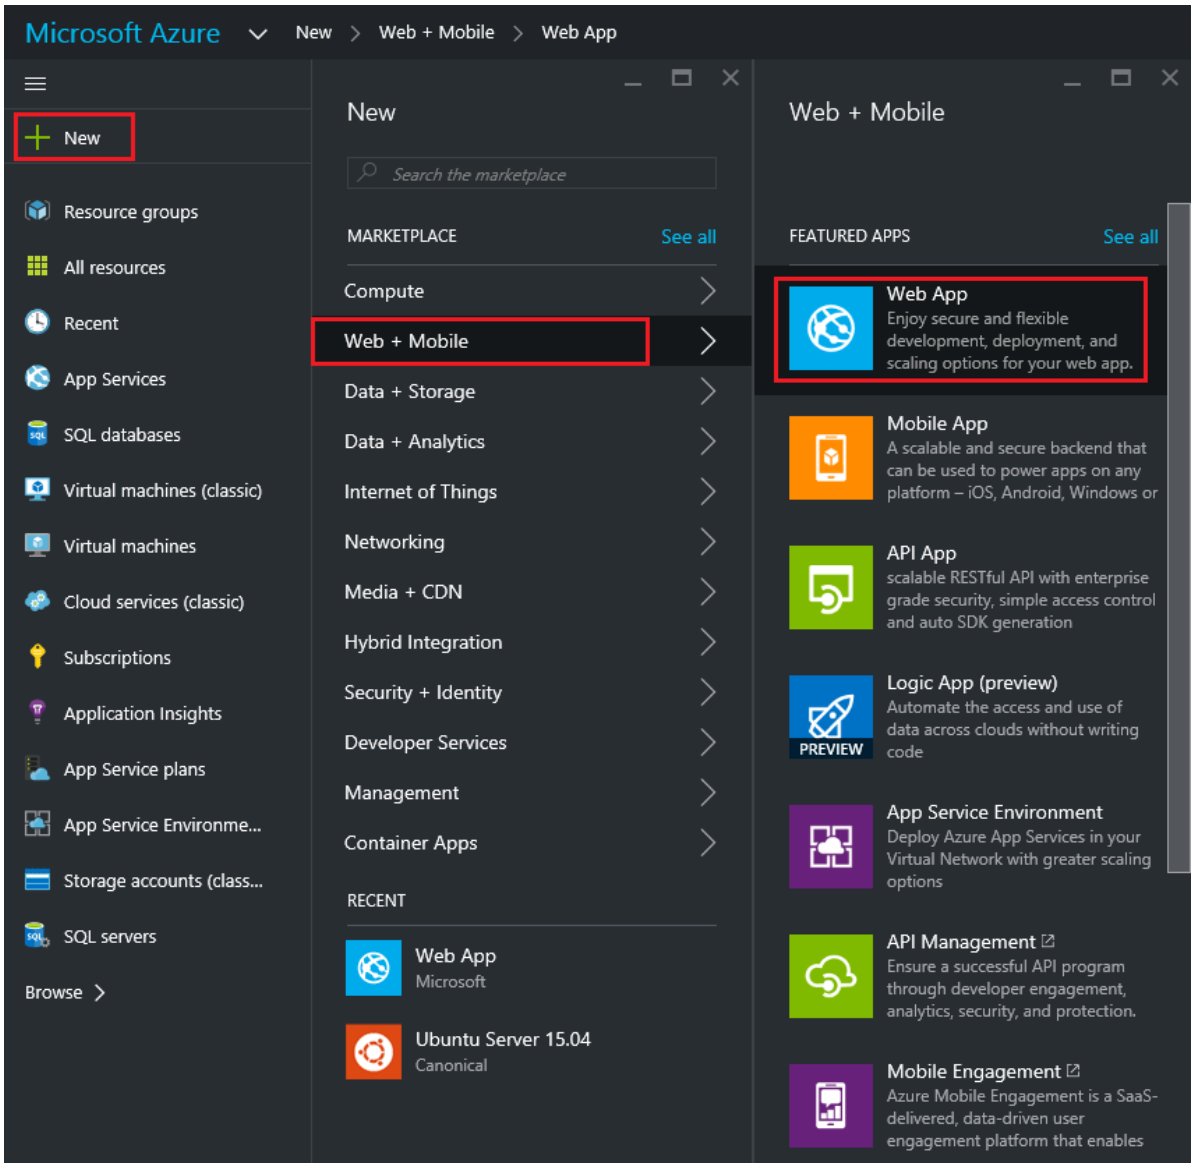


2. After reviewing the running Web app, close the browser and select the "Stop Debugging" icon in the toolbar of Visual Studio to stop the app.

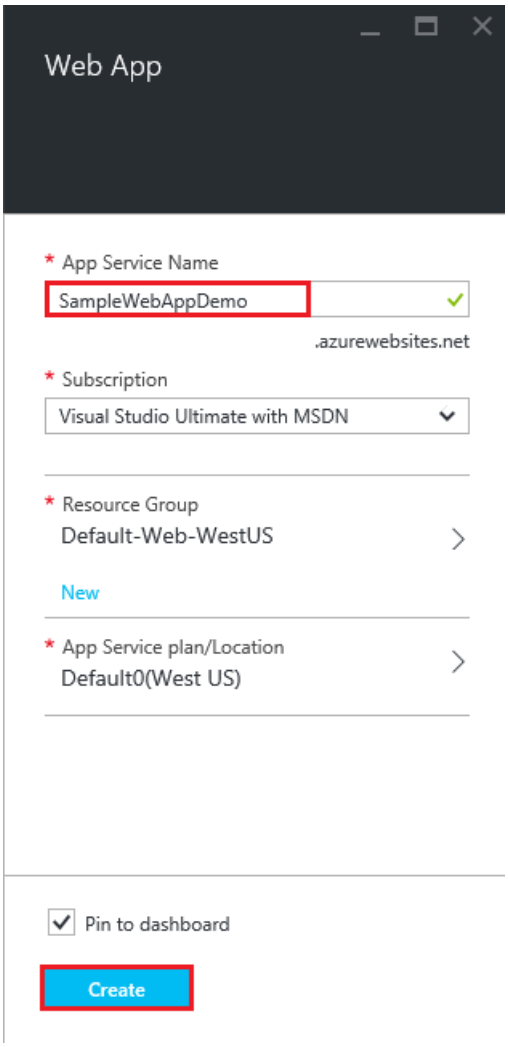
Create a web app in the Azure Portal

The following steps create a web app in the Azure Portal:

1. Log in to the Azure Portal.
2. Select **NEW** at the top left of the portal interface.
3. Select **Web + Mobile** > **Web App**.



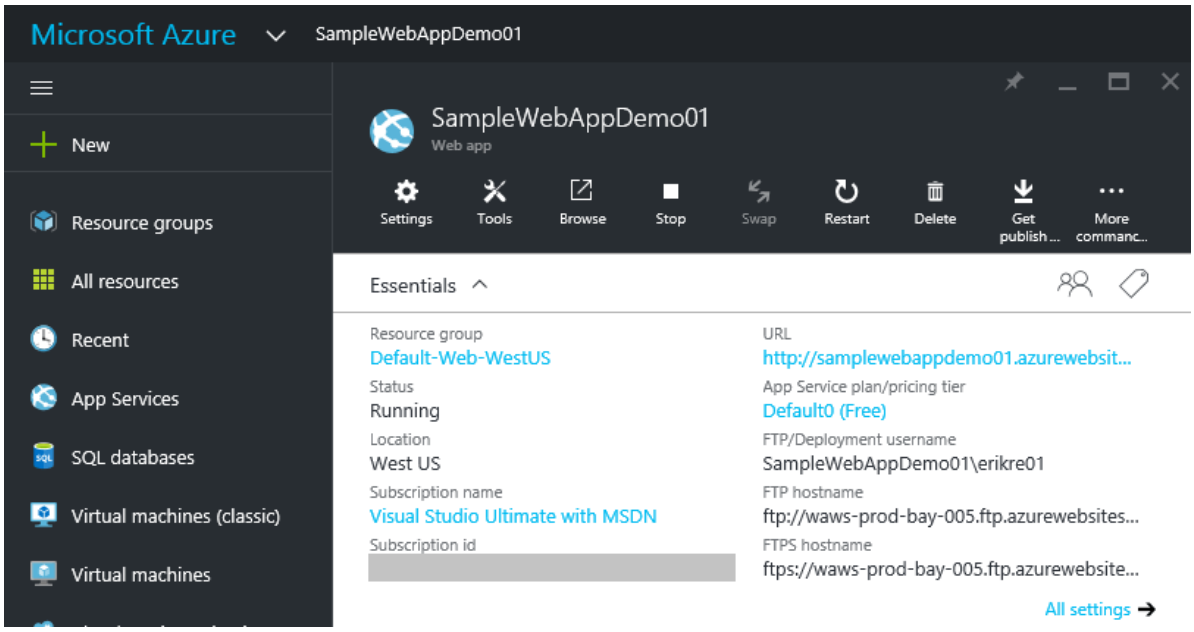
4. In the **Web App** blade, enter a unique value for the **App Service Name**.



> **NOTE**
>
> The **App Service Name** name must be unique. The portal enforces this rule when the name is provided. If providing a different value, substitute that value for each occurrence of **SampleWebAppDemo** in this tutorial.

Also in the **Web App** blade, select an existing **App Service Plan/Location** or create a new one. If creating a new plan, select the pricing tier, location, and other options. For more information on App Service plans, see Azure App Service plans in-depth overview.

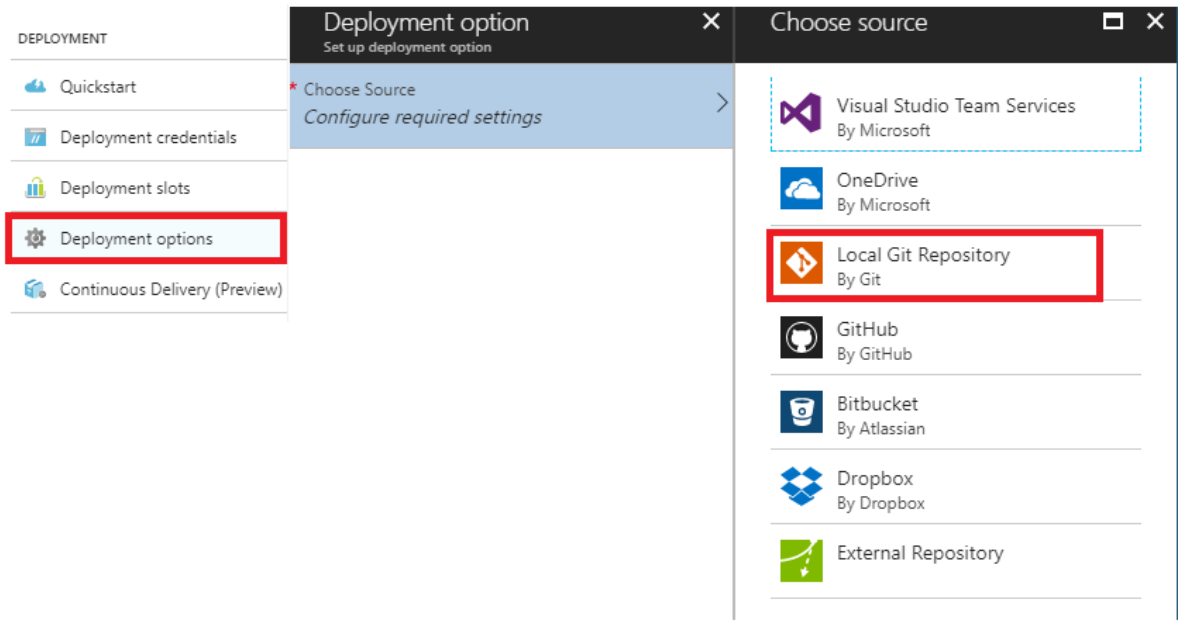
5. Select **Create**. Azure will provision and start the web app.



Enable Git publishing for the new web app

Git is a distributed version control system that can be used to deploy an Azure App Service web app. Web app code is stored in a local Git repository, and the code is deployed to Azure by pushing to a remote repository.

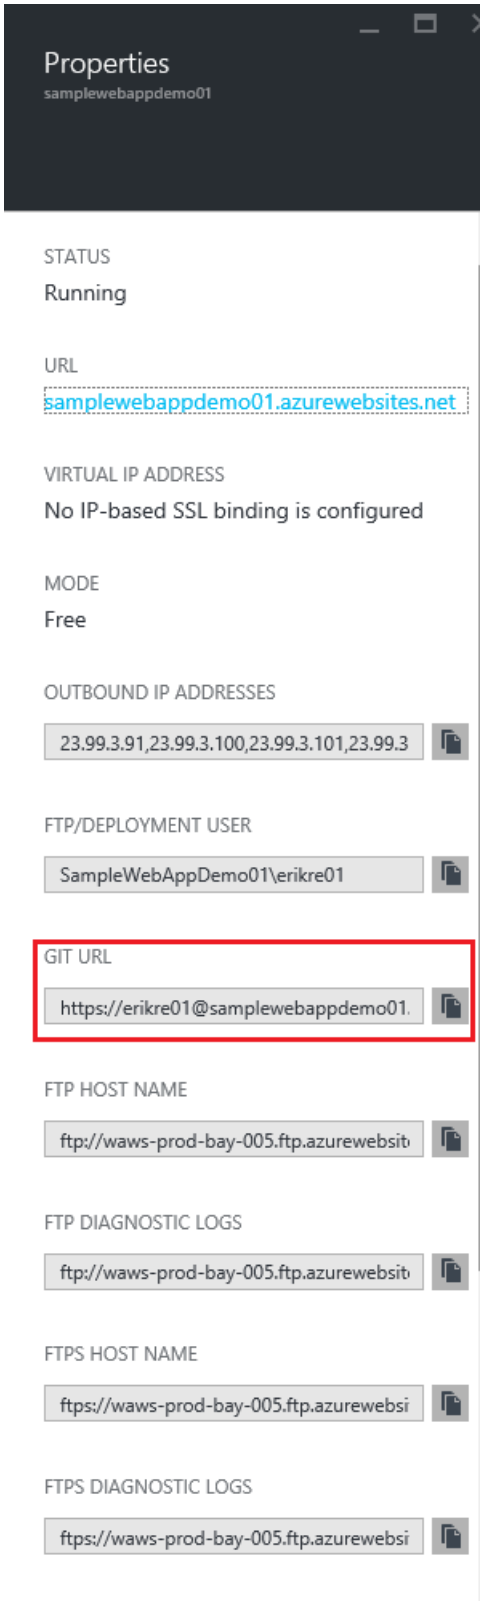
1. Log into the Azure Portal.
2. Select **App Services** to view a list of the app services associated with the Azure subscription.
3. Select the web app created in the previous section of this tutorial.
4. In the **Deployment** blade, select **Deployment options** > **Choose Source** > **Local Git Repository**.



5. Select **OK**.
6. If deployment credentials for publishing a web app or other App Service app haven't previously been set up, set them up now:
   - Select **Settings** > **Deployment credentials**. The **Set deployment credentials** blade is displayed.
   - Create a user name and password. Save the password for later use when setting up Git.
   - Select **Save**.
7. In the **Web App** blade, select **Settings** > **Properties**. The URL of the remote Git repository to deploy to is

shown under **GIT URL**.

8. Copy the **GIT URL** value for later use in the tutorial.

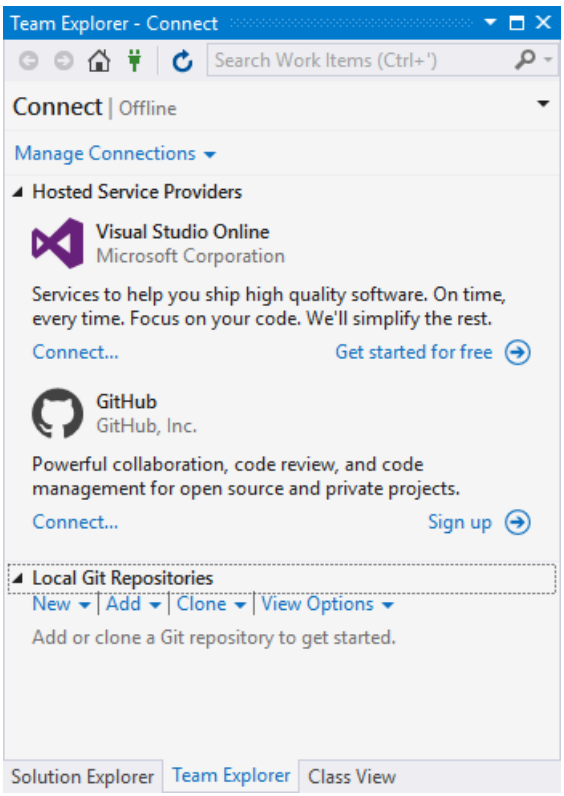


Publish the web app to Azure App Service

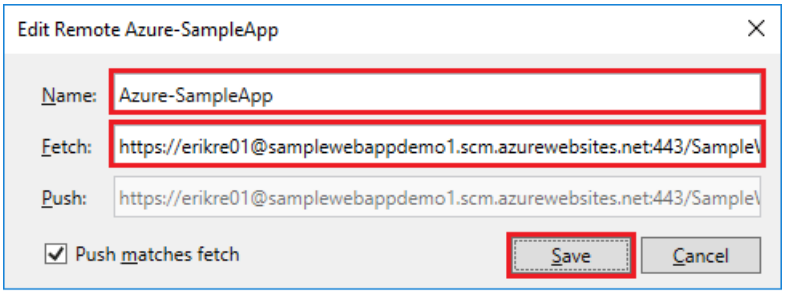
In this section, create a local Git repository using Visual Studio and push from that repository to Azure to deploy the web app. The steps involved include the following:

- Add the remote repository setting using the GIT URL value, so the local repository can be deployed to Azure.
- Commit project changes.
- Push project changes from the local repository to the remote repository on Azure.

1. In **Solution Explorer** right-click **Solution 'SampleWebAppDemo'** and select **Commit**. The **Team Explorer** is displayed.

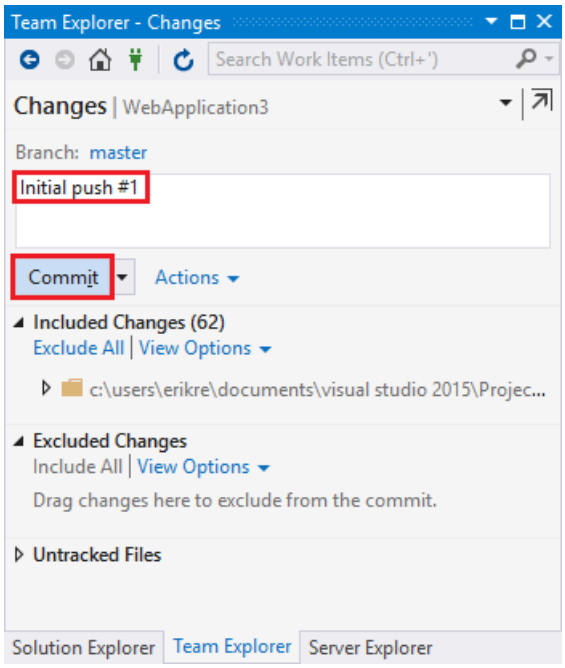


2. In **Team Explorer**, select the **Home** (home icon) > **Settings** > **Repository Settings**.
3. In the **Remotes** section of the **Repository Settings**, select **Add**. The **Add Remote** dialog box is displayed.
4. Set the **Name** of the remote to **Azure-SampleApp**.
5. Set the value for **Fetch** to the **Git URL** that copied from Azure earlier in this tutorial. Note that this is the URL that ends with **.git**.



> **NOTE**
>
> As an alternative, specify the remote repository from the **Command Window** by opening the **Command Window**, changing to the project directory, and entering the command. Example:
>
> ```
> git remote add Azure-SampleApp https://me@sampleapp.scm.azurewebsites.net:443/SampleApp.git
> ```

6. Select the **Home** (home icon) > **Settings** > **Global Settings**. Confirm that the name and email address are set. Select **Update** if required.
7. Select **Home** > **Changes** to return to the **Changes** view.
8. Enter a commit message, such as **Initial Push #1** and select **Commit**. This action creates a *commit* locally.



> **NOTE**
>
> As an alternative, commit changes from the **Command Window** by opening the **Command Window**, changing to the project directory, and entering the git commands. Example:
>
> ```
> git add .
> ```
>
> ```
> git commit -am "Initial Push #1"
> ```

9. Select **Home** > **Sync** > **Actions** > **Open Command Prompt**. The command prompt opens to the project directory.

10. Enter the following command in the command window:

    ```
    git push -u Azure-SampleApp master
    ```

11. Enter the Azure **deployment credentials** password created earlier in Azure.

    This command starts the process of pushing the local project files to Azure. The output from the above command ends with a message that the deployment was successful.

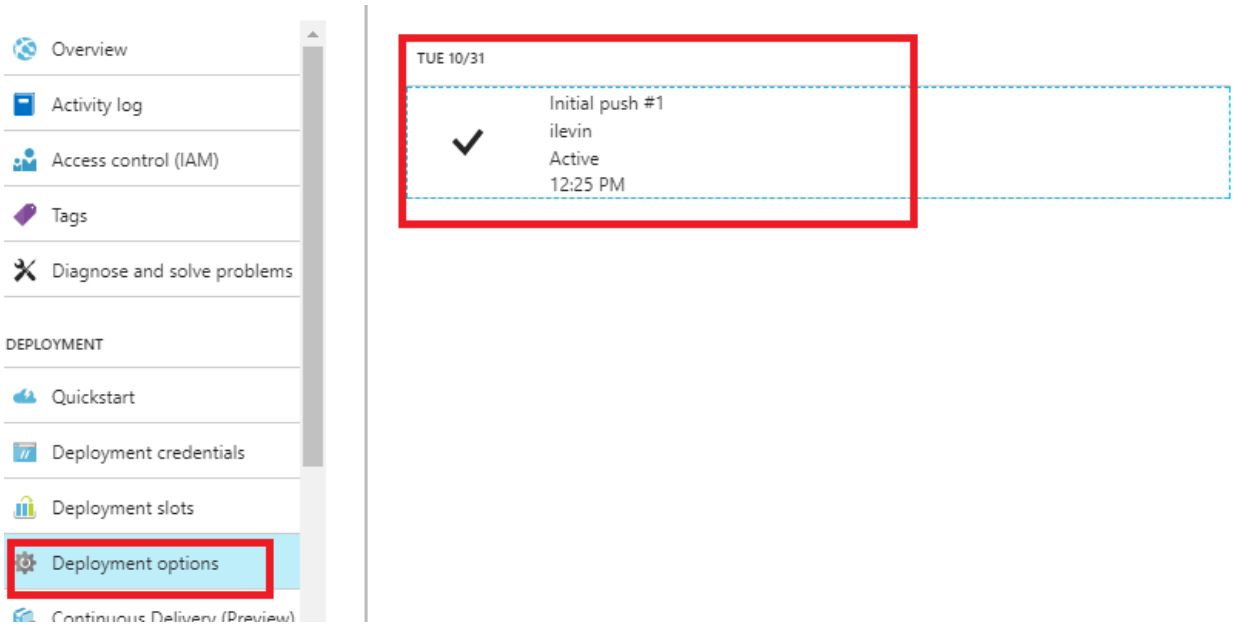
    ```
    remote: Finished successfully.
    remote: Running post deployment command(s)...
    remote: Deployment successful.
    To https://username@samplewebappdemo01.scm.azurewebsites.net:443/SampleWebAppDemo01.git
    * [new branch]      master -> master
    Branch master set up to track remote branch master from Azure-SampleApp.
    ```

> **NOTE**
>
> If collaboration on the project is required, consider pushing to GitHub before pushing to Azure.

Verify the Active Deployment

Verify that the web app transfer from the local environment to Azure is successful.

In the Azure Portal, select the web app. Select **Deployment** > **Deployment options**.



Run the app in Azure

Now that the web app is deployed to Azure, run the app.

This can be accomplished in two ways:

- In the Azure Portal, locate the web app blade for the web app. Select **Browse** to view the app in the default browser.
- Open a browser and enter the URL for the web app. Example: `http://SampleWebAppDemo.azurewebsites.net`

Update the web app and republish

After making changes to the local code, republish:

1. In **Solution Explorer** of Visual Studio, open the *Startup.cs* file.
2. In the `Configure` method, modify the `Response.WriteAsync` method so that it appears as follows:

```
await context.Response.WriteAsync("Hello World! Deploy to Azure.");
```

3. Save the changes to *Startup.cs*.
4. In **Solution Explorer**, right-click **Solution 'SampleWebAppDemo'** and select **Commit**. The **Team Explorer** is displayed.
5. Enter a commit message, such as `Update #2`.
6. Press the **Commit** button to commit the project changes.
7. Select **Home** > **Sync** > **Actions** > **Push**.

> **NOTE**
>
> As an alternative, push the changes from the **Command Window** by opening the **Command Window**, changing to the project directory, and entering a git command. Example:
>
> `git push -u Azure-SampleApp master`

View the updated web app in Azure

View the updated web app by selecting **Browse** from the web app blade in the Azure Portal or by opening a browser and entering the URL for the web app. Example: `http://SampleWebAppDemo.azurewebsites.net`

ASP.NET Core Module

9/22/2020 • 40 minutes to read • Edit Online

By Tom Dykstra, Rick Strahl, Chris Ross, Rick Anderson, Sourabh Shirhatti, and Justin Kotalik

The ASP.NET Core Module is a native IIS module that plugs into the IIS pipeline to either:

- Host an ASP.NET Core app inside of the IIS worker process (`w3wp.exe`), called the in-process hosting model.
- Forward web requests to a backend ASP.NET Core app running the Kestrel server, called the out-of-process hosting model.

Supported Windows versions:

- Windows 7 or later
- Windows Server 2012 R2 or later

When hosting in-process, the module uses an in-process server implementation for IIS, called IIS HTTP Server (`IISHttpServer`).

When hosting out-of-process, the module only works with Kestrel. The module doesn't function with HTTP.sys.

Hosting models

In-process hosting model

ASP.NET Core apps default to the in-process hosting model.

The following characteristics apply when hosting in-process:

- IIS HTTP Server (`IISHttpServer`) is used instead of Kestrel server. For in-process, CreateDefaultBuilder calls UseIIS to:
  - Register the `IISHttpServer`.
  - Configure the port and base path the server should listen on when running behind the ASP.NET Core Module.
  - Configure the host to capture startup errors.
- The requestTimeout attribute doesn't apply to in-process hosting.
- Sharing an app pool among apps isn't supported. Use one app pool per app.
- When using Web Deploy or manually placing an app_offline.htm file in the deployment, the app might not shut down immediately if there's an open connection. For example, a websocket connection may delay app shut down.
- The architecture (bitness) of the app and installed runtime (x64 or x86) must match the architecture of the app pool.
- Client disconnects are detected. The HttpContext.RequestAborted cancellation token is cancelled when the client disconnects.
- In ASP.NET Core 2.2.1 or earlier, GetCurrentDirectory returns the worker directory of the process started by IIS rather than the app's directory (for example, *C:\Windows\System32\inetsrv* for *w3wp.exe*).

  For sample code that sets the app's current directory, see the CurrentDirectoryHelpers class. Call the `SetCurrentDirectory` method. Subsequent calls to GetCurrentDirectory provide the app's directory.

- When hosting in-process, AuthenticateAsync isn't called internally to initialize a user. Therefore, an IClaimsTransformation implementation used to transform claims after every authentication isn't activated by default. When transforming claims with an IClaimsTransformation implementation, call AddAuthentication to add authentication services:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddTransient<IClaimsTransformation, ClaimsTransformer>();
    services.AddAuthentication(IISServerDefaults.AuthenticationScheme);
}

public void Configure(IApplicationBuilder app)
{
    app.UseAuthentication();
}
```

  - Web Package (single-file) deployments aren't supported.

Out-of-process hosting model

To configure an app for out-of-process hosting, set the value of the `<AspNetCoreHostingModel>` property to `OutOfProcess` in the project file (*.csproj*):

```
<PropertyGroup>
  <AspNetCoreHostingModel>OutOfProcess</AspNetCoreHostingModel>
</PropertyGroup>
```

In-process hosting is set with `InProcess`, which is the default value.

The value of `<AspNetCoreHostingModel>` is case insensitive, so `inprocess` and `outofprocess` are valid values.

Kestrel server is used instead of IIS HTTP Server (`IISHttpServer`).

For out-of-process, CreateDefaultBuilder calls UseIISIntegration to:

- Configure the port and base path the server should listen on when running behind the ASP.NET Core Module.
- Configure the host to capture startup errors.

Hosting model changes

If the `hostingModel` setting is changed in the *web.config* file (explained in the Configuration with web.config section), the module recycles the worker process for IIS.

For IIS Express, the module doesn't recycle the worker process but instead triggers a graceful shutdown of the current IIS Express process. The next request to the app spawns a new IIS Express process.

Process name

`Process.GetCurrentProcess().ProcessName` reports `w3wp` / `iisexpress` (in-process) or `dotnet` (out-of-process).

Many native modules, such as Windows Authentication, remain active. To learn more about IIS modules active with the ASP.NET Core Module, see IIS modules with ASP.NET Core.

The ASP.NET Core Module can also:

- Set environment variables for the worker process.
- Log stdout output to file storage for troubleshooting startup issues.
- Forward Windows authentication tokens.

How to install and use the ASP.NET Core Module

For instructions on how to install the ASP.NET Core Module, see Install the .NET Core Hosting Bundle.

Configuration with web.config

The ASP.NET Core Module is configured with the `aspNetCore` section of the `system.webServer` node in the site's *web.config* file.

The following *web.config* file is published for a framework-dependent deployment and configures the ASP.NET Core Module to handle site requests:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <location path="." inheritInChildApplications="false">
    <system.webServer>
      <handlers>
        <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModuleV2" resourceType="Unspecified" />
      </handlers>
      <aspNetCore processPath="dotnet"
                  arguments=".\MyApp.dll"
                  stdoutLogEnabled="false"
                  stdoutLogFile=".\logs\stdout"
                  hostingModel="inprocess" />
    </system.webServer>
  </location>
</configuration>
```

The following *web.config* is published for a self-contained deployment:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <location path="." inheritInChildApplications="false">
    <system.webServer>
      <handlers>
        <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModuleV2" resourceType="Unspecified" />
      </handlers>
      <aspNetCore processPath=".\MyApp.exe"
                  stdoutLogEnabled="false"
                  stdoutLogFile=".\logs\stdout"
                  hostingModel="inprocess" />
    </system.webServer>
  </location>
</configuration>
```

The InheritInChildApplications property is set to `false` to indicate that the settings specified within the <location> element aren't inherited by apps that reside in a subdirectory of the app.

When an app is deployed to Azure App Service, the `stdoutLogFile` path is set to `\\?\%home%\LogFiles\stdout`. The path saves stdout logs to the *LogFiles* folder, which is a location automatically created by the service.

For information on IIS sub-application configuration, see Host ASP.NET Core on Windows with IIS.

Attributes of the aspNetCore element

ATTRIBUTE	DESCRIPTION	DEFAULT
`arguments`	Optional string attribute. Arguments to the executable specified in **processPath**.	

ATTRIBUTE	DESCRIPTION	DEFAULT
`disableStartUpErrorPage`	Optional Boolean attribute. If true, the **502.5 - Process Failure** page is suppressed, and the 502 status code page configured in the *web.config* takes precedence.	`false`
`forwardWindowsAuthToken`	Optional Boolean attribute. If true, the token is forwarded to the child process listening on %ASPNETCORE_PORT% as a header 'MS-ASPNETCORE-WINAUTHTOKEN' per request. It's the responsibility of that process to call CloseHandle on this token per request.	`true`
`hostingModel`	Optional string attribute. Specifies the hosting model as in-process (`InProcess` / `inprocess`) or out-of-process (`OutOfProcess` / `outofprocess`).	`InProcess` `inprocess`
`processesPerApplication`	Optional integer attribute. Specifies the number of instances of the process specified in the **processPath** setting that can be spun up per app. †For in-process hosting, the value is limited to `1` . Setting `processesPerApplication` is discouraged. This attribute will be removed in a future release.	Default: `1` Min: `1` Max: `100` †
`processPath`	Required string attribute. Path to the executable that launches a process listening for HTTP requests. Relative paths are supported. If the path begins with `.` , the path is considered to be relative to the site root.	

ATTRIBUTE	DESCRIPTION	DEFAULT
`rapidFailsPerMinute`	Optional integer attribute. Specifies the number of times the process specified in **processPath** is allowed to crash per minute. If this limit is exceeded, the module stops launching the process for the remainder of the minute. Not supported with in-process hosting.	Default: `10` Min: `0` Max: `100`
`requestTimeout`	Optional timespan attribute. Specifies the duration for which the ASP.NET Core Module waits for a response from the process listening on %ASPNETCORE_PORT%. In versions of the ASP.NET Core Module that shipped with the release of ASP.NET Core 2.1 or later, the `requestTimeout` is specified in hours, minutes, and seconds. Doesn't apply to in-process hosting. For in-process hosting, the module waits for the app to process the request. Valid values for minutes and seconds segments of the string are in the range 0-59. Use of **60** in the value for minutes or seconds results in a *500 - Internal Server Error*.	Default: `00:02:00` Min: `00:00:00` Max: `360:00:00`
`shutdownTimeLimit`	Optional integer attribute. Duration in seconds that the module waits for the executable to gracefully shutdown when the *app_offline.htm* file is detected.	Default: `10` Min: `0` Max: `600`

ATTRIBUTE	DESCRIPTION	DEFAULT
`startupTimeLimit`	Optional integer attribute. Duration in seconds that the module waits for the executable to start a process listening on the port. If this time limit is exceeded, the module kills the process. When hosting *in-process*: The process is **not** restarted and does **not** use the **rapidFailsPerMinute** setting. When hosting *out-of-process*: The module attempts to relaunch the process when it receives a new request and continues to attempt to restart the process on subsequent incoming requests unless the app fails to start **rapidFailsPerMinute** number of times in the last rolling minute. A value of 0 (zero) is **not** considered an infinite timeout.	Default: `120` Min: `0` Max: `3600`
`stdoutLogEnabled`	Optional Boolean attribute. If true, **stdout** and **stderr** for the process specified in **processPath** are redirected to the file specified in **stdoutLogFile**.	`false`
`stdoutLogFile`	Optional string attribute. Specifies the relative or absolute file path for which **stdout** and **stderr** from the process specified in **processPath** are logged. Relative paths are relative to the root of the site. Any path starting with `.` are relative to the site root and all other paths are treated as absolute paths. Any folders provided in the path are created by the module when the log file is created. Using underscore delimiters, a timestamp, process ID, and file extension (*.log*) are added to the last segment of the **stdoutLogFile** path. If `.\logs\stdout` is supplied as a value, an example stdout log is saved as *stdout_20180205194132_1934.log* in the *logs* folder when saved on 2/5/2018 at 19:41:32 with a process ID of 1934.	`aspnetcore-stdout`

Set environment variables

Environment variables can be specified for the process in the `processPath` attribute. Specify an environment

variable with the `<environmentVariable>` child element of an `<environmentVariables>` collection element. Environment variables set in this section take precedence over system environment variables.

The following example sets two environment variables in *web.config*. `ASPNETCORE_ENVIRONMENT` configures the app's environment to `Development`. A developer may temporarily set this value in the *web.config* file in order to force the Developer Exception Page to load when debugging an app exception. `CONFIG_DIR` is an example of a user-defined environment variable, where the developer has written code that reads the value on startup to form a path for loading the app's configuration file.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout"
      hostingModel="inprocess">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
    <environmentVariable name="CONFIG_DIR" value="f:\application_config" />
  </environmentVariables>
</aspNetCore>
```

NOTE

An alternative to setting the environment directly in *web.config* is to include the `<EnvironmentName>` property in the publish profile (.pubxml) or project file. This approach sets the environment in *web.config* when the project is published:

```
<PropertyGroup>
  <EnvironmentName>Development</EnvironmentName>
</PropertyGroup>
```

WARNING

Only set the `ASPNETCORE_ENVIRONMENT` environment variable to `Development` on staging and testing servers that aren't accessible to untrusted networks, such as the Internet.

app_offline.htm

If a file with the name *app_offline.htm* is detected in the root directory of an app, the ASP.NET Core Module attempts to gracefully shutdown the app and stop processing incoming requests. If the app is still running after the number of seconds defined in `shutdownTimeLimit`, the ASP.NET Core Module kills the running process.

While the *app_offline.htm* file is present, the ASP.NET Core Module responds to requests by sending back the contents of the *app_offline.htm* file. When the *app_offline.htm* file is removed, the next request starts the app.

When using the out-of-process hosting model, the app might not shut down immediately if there's an open connection. For example, a websocket connection may delay app shut down.

Start-up error page

Both in-process and out-of-process hosting produce custom error pages when they fail to start the app.

If the ASP.NET Core Module fails to find either the in-process or out-of-process request handler, a *500.0 - In-Process/Out-Of-Process Handler Load Failure* status code page appears.

For in-process hosting if the ASP.NET Core Module fails to start the app, a *500.30 - Start Failure* status code page appears.

For out-of-process hosting if the ASP.NET Core Module fails to launch the backend process or the backend process starts but fails to listen on the configured port, a *502.5 - Process Failure* status code page appears.

To suppress this page and revert to the default IIS 5xx status code page, use the `disableStartUpErrorPage` attribute. For more information on configuring custom error messages, see HTTP Errors <httpErrors>.

Log creation and redirection

The ASP.NET Core Module redirects stdout and stderr console output to disk if the `stdoutLogEnabled` and `stdoutLogFile` attributes of the `aspNetCore` element are set. Any folders in the `stdoutLogFile` path are created by the module when the log file is created. The app pool must have write access to the location where the logs are written (use `IIS AppPool\<app_pool_name>` to provide write permission).

Logs aren't rotated, unless process recycling/restart occurs. It's the responsibility of the hoster to limit the disk space the logs consume.

Using the stdout log is only recommended for troubleshooting app startup issues when hosting on IIS or when using development-time support for IIS with Visual Studio, not while debugging locally and running the app with IIS Express.

Don't use the stdout log for general app logging purposes. For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

A timestamp and file extension are added automatically when the log file is created. The log file name is composed by appending the timestamp, process ID, and file extension (*.log*) to the last segment of the `stdoutLogFile` path (typically *stdout*) delimited by underscores. If the `stdoutLogFile` path ends with *stdout*, a log for an app with a PID of 1934 created on 2/5/2018 at 19:42:32 has the file name *stdout_20180205194132_1934.log*.

If `stdoutLogEnabled` is false, errors that occur on app startup are captured and emitted to the event log up to 30 KB. After startup, all additional logs are discarded.

The following sample `aspNetCore` element configures stdout logging at the relative path `.\log\`. Confirm that the AppPool user identity has permission to write to the path provided.

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="true"
    stdoutLogFile=".\logs\stdout"
    hostingModel="inprocess">
</aspNetCore>
```

When publishing an app for Azure App Service deployment, the Web SDK sets the `stdoutLogFile` value to `\\?\%home%\LogFiles\stdout`. The `%home` environment variable is predefined for apps hosted by Azure App Service.

To create logging filter rules, see the Configuration and Log filtering sections of the ASP.NET Core logging documentation.

For more information on path formats, see File path formats on Windows systems.

Enhanced diagnostic logs

The ASP.NET Core Module is configurable to provide enhanced diagnostics logs. Add the `<handlerSettings>` element to the `<aspNetCore>` element in *web.config*. Setting the `debugLevel` to `TRACE` exposes a higher fidelity of diagnostic information:

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="false"
    stdoutLogFile="\\?\%home%\LogFiles\stdout"
    hostingModel="inprocess">
  <handlerSettings>
    <handlerSetting name="debugFile" value=".\logs\aspnetcore-debug.log" />
    <handlerSetting name="debugLevel" value="FILE,TRACE" />
  </handlerSettings>
</aspNetCore>
```

Any folders in the path (*logs* in the preceding example) are created by the module when the log file is created. The app pool must have write access to the location where the logs are written (use `IIS AppPool\<app_pool_name>` to provide write permission).

Debug level (`debugLevel`) values can include both the level and the location.

Levels (in order from least to most verbose):

- ERROR
- WARNING
- INFO
- TRACE

Locations (multiple locations are permitted):

- CONSOLE
- EVENTLOG
- FILE

The handler settings can also be provided via environment variables:

- `ASPNETCORE_MODULE_DEBUG_FILE`: Path to the debug log file. (Default: *aspnetcore-debug.log*)
- `ASPNETCORE_MODULE_DEBUG`: Debug level setting.

> **WARNING**
> Do **not** leave debug logging enabled in the deployment for longer than required to troubleshoot an issue. The size of the log isn't limited. Leaving the debug log enabled can exhaust the available disk space and crash the server or app service.

See Configuration with web.config for an example of the `aspNetCore` element in the *web.config* file.

Modify the stack size

Only applies when using the in-process hosting model.

Configure the managed stack size using the `stackSize` setting in bytes in *web.config*. The default size is `1048576` bytes (1 MB).

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="false"
    stdoutLogFile="\\?\%home%\LogFiles\stdout"
    hostingModel="inprocess">
  <handlerSettings>
    <handlerSetting name="stackSize" value="2097152" />
  </handlerSettings>
</aspNetCore>
```

Proxy configuration uses HTTP protocol and a pairing token

Only applies to out-of-process hosting.

The proxy created between the ASP.NET Core Module and Kestrel uses the HTTP protocol. There's no risk of eavesdropping the traffic between the module and Kestrel from a location off of the server.

A pairing token is used to guarantee that the requests received by Kestrel were proxied by IIS and didn't come from some other source. The pairing token is created and set into an environment variable (`ASPNETCORE_TOKEN`) by the module. The pairing token is also set into a header (`MS-ASPNETCORE-TOKEN`) on every proxied request. IIS Middleware checks each request it receives to confirm that the pairing token header value matches the environment variable value. If the token values are mismatched, the request is logged and rejected. The pairing token environment variable and the traffic between the module and Kestrel aren't accessible from a location off of the server. Without knowing the pairing token value, an attacker can't submit requests that bypass the check in the IIS Middleware.

ASP.NET Core Module with an IIS Shared Configuration

The ASP.NET Core Module installer runs with the privileges of the **TrustedInstaller** account. Because the local system account doesn't have modify permission for the share path used by the IIS Shared Configuration, the installer throws an access denied error when attempting to configure the module settings in the *applicationHost.config* file on the share.

When using an IIS Shared Configuration on the same machine as the IIS installation, run the ASP.NET Core Hosting Bundle installer with the `OPT_NO_SHARED_CONFIG_CHECK` parameter set to `1`:

```
dotnet-hosting-{VERSION}.exe OPT_NO_SHARED_CONFIG_CHECK=1
```

When the path to the shared configuration isn't on the same machine as the IIS installation, follow these steps:

1. Disable the IIS Shared Configuration.
2. Run the installer.
3. Export the updated *applicationHost.config* file to the share.
4. Re-enable the IIS Shared Configuration.

Module version and Hosting Bundle installer logs

To determine the version of the installed ASP.NET Core Module:

1. On the hosting system, navigate to *%windir%\System32\inetsrv*.
2. Locate the *aspnetcore.dll* file.
3. Right-click the file and select **Properties** from the contextual menu.
4. Select the **Details** tab. The **File version** and **Product version** represent the installed version of the module.

The Hosting Bundle installer logs for the module are found at *C:\Users\%UserName%\AppData\Local\Temp*. The file

is named *dd_DotNetCoreWinSvrHosting__ <timestamp>_000_AspNetCoreModule_x64.log*.

Module, schema, and configuration file locations

Module

IIS (x86/amd64):

- %windir%\System32\inetsrv\aspnetcore.dll
- %windir%\SysWOW64\inetsrv\aspnetcore.dll
- %ProgramFiles%\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll
- %ProgramFiles(x86)%\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll

IIS Express (x86/amd64):

- %ProgramFiles%\IIS Express\aspnetcore.dll
- %ProgramFiles(x86)%\IIS Express\aspnetcore.dll
- %ProgramFiles%\IIS Express\Asp.Net Core Module\V2\aspnetcorev2.dll
- %ProgramFiles(x86)%\IIS Express\Asp.Net Core Module\V2\aspnetcorev2.dll

Schema

IIS

- %windir%\System32\inetsrv\config\schema\aspnetcore_schema.xml
- %windir%\System32\inetsrv\config\schema\aspnetcore_schema_v2.xml

IIS Express

- %ProgramFiles%\IIS Express\config\schema\aspnetcore_schema.xml
- %ProgramFiles%\IIS Express\config\schema\aspnetcore_schema_v2.xml

Configuration

IIS

- %windir%\System32\inetsrv\config\applicationHost.config

IIS Express

- Visual Studio: {APPLICATION ROOT}\.vs\config\applicationHost.config
- *iisexpress.exe* CLI: %USERPROFILE%\Documents\IISExpress\config\applicationhost.config

The files can be found by searching for *aspnetcore* in the *applicationHost.config* file.

The ASP.NET Core Module is a native IIS module that plugs into the IIS pipeline to either:

- Host an ASP.NET Core app inside of the IIS worker process (`w3wp.exe`), called the in-process hosting model.
- Forward web requests to a backend ASP.NET Core app running the Kestrel server, called the out-of-process hosting model.

Supported Windows versions:

- Windows 7 or later
- Windows Server 2008 R2 or later

When hosting in-process, the module uses an in-process server implementation for IIS, called IIS HTTP Server (`IISHttpServer`).

When hosting out-of-process, the module only works with Kestrel. The module doesn't function with HTTP.sys.

Hosting models

In-process hosting model

To configure an app for in-process hosting, add the `<AspNetCoreHostingModel>` property to the app's project file with a value of `InProcess` (out-of-process hosting is set with `OutOfProcess`):

```
<PropertyGroup>
  <AspNetCoreHostingModel>InProcess</AspNetCoreHostingModel>
</PropertyGroup>
```

The in-process hosting model isn't supported for ASP.NET Core apps that target the .NET Framework.

The value of `<AspNetCoreHostingModel>` is case insensitive, so `inprocess` and `outofprocess` are valid values.

If the `<AspNetCoreHostingModel>` property isn't present in the file, the default value is `OutOfProcess` .

The following characteristics apply when hosting in-process:

- IIS HTTP Server (`IISHttpServer`) is used instead of Kestrel server. For in-process, CreateDefaultBuilder calls UseIIS to:
  - Register the `IISHttpServer` .
  - Configure the port and base path the server should listen on when running behind the ASP.NET Core Module.
  - Configure the host to capture startup errors.
- The requestTimeout attribute doesn't apply to in-process hosting.
- Sharing an app pool among apps isn't supported. Use one app pool per app.
- When using Web Deploy or manually placing an app_offline.htm file in the deployment, the app might not shut down immediately if there's an open connection. For example, a websocket connection may delay app shut down.
- The architecture (bitness) of the app and installed runtime (x64 or x86) must match the architecture of the app pool.
- Client disconnects are detected. The HttpContext.RequestAborted cancellation token is cancelled when the client disconnects.
- In ASP.NET Core 2.2.1 or earlier, GetCurrentDirectory returns the worker directory of the process started by IIS rather than the app's directory (for example, *C:\Windows\System32\inetsrv* for *w3wp.exe*).

  For sample code that sets the app's current directory, see the CurrentDirectoryHelpers class. Call the `SetCurrentDirectory` method. Subsequent calls to GetCurrentDirectory provide the app's directory.
- When hosting in-process, AuthenticateAsync isn't called internally to initialize a user. Therefore, an IClaimsTransformation implementation used to transform claims after every authentication isn't activated by default. When transforming claims with an IClaimsTransformation implementation, call AddAuthentication to add authentication services:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddTransient<IClaimsTransformation, ClaimsTransformer>();
    services.AddAuthentication(IISServerDefaults.AuthenticationScheme);
}

public void Configure(IApplicationBuilder app)
{
    app.UseAuthentication();
}
```

Out-of-process hosting model

To configure an app for out-of-process hosting, use either of the following approaches in the project file:

- Don't specify the `<AspNetCoreHostingModel>` property. If the `<AspNetCoreHostingModel>` property isn't present in the file, the default value is `OutOfProcess`.
- Set the value of the `<AspNetCoreHostingModel>` property to `OutOfProcess` (in-process hosting is set with `InProcess`):

```
<PropertyGroup>
  <AspNetCoreHostingModel>OutOfProcess</AspNetCoreHostingModel>
</PropertyGroup>
```

The value is case insensitive, so `inprocess` and `outofprocess` are valid values.

Kestrel server is used instead of IIS HTTP Server (`IISHttpServer`).

For out-of-process, CreateDefaultBuilder calls UseIISIntegration to:

- Configure the port and base path the server should listen on when running behind the ASP.NET Core Module.
- Configure the host to capture startup errors.

Hosting model changes

If the `hostingModel` setting is changed in the *web.config* file (explained in the Configuration with web.config section), the module recycles the worker process for IIS.

For IIS Express, the module doesn't recycle the worker process but instead triggers a graceful shutdown of the current IIS Express process. The next request to the app spawns a new IIS Express process.

Process name

`Process.GetCurrentProcess().ProcessName` reports `w3wp` / `iisexpress` (in-process) or `dotnet` (out-of-process).

Many native modules, such as Windows Authentication, remain active. To learn more about IIS modules active with the ASP.NET Core Module, see IIS modules with ASP.NET Core.

The ASP.NET Core Module can also:

- Set environment variables for the worker process.
- Log stdout output to file storage for troubleshooting startup issues.
- Forward Windows authentication tokens.

How to install and use the ASP.NET Core Module

For instructions on how to install the ASP.NET Core Module, see Install the .NET Core Hosting Bundle.

Configuration with web.config

The ASP.NET Core Module is configured with the `aspNetCore` section of the `system.webServer` node in the site's *web.config* file.

The following *web.config* file is published for a framework-dependent deployment and configures the ASP.NET Core Module to handle site requests:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <location path="." inheritInChildApplications="false">
    <system.webServer>
      <handlers>
        <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModuleV2" resourceType="Unspecified" />
      </handlers>
      <aspNetCore processPath="dotnet"
                  arguments=".\MyApp.dll"
                  stdoutLogEnabled="false"
                  stdoutLogFile=".\logs\stdout"
                  hostingModel="inprocess" />
    </system.webServer>
  </location>
</configuration>
```

The following *web.config* is published for a self-contained deployment:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <location path="." inheritInChildApplications="false">
    <system.webServer>
      <handlers>
        <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModuleV2" resourceType="Unspecified" />
      </handlers>
      <aspNetCore processPath=".\MyApp.exe"
                  stdoutLogEnabled="false"
                  stdoutLogFile=".\logs\stdout"
                  hostingModel="inprocess" />
    </system.webServer>
  </location>
</configuration>
```

The InheritInChildApplications property is set to `false` to indicate that the settings specified within the <location> element aren't inherited by apps that reside in a subdirectory of the app.

When an app is deployed to Azure App Service, the `stdoutLogFile` path is set to `\\?\%home%\LogFiles\stdout`. The path saves stdout logs to the *LogFiles* folder, which is a location automatically created by the service.

For information on IIS sub-application configuration, see Host ASP.NET Core on Windows with IIS.

Attributes of the aspNetCore element

ATTRIBUTE	DESCRIPTION	DEFAULT
`arguments`	Optional string attribute. Arguments to the executable specified in **processPath**.	

ATTRIBUTE	DESCRIPTION	DEFAULT
`disableStartUpErrorPage`	Optional Boolean attribute. If true, the **502.5 - Process Failure** page is suppressed, and the 502 status code page configured in the *web.config* takes precedence.	`false`
`forwardWindowsAuthToken`	Optional Boolean attribute. If true, the token is forwarded to the child process listening on %ASPNETCORE_PORT% as a header 'MS-ASPNETCORE-WINAUTHTOKEN' per request. It's the responsibility of that process to call CloseHandle on this token per request.	`true`
`hostingModel`	Optional string attribute. Specifies the hosting model as in-process (`InProcess` / `inprocess`) or out-of-process (`OutOfProcess` / `outofprocess`).	`OutOfProcess` `outofprocess`
`processesPerApplication`	Optional integer attribute. Specifies the number of instances of the process specified in the **processPath** setting that can be spun up per app. †For in-process hosting, the value is limited to `1`. Setting `processesPerApplication` is discouraged. This attribute will be removed in a future release.	Default: `1` Min: `1` Max: `100` †
`processPath`	Required string attribute. Path to the executable that launches a process listening for HTTP requests. Relative paths are supported. If the path begins with `.`, the path is considered to be relative to the site root.	

ATTRIBUTE	DESCRIPTION	DEFAULT
`rapidFailsPerMinute`	Optional integer attribute. Specifies the number of times the process specified in **processPath** is allowed to crash per minute. If this limit is exceeded, the module stops launching the process for the remainder of the minute. Not supported with in-process hosting.	Default: `10` Min: `0` Max: `100`
`requestTimeout`	Optional timespan attribute. Specifies the duration for which the ASP.NET Core Module waits for a response from the process listening on %ASPNETCORE_PORT%. In versions of the ASP.NET Core Module that shipped with the release of ASP.NET Core 2.1 or later, the `requestTimeout` is specified in hours, minutes, and seconds. Doesn't apply to in-process hosting. For in-process hosting, the module waits for the app to process the request. Valid values for minutes and seconds segments of the string are in the range 0-59. Use of **60** in the value for minutes or seconds results in a *500 - Internal Server Error*.	Default: `00:02:00` Min: `00:00:00` Max: `360:00:00`
`shutdownTimeLimit`	Optional integer attribute. Duration in seconds that the module waits for the executable to gracefully shutdown when the *app_offline.htm* file is detected.	Default: `10` Min: `0` Max: `600`

ATTRIBUTE	DESCRIPTION	DEFAULT
`startupTimeLimit`	Optional integer attribute. Duration in seconds that the module waits for the executable to start a process listening on the port. If this time limit is exceeded, the module kills the process. When hosting *in-process*: The process is **not** restarted and does **not** use the **rapidFailsPerMinute** setting. When hosting *out-of-process*: The module attempts to relaunch the process when it receives a new request and continues to attempt to restart the process on subsequent incoming requests unless the app fails to start **rapidFailsPerMinute** number of times in the last rolling minute. A value of 0 (zero) is **not** considered an infinite timeout.	Default: `120` Min: `0` Max: `3600`
`stdoutLogEnabled`	Optional Boolean attribute. If true, **stdout** and **stderr** for the process specified in **processPath** are redirected to the file specified in **stdoutLogFile**.	`false`
`stdoutLogFile`	Optional string attribute. Specifies the relative or absolute file path for which **stdout** and **stderr** from the process specified in **processPath** are logged. Relative paths are relative to the root of the site. Any path starting with `.` are relative to the site root and all other paths are treated as absolute paths. Any folders provided in the path are created by the module when the log file is created. Using underscore delimiters, a timestamp, process ID, and file extension (*.log*) are added to the last segment of the **stdoutLogFile** path. If `.\logs\stdout` is supplied as a value, an example stdout log is saved as *stdout_20180205194132_1934.log* in the *logs* folder when saved on 2/5/2018 at 19:41:32 with a process ID of 1934.	`aspnetcore-stdout`

Setting environment variables

Environment variables can be specified for the process in the `processPath` attribute. Specify an environment variable with the `<environmentVariable>` child element of an `<environmentVariables>` collection element. Environment variables set in this section take precedence over system environment variables.

The following example sets two environment variables. `ASPNETCORE_ENVIRONMENT` configures the app's environment to `Development`. A developer may temporarily set this value in the *web.config* file in order to force the Developer Exception Page to load when debugging an app exception. `CONFIG_DIR` is an example of a user-defined environment variable, where the developer has written code that reads the value on startup to form a path for loading the app's configuration file.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout"
      hostingModel="inprocess">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
    <environmentVariable name="CONFIG_DIR" value="f:\application_config" />
  </environmentVariables>
</aspNetCore>
```

NOTE

An alternative to setting the environment directly in *web.config* is to include the `<EnvironmentName>` property in the publish profile (.pubxml) or project file. This approach sets the environment in *web.config* when the project is published:

```
<PropertyGroup>
  <EnvironmentName>Development</EnvironmentName>
</PropertyGroup>
```

WARNING

Only set the `ASPNETCORE_ENVIRONMENT` environment variable to `Development` on staging and testing servers that aren't accessible to untrusted networks, such as the Internet.

app_offline.htm

If a file with the name *app_offline.htm* is detected in the root directory of an app, the ASP.NET Core Module attempts to gracefully shutdown the app and stop processing incoming requests. If the app is still running after the number of seconds defined in `shutdownTimeLimit`, the ASP.NET Core Module kills the running process.

While the *app_offline.htm* file is present, the ASP.NET Core Module responds to requests by sending back the contents of the *app_offline.htm* file. When the *app_offline.htm* file is removed, the next request starts the app.

When using the out-of-process hosting model, the app might not shut down immediately if there's an open connection. For example, a websocket connection may delay app shut down.

Start-up error page

Both in-process and out-of-process hosting produce custom error pages when they fail to start the app.

If the ASP.NET Core Module fails to find either the in-process or out-of-process request handler, a *500.0 - In-Process/Out-Of-Process Handler Load Failure* status code page appears.

For in-process hosting if the ASP.NET Core Module fails to start the app, a *500.30 - Start Failure* status code page

appears.

For out-of-process hosting if the ASP.NET Core Module fails to launch the backend process or the backend process starts but fails to listen on the configured port, a *502.5 - Process Failure* status code page appears.

To suppress this page and revert to the default IIS 5xx status code page, use the `disableStartUpErrorPage` attribute. For more information on configuring custom error messages, see HTTP Errors <httpErrors>.

Log creation and redirection

The ASP.NET Core Module redirects stdout and stderr console output to disk if the `stdoutLogEnabled` and `stdoutLogFile` attributes of the `aspNetCore` element are set. Any folders in the `stdoutLogFile` path are created by the module when the log file is created. The app pool must have write access to the location where the logs are written (use `IIS AppPool\<app_pool_name>` to provide write permission).

Logs aren't rotated, unless process recycling/restart occurs. It's the responsibility of the hoster to limit the disk space the logs consume.

Using the stdout log is only recommended for troubleshooting app startup issues when hosting on IIS or when using development-time support for IIS with Visual Studio, not while debugging locally and running the app with IIS Express.

Don't use the stdout log for general app logging purposes. For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

A timestamp and file extension are added automatically when the log file is created. The log file name is composed by appending the timestamp, process ID, and file extension (*.log*) to the last segment of the `stdoutLogFile` path (typically *stdout*) delimited by underscores. If the `stdoutLogFile` path ends with *stdout*, a log for an app with a PID of 1934 created on 2/5/2018 at 19:42:32 has the file name *stdout_20180205194132_1934.log*.

If `stdoutLogEnabled` is false, errors that occur on app startup are captured and emitted to the event log up to 30 KB. After startup, all additional logs are discarded.

The following sample `aspNetCore` element configures stdout logging at the relative path `.\log\`. Confirm that the AppPool user identity has permission to write to the path provided.

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="true"
    stdoutLogFile=".\logs\stdout"
    hostingModel="inprocess">
</aspNetCore>
```

When publishing an app for Azure App Service deployment, the Web SDK sets the `stdoutLogFile` value to `\\?\%home%\LogFiles\stdout`. The `%home` environment variable is predefined for apps hosted by Azure App Service.

For more information on path formats, see File path formats on Windows systems.

Enhanced diagnostic logs

The ASP.NET Core Module is configurable to provide enhanced diagnostics logs. Add the `<handlerSettings>` element to the `<aspNetCore>` element in *web.config*. Setting the `debugLevel` to `TRACE` exposes a higher fidelity of diagnostic information:

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="false"
    stdoutLogFile="\\?\%home%\LogFiles\stdout"
    hostingModel="inprocess">
  <handlerSettings>
    <handlerSetting name="debugFile" value=".\logs\aspnetcore-debug.log" />
    <handlerSetting name="debugLevel" value="FILE,TRACE" />
  </handlerSettings>
</aspNetCore>
```

Folders in the path provided to the `<handlerSetting>` value (*logs* in the preceding example) aren't created by the module automatically and should pre-exist in the deployment. The app pool must have write access to the location where the logs are written (use `IIS AppPool\<app_pool_name>` to provide write permission).

Debug level (`debugLevel`) values can include both the level and the location.

Levels (in order from least to most verbose):

- ERROR
- WARNING
- INFO
- TRACE

Locations (multiple locations are permitted):

- CONSOLE
- EVENTLOG
- FILE

The handler settings can also be provided via environment variables:

- `ASPNETCORE_MODULE_DEBUG_FILE`: Path to the debug log file. (Default: *aspnetcore-debug.log*)
- `ASPNETCORE_MODULE_DEBUG`: Debug level setting.

> **WARNING**
> Do **not** leave debug logging enabled in the deployment for longer than required to troubleshoot an issue. The size of the log isn't limited. Leaving the debug log enabled can exhaust the available disk space and crash the server or app service.

See Configuration with web.config for an example of the `aspNetCore` element in the *web.config* file.

Proxy configuration uses HTTP protocol and a pairing token

Only applies to out-of-process hosting.

The proxy created between the ASP.NET Core Module and Kestrel uses the HTTP protocol. There's no risk of eavesdropping the traffic between the module and Kestrel from a location off of the server.

A pairing token is used to guarantee that the requests received by Kestrel were proxied by IIS and didn't come from some other source. The pairing token is created and set into an environment variable (`ASPNETCORE_TOKEN`) by the module. The pairing token is also set into a header (`MS-ASPNETCORE-TOKEN`) on every proxied request. IIS Middleware checks each request it receives to confirm that the pairing token header value matches the environment variable value. If the token values are mismatched, the request is logged and rejected. The pairing token environment variable and the traffic between the module and Kestrel aren't accessible from a location off of the server. Without knowing the pairing token value, an attacker can't submit requests that bypass the check in the IIS Middleware.

ASP.NET Core Module with an IIS Shared Configuration

The ASP.NET Core Module installer runs with the privileges of the **TrustedInstaller** account. Because the local system account doesn't have modify permission for the share path used by the IIS Shared Configuration, the installer throws an access denied error when attempting to configure the module settings in the *applicationHost.config* file on the share.

When using an IIS Shared Configuration on the same machine as the IIS installation, run the ASP.NET Core Hosting Bundle installer with the `OPT_NO_SHARED_CONFIG_CHECK` parameter set to `1`:

```
dotnet-hosting-{VERSION}.exe OPT_NO_SHARED_CONFIG_CHECK=1
```

When the path to the shared configuration isn't on the same machine as the IIS installation, follow these steps:

1. Disable the IIS Shared Configuration.
2. Run the installer.
3. Export the updated *applicationHost.config* file to the share.
4. Re-enable the IIS Shared Configuration.

Module version and Hosting Bundle installer logs

To determine the version of the installed ASP.NET Core Module:

1. On the hosting system, navigate to *%windir%\System32\inetsrv*.
2. Locate the *aspnetcore.dll* file.
3. Right-click the file and select **Properties** from the contextual menu.
4. Select the **Details** tab. The **File version** and **Product version** represent the installed version of the module.

The Hosting Bundle installer logs for the module are found at *C:\Users\%UserName%\AppData\Local\Temp*. The file is named *dd_DotNetCoreWinSvrHosting__<timestamp>_000_AspNetCoreModule_x64.log*.

Module, schema, and configuration file locations

Module

IIS (x86/amd64):

- %windir%\System32\inetsrv\aspnetcore.dll
- %windir%\SysWOW64\inetsrv\aspnetcore.dll
- %ProgramFiles%\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll
- %ProgramFiles(x86)%\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll

IIS Express (x86/amd64):

- %ProgramFiles%\IIS Express\aspnetcore.dll
- %ProgramFiles(x86)%\IIS Express\aspnetcore.dll
- %ProgramFiles%\IIS Express\Asp.Net Core Module\V2\aspnetcorev2.dll
- %ProgramFiles(x86)%\IIS Express\Asp.Net Core Module\V2\aspnetcorev2.dll

Schema

IIS

- %windir%\System32\inetsrv\config\schema\aspnetcore_schema.xml
- %windir%\System32\inetsrv\config\schema\aspnetcore_schema_v2.xml

IIS Express

- %ProgramFiles%\IIS Express\config\schema\aspnetcore_schema.xml
- %ProgramFiles%\IIS Express\config\schema\aspnetcore_schema_v2.xml

Configuration

IIS

- %windir%\System32\inetsrv\config\applicationHost.config

IIS Express

- Visual Studio: {APPLICATION ROOT}\.vs\config\applicationHost.config
- *iisexpress.exe* CLI: %USERPROFILE%\Documents\IISExpress\config\applicationhost.config

The files can be found by searching for *aspnetcore* in the *applicationHost.config* file.

The ASP.NET Core Module is a native IIS module that plugs into the IIS pipeline to forward web requests to backend ASP.NET Core apps.

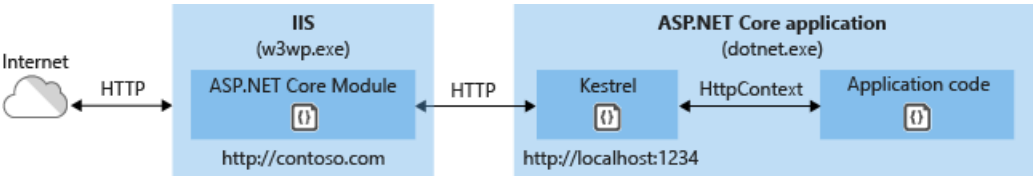
Supported Windows versions:

- Windows 7 or later
- Windows Server 2008 R2 or later

The module only works with Kestrel. The module is incompatible with HTTP.sys.

Because ASP.NET Core apps run in a process separate from the IIS worker process, the module also handles process management. The module starts the process for the ASP.NET Core app when the first request arrives and restarts the app if it crashes. This is essentially the same behavior as seen with ASP.NET 4.x apps that run in-process in IIS that are managed by the Windows Process Activation Service (WAS).

The following diagram illustrates the relationship between IIS, the ASP.NET Core Module, and an app:



Requests arrive from the web to the kernel-mode HTTP.sys driver. The driver routes the requests to IIS on the website's configured port, usually 80 (HTTP) or 443 (HTTPS). The module forwards the requests to Kestrel on a random port for the app, which isn't port 80 or 443.

The module specifies the port via an environment variable at startup, and the IIS Integration Middleware configures the server to listen on `http://localhost:{port}`. Additional checks are performed, and requests that don't originate from the module are rejected. The module doesn't support HTTPS forwarding, so requests are forwarded over HTTP even if received by IIS over HTTPS.

After Kestrel picks up the request from the module, the request is pushed into the ASP.NET Core middleware pipeline. The middleware pipeline handles the request and passes it on as an `HttpContext` instance to the app's logic. Middleware added by IIS Integration updates the scheme, remote IP, and pathbase to account for forwarding the request to Kestrel. The app's response is passed back to IIS, which pushes it back out to the HTTP client that initiated the request.

Many native modules, such as Windows Authentication, remain active. To learn more about IIS modules active with the ASP.NET Core Module, see IIS modules with ASP.NET Core.

The ASP.NET Core Module can also:

- Set environment variables for the worker process.
- Log stdout output to file storage for troubleshooting startup issues.
- Forward Windows authentication tokens.

How to install and use the ASP.NET Core Module

For instructions on how to install the ASP.NET Core Module, see Install the .NET Core Hosting Bundle.

Configuration with web.config

The ASP.NET Core Module is configured with the `aspNetCore` section of the `system.webServer` node in the site's *web.config* file.

The following *web.config* file is published for a framework-dependent deployment and configures the ASP.NET Core Module to handle site requests:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <system.webServer>
    <handlers>
      <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModule" resourceType="Unspecified" />
    </handlers>
    <aspNetCore processPath="dotnet"
                arguments=".\MyApp.dll"
                stdoutLogEnabled="false"
                stdoutLogFile=".\logs\stdout" />
  </system.webServer>
</configuration>
```

The following *web.config* is published for a self-contained deployment:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <system.webServer>
    <handlers>
      <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModule" resourceType="Unspecified" />
    </handlers>
    <aspNetCore processPath=".\MyApp.exe"
                stdoutLogEnabled="false"
                stdoutLogFile=".\logs\stdout" />
  </system.webServer>
</configuration>
```

When an app is deployed to Azure App Service, the `stdoutLogFile` path is set to `\\?\%home%\LogFiles\stdout`. The path saves stdout logs to the *LogFiles* folder, which is a location automatically created by the service.

For information on IIS sub-application configuration, see Host ASP.NET Core on Windows with IIS.

Attributes of the aspNetCore element

ATTRIBUTE	DESCRIPTION	DEFAULT

ATTRIBUTE	DESCRIPTION	DEFAULT
`arguments`	Optional string attribute. Arguments to the executable specified in **processPath**.	
`disableStartUpErrorPage`	Optional Boolean attribute. If true, the **502.5 - Process Failure** page is suppressed, and the 502 status code page configured in the *web.config* takes precedence.	`false`
`forwardWindowsAuthToken`	Optional Boolean attribute. If true, the token is forwarded to the child process listening on %ASPNETCORE_PORT% as a header 'MS-ASPNETCORE-WINAUTHTOKEN' per request. It's the responsibility of that process to call CloseHandle on this token per request.	`true`
`processesPerApplication`	Optional integer attribute. Specifies the number of instances of the process specified in the **processPath** setting that can be spun up per app. Setting `processesPerApplication` is discouraged. This attribute will be removed in a future release.	Default: `1` Min: `1` Max: `100`
`processPath`	Required string attribute. Path to the executable that launches a process listening for HTTP requests. Relative paths are supported. If the path begins with `.`, the path is considered to be relative to the site root.	
`rapidFailsPerMinute`	Optional integer attribute. Specifies the number of times the process specified in **processPath** is allowed to crash per minute. If this limit is exceeded, the module stops launching the process for the remainder of the minute.	Default: `10` Min: `0` Max: `100`

ATTRIBUTE	DESCRIPTION	DEFAULT
`requestTimeout`	Optional timespan attribute. Specifies the duration for which the ASP.NET Core Module waits for a response from the process listening on %ASPNETCORE_PORT%. In versions of the ASP.NET Core Module that shipped with the release of ASP.NET Core 2.1 or later, the `requestTimeout` is specified in hours, minutes, and seconds.	Default: `00:02:00` Min: `00:00:00` Max: `360:00:00`
`shutdownTimeLimit`	Optional integer attribute. Duration in seconds that the module waits for the executable to gracefully shutdown when the *app_offline.htm* file is detected.	Default: `10` Min: `0` Max: `600`
`startupTimeLimit`	Optional integer attribute. Duration in seconds that the module waits for the executable to start a process listening on the port. If this time limit is exceeded, the module kills the process. The module attempts to relaunch the process when it receives a new request and continues to attempt to restart the process on subsequent incoming requests unless the app fails to start **rapidFailsPerMinute** number of times in the last rolling minute. A value of 0 (zero) is **not** considered an infinite timeout.	Default: `120` Min: `0` Max: `3600`
`stdoutLogEnabled`	Optional Boolean attribute. If true, **stdout** and **stderr** for the process specified in **processPath** are redirected to the file specified in **stdoutLogFile**.	`false`

ATTRIBUTE	DESCRIPTION	DEFAULT
`stdoutLogFile`	Optional string attribute. Specifies the relative or absolute file path for which **stdout** and **stderr** from the process specified in **processPath** are logged. Relative paths are relative to the root of the site. Any path starting with `.` are relative to the site root and all other paths are treated as absolute paths. Any folders provided in the path must exist in order for the module to create the log file. Using underscore delimiters, a timestamp, process ID, and file extension (*.log*) are added to the last segment of the **stdoutLogFile** path. If `.\logs\stdout` is supplied as a value, an example stdout log is saved as *stdout_20180205194132_1934.log* in the *logs* folder when saved on 2/5/2018 at 19:41:32 with a process ID of 1934.	`aspnetcore-stdout`

Setting environment variables

Environment variables can be specified for the process in the `processPath` attribute. Specify an environment variable with the `<environmentVariable>` child element of an `<environmentVariables>` collection element.

> **WARNING**
>
> Environment variables set in this section conflict with system environment variables set with the same name. If an environment variable is set in both the *web.config* file and at the system level in Windows, the value from the *web.config* file becomes appended to the system environment variable value (for example, `ASPNETCORE_ENVIRONMENT: Development;Development`), which prevents the app from starting.

The following example sets two environment variables. `ASPNETCORE_ENVIRONMENT` configures the app's environment to `Development`. A developer may temporarily set this value in the *web.config* file in order to force the Developer Exception Page to load when debugging an app exception. `CONFIG_DIR` is an example of a user-defined environment variable, where the developer has written code that reads the value on startup to form a path for loading the app's configuration file.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile="\\?\%home%\LogFiles\stdout">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
    <environmentVariable name="CONFIG_DIR" value="f:\application_config" />
  </environmentVariables>
</aspNetCore>
```

WARNING

Only set the `ASPNETCORE_ENVIRONMENT` environment variable to `Development` on staging and testing servers that aren't accessible to untrusted networks, such as the Internet.

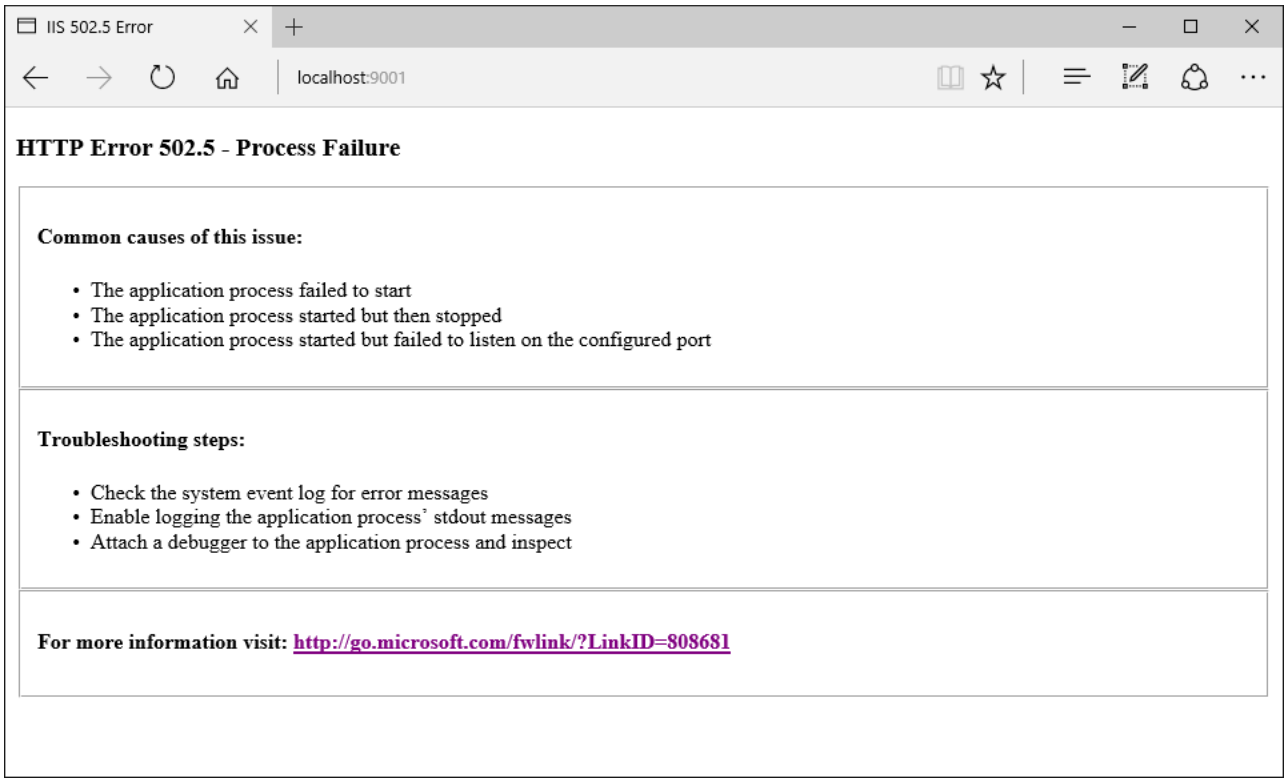
app_offline.htm

If a file with the name *app_offline.htm* is detected in the root directory of an app, the ASP.NET Core Module attempts to gracefully shutdown the app and stop processing incoming requests. If the app is still running after the number of seconds defined in `shutdownTimeLimit`, the ASP.NET Core Module kills the running process.

While the *app_offline.htm* file is present, the ASP.NET Core Module responds to requests by sending back the contents of the *app_offline.htm* file. When the *app_offline.htm* file is removed, the next request starts the app.

Start-up error page

If the ASP.NET Core Module fails to launch the backend process or the backend process starts but fails to listen on the configured port, a *502.5 - Process Failure* status code page appears. To suppress this page and revert to the default IIS 502 status code page, use the `disableStartUpErrorPage` attribute. For more information on configuring custom error messages, see HTTP Errors <httpErrors>.



Log creation and redirection

The ASP.NET Core Module redirects stdout and stderr console output to disk if the `stdoutLogEnabled` and `stdoutLogFile` attributes of the `aspNetCore` element are set. Any folders in the `stdoutLogFile` path are created by the module when the log file is created. The app pool must have write access to the location where the logs are written (use `IIS AppPool\<app_pool_name>` to provide write permission).

Logs aren't rotated, unless process recycling/restart occurs. It's the responsibility of the hoster to limit the disk space the logs consume.

Using the stdout log is only recommended for troubleshooting app startup issues when hosting on IIS or when using development-time support for IIS with Visual Studio, not while debugging locally and running the app with IIS

Express.

Don't use the stdout log for general app logging purposes. For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

A timestamp and file extension are added automatically when the log file is created. The log file name is composed by appending the timestamp, process ID, and file extension (*.log*) to the last segment of the `stdoutLogFile` path (typically *stdout*) delimited by underscores. If the `stdoutLogFile` path ends with *stdout*, a log for an app with a PID of 1934 created on 2/5/2018 at 19:42:32 has the file name *stdout_20180205194132_1934.log*.

The following sample `aspNetCore` element configures stdout logging at the relative path `.\log\`. Confirm that the AppPool user identity has permission to write to the path provided.

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="true"
    stdoutLogFile=".\logs\stdout">
</aspNetCore>
```

When publishing an app for Azure App Service deployment, the Web SDK sets the `stdoutLogFile` value to `\\?\%home%\LogFiles\stdout`. The `%home` environment variable is predefined for apps hosted by Azure App Service.

To create logging filter rules, see the Configuration and Log filtering sections of the ASP.NET Core logging documentation.

For more information on path formats, see File path formats on Windows systems.

Proxy configuration uses HTTP protocol and a pairing token

The proxy created between the ASP.NET Core Module and Kestrel uses the HTTP protocol. There's no risk of eavesdropping the traffic between the module and Kestrel from a location off of the server.

A pairing token is used to guarantee that the requests received by Kestrel were proxied by IIS and didn't come from some other source. The pairing token is created and set into an environment variable (`ASPNETCORE_TOKEN`) by the module. The pairing token is also set into a header (`MS-ASPNETCORE-TOKEN`) on every proxied request. IIS Middleware checks each request it receives to confirm that the pairing token header value matches the environment variable value. If the token values are mismatched, the request is logged and rejected. The pairing token environment variable and the traffic between the module and Kestrel aren't accessible from a location off of the server. Without knowing the pairing token value, an attacker can't submit requests that bypass the check in the IIS Middleware.

ASP.NET Core Module with an IIS Shared Configuration

The ASP.NET Core Module installer runs with the privileges of the **TrustedInstaller** account. Because the local system account doesn't have modify permission for the share path used by the IIS Shared Configuration, the installer throws an access denied error when attempting to configure the module settings in the *applicationHost.config* file on the share.

When using an IIS Shared Configuration, follow these steps:

1. Disable the IIS Shared Configuration.
2. Run the installer.
3. Export the updated *applicationHost.config* file to the share.
4. Re-enable the IIS Shared Configuration.

Module version and Hosting Bundle installer logs

To determine the version of the installed ASP.NET Core Module:

1. On the hosting system, navigate to *%windir%\System32\inetsrv*.
2. Locate the *aspnetcore.dll* file.
3. Right-click the file and select **Properties** from the contextual menu.
4. Select the **Details** tab. The **File version** and **Product version** represent the installed version of the module.

The Hosting Bundle installer logs for the module are found at *C:\Users\%UserName%\AppData\Local\Temp*. The file is named *dd_DotNetCoreWinSvrHosting__ <timestamp>_000_AspNetCoreModule_x64.log*.

Module, schema, and configuration file locations

Module

IIS (x86/amd64):

- %windir%\System32\inetsrv\aspnetcore.dll
- %windir%\SysWOW64\inetsrv\aspnetcore.dll

IIS Express (x86/amd64):

- %ProgramFiles%\IIS Express\aspnetcore.dll
- %ProgramFiles(x86)%\IIS Express\aspnetcore.dll

Schema

IIS

- %windir%\System32\inetsrv\config\schema\aspnetcore_schema.xml

IIS Express

- %ProgramFiles%\IIS Express\config\schema\aspnetcore_schema.xml

Configuration

IIS

- %windir%\System32\inetsrv\config\applicationHost.config

IIS Express

- Visual Studio: {APPLICATION ROOT}\.vs\config\applicationHost.config
- *iisexpress.exe* CLI: %USERPROFILE%\Documents\IISExpress\config\applicationhost.config

The files can be found by searching for *aspnetcore* in the *applicationHost.config* file.

Additional resources

- Host ASP.NET Core on Windows with IIS
- Deploy ASP.NET Core apps to Azure App Service
- ASP.NET Core Module reference source (master branch): Use the **Branch** drop down list to select a specific release (for example, `release/3.1`).
- IIS modules with ASP.NET Core

Troubleshoot ASP.NET Core on Azure App Service and IIS

9/22/2020 • 59 minutes to read • Edit Online

By Justin Kotalik

This article provides information on common app startup errors and instructions on how to diagnose errors when an app is deployed to Azure App Service or IIS:

App startup errors
Explains common startup HTTP status code scenarios.

Troubleshoot on Azure App Service
Provides troubleshooting advice for apps deployed to Azure App Service.

Troubleshoot on IIS
Provides troubleshooting advice for apps deployed to IIS or running on IIS Express locally. The guidance applies to both Windows Server and Windows desktop deployments.

Clear package caches
Explains what to do when incoherent packages break an app when performing major upgrades or changing package versions.

Additional resources
Lists additional troubleshooting topics.

App startup errors

In Visual Studio, an ASP.NET Core project defaults to IIS Express hosting during debugging. A *502.5 - Process Failure* or a *500.30 - Start Failure* that occurs when debugging locally can be diagnosed using the advice in this topic.

403.14 Forbidden

The app fails to start. The following error is logged:

```
The Web server is configured to not list the contents of this directory.
```

The error is usually caused by a broken deployment on the hosting system, which includes any of the following scenarios:

- The app is deployed to the wrong folder on the hosting system.
- The deployment process failed to move all of the app's files and folders to the deployment folder on the hosting system.
- The *web.config* file is missing from the deployment, or the *web.config* file contents are malformed.

Perform the following steps:

1. Delete all of the files and folders from the deployment folder on the hosting system.
2. Redeploy the contents of the app's *publish* folder to the hosting system using your normal method of deployment, such as Visual Studio, PowerShell, or manual deployment:
   - Confirm that the *web.config* file is present in the deployment and that its contents are correct.
   - When hosting on Azure App Service, confirm that the app is deployed to the `D:\home\site\wwwroot` folder.

- When the app is hosted by IIS, confirm that the app is deployed to the IIS **Physical path** shown in **IIS Manager**'s **Basic Settings**.

3. Confirm that all of the app's files and folders are deployed by comparing the deployment on the hosting system to the contents of the project's *publish* folder.

For more information on the layout of a published ASP.NET Core app, see ASP.NET Core directory structure. For more information on the *web.config* file, see ASP.NET Core Module.

500 Internal Server Error

The app starts, but an error prevents the server from fulfilling the request.

This error occurs within the app's code during startup or while creating a response. The response may contain no content, or the response may appear as a *500 Internal Server Error* in the browser. The Application Event Log usually states that the app started normally. From the server's perspective, that's correct. The app did start, but it can't generate a valid response. Run the app at a command prompt on the server or enable the ASP.NET Core Module stdout log to troubleshoot the problem.

500.0 In-Process Handler Load Failure

The worker process fails. The app doesn't start.

An unknown error occurred loading ASP.NET Core Module components. Take one of the following actions:

- Contact Microsoft Support (select **Developer Tools** then **ASP.NET Core**).
- Ask a question on Stack Overflow.
- File an issue on our GitHub repository.

500.30 In-Process Startup Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the .NET Core CLR in-process, but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

Common failure conditions:

- The app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine.
- Using Azure Key Vault, lack of permissions to the Key Vault. Check the access policies in the targeted Key Vault to ensure that the correct permissions are granted.

500.31 ANCM Failed to Find Native Dependencies

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the .NET Core runtime in-process, but it fails to start. The most common cause of this startup failure is when the `Microsoft.NETCore.App` or `Microsoft.AspNetCore.App` runtime isn't installed. If the app is deployed to target ASP.NET Core 3.0 and that version doesn't exist on the machine, this error occurs. An example error message follows:

```
The specified framework 'Microsoft.NETCore.App', version '3.0.0' was not found.
  - The following frameworks were found:
      2.2.1 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview5-27626-15 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27713-13 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27714-15 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27723-08 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
```

The error message lists all the installed .NET Core versions and the version requested by the app. To fix this error,

either:

- Install the appropriate version of .NET Core on the machine.
- Change the app to target a version of .NET Core that's present on the machine.
- Publish the app as a self-contained deployment.

When running in development (the `ASPNETCORE_ENVIRONMENT` environment variable is set to `Development`), the specific error is written to the HTTP response. The cause of a process startup failure is also found in the Application Event Log.

500.32 ANCM Failed to Load dll

The worker process fails. The app doesn't start.

The most common cause for this error is that the app is published for an incompatible processor architecture. If the worker process is running as a 32-bit app and the app was published to target 64-bit, this error occurs.

To fix this error, either:

- Republish the app for the same processor architecture as the worker process.
- Publish the app as a framework-dependent deployment.

500.33 ANCM Request Handler Load Failure

The worker process fails. The app doesn't start.

The app didn't reference the `Microsoft.AspNetCore.App` framework. Only apps targeting the `Microsoft.AspNetCore.App` framework can be hosted by the ASP.NET Core Module.

To fix this error, confirm that the app is targeting the `Microsoft.AspNetCore.App` framework. Check the `.runtimeconfig.json` to verify the framework targeted by the app.

500.34 ANCM Mixed Hosting Models Not Supported

The worker process can't run both an in-process app and an out-of-process app in the same process.

To fix this error, run apps in separate IIS application pools.

500.35 ANCM Multiple In-Process Applications in same Process

The worker process can't run multiple in-process apps in the same process.

To fix this error, run apps in separate IIS application pools.

500.36 ANCM Out-Of-Process Handler Load Failure

The out-of-process request handler, *aspnetcorev2_outofprocess.dll*, isn't next to the *aspnetcorev2.dll* file. This indicates a corrupted installation of the ASP.NET Core Module.

To fix this error, repair the installation of the .NET Core Hosting Bundle (for IIS) or Visual Studio (for IIS Express).

500.37 ANCM Failed to Start Within Startup Time Limit

ANCM failed to start within the provided startup time limit. By default, the timeout is 120 seconds.

This error can occur when starting a large number of apps on the same machine. Check for CPU/Memory usage spikes on the server during startup. You may need to stagger the startup process of multiple apps.

500.38 ANCM Application DLL Not Found

ANCM failed to locate the application DLL, which should be next to the executable.

This error occurs when hosting an app packaged as a single-file executable using the in-process hosting model. The in-process model requires that the ANCM load the .NET Core app into the existing IIS process. This scenario isn't supported by the single-file deployment model. Use **one** of the following approaches in the app's project file to fix

this error:

1. Disable single-file publishing by setting the `PublishSingleFile` MSBuild property to `false`.
2. Switch to the out-of-process hosting model by setting the `AspNetCoreHostingModel` MSBuild property to `OutOfProcess`.

502.5 Process Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the worker process but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

A common failure condition is the app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and referenced by a metapackage such as `Microsoft.AspNetCore.App`. The metapackage reference can specify a minimum required version. For more information, see The shared framework.

The *502.5 Process Failure* error page is returned when a hosting or app misconfiguration causes the worker process to fail:

Failed to start application (ErrorCode '0x800700c1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/6/ROOT/', ErrorCode '0x800700c1'.
```

The app failed to start because the app's assembly (*.dll*) couldn't be loaded.

This error occurs when there's a bitness mismatch between the published app and the w3wp/iisexpress process.

Confirm that the app pool's 32-bit setting is correct:

1. Select the app pool in IIS Manager's **Application Pools**.
2. Select **Advanced Settings** under **Edit Application Pool** in the **Actions** panel.
3. Set **Enable 32-Bit Applications**:
   - If deploying a 32-bit (x86) app, set the value to `True`.
   - If deploying a 64-bit (x64) app, set the value to `False`.

Confirm that there isn't a conflict between a `<Platform>` MSBuild property in the project file and the published bitness of the app.

Connection reset

If an error occurs after the headers are sent, it's too late for the server to send a **500 Internal Server Error** when an error occurs. This often happens when an error occurs during the serialization of complex objects for a response. This type of error appears as a *connection reset* error on the client. Application logging can help troubleshoot these types of errors.

Default startup limits

The ASP.NET Core Module is configured with a default *startupTimeLimit* of 120 seconds. When left at the default value, an app may take up to two minutes to start before the module logs a process failure. For information on configuring the module, see Attributes of the aspNetCore element.

Troubleshoot on Azure App Service

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

Application Event Log (Azure App Service)

To access the Application Event Log, use the **Diagnose and solve problems** blade in the Azure portal:

1. In the Azure portal, open the app in **App Services**.
2. Select **Diagnose and solve problems**.
3. Select the **Diagnostic Tools** heading.
4. Under **Support Tools**, select the **Application Events** button.
5. Examine the latest error provided by the *IIS AspNetCoreModule* or *IIS AspNetCoreModule V2* entry in the **Source** column.

An alternative to using the **Diagnose and solve problems** blade is to examine the Application Event Log file directly using Kudu:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the **LogFiles** folder.
4. Select the pencil icon next to the *eventlog.xml* file.
5. Examine the log. Scroll to the bottom of the log to see the most recent events.

Run the app in the Kudu console

Many startup errors don't produce useful information in the Application Event Log. You can run the app in the Kudu Remote Execution Console to discover the error:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.

Test a 32-bit (x86) app

Current release

1. `cd d:\home\site\wwwroot`
2. Run the app:
   - If the app is a framework-dependent deployment:

     ```
     dotnet .\{ASSEMBLY NAME}.dll
     ```

   - If the app is a self-contained deployment:

     ```
     {ASSEMBLY NAME}.exe
     ```

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x86) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x32` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

Test a 64-bit (x64) app

Current release

- If the app is a 64-bit (x64) framework-dependent deployment:
  1. `cd D:\Program Files\dotnet`
  2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`
- If the app is a self-contained deployment:
  1. `cd D:\home\site\wwwroot`
  2. Run the app: `{ASSEMBLY NAME}.exe`

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x64) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x64` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

ASP.NET Core Module stdout log (Azure App Service)

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created. Only use stdout logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

The ASP.NET Core Module stdout log often records useful error messages not found in the Application Event Log. To enable and view stdout logs:

1. In the Azure Portal, navigate to the web app.
2. In the **App Service** blade, enter **kudu** in the search box.
3. Select **Advanced Tools** > **Go**.
4. Select **Debug console** > **CMD**.
5. Navigate to *site/wwwroot*
6. Select the pencil icon to edit the *web.config* file.
7. In the `<aspNetCore />` element, set `stdoutLogEnabled="true"` and select **Save**.

Disable stdout logging when troubleshooting is complete by setting `stdoutLogEnabled="false"`.

For more information, see ASP.NET Core Module.

ASP.NET Core Module debug log (Azure App Service)

The ASP.NET Core Module debug log provides additional, deeper logging from the ASP.NET Core Module. To enable and view stdout logs:

1. To enable the enhanced diagnostic log, perform either of the following:
   - Follow the instructions in Enhanced diagnostic logs to configure the app for an enhanced diagnostic

logging. Redeploy the app.

- Add the `<handlerSettings>` shown in Enhanced diagnostic logs to the live app's *web.config* file using the Kudu console:
  a. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
  b. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
  c. Open the folders to the path **site** > **wwwroot**. Edit the *web.config* file by selecting the pencil button. Add the `<handlerSettings>` section as shown in Enhanced diagnostic logs. Select the **Save** button.

2. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
3. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
4. Open the folders to the path **site** > **wwwroot**. If you didn't supply a path for the *aspnetcore-debug.log* file, the file appears in the list. If you supplied a path, navigate to the location of the log file.
5. Open the log file with the pencil button next to the file name.

Disable debug logging when troubleshooting is complete:

To disable the enhanced debug log, perform either of the following:

- Remove the `<handlerSettings>` from the *web.config* file locally and redeploy the app.
- Use the Kudu console to edit the *web.config* file and remove the `<handlerSettings>` section. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
> Failure to disable the debug log can lead to app or server failure. There's no limit on log file size. Only use debug logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Slow or hanging app (Azure App Service)

When an app responds slowly or hangs on a request, see the following articles:

- Troubleshoot slow web app performance issues in Azure App Service
- Use Crash Diagnoser Site Extension to Capture Dump for Intermittent Exception issues or performance issues on Azure Web App

Monitoring blades

Monitoring blades provide an alternative troubleshooting experience to the methods described earlier in the topic. These blades can be used to diagnose 500-series errors.

Confirm that the ASP.NET Core Extensions are installed. If the extensions aren't installed, install them manually:

1. In the **DEVELOPMENT TOOLS** blade section, select the **Extensions** blade.
2. The **ASP.NET Core Extensions** should appear in the list.
3. If the extensions aren't installed, select the **Add** button.
4. Choose the **ASP.NET Core Extensions** from the list.
5. Select **OK** to accept the legal terms.
6. Select **OK** on the **Add extension** blade.
7. An informational pop-up message indicates when the extensions are successfully installed.

If stdout logging isn't enabled, follow these steps:

1. In the Azure portal, select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the folders to the path **site** > **wwwroot** and scroll down to reveal the *web.config* file at the bottom of the list.
4. Click the pencil icon next to the *web.config* file.
5. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
6. Select **Save** to save the updated *web.config* file.

Proceed to activate diagnostic logging:

1. In the Azure portal, select the **Diagnostics logs** blade.
2. Select the **On** switch for **Application Logging (Filesystem)** and **Detailed error messages**. Select the **Save** button at the top of the blade.
3. To include failed request tracing, also known as Failed Request Event Buffering (FREB) logging, select the **On** switch for **Failed request tracing**.
4. Select the **Log stream** blade, which is listed immediately under the **Diagnostics logs** blade in the portal.
5. Make a request to the app.
6. Within the log stream data, the cause of the error is indicated.

Be sure to disable stdout logging when troubleshooting is complete.

To view the failed request tracing logs (FREB logs):

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Select **Failed Request Tracing Logs** from the **SUPPORT TOOLS** area of the sidebar.

See Failed request traces section of the Enable diagnostics logging for web apps in Azure App Service topic and the Application performance FAQs for Web Apps in Azure: How do I turn on failed request tracing? for more information.

For more information, see Enable diagnostics logging for web apps in Azure App Service.

> **WARNING**
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Troubleshoot on IIS

Application Event Log (IIS)

Access the Application Event Log:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.
2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app. Errors have a value of *IIS AspNetCore Module* or *IIS Express AspNetCore Module* in the *Source* column.

Run the app at a command prompt

Many startup errors don't produce useful information in the Application Event Log. You can find the cause of some errors by running the app at a command prompt on the hosting system.

Framework-dependent deployment

If the app is a framework-dependent deployment:

1. At a command prompt, navigate to the deployment folder and run the app by executing the app's assembly with *dotnet.exe*. In the following command, substitute the name of the app's assembly for <assembly_name>: `dotnet .\<assembly_name>.dll`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

Self-contained deployment

If the app is a self-contained deployment:

1. At a command prompt, navigate to the deployment folder and run the app's executable. In the following command, substitute the name of the app's assembly for <assembly_name>: `<assembly_name>.exe`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

ASP.NET Core Module stdout log (IIS)

To enable and view stdout logs:

1. Navigate to the site's deployment folder on the hosting system.
2. If the *logs* folder isn't present, create the folder. For instructions on how to enable MSBuild to create the *logs* folder in the deployment automatically, see the Directory structure topic.
3. Edit the *web.config* file. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to point to the *logs* folder (for example, `.\logs\stdout`). `stdout` in the path is the log file name prefix. A timestamp, process id, and file extension are added automatically when the log is created. Using `stdout` as the file name prefix, a typical log file is named *stdout_20180205184032_5412.log*.
4. Ensure your application pool's identity has write permissions to the *logs* folder.
5. Save the updated *web.config* file.
6. Make a request to the app.
7. Navigate to the *logs* folder. Find and open the most recent stdout log.
8. Study the log for errors.

Disable stdout logging when troubleshooting is complete:

1. Edit the *web.config* file.
2. Set **stdoutLogEnabled** to `false`.
3. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

ASP.NET Core Module debug log (IIS)

Add the following handler settings to the app's *web.config* file to enable ASP.NET Core Module debug log:

```
<aspNetCore ...>
  <handlerSettings>
    <handlerSetting name="debugLevel" value="file" />
    <handlerSetting name="debugFile" value="c:\temp\ancm.log" />
  </handlerSettings>
</aspNetCore>
```

Confirm that the path specified for the log exists and that the app pool's identity has write permissions to the location.

For more information, see ASP.NET Core Module.

Enable the Developer Exception Page

The `ASPNETCORE_ENVIRONMENT` environment variable can be added to web.config to run the app in the Development environment. As long as the environment isn't overridden in app startup by `UseEnvironment` on the host builder, setting the environment variable allows the Developer Exception Page to appear when the app is run.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout"
      hostingModel="InProcess">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
  </environmentVariables>
</aspNetCore>
```

Setting the environment variable for `ASPNETCORE_ENVIRONMENT` is only recommended for use on staging and testing servers that aren't exposed to the Internet. Remove the environment variable from the *web.config* file after troubleshooting. For information on setting environment variables in *web.config*, see environmentVariables child element of aspNetCore.

Obtain data from an app

If an app is capable of responding to requests, obtain request, connection, and additional data from the app using terminal inline middleware. For more information and sample code, see Troubleshoot and debug ASP.NET Core projects.

Slow or hanging app (IIS)

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`. The app pool must have write access to the folder.

2. Run the EnableDumps PowerShell script:

   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\EnableDumps w3wp.exe c:\dumps
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\EnableDumps dotnet.exe c:\dumps
     ```

3. Run the app under the conditions that cause the crash to occur.

4. After the crash has occurred, run the DisableDumps PowerShell script:

   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\DisableDumps w3wp.exe
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\DisableDumps dotnet.exe
     ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> **WARNING**
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App hangs, fails during startup, or runs normally

When an app *hangs* (stops responding but doesn't crash), fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.

2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.

3. Restore and rebuild the project.

4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

This article provides information on common app startup errors and instructions on how to diagnose errors when an app is deployed to Azure App Service or IIS:

App startup errors
Explains common startup HTTP status code scenarios.

Troubleshoot on Azure App Service
Provides troubleshooting advice for apps deployed to Azure App Service.

Troubleshoot on IIS
Provides troubleshooting advice for apps deployed to IIS or running on IIS Express locally. The guidance applies to both Windows Server and Windows desktop deployments.

Clear package caches
Explains what to do when incoherent packages break an app when performing major upgrades or changing package versions.

Additional resources
Lists additional troubleshooting topics.

App startup errors

In Visual Studio, an ASP.NET Core project defaults to IIS Express hosting during debugging. A *502.5 - Process Failure* or a *500.30 - Start Failure* that occurs when debugging locally can be diagnosed using the advice in this topic.

403.14 Forbidden

The app fails to start. The following error is logged:

```
The Web server is configured to not list the contents of this directory.
```

The error is usually caused by a broken deployment on the hosting system, which includes any of the following scenarios:

- The app is deployed to the wrong folder on the hosting system.
- The deployment process failed to move all of the app's files and folders to the deployment folder on the hosting system.
- The *web.config* file is missing from the deployment, or the *web.config* file contents are malformed.

Perform the following steps:

1. Delete all of the files and folders from the deployment folder on the hosting system.
2. Redeploy the contents of the app's *publish* folder to the hosting system using your normal method of deployment, such as Visual Studio, PowerShell, or manual deployment:
   - Confirm that the *web.config* file is present in the deployment and that its contents are correct.
   - When hosting on Azure App Service, confirm that the app is deployed to the `D:\home\site\wwwroot` folder.
   - When the app is hosted by IIS, confirm that the app is deployed to the IIS **Physical path** shown in **IIS Manager**'s **Basic Settings**.
3. Confirm that all of the app's files and folders are deployed by comparing the deployment on the hosting system to the contents of the project's *publish* folder.

For more information on the layout of a published ASP.NET Core app, see ASP.NET Core directory structure. For more information on the *web.config* file, see ASP.NET Core Module.

500 Internal Server Error

The app starts, but an error prevents the server from fulfilling the request.

This error occurs within the app's code during startup or while creating a response. The response may contain no content, or the response may appear as a *500 Internal Server Error* in the browser. The Application Event Log usually states that the app started normally. From the server's perspective, that's correct. The app did start, but it can't generate a valid response. Run the app at a command prompt on the server or enable the ASP.NET Core Module stdout log to troubleshoot the problem.

500.0 In-Process Handler Load Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module fails to find the .NET Core CLR and find the in-process request handler (*aspnetcorev2_inprocess.dll*). Check that:

- The app targets either the Microsoft.AspNetCore.Server.IIS NuGet package or the Microsoft.AspNetCore.App metapackage.
- The version of the ASP.NET Core shared framework that the app targets is installed on the target machine.

500.0 Out-Of-Process Handler Load Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module fails to find the out-of-process hosting request handler. Make sure the *aspnetcorev2_outofprocess.dll* is present in a subfolder next to *aspnetcorev2.dll*.

502.5 Process Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the worker process but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout

log.

A common failure condition is the app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and referenced by a metapackage such as `Microsoft.AspNetCore.App`. The metapackage reference can specify a minimum required version. For more information, see The shared framework.

The *502.5 Process Failure* error page is returned when a hosting or app misconfiguration causes the worker process to fail:

Failed to start application (ErrorCode '0x800700c1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/6/ROOT/', ErrorCode '0x800700c1'.
```

The app failed to start because the app's assembly (*.dll*) couldn't be loaded.

This error occurs when there's a bitness mismatch between the published app and the w3wp/iisexpress process.

Confirm that the app pool's 32-bit setting is correct:

1. Select the app pool in IIS Manager's **Application Pools**.
2. Select **Advanced Settings** under **Edit Application Pool** in the **Actions** panel.
3. Set **Enable 32-Bit Applications**:
   - If deploying a 32-bit (x86) app, set the value to `True`.
   - If deploying a 64-bit (x64) app, set the value to `False`.

Confirm that there isn't a conflict between a `<Platform>` MSBuild property in the project file and the published bitness of the app.

Connection reset

If an error occurs after the headers are sent, it's too late for the server to send a **500 Internal Server Error** when an error occurs. This often happens when an error occurs during the serialization of complex objects for a response. This type of error appears as a *connection reset* error on the client. Application logging can help troubleshoot these types of errors.

Default startup limits

The ASP.NET Core Module is configured with a default *startupTimeLimit* of 120 seconds. When left at the default value, an app may take up to two minutes to start before the module logs a process failure. For information on configuring the module, see Attributes of the aspNetCore element.

Troubleshoot on Azure App Service

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

Application Event Log (Azure App Service)

To access the Application Event Log, use the **Diagnose and solve problems** blade in the Azure portal:

1. In the Azure portal, open the app in **App Services**.

2. Select **Diagnose and solve problems**.
3. Select the **Diagnostic Tools** heading.
4. Under **Support Tools**, select the **Application Events** button.
5. Examine the latest error provided by the *IIS AspNetCoreModule* or *IIS AspNetCoreModule V2* entry in the **Source** column.

An alternative to using the **Diagnose and solve problems** blade is to examine the Application Event Log file directly using Kudu:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the **LogFiles** folder.
4. Select the pencil icon next to the *eventlog.xml* file.
5. Examine the log. Scroll to the bottom of the log to see the most recent events.

Run the app in the Kudu console

Many startup errors don't produce useful information in the Application Event Log. You can run the app in the Kudu Remote Execution Console to discover the error:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.

Test a 32-bit (x86) app

Current release

1. `cd d:\home\site\wwwroot`
2. Run the app:
   - If the app is a framework-dependent deployment:

     ```
     dotnet .\{ASSEMBLY NAME}.dll
     ```

   - If the app is a self-contained deployment:

     ```
     {ASSEMBLY NAME}.exe
     ```

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x86) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x32` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

Test a 64-bit (x64) app

Current release

- If the app is a 64-bit (x64) framework-dependent deployment:
  1. `cd D:\Program Files\dotnet`
  2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

- If the app is a self-contained deployment:
  1. `cd D:\home\site\wwwroot`
  2. Run the app: `{ASSEMBLY NAME}.exe`

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x64) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x64` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

ASP.NET Core Module stdout log (Azure App Service)

The ASP.NET Core Module stdout log often records useful error messages not found in the Application Event Log. To enable and view stdout logs:

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Under **SELECT PROBLEM CATEGORY**, select the **Web App Down** button.
3. Under **Suggested Solutions** > **Enable Stdout Log Redirection**, select the button to **Open Kudu Console to edit Web.Config**.
4. In the Kudu **Diagnostic Console**, open the folders to the path **site** > **wwwroot**. Scroll down to reveal the *web.config* file at the bottom of the list.
5. Click the pencil icon next to the *web.config* file.
6. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
7. Select **Save** to save the updated *web.config* file.
8. Make a request to the app.
9. Return to the Azure portal. Select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
10. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
11. Select the **LogFiles** folder.
12. Inspect the **Modified** column and select the pencil icon to edit the stdout log with the latest modification date.
13. When the log file opens, the error is displayed.

Disable stdout logging when troubleshooting is complete:

1. In the Kudu **Diagnostic Console**, return to the path **site** > **wwwroot** to reveal the *web.config* file. Open the **web.config** file again by selecting the pencil icon.
2. Set **stdoutLogEnabled** to `false`.
3. Select **Save** to save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created. Only use stdout logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

ASP.NET Core Module debug log (Azure App Service)

The ASP.NET Core Module debug log provides additional, deeper logging from the ASP.NET Core Module. To enable and view stdout logs:

1. To enable the enhanced diagnostic log, perform either of the following:
   - Follow the instructions in Enhanced diagnostic logs to configure the app for an enhanced diagnostic logging. Redeploy the app.
   - Add the `<handlerSettings>` shown in Enhanced diagnostic logs to the live app's *web.config* file using the Kudu console:
     a. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
     b. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
     c. Open the folders to the path **site** > **wwwroot**. Edit the *web.config* file by selecting the pencil button. Add the `<handlerSettings>` section as shown in Enhanced diagnostic logs. Select the **Save** button.
2. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
3. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
4. Open the folders to the path **site** > **wwwroot**. If you didn't supply a path for the *aspnetcore-debug.log* file, the file appears in the list. If you supplied a path, navigate to the location of the log file.
5. Open the log file with the pencil button next to the file name.

Disable debug logging when troubleshooting is complete:

To disable the enhanced debug log, perform either of the following:

- Remove the `<handlerSettings>` from the *web.config* file locally and redeploy the app.
- Use the Kudu console to edit the *web.config* file and remove the `<handlerSettings>` section. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
> Failure to disable the debug log can lead to app or server failure. There's no limit on log file size. Only use debug logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Slow or hanging app (Azure App Service)

When an app responds slowly or hangs on a request, see the following articles:

- Troubleshoot slow web app performance issues in Azure App Service
- Use Crash Diagnoser Site Extension to Capture Dump for Intermittent Exception issues or performance issues on Azure Web App

Monitoring blades

Monitoring blades provide an alternative troubleshooting experience to the methods described earlier in the topic. These blades can be used to diagnose 500-series errors.

Confirm that the ASP.NET Core Extensions are installed. If the extensions aren't installed, install them manually:

1. In the **DEVELOPMENT TOOLS** blade section, select the **Extensions** blade.
2. The **ASP.NET Core Extensions** should appear in the list.
3. If the extensions aren't installed, select the **Add** button.

4. Choose the **ASP.NET Core Extensions** from the list.
5. Select **OK** to accept the legal terms.
6. Select **OK** on the **Add extension** blade.
7. An informational pop-up message indicates when the extensions are successfully installed.

If stdout logging isn't enabled, follow these steps:

1. In the Azure portal, select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the folders to the path **site** > **wwwroot** and scroll down to reveal the *web.config* file at the bottom of the list.
4. Click the pencil icon next to the *web.config* file.
5. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
6. Select **Save** to save the updated *web.config* file.

Proceed to activate diagnostic logging:

1. In the Azure portal, select the **Diagnostics logs** blade.
2. Select the **On** switch for **Application Logging (Filesystem)** and **Detailed error messages**. Select the **Save** button at the top of the blade.
3. To include failed request tracing, also known as Failed Request Event Buffering (FREB) logging, select the **On** switch for **Failed request tracing**.
4. Select the **Log stream** blade, which is listed immediately under the **Diagnostics logs** blade in the portal.
5. Make a request to the app.
6. Within the log stream data, the cause of the error is indicated.

Be sure to disable stdout logging when troubleshooting is complete.

To view the failed request tracing logs (FREB logs):

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Select **Failed Request Tracing Logs** from the **SUPPORT TOOLS** area of the sidebar.

See Failed request traces section of the Enable diagnostics logging for web apps in Azure App Service topic and the Application performance FAQs for Web Apps in Azure: How do I turn on failed request tracing? for more information.

For more information, see Enable diagnostics logging for web apps in Azure App Service.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Troubleshoot on IIS

Application Event Log (IIS)

Access the Application Event Log:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.

2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app. Errors have a value of *IIS AspNetCore Module* or *IIS Express AspNetCore Module* in the *Source* column.

Run the app at a command prompt

Many startup errors don't produce useful information in the Application Event Log. You can find the cause of some errors by running the app at a command prompt on the hosting system.

Framework-dependent deployment

If the app is a framework-dependent deployment:

1. At a command prompt, navigate to the deployment folder and run the app by executing the app's assembly with *dotnet.exe*. In the following command, substitute the name of the app's assembly for <assembly_name>: `dotnet .\<assembly_name>.dll`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

Self-contained deployment

If the app is a self-contained deployment:

1. At a command prompt, navigate to the deployment folder and run the app's executable. In the following command, substitute the name of the app's assembly for <assembly_name>: `<assembly_name>.exe`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

ASP.NET Core Module stdout log (IIS)

To enable and view stdout logs:

1. Navigate to the site's deployment folder on the hosting system.
2. If the *logs* folder isn't present, create the folder. For instructions on how to enable MSBuild to create the *logs* folder in the deployment automatically, see the Directory structure topic.
3. Edit the *web.config* file. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to point to the *logs* folder (for example, `.\logs\stdout`). `stdout` in the path is the log file name prefix. A timestamp, process id, and file extension are added automatically when the log is created. Using `stdout` as the file name prefix, a typical log file is named *stdout_20180205184032_5412.log*.
4. Ensure your application pool's identity has write permissions to the *logs* folder.
5. Save the updated *web.config* file.
6. Make a request to the app.
7. Navigate to the *logs* folder. Find and open the most recent stdout log.
8. Study the log for errors.

Disable stdout logging when troubleshooting is complete:

1. Edit the *web.config* file.
2. Set **stdoutLogEnabled** to `false`.
3. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

ASP.NET Core Module debug log (IIS)

Add the following handler settings to the app's *web.config* file to enable ASP.NET Core Module debug log:

```
<aspNetCore ...>
  <handlerSettings>
    <handlerSetting name="debugLevel" value="file" />
    <handlerSetting name="debugFile" value="c:\temp\ancm.log" />
  </handlerSettings>
</aspNetCore>
```

Confirm that the path specified for the log exists and that the app pool's identity has write permissions to the location.

For more information, see ASP.NET Core Module.

Enable the Developer Exception Page

The `ASPNETCORE_ENVIRONMENT` environment variable can be added to web.config to run the app in the Development environment. As long as the environment isn't overridden in app startup by `UseEnvironment` on the host builder, setting the environment variable allows the Developer Exception Page to appear when the app is run.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout"
      hostingModel="InProcess">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
  </environmentVariables>
</aspNetCore>
```

Setting the environment variable for `ASPNETCORE_ENVIRONMENT` is only recommended for use on staging and testing servers that aren't exposed to the Internet. Remove the environment variable from the *web.config* file after troubleshooting. For information on setting environment variables in *web.config*, see environmentVariables child element of aspNetCore.

Obtain data from an app

If an app is capable of responding to requests, obtain request, connection, and additional data from the app using terminal inline middleware. For more information and sample code, see Troubleshoot and debug ASP.NET Core projects.

Slow or hanging app (IIS)

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`. The app pool must have write access to the folder.
2. Run the EnableDumps PowerShell script:
   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\EnableDumps w3wp.exe c:\dumps
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\EnableDumps dotnet.exe c:\dumps
     ```

3. Run the app under the conditions that cause the crash to occur.
4. After the crash has occurred, run the DisableDumps PowerShell script:
   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\DisableDumps w3wp.exe
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\DisableDumps dotnet.exe
     ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> **WARNING**
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App hangs, fails during startup, or runs normally

When an app *hangs* (stops responding but doesn't crash), fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.
2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

This article provides information on common app startup errors and instructions on how to diagnose errors when an app is deployed to Azure App Service or IIS:

App startup errors
Explains common startup HTTP status code scenarios.

Troubleshoot on Azure App Service
Provides troubleshooting advice for apps deployed to Azure App Service.

Troubleshoot on IIS
Provides troubleshooting advice for apps deployed to IIS or running on IIS Express locally. The guidance applies to both Windows Server and Windows desktop deployments.

Clear package caches
Explains what to do when incoherent packages break an app when performing major upgrades or changing package versions.

Additional resources
Lists additional troubleshooting topics.

App startup errors

In Visual Studio, an ASP.NET Core project defaults to IIS Express hosting during debugging. A *502.5 Process Failure* that occurs when debugging locally can be diagnosed using the advice in this topic.

403.14 Forbidden

The app fails to start. The following error is logged:

```
The Web server is configured to not list the contents of this directory.
```

The error is usually caused by a broken deployment on the hosting system, which includes any of the following scenarios:

- The app is deployed to the wrong folder on the hosting system.
- The deployment process failed to move all of the app's files and folders to the deployment folder on the hosting system.
- The *web.config* file is missing from the deployment, or the *web.config* file contents are malformed.

Perform the following steps:

1. Delete all of the files and folders from the deployment folder on the hosting system.
2. Redeploy the contents of the app's *publish* folder to the hosting system using your normal method of deployment, such as Visual Studio, PowerShell, or manual deployment:
   - Confirm that the *web.config* file is present in the deployment and that its contents are correct.
   - When hosting on Azure App Service, confirm that the app is deployed to the `D:\home\site\wwwroot` folder.
   - When the app is hosted by IIS, confirm that the app is deployed to the IIS **Physical path** shown in **IIS Manager**'s **Basic Settings**.
3. Confirm that all of the app's files and folders are deployed by comparing the deployment on the hosting system to the contents of the project's *publish* folder.

For more information on the layout of a published ASP.NET Core app, see ASP.NET Core directory structure. For more information on the *web.config* file, see ASP.NET Core Module.

500 Internal Server Error

The app starts, but an error prevents the server from fulfilling the request.

This error occurs within the app's code during startup or while creating a response. The response may contain no content, or the response may appear as a *500 Internal Server Error* in the browser. The Application Event Log usually states that the app started normally. From the server's perspective, that's correct. The app did start, but it can't generate a valid response. Run the app at a command prompt on the server or enable the ASP.NET Core Module stdout log to troubleshoot the problem.

502.5 Process Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the worker process but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

A common failure condition is the app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and referenced by a metapackage such as `Microsoft.AspNetCore.App`. The metapackage reference can specify a minimum required version. For more information, see The shared framework.

The *502.5 Process Failure* error page is returned when a hosting or app misconfiguration causes the worker process to fail:

Failed to start application (ErrorCode '0x800700c1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/6/ROOT/', ErrorCode '0x800700c1'.
```

The app failed to start because the app's assembly (*.dll*) couldn't be loaded.

This error occurs when there's a bitness mismatch between the published app and the w3wp/iisexpress process.

Confirm that the app pool's 32-bit setting is correct:

1. Select the app pool in IIS Manager's **Application Pools**.
2. Select **Advanced Settings** under **Edit Application Pool** in the **Actions** panel.
3. Set **Enable 32-Bit Applications**:
   - If deploying a 32-bit (x86) app, set the value to `True`.
   - If deploying a 64-bit (x64) app, set the value to `False`.

Confirm that there isn't a conflict between a `<Platform>` MSBuild property in the project file and the published bitness of the app.

Connection reset

If an error occurs after the headers are sent, it's too late for the server to send a **500 Internal Server Error** when an error occurs. This often happens when an error occurs during the serialization of complex objects for a response. This type of error appears as a *connection reset* error on the client. Application logging can help troubleshoot these types of errors.

Default startup limits

The ASP.NET Core Module is configured with a default *startupTimeLimit* of 120 seconds. When left at the default value, an app may take up to two minutes to start before the module logs a process failure. For information on configuring the module, see Attributes of the aspNetCore element.

Troubleshoot on Azure App Service

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

Application Event Log (Azure App Service)

To access the Application Event Log, use the **Diagnose and solve problems** blade in the Azure portal:

1. In the Azure portal, open the app in **App Services**.
2. Select **Diagnose and solve problems**.
3. Select the **Diagnostic Tools** heading.
4. Under **Support Tools**, select the **Application Events** button.
5. Examine the latest error provided by the *IIS AspNetCoreModule* or *IIS AspNetCoreModule V2* entry in the **Source** column.

An alternative to using the **Diagnose and solve problems** blade is to examine the Application Event Log file directly using Kudu:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.

2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the **LogFiles** folder.
4. Select the pencil icon next to the *eventlog.xml* file.
5. Examine the log. Scroll to the bottom of the log to see the most recent events.

Run the app in the Kudu console

Many startup errors don't produce useful information in the Application Event Log. You can run the app in the Kudu Remote Execution Console to discover the error:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.

Test a 32-bit (x86) app

Current release

1. `cd d:\home\site\wwwroot`
2. Run the app:
   - If the app is a framework-dependent deployment:

     ```
     dotnet .\{ASSEMBLY NAME}.dll
     ```

   - If the app is a self-contained deployment:

     ```
     {ASSEMBLY NAME}.exe
     ```

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x86) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x32` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

Test a 64-bit (x64) app

Current release

- If the app is a 64-bit (x64) framework-dependent deployment:
  1. `cd D:\Program Files\dotnet`
  2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`
- If the app is a self-contained deployment:
  1. `cd D:\home\site\wwwroot`
  2. Run the app: `{ASSEMBLY NAME}.exe`

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x64) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x64` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

ASP.NET Core Module stdout log (Azure App Service)

The ASP.NET Core Module stdout log often records useful error messages not found in the Application Event Log. To enable and view stdout logs:

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Under **SELECT PROBLEM CATEGORY**, select the **Web App Down** button.
3. Under **Suggested Solutions** > **Enable Stdout Log Redirection**, select the button to **Open Kudu Console to edit Web.Config**.
4. In the Kudu **Diagnostic Console**, open the folders to the path **site** > **wwwroot**. Scroll down to reveal the *web.config* file at the bottom of the list.
5. Click the pencil icon next to the *web.config* file.
6. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
7. Select **Save** to save the updated *web.config* file.
8. Make a request to the app.
9. Return to the Azure portal. Select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
10. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
11. Select the **LogFiles** folder.
12. Inspect the **Modified** column and select the pencil icon to edit the stdout log with the latest modification date.
13. When the log file opens, the error is displayed.

Disable stdout logging when troubleshooting is complete:

1. In the Kudu **Diagnostic Console**, return to the path **site** > **wwwroot** to reveal the *web.config* file. Open the **web.config** file again by selecting the pencil icon.
2. Set **stdoutLogEnabled** to `false`.
3. Select **Save** to save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created. Only use stdout logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Slow or hanging app (Azure App Service)

When an app responds slowly or hangs on a request, see the following articles:

- Troubleshoot slow web app performance issues in Azure App Service
- Use Crash Diagnoser Site Extension to Capture Dump for Intermittent Exception issues or performance issues on Azure Web App

Monitoring blades

Monitoring blades provide an alternative troubleshooting experience to the methods described earlier in the topic. These blades can be used to diagnose 500-series errors.

Confirm that the ASP.NET Core Extensions are installed. If the extensions aren't installed, install them manually:

1. In the **DEVELOPMENT TOOLS** blade section, select the **Extensions** blade.

2. The **ASP.NET Core Extensions** should appear in the list.
3. If the extensions aren't installed, select the **Add** button.
4. Choose the **ASP.NET Core Extensions** from the list.
5. Select **OK** to accept the legal terms.
6. Select **OK** on the **Add extension** blade.
7. An informational pop-up message indicates when the extensions are successfully installed.

If stdout logging isn't enabled, follow these steps:

1. In the Azure portal, select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the folders to the path **site** > **wwwroot** and scroll down to reveal the *web.config* file at the bottom of the list.
4. Click the pencil icon next to the *web.config* file.
5. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
6. Select **Save** to save the updated *web.config* file.

Proceed to activate diagnostic logging:

1. In the Azure portal, select the **Diagnostics logs** blade.
2. Select the **On** switch for **Application Logging (Filesystem)** and **Detailed error messages**. Select the **Save** button at the top of the blade.
3. To include failed request tracing, also known as Failed Request Event Buffering (FREB) logging, select the **On** switch for **Failed request tracing**.
4. Select the **Log stream** blade, which is listed immediately under the **Diagnostics logs** blade in the portal.
5. Make a request to the app.
6. Within the log stream data, the cause of the error is indicated.

Be sure to disable stdout logging when troubleshooting is complete.

To view the failed request tracing logs (FREB logs):

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Select **Failed Request Tracing Logs** from the **SUPPORT TOOLS** area of the sidebar.

See Failed request traces section of the Enable diagnostics logging for web apps in Azure App Service topic and the Application performance FAQs for Web Apps in Azure: How do I turn on failed request tracing? for more information.

For more information, see Enable diagnostics logging for web apps in Azure App Service.

> **WARNING**
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Troubleshoot on IIS

Application Event Log (IIS)

Access the Application Event Log:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.
2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app. Errors have a value of *IIS AspNetCore Module* or *IIS Express AspNetCore Module* in the *Source* column.

Run the app at a command prompt

Many startup errors don't produce useful information in the Application Event Log. You can find the cause of some errors by running the app at a command prompt on the hosting system.

Framework-dependent deployment

If the app is a framework-dependent deployment:

1. At a command prompt, navigate to the deployment folder and run the app by executing the app's assembly with *dotnet.exe*. In the following command, substitute the name of the app's assembly for <assembly_name>: `dotnet .\<assembly_name>.dll`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

Self-contained deployment

If the app is a self-contained deployment:

1. At a command prompt, navigate to the deployment folder and run the app's executable. In the following command, substitute the name of the app's assembly for <assembly_name>: `<assembly_name>.exe`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

ASP.NET Core Module stdout log (IIS)

To enable and view stdout logs:

1. Navigate to the site's deployment folder on the hosting system.
2. If the *logs* folder isn't present, create the folder. For instructions on how to enable MSBuild to create the *logs* folder in the deployment automatically, see the Directory structure topic.
3. Edit the *web.config* file. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to point to the *logs* folder (for example, `.\logs\stdout`). `stdout` in the path is the log file name prefix. A timestamp, process id, and file extension are added automatically when the log is created. Using `stdout` as the file name prefix, a typical log file is named *stdout_20180205184032_5412.log*.
4. Ensure your application pool's identity has write permissions to the *logs* folder.
5. Save the updated *web.config* file.
6. Make a request to the app.
7. Navigate to the *logs* folder. Find and open the most recent stdout log.
8. Study the log for errors.

Disable stdout logging when troubleshooting is complete:

1. Edit the *web.config* file.
2. Set **stdoutLogEnabled** to `false`.

3. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Enable the Developer Exception Page

The `ASPNETCORE_ENVIRONMENT` environment variable can be added to web.config to run the app in the Development environment. As long as the environment isn't overridden in app startup by `UseEnvironment` on the host builder, setting the environment variable allows the Developer Exception Page to appear when the app is run.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
  </environmentVariables>
</aspNetCore>
```

Setting the environment variable for `ASPNETCORE_ENVIRONMENT` is only recommended for use on staging and testing servers that aren't exposed to the Internet. Remove the environment variable from the *web.config* file after troubleshooting. For information on setting environment variables in *web.config*, see environmentVariables child element of aspNetCore.

Obtain data from an app

If an app is capable of responding to requests, obtain request, connection, and additional data from the app using terminal inline middleware. For more information and sample code, see Troubleshoot and debug ASP.NET Core projects.

Slow or hanging app (IIS)

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`. The app pool must have write access to the folder.
2. Run the EnableDumps PowerShell script:
   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\EnableDumps w3wp.exe c:\dumps
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\EnableDumps dotnet.exe c:\dumps
     ```

3. Run the app under the conditions that cause the crash to occur.
4. After the crash has occurred, run the DisableDumps PowerShell script:
   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\DisableDumps w3wp.exe
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\DisableDumps dotnet.exe
     ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> **WARNING**
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App hangs, fails during startup, or runs normally

When an app *hangs* (stops responding but doesn't crash), fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.
2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

Common errors reference for Azure App Service and IIS with ASP.NET Core

9/22/2020 • 22 minutes to read • Edit Online

This topic describes common errors and provides troubleshooting advice for specific errors when hosting ASP.NET Core apps on Azure Apps Service and IIS.

For general troubleshooting guidance, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

Collect the following information:

- Browser behavior (status code and error message)
- Application Event Log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS
    1. Select **Start** on the **Windows** menu, type *Event Viewer*, and press **Enter**.
    2. After the **Event Viewer** opens, expand **Windows Logs** > **Application** in the sidebar.
- ASP.NET Core Module stdout and debug log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS: Follow the instructions in the Log creation and redirection and Enhanced diagnostic logs sections of the ASP.NET Core Module topic.

Compare error information to the following common errors. If a match is found, follow the troubleshooting advice.

The list of errors in this topic isn't exhaustive. If you encounter an error not listed here, open a new issue using the **Content feedback** button at the bottom of this topic with detailed instructions on how to reproduce the error.

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

OS upgrade removed the 32-bit ASP.NET Core Module

Application Log: The Module DLL **C:\WINDOWS\system32\inetsrv\aspnetcore.dll** failed to load. The data is the error.

Troubleshooting:

Non-OS files in the **C:\Windows\SysWOW64\inetsrv** directory aren't preserved during an OS upgrade. If the ASP.NET Core Module is installed prior to an OS upgrade and then any app pool is run in 32-bit mode after an OS upgrade, this issue is encountered. After an OS upgrade, repair the ASP.NET Core Module. See Install the .NET Core Hosting bundle. Select **Repair** when the installer is run.

Missing site extension, 32-bit (x86) and 64-bit (x64) site extensions installed, or wrong process bitness set

Applies to apps hosted by Azure App Services.

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found. Failed to start application '/LM/W3SVC/1416782824/ROOT', ErrorCode '0x8000ffff'.
- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.
- **ASP.NET Core Module Debug Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Failed HRESULT returned: 0x8000ffff. Could not find inprocess request handler. It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.

Troubleshooting:

- If running the app on a preview runtime, install either the 32-bit (x86) **or** 64-bit (x64) site extension that matches the bitness of the app and the app's runtime version. **Don't install both extensions or multiple runtime versions of the extension.**
  - ASP.NET Core {RUNTIME VERSION} (x86) Runtime
  - ASP.NET Core {RUNTIME VERSION} (x64) Runtime

  Restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and both the 32-bit (x86) and 64-bit (x64) site extensions are installed, uninstall the site extension that doesn't match the bitness of the app. After removing the site extension, restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and the site extension's bitness matches that of the app, confirm that the preview site extension's *runtime version* matches the app's runtime version.
- Confirm that the app's **Platform** in **Application Settings** matches the bitness of the app.

For more information, see Deploy ASP.NET Core apps to Azure App Service.

An x86 app is deployed but the app pool isn't enabled for 32-bit apps

- **Browser:** HTTP Error 500.30 - ANCM In-Process Start Failure
- **Application Log:** Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' hit unexpected managed exception, exception code = '0xe0434352'. Please check the stderr logs for more information. Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' failed to load clr and managed application. CLR worker thread exited prematurely
- **ASP.NET Core Module stdout Log:** The log file is created but empty.
- **ASP.NET Core Module Debug Log:** Failed HRESULT returned: 0x8007023e

This scenario is trapped by the SDK when publishing a self-contained app. The SDK produces an error if the RID doesn't match the platform target (for example, `win10-x64` RID with `<PlatformTarget>x86</PlatformTarget>` in the project file).

Troubleshooting:

For an x86 framework-dependent deployment (`<PlatformTarget>x86</PlatformTarget>`), enable the IIS app pool for 32-bit apps. In IIS Manager, open the app pool's **Advanced Settings** and set **Enable 32-Bit Applications** to **True**.

Platform conflicts with RID

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"C:{PATH}{ASSEMBLY}.{exe|dll}" ', ErrorCode = '0x80004005 : ff.
- **ASP.NET Core Module stdout Log:** Unhandled Exception: System.BadImageFormatException: Could not load file or assembly '{ASSEMBLY}.dll'. An attempt was made to load a program with an incorrect format.

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- If this exception occurs for an Azure Apps deployment when upgrading an app and deploying newer assemblies, manually delete all files from the prior deployment. Lingering incompatible assemblies can result in a `System.BadImageFormatException` exception when deploying an upgraded app.

URI endpoint wrong or stopped website

- **Browser:** ERR_CONNECTION_REFUSED --**OR**-- Unable to connect
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

- Confirm the correct URI endpoint for the app is in use. Check the bindings.
- Confirm that the IIS website isn't in the *Stopped* state.

CoreWebEngine or W3SVC server features disabled

OS Exception: The IIS 7.0 CoreWebEngine and W3SVC features must be installed to use the ASP.NET Core Module.

Troubleshooting:

Confirm that the proper role and features are enabled. See IIS Configuration.

Incorrect website physical path or app missing

- **Browser:** 403 Forbidden - Access is denied --**OR**-- 403.14 Forbidden - The Web server is configured to not list the contents of this directory.
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

Check the IIS website **Basic Settings** and the physical app folder. Confirm that the app is in the folder at the IIS

website **Physical path**.

Incorrect role, ASP.NET Core Module not installed, or incorrect permissions

- **Browser:** 500.19 Internal Server Error - The requested page cannot be accessed because the related configuration data for the page is invalid. **--OR--** This page can't be displayed
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

- Confirm that the proper role is enabled. See IIS Configuration.
- Open **Programs & Features** or **Apps & features** and confirm that **Windows Server Hosting** is installed. If **Windows Server Hosting** isn't present in the list of installed programs, download and install the .NET Core Hosting Bundle.

  Current .NET Core Hosting Bundle installer (direct download)

  For more information, see Install the .NET Core Hosting Bundle.
- Make sure that the **Application Pool** > **Process Model** > **Identity** is set to **ApplicationPoolIdentity** or the custom identity has the correct permissions to access the app's deployment folder.
- If you uninstalled the ASP.NET Core Hosting Bundle and installed an earlier version of the hosting bundle, the *applicationHost.config* file doesn't include a section for the ASP.NET Core Module. Open *applicationHost.config* at *%windir%/System32/inetsrv/config* and find the `<configuration><configSections><sectionGroup name="system.webServer">` section group. If the section for the ASP.NET Core Module is missing from the section group, add the section element:

  ```
  <section name="aspNetCore" overrideModeDefault="Allow" />
  ```

  Alternatively, install the latest version of the ASP.NET Core Hosting Bundle. The latest version is backwards-compatible with supported ASP.NET Core apps.

Incorrect processPath, missing PATH variable, Hosting Bundle not installed, system/IIS not restarted, VC++ Redistributable not installed, or dotnet.exe access violation

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"{...}" ', ErrorCode = '0x80070002 : 0. Application '{PATH}' wasn't able to start. Executable was not found at '{PATH}'. Failed to start application '/LM/W3SVC/2/ROOT', ErrorCode '0x8007023e'.
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** Event Log: 'Application '{PATH}' wasn't able to start. Executable was not found at '{PATH}'. Failed HRESULT returned: 0x8007023e

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Check the *processPath* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's `dotnet` for a framework-dependent deployment (FDD) or `.\{ASSEMBLY}.exe` for a self-contained deployment (SCD).
- For an FDD, *dotnet.exe* might not be accessible via the PATH settings. Confirm that *C:\Program Files\dotnet* exists in the System PATH settings.
- For an FDD, *dotnet.exe* might not be accessible for the user identity of the app pool. Confirm that the app pool user identity has access to the *C:\Program Files\dotnet* directory. Confirm that there are no deny rules configured for the app pool user identity on the *C:\Program Files\dotnet* and app directories.
- An FDD may have been deployed and .NET Core installed without restarting IIS. Either restart the server or restart IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.
- An FDD may have been deployed without installing the .NET Core runtime on the hosting system. If the .NET Core runtime hasn't been installed, run the **.NET Core Hosting Bundle installer** on the system.

  Current .NET Core Hosting Bundle installer (direct download)

  For more information, see Install the .NET Core Hosting Bundle.

  If a specific runtime is required, download the runtime from the .NET Download Archives and install it on the system. Complete the installation by restarting the system or restarting IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.

Incorrect arguments of <aspNetCore> element

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Could not find inprocess request handler. Captured output from invoking hostfxr: Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409 Failed to start application '/LM/W3SVC/3/ROOT', ErrorCode '0x8000ffff'.
- **ASP.NET Core Module stdout Log:** Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409
- **ASP.NET Core Module Debug Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Failed HRESULT returned: 0x8000ffff Could not find inprocess request handler. Captured output from invoking hostfxr: Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409 Failed HRESULT returned: 0x8000ffff

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Examine the *arguments* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's either (a) `.\{ASSEMBLY}.dll` for a framework-dependent deployment (FDD); or (b) not present, an empty string (`arguments=""`), or a list of the app's arguments (`arguments="{ARGUMENT_1}, {ARGUMENT_2}, ... {ARGUMENT_X}"`) for a self-contained deployment (SCD).

Missing .NET Core shared framework

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}' was not found.

Failed to start application '/LM/W3SVC/5/ROOT', ErrorCode '0x8000ffff'.

- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}' was not found.
- **ASP.NET Core Module Debug Log:** Failed HRESULT returned: 0x8000ffff

Troubleshooting:

For a framework-dependent deployment (FDD), confirm that the correct runtime installed on the system.

Stopped Application Pool

- **Browser:** 503 Service Unavailable
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

Confirm that the Application Pool isn't in the *Stopped* state.

Sub-application includes a <handlers> section

- **Browser:** HTTP Error 500.19 - Internal Server Error
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.
- **ASP.NET Core Module Debug Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.

Troubleshooting:

Confirm that the sub-app's *web.config* file doesn't include a `<handlers>` section or that the sub-app doesn't inherit the parent app's handlers.

The parent app's `<system.webServer>` section of *web.config* is placed inside of a `<location>` element. The InheritInChildApplications property is set to `false` to indicate that the settings specified within the <location> element aren't inherited by apps that reside in a subdirectory of the parent app. For more information, see ASP.NET Core Module.

stdout log path incorrect

- **Browser:** The app responds normally.
- **Application Log:** Could not start stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070005 returned at {PATH}\aspnetcoremodulev2\commonlib\fileoutputmanager.cpp:84. Could not stop stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070002 returned at {PATH}. Could not start stdout redirection in {PATH}\aspnetcorev2_inprocess.dll.
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module debug Log:** Could not start stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070005 returned at {PATH}\aspnetcoremodulev2\commonlib\fileoutputmanager.cpp:84. Could not stop stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070002 returned at {PATH}. Could not start stdout redirection in {PATH}\aspnetcorev2_inprocess.dll.

Troubleshooting:

- The `stdoutLogFile` path specified in the `<aspNetCore>` element of *web.config* doesn't exist. For more information, see ASP.NET Core Module: Log creation and redirection.
- The app pool user doesn't have write access to the stdout log path.

Application configuration general issue

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure --**OR**-- HTTP Error 500.30 - ANCM In-Process Start Failure
- **Application Log:** Variable
- **ASP.NET Core Module stdout Log:** The log file is created but empty or created with normal entries until the point of the app failing.
- **ASP.NET Core Module Debug Log:** Variable

Troubleshooting:

The process failed to start, most likely due to an app configuration or programming issue.

For more information, see the following topics:

- Troubleshoot ASP.NET Core on Azure App Service and IIS
- Troubleshoot and debug ASP.NET Core projects

This topic describes common errors and provides troubleshooting advice for specific errors when hosting ASP.NET Core apps on Azure Apps Service and IIS.

For general troubleshooting guidance, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

Collect the following information:

- Browser behavior (status code and error message)
- Application Event Log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS
    1. Select **Start** on the **Windows** menu, type *Event Viewer*, and press **Enter**.
    2. After the **Event Viewer** opens, expand **Windows Logs** > **Application** in the sidebar.
- ASP.NET Core Module stdout and debug log entries

- Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
- IIS: Follow the instructions in the Log creation and redirection and Enhanced diagnostic logs sections of the ASP.NET Core Module topic.

Compare error information to the following common errors. If a match is found, follow the troubleshooting advice.

The list of errors in this topic isn't exhaustive. If you encounter an error not listed here, open a new issue using the **Content feedback** button at the bottom of this topic with detailed instructions on how to reproduce the error.

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

OS upgrade removed the 32-bit ASP.NET Core Module

Application Log: The Module DLL **C:\WINDOWS\system32\inetsrv\aspnetcore.dll** failed to load. The data is the error.

Troubleshooting:

Non-OS files in the **C:\Windows\SysWOW64\inetsrv** directory aren't preserved during an OS upgrade. If the ASP.NET Core Module is installed prior to an OS upgrade and then any app pool is run in 32-bit mode after an OS upgrade, this issue is encountered. After an OS upgrade, repair the ASP.NET Core Module. See Install the .NET Core Hosting bundle. Select **Repair** when the installer is run.

Missing site extension, 32-bit (x86) and 64-bit (x64) site extensions installed, or wrong process bitness set

Applies to apps hosted by Azure App Services.

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found. Failed to start application '/LM/W3SVC/1416782824/ROOT', ErrorCode '0x8000ffff'.
- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.

Troubleshooting:

- If running the app on a preview runtime, install either the 32-bit (x86) **or** 64-bit (x64) site extension that matches the bitness of the app and the app's runtime version. **Don't install both extensions or multiple runtime versions of the extension.**
  - ASP.NET Core {RUNTIME VERSION} (x86) Runtime
  - ASP.NET Core {RUNTIME VERSION} (x64) Runtime

  Restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and both the 32-bit (x86) and 64-bit (x64) site extensions are installed, uninstall the site extension that doesn't match the bitness of the app. After removing the site

extension, restart the app. Wait several seconds for the app to restart.

- If running the app on a preview runtime and the site extension's bitness matches that of the app, confirm that the preview site extension's *runtime version* matches the app's runtime version.
- Confirm that the app's **Platform** in **Application Settings** matches the bitness of the app.

For more information, see Deploy ASP.NET Core apps to Azure App Service.

An x86 app is deployed but the app pool isn't enabled for 32-bit apps

- **Browser:** HTTP Error 500.30 - ANCM In-Process Start Failure
- **Application Log:** Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' hit unexpected managed exception, exception code = '0xe0434352'. Please check the stderr logs for more information. Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' failed to load clr and managed application. CLR worker thread exited prematurely
- **ASP.NET Core Module stdout Log:** The log file is created but empty.

This scenario is trapped by the SDK when publishing a self-contained app. The SDK produces an error if the RID doesn't match the platform target (for example, `win10-x64` RID with `<PlatformTarget>x86</PlatformTarget>` in the project file).

Troubleshooting:

For an x86 framework-dependent deployment (`<PlatformTarget>x86</PlatformTarget>`), enable the IIS app pool for 32-bit apps. In IIS Manager, open the app pool's **Advanced Settings** and set **Enable 32-Bit Applications** to **True**.

Platform conflicts with RID

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"C:{PATH}{ASSEMBLY}.{exe|dll}" ', ErrorCode = '0x80004005 : ff.
- **ASP.NET Core Module stdout Log:** Unhandled Exception: System.BadImageFormatException: Could not load file or assembly '{ASSEMBLY}.dll'. An attempt was made to load a program with an incorrect format.

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- If this exception occurs for an Azure Apps deployment when upgrading an app and deploying newer assemblies, manually delete all files from the prior deployment. Lingering incompatible assemblies can result in a `System.BadImageFormatException` exception when deploying an upgraded app.

URI endpoint wrong or stopped website

- **Browser:** ERR_CONNECTION_REFUSED --**OR**-- Unable to connect
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

- Confirm the correct URI endpoint for the app is in use. Check the bindings.

- Confirm that the IIS website isn't in the *Stopped* state.

CoreWebEngine or W3SVC server features disabled

OS Exception: The IIS 7.0 CoreWebEngine and W3SVC features must be installed to use the ASP.NET Core Module.

Troubleshooting:

Confirm that the proper role and features are enabled. See IIS Configuration.

Incorrect website physical path or app missing

- **Browser:** 403 Forbidden - Access is denied --**OR**-- 403.14 Forbidden - The Web server is configured to not list the contents of this directory.
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

Check the IIS website **Basic Settings** and the physical app folder. Confirm that the app is in the folder at the IIS website **Physical path**.

Incorrect role, ASP.NET Core Module not installed, or incorrect permissions

- **Browser:** 500.19 Internal Server Error - The requested page cannot be accessed because the related configuration data for the page is invalid. --**OR**-- This page can't be displayed
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

- Confirm that the proper role is enabled. See IIS Configuration.
- Open **Programs & Features** or **Apps & features** and confirm that **Windows Server Hosting** is installed. If **Windows Server Hosting** isn't present in the list of installed programs, download and install the .NET Core Hosting Bundle.

  Current .NET Core Hosting Bundle installer (direct download)

  For more information, see Install the .NET Core Hosting Bundle.
- Make sure that the **Application Pool** > **Process Model** > **Identity** is set to **ApplicationPoolIdentity** or the custom identity has the correct permissions to access the app's deployment folder.
- If you uninstalled the ASP.NET Core Hosting Bundle and installed an earlier version of the hosting bundle, the *applicationHost.config* file doesn't include a section for the ASP.NET Core Module. Open *applicationHost.config* at *%windir%/System32/inetsrv/config* and find the `<configuration><configSections><sectionGroup name="system.webServer">` section group. If the section for the ASP.NET Core Module is missing from the section group, add the section element:

  ```
  <section name="aspNetCore" overrideModeDefault="Allow" />
  ```

  Alternatively, install the latest version of the ASP.NET Core Hosting Bundle. The latest version is backwards-

compatible with supported ASP.NET Core apps.

Incorrect processPath, missing PATH variable, Hosting Bundle not installed, system/IIS not restarted, VC++ Redistributable not installed, or dotnet.exe access violation

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"{...}" ', ErrorCode = '0x80070002 : 0.
- **ASP.NET Core Module stdout Log:** The log file is created but empty.

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Check the *processPath* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's `dotnet` for a framework-dependent deployment (FDD) or `.\{ASSEMBLY}.exe` for a self-contained deployment (SCD).
- For an FDD, *dotnet.exe* might not be accessible via the PATH settings. Confirm that *C:\Program Files\dotnet* exists in the System PATH settings.
- For an FDD, *dotnet.exe* might not be accessible for the user identity of the app pool. Confirm that the app pool user identity has access to the *C:\Program Files\dotnet* directory. Confirm that there are no deny rules configured for the app pool user identity on the *C:\Program Files\dotnet* and app directories.
- An FDD may have been deployed and .NET Core installed without restarting IIS. Either restart the server or restart IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.
- An FDD may have been deployed without installing the .NET Core runtime on the hosting system. If the .NET Core runtime hasn't been installed, run the **.NET Core Hosting Bundle installer** on the system.

  Current .NET Core Hosting Bundle installer (direct download)

  For more information, see Install the .NET Core Hosting Bundle.

  If a specific runtime is required, download the runtime from the .NET Download Archives and install it on the system. Complete the installation by restarting the system or restarting IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.

Incorrect arguments of <aspNetCore> element

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"dotnet" .{ASSEMBLY}.dll', ErrorCode = '0x80004005 : 80008081.
- **ASP.NET Core Module stdout Log:** The application to execute does not exist: 'PATH{ASSEMBLY}.dll'

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Examine the *arguments* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's either (a) `.\{ASSEMBLY}.dll` for a framework-dependent deployment (FDD); or (b) not present, an empty string (`arguments=""`), or a list of the app's arguments (`arguments="{ARGUMENT_1}, {ARGUMENT_2}, ... {ARGUMENT_X}"`)

for a self-contained deployment (SCD).

Troubleshooting:

For a framework-dependent deployment (FDD), confirm that the correct runtime installed on the system.

Stopped Application Pool

- **Browser:** 503 Service Unavailable
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

Confirm that the Application Pool isn't in the *Stopped* state.

Sub-application includes a <handlers> section

- **Browser:** HTTP Error 500.19 - Internal Server Error
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.

Troubleshooting:

Confirm that the sub-app's *web.config* file doesn't include a `<handlers>` section.

stdout log path incorrect

- **Browser:** The app responds normally.
- **Application Log:** Warning: Could not create stdoutLogFile \?{PATH}\path_doesnt_exist\stdout_{PROCESS ID}_{TIMESTAMP}.log, ErrorCode = -2147024893.
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

- The `stdoutLogFile` path specified in the `<aspNetCore>` element of *web.config* doesn't exist. For more information, see ASP.NET Core Module: Log creation and redirection.
- The app pool user doesn't have write access to the stdout log path.

Application configuration general issue

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' created process with commandline '"C:{PATH}{ASSEMBLY}.{exe|dll}" ' but either crashed or did not respond or did not listen on the given port '{PORT}', ErrorCode = '{ERROR CODE}'
- **ASP.NET Core Module stdout Log:** The log file is created but empty.

Troubleshooting:

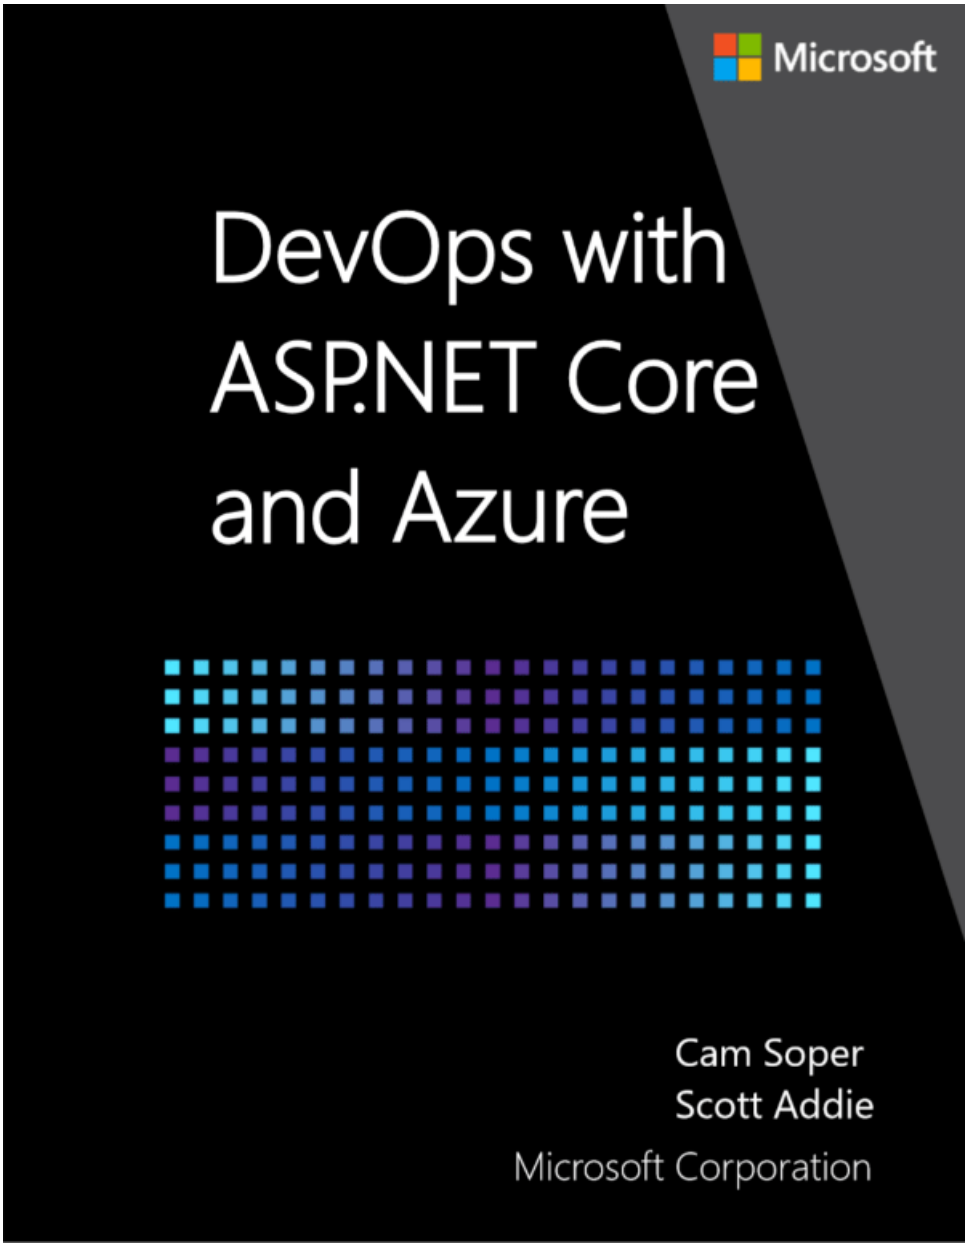
The process failed to start, most likely due to an app configuration or programming issue.

For more information, see the following topics:

- Troubleshoot ASP.NET Core on Azure App Service and IIS
- Troubleshoot and debug ASP.NET Core projects

DevOps with ASP.NET Core and Azure

9/22/2020 • 2 minutes to read • Edit Online



By Cam Soper and Scott Addie

This guide is available as a downloadable PDF e-book.

Welcome

Welcome to the Azure Development Lifecycle guide for .NET! This guide introduces the basic concepts of building a development lifecycle around Azure using .NET tools and processes. After finishing this guide, you'll reap the benefits of a mature DevOps toolchain.

Who this guide is for

You should be an experienced ASP.NET Core developer (200-300 level). You don't need to know anything about Azure, as we'll cover that in this introduction. This guide may also be useful for DevOps engineers who are more focused on operations than development.

This guide targets Windows developers. However, Linux and macOS are fully supported by .NET Core. To adapt this guide for Linux/macOS, watch for callouts for Linux/macOS differences.

What this guide doesn't cover

This guide is focused on an end-to-end continuous deployment experience for .NET developers. It's not an exhaustive guide to all things Azure, and it doesn't focus extensively on .NET APIs for Azure services. The emphasis is all around continuous integration, deployment, monitoring, and debugging. Near the end of the guide, recommendations for next steps are offered. Included in the suggestions are Azure platform services that are useful to ASP.NET Core developers.

What's in this guide

Tools and downloads

Learn where to acquire the tools used in this guide.

Deploy to App Service

Learn the various methods for deploying an ASP.NET Core app to Azure App Service.

Continuous integration and deployment

Build an end-to-end continuous integration and deployment solution for your ASP.NET Core app with GitHub, Azure DevOps Services, and Azure.

Monitor and debug

Use Azure's tools to monitor, troubleshoot, and tune your application.

Next steps

Other learning paths for the ASP.NET Core developer learning Azure.

Additional introductory reading

If this is your first exposure to cloud computing, these articles explain the basics.

- What is Cloud Computing?
- Examples of Cloud Computing
- What is IaaS?
- What is PaaS?

Tools and downloads

9/22/2020 • 2 minutes to read • Edit Online

Azure has several interfaces for provisioning and managing resources, such as the Azure portal, Azure CLI, Azure PowerShell, Azure Cloud Shell, and Visual Studio. This guide takes a minimalist approach and uses the Azure Cloud Shell whenever possible to reduce the steps required. However, the Azure portal must be used for some portions.

Prerequisites

The following subscriptions are required:

- Azure — If you don't have an account, get a free trial.
- Azure DevOps Services — your Azure DevOps subscription and organization is created in Chapter 4.
- GitHub — If you don't have an account, sign up for free.

The following tools are required:

- Git — A fundamental understanding of Git is recommended for this guide. Review the Git documentation, specifically git remote and git push.
- .NET Core SDK — Version 2.1.300 or later is required to build and run the sample app. If Visual Studio is installed with the **.NET Core cross-platform development** workload, the .NET Core SDK is already installed.

  Verify your .NET Core SDK installation. Open a command shell, and run the following command:

  ```
  dotnet --version
  ```

Recommended tools (Windows only)

- Visual Studio's robust Azure tools provide a GUI for most of the functionality described in this guide. Any edition of Visual Studio will work, including the free Visual Studio Community Edition. The tutorials are written to demonstrate development, deployment, and DevOps both with and without Visual Studio.

  Confirm that Visual Studio has the following workloads installed:

  - ASP.NET and web development
  - Azure development
  - .NET Core cross-platform development

Deploy an app to App Service

9/22/2020 • 7 minutes to read • Edit Online

Azure App Service is Azure's web hosting platform. Deploying a web app to Azure App Service can be done manually or by an automated process. This section of the guide discusses deployment methods that can be triggered manually or by script using the command line, or triggered manually using Visual Studio.

In this section, you'll accomplish the following tasks:

- Download and build the sample app.
- Create an Azure App Service Web App using the Azure Cloud Shell.
- Deploy the sample app to Azure using Git.
- Deploy a change to the app using Visual Studio.
- Add a staging slot to the web app.
- Deploy an update to the staging slot.
- Swap the staging and production slots.

Download and test the app

The app used in this guide is a pre-built ASP.NET Core app, Simple Feed Reader. It's a Razor Pages app that uses the `Microsoft.SyndicationFeed.ReaderWriter` API to retrieve an RSS/Atom feed and display the news items in a list.

Feel free to review the code, but it's important to understand that there's nothing special about this app. It's just a simple ASP.NET Core app for illustrative purposes.

From a command shell, download the code, build the project, and run it as follows.

> *Note: Linux/macOS users should make appropriate changes for paths, e.g., using forward slash (`/`) rather than back slash (`\`).*

1. Clone the code to a folder on your local machine.

   ```
   git clone https://github.com/Azure-Samples/simple-feed-reader/
   ```

2. Change your working folder to the *simple-feed-reader* folder that was created.

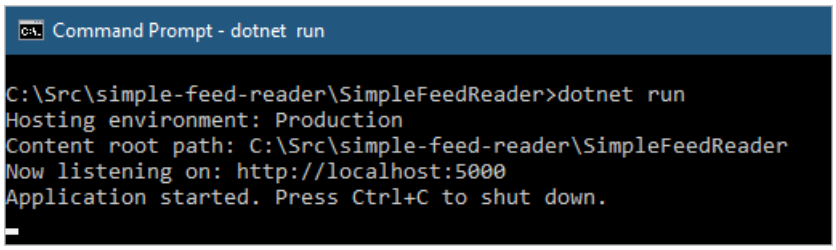
   ```
   cd .\simple-feed-reader\SimpleFeedReader
   ```

3. Restore the packages, and build the solution.

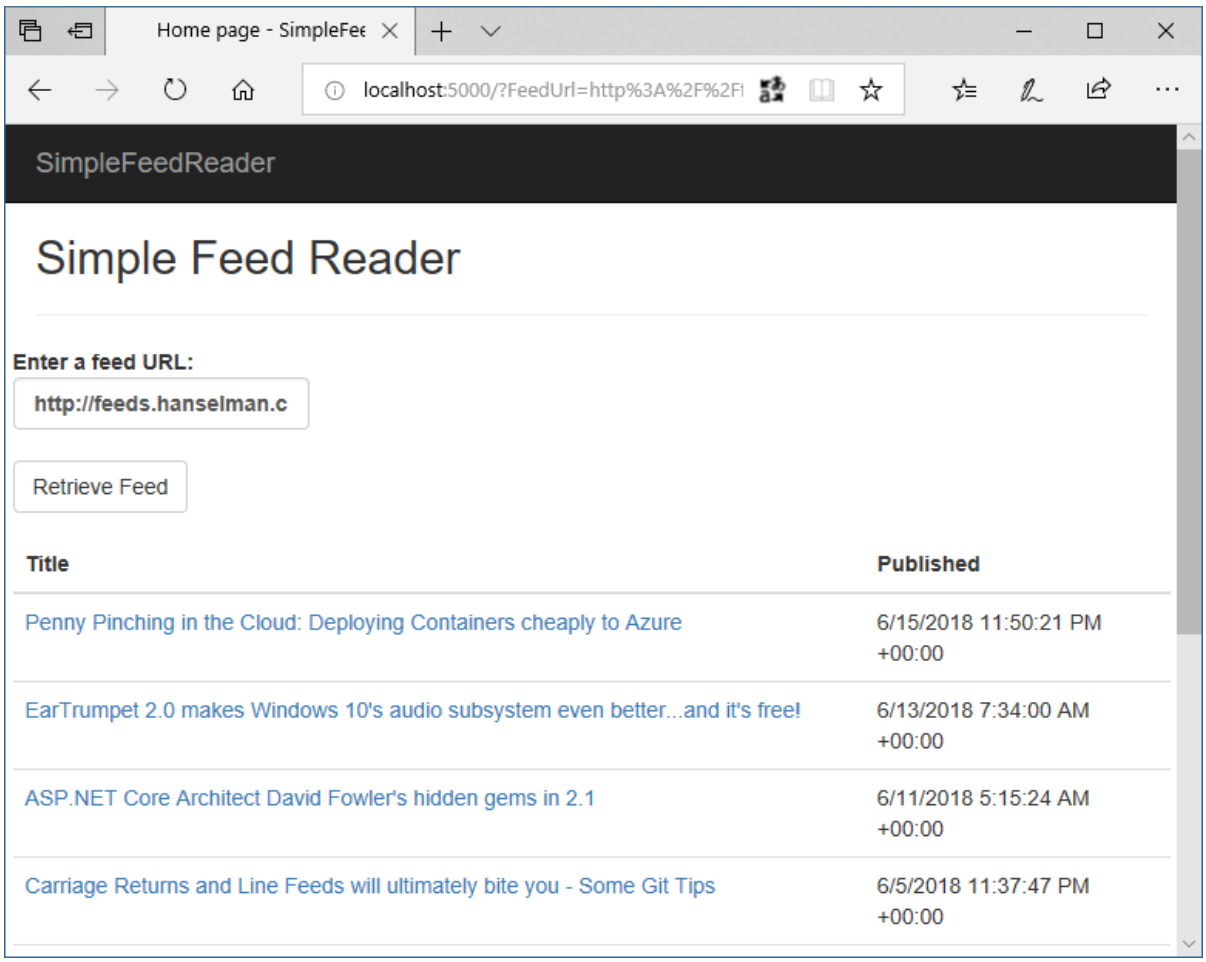
   ```
   dotnet build
   ```

4. Run the app.

   ```
   dotnet run
   ```



5. Open a browser and navigate to `http://localhost:5000`. The app allows you to type or paste a syndication feed URL and view a list of news items.



6. Once you're satisfied the app is working correctly, shut it down by pressing **Ctrl**+**C** in the command shell.

Create the Azure App Service Web App

To deploy the app, you'll need to create an App Service Web App. After creation of the Web App, you'll deploy to it from your local machine using Git.

1. Sign in to the Azure Cloud Shell. Note: When you sign in for the first time, Cloud Shell prompts to create a storage account for configuration files. Accept the defaults or provide a unique name.

2. Use the Cloud Shell for the following steps.

   a. Declare a variable to store your web app's name. The name must be unique to be used in the default URL. Using the `$RANDOM` Bash function to construct the name guarantees uniqueness and results in the format `webappname99999`.

   ```
   webappname=mywebapp$RANDOM
   ```

   b. Create a resource group. Resource groups provide a means to aggregate Azure resources to be managed

as a group.

```
az group create --location centralus --name AzureTutorial
```

The `az` command invokes the Azure CLI. The CLI can be run locally, but using it in the Cloud Shell saves time and configuration.

c. Create an App Service plan in the S1 tier. An App Service plan is a grouping of web apps that share the same pricing tier. The S1 tier isn't free, but it's required for the staging slots feature.

```
az appservice plan create --name $webappname --resource-group AzureTutorial --sku S1
```

d. Create the web app resource using the App Service plan in the same resource group.

```
az webapp create --name $webappname --resource-group AzureTutorial --plan $webappname
```

e. Set the deployment credentials. These deployment credentials apply to all the web apps in your subscription. Don't use special characters in the user name.

```
az webapp deployment user set --user-name REPLACE_WITH_USER_NAME --password REPLACE_WITH_PASSWORD
```

f. Configure the web app to accept deployments from local Git and display the *Git deployment URL*. **Note this URL for reference later**.

```
echo Git deployment URL: $(az webapp deployment source config-local-git --name $webappname --resource-
group AzureTutorial --query url --output tsv)
```

g. Display the *web app URL*. Browse to this URL to see the blank web app. **Note this URL for reference later**.

```
echo Web app URL: http://$webappname.azurewebsites.net
```

3. Using a command shell on your local machine, navigate to the web app's project folder (for example, `.\simple-feed-reader\SimpleFeedReader`). Execute the following commands to set up Git to push to the deployment URL:

   a. Add the remote URL to the local repository.

   ```
   git remote add azure-prod GIT_DEPLOYMENT_URL
   ```

   b. Push the local *master* branch to the *azure-prod* remote's *master* branch.

   ```
   git push azure-prod master
   ```

   You'll be prompted for the deployment credentials you created earlier. Observe the output in the command shell. Azure builds the ASP.NET Core app remotely.

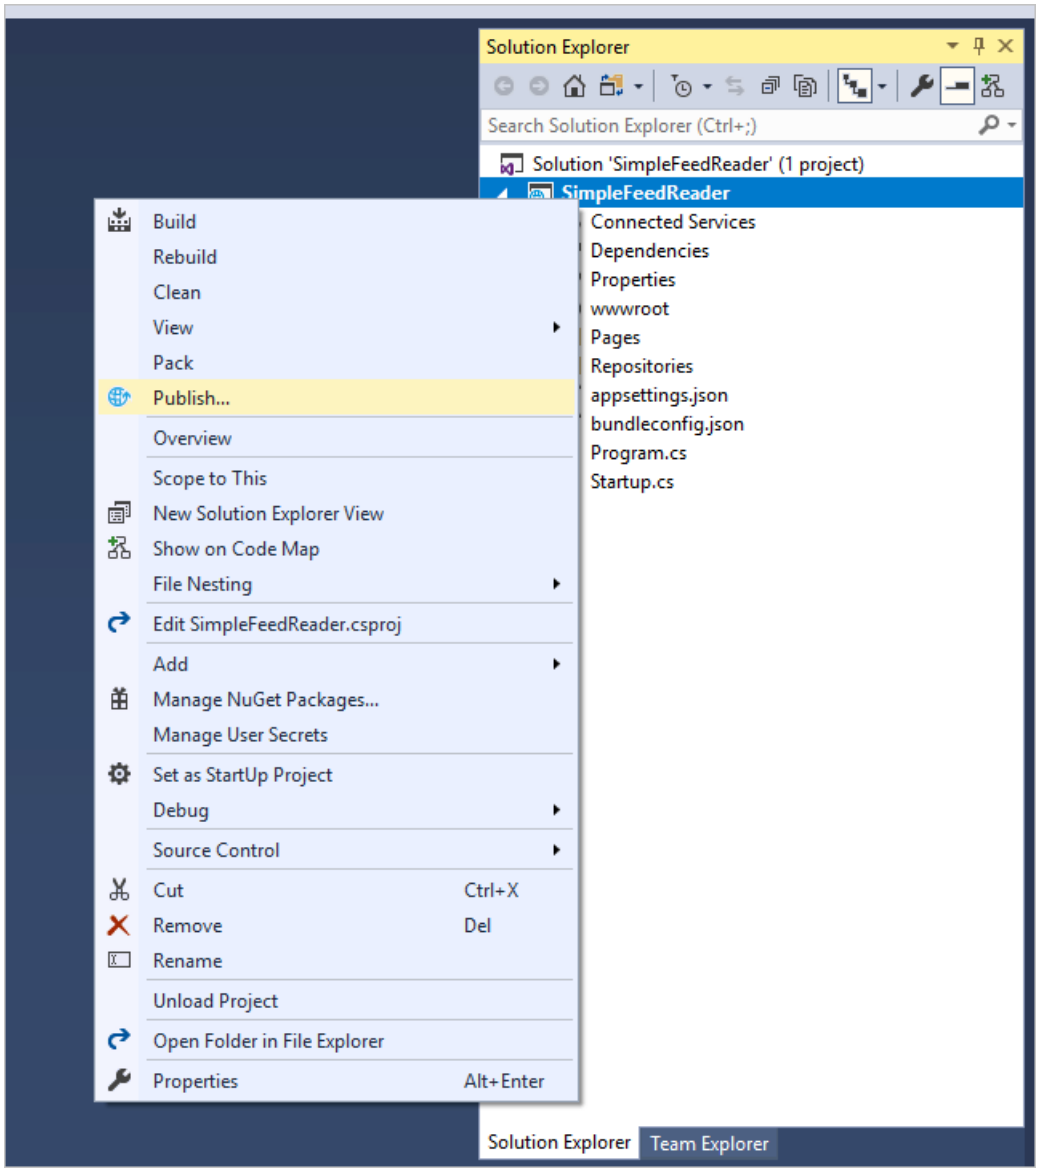
4. In a browser, navigate to the *Web app URL* and note the app has been built and deployed. Additional changes can be committed to the local Git repository with `git commit`. These changes are pushed to Azure with the preceding `git push` command.

Deployment with Visual Studio

> *Note: This section applies to Windows only. Linux and macOS users should make the change described in step 2 below. Save the file, and commit the change to the local repository with* `git commit`*. Finally, push the change with* `git push`*, as in the first section.*

The app has already been deployed from the command shell. Let's use Visual Studio's integrated tools to deploy an update to the app. Behind the scenes, Visual Studio accomplishes the same thing as the command line tooling, but within Visual Studio's familiar UI.

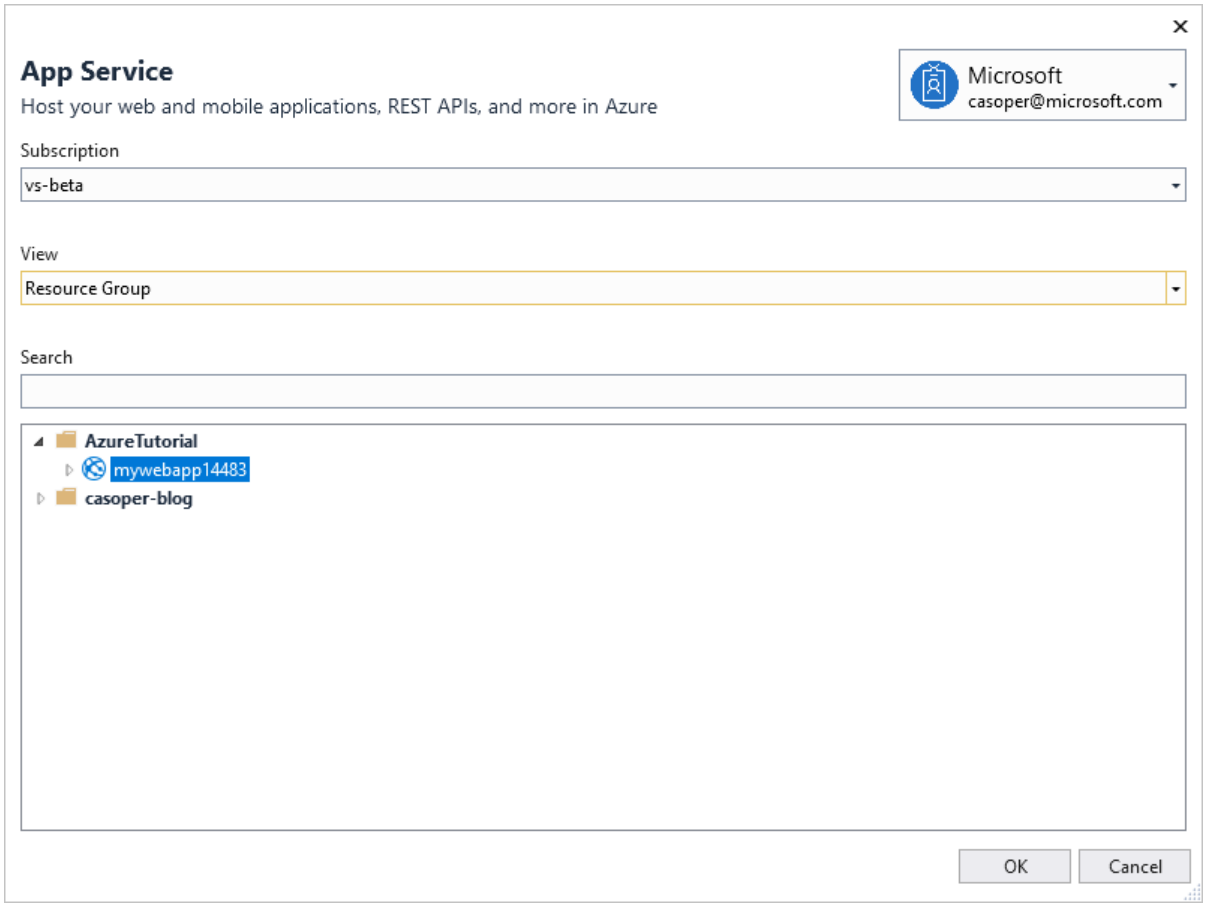
1. Open *SimpleFeedReader.sln* in Visual Studio.
2. In Solution Explorer, open *Pages\Index.cshtml*. Change `<h2>Simple Feed Reader</h2>` to `<h2>Simple Feed Reader - V2</h2>`.
3. Press **Ctrl**+**Shift**+**B** to build the app.
4. In Solution Explorer, right-click on the project and click **Publish**.



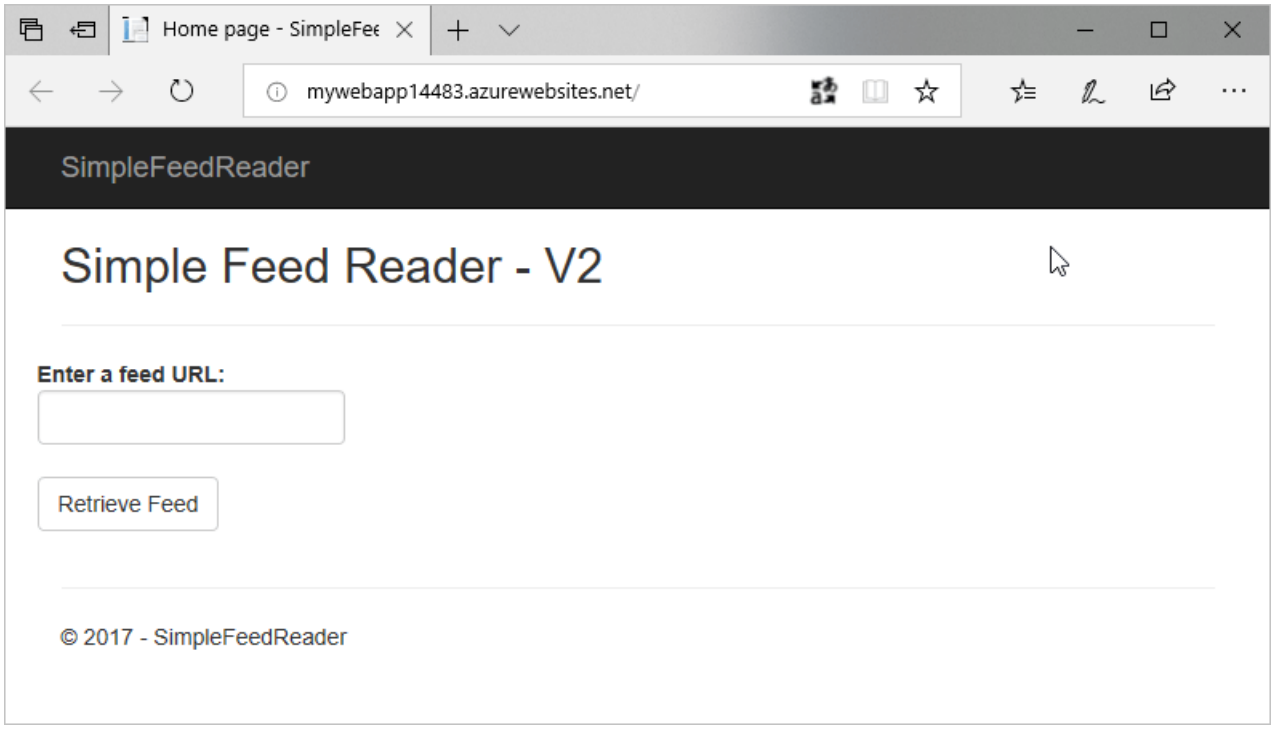
5. Visual Studio can create a new App Service resource, but this update will be published over the existing deployment. In the **Pick a publish target** dialog, select **App Service** from the list on the left, and then select **Select Existing**. Click **Publish**.
6. In the **App Service** dialog, confirm that the Microsoft or Organizational account used to create your Azure

subscription is displayed in the upper right. If it's not, click the drop-down and add it.

7. Confirm that the correct Azure **Subscription** is selected. For **View**, select **Resource Group**. Expand the **AzureTutorial** resource group and then select the existing web app. Click **OK**.



Visual Studio builds and deploys the app to Azure. Browse to the web app URL. Validate that the `<h2>` element modification is live.



Deployment slots

Deployment slots support the staging of changes without impacting the app running in production. Once the

staged version of the app is validated by a quality assurance team, the production and staging slots can be swapped. The app in staging is promoted to production in this manner. The following steps create a staging slot, deploy some changes to it, and swap the staging slot with production after verification.

1. Sign in to the Azure Cloud Shell, if not already signed in.

2. Create the staging slot.

   a. Create a deployment slot with the name *staging*.

   ```
   az webapp deployment slot create --name $webappname --resource-group AzureTutorial --slot staging
   ```

   b. Configure the staging slot to use deployment from local Git and get the **staging** deployment URL. **Note this URL for reference later**.

   ```
   echo Git deployment URL for staging: $(az webapp deployment source config-local-git --name $webappname --resource-group AzureTutorial --slot staging --query url --output tsv)
   ```

   c. Display the staging slot's URL. Browse to the URL to see the empty staging slot. **Note this URL for reference later**.

   ```
   echo Staging web app URL: http://$webappname-staging.azurewebsites.net
   ```

3. In a text editor or Visual Studio, modify *Pages/Index.cshtml* again so that the `<h2>` element reads `<h2>Simple Feed Reader - V3</h2>` and save the file.

4. Commit the file to the local Git repository, using either the **Changes** page in Visual Studio's *Team Explorer* tab, or by entering the following using the local machine's command shell:

   ```
   git commit -a -m "upgraded to V3"
   ```

5. Using the local machine's command shell, add the staging deployment URL as a Git remote and push the committed changes:

   a. Add the remote URL for staging to the local Git repository.

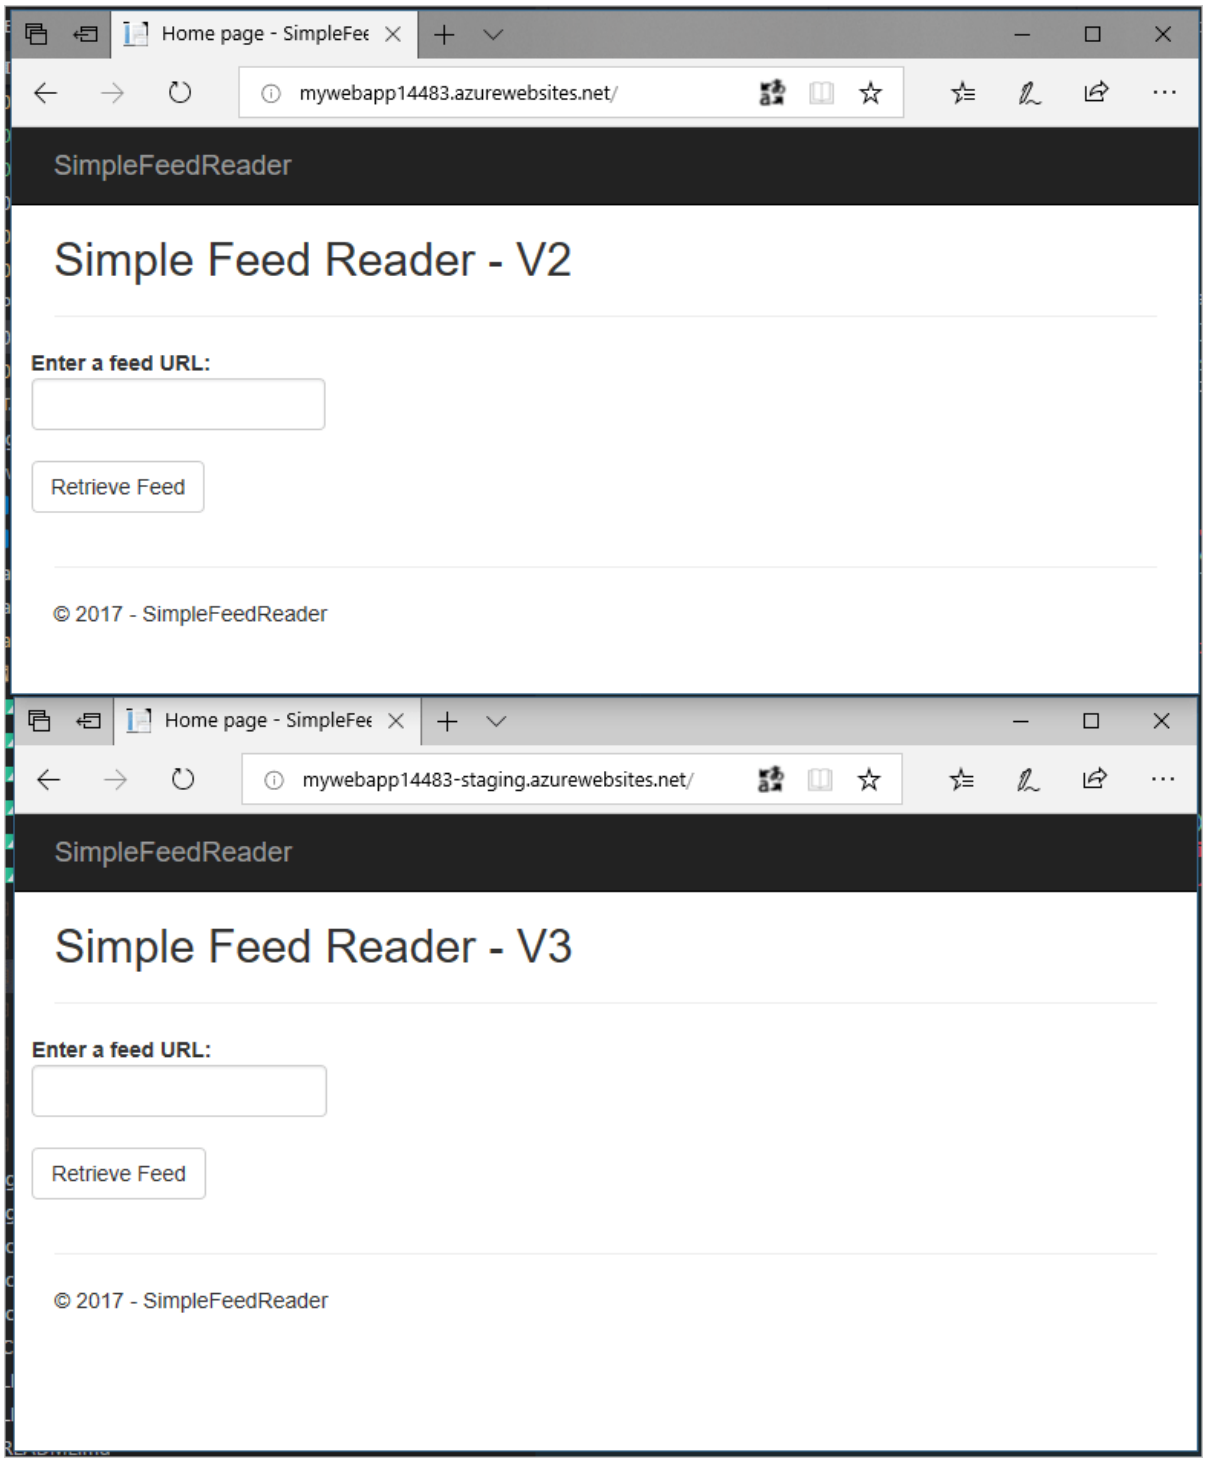
   ```
   git remote add azure-staging <Git_staging_deployment_URL>
   ```

   b. Push the local *master* branch to the *azure-staging* remote's *master* branch.

   ```
   git push azure-staging master
   ```

   Wait while Azure builds and deploys the app.

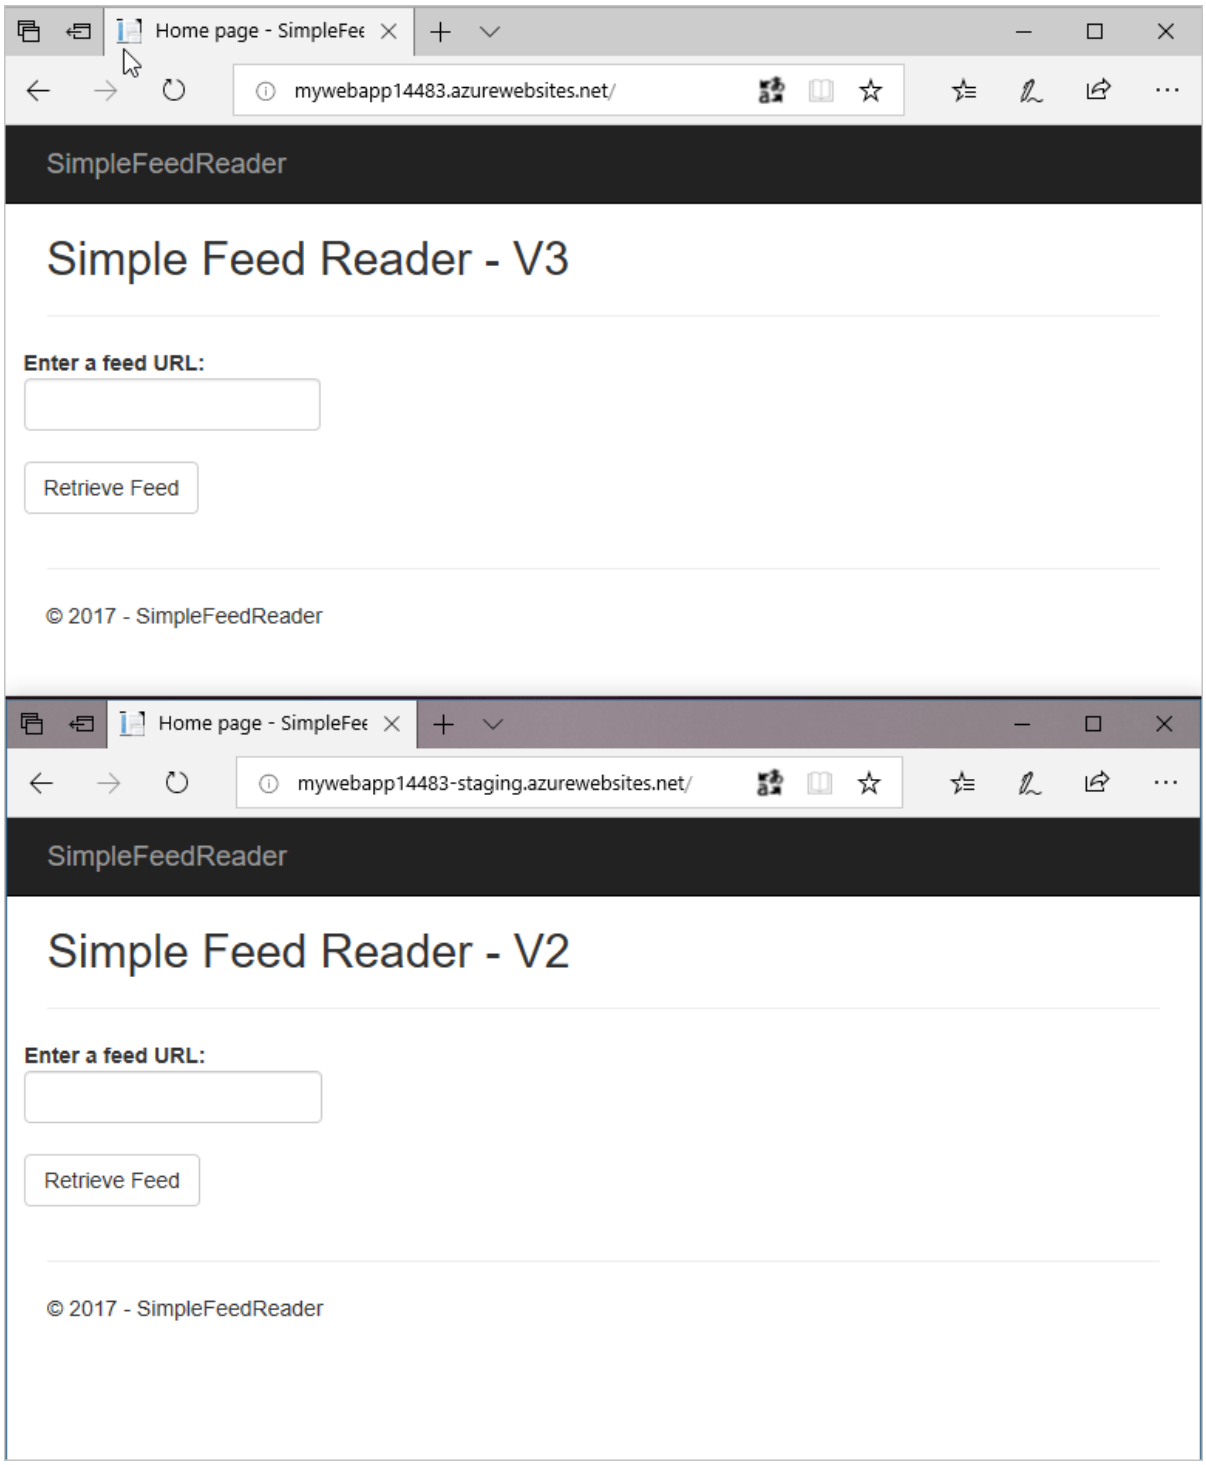
6. To verify that V3 has been deployed to the staging slot, open two browser windows. In one window, navigate to the original web app URL. In the other window, navigate to the staging web app URL. The production URL serves V2 of the app. The staging URL serves V3 of the app.



7. In the Cloud Shell, swap the verified/warmed-up staging slot into production.

```
az webapp deployment slot swap --name $webappname --resource-group AzureTutorial --slot staging
```

8. Verify that the swap occurred by refreshing the two browser windows.



Summary

In this section, the following tasks were completed:

- Downloaded and built the sample app.
- Created an Azure App Service Web App using the Azure Cloud Shell.
- Deployed the sample app to Azure using Git.
- Deployed a change to the app using Visual Studio.
- Added a staging slot to the web app.
- Deployed an update to the staging slot.
- Swapped the staging and production slots.

In the next section, you'll learn how to build a DevOps pipeline with Azure Pipelines.

Additional reading

- Web Apps overview
- Build a .NET Core and SQL Database web app in Azure App Service
- Configure deployment credentials for Azure App Service
- Set up staging environments in Azure App Service

Continuous integration and deployment

9/22/2020 • 10 minutes to read • Edit Online

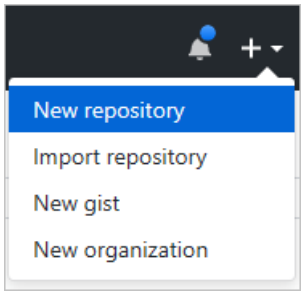
In the previous chapter, you created a local Git repository for the Simple Feed Reader app. In this chapter, you'll publish that code to a GitHub repository and construct an Azure DevOps Services pipeline using Azure Pipelines. The pipeline enables continuous builds and deployments of the app. Any commit to the GitHub repository triggers a build and a deployment to the Azure Web App's staging slot.

In this section, you'll complete the following tasks:

- Publish the app's code to GitHub
- Disconnect local Git deployment
- Create an Azure DevOps organization
- Create a team project in Azure DevOps Services
- Create a build definition
- Create a release pipeline
- Commit changes to GitHub and automatically deploy to Azure
- Examine the Azure Pipelines pipeline

Publish the app's code to GitHub

1. Open a browser window, and navigate to `https://github.com`.
2. Click the **+** drop-down in the header, and select **New repository**:



3. Select your account in the **Owner** drop-down, and enter *simple-feed-reader* in the **Repository name** textbox.
4. Click the **Create repository** button.
5. Open your local machine's command shell. Navigate to the directory in which the *simple-feed-reader* Git repository is stored.
6. Rename the existing *origin* remote to *upstream*. Execute the following command:

```
git remote rename origin upstream
```

7. Add a new *origin* remote pointing to your copy of the repository on GitHub. Execute the following command:

```
git remote add origin https://github.com/<GitHub_username>/simple-feed-reader/
```

8. Publish your local Git repository to the newly created GitHub repository. Execute the following command:

```
git push -u origin master
```

9. Open a browser window, and navigate to `https://github.com/<GitHub_username>/simple-feed-reader/`. Validate that your code appears in the GitHub repository.

Disconnect local Git deployment

Remove the local Git deployment with the following steps. Azure Pipelines (an Azure DevOps service) both replaces and augments that functionality.

1. Open the Azure portal, and navigate to the *staging (mywebapp<unique_number>/staging)* Web App. The Web App can be quickly located by entering *staging* in the portal's search box:

2. Click **Deployment Center**. A new panel appears. Click **Disconnect** to remove the local Git source control configuration that was added in the previous chapter. Confirm the removal operation by clicking the **Yes** button.

3. Navigate to the *mywebapp<unique_number>* App Service. As a reminder, the portal's search box can be used to quickly locate the App Service.

4. Click **Deployment Center**. A new panel appears. Click **Disconnect** to remove the local Git source control configuration that was added in the previous chapter. Confirm the removal operation by clicking the **Yes** button.

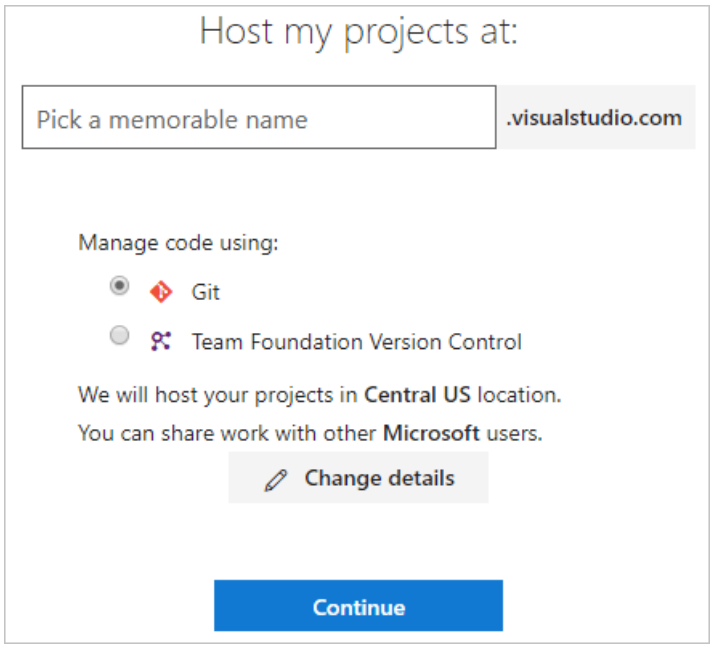
Create an Azure DevOps organization

1. Open a browser, and navigate to the Azure DevOps organization creation page.

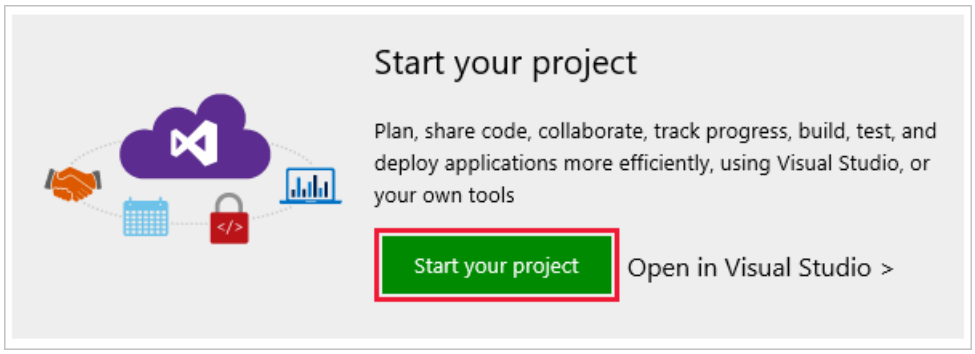
2. Type a unique name into the **Pick a memorable name** textbox to form the URL for accessing your Azure DevOps organization.

3. Select the **Git** radio button, since the code is hosted in a GitHub repository.

4. Click the **Continue** button. After a short wait, an account and a team project, named *MyFirstProject*, are created.



5. Open the confirmation email indicating that the Azure DevOps organization and project are ready for use. Click the **Start your project** button:



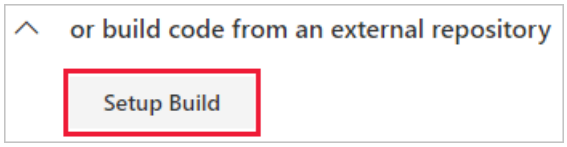
6. A browser opens to *<account_name>.visualstudio.com*. Click the *MyFirstProject* link to begin configuring the project's DevOps pipeline.

Configure the Azure Pipelines pipeline

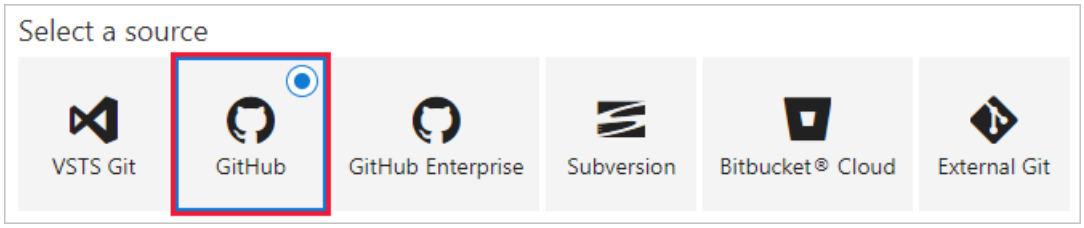
There are three distinct steps to complete. Completing the steps in the following three sections results in an operational DevOps pipeline.

Grant Azure DevOps access to the GitHub repository

1. Expand the **or build code from an external repository** accordion. Click the **Setup Build** button:

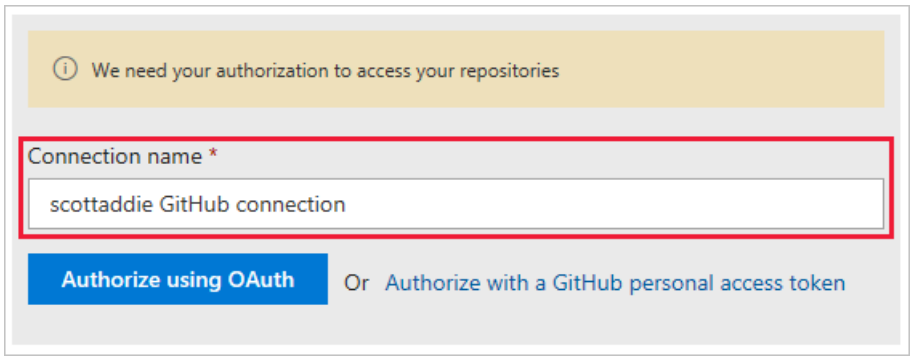


2. Select the **GitHub** option from the **Select a source** section:



3. Authorization is required before Azure DevOps can access your GitHub repository. Enter

<GitHub_username> GitHub connection in the **Connection name** textbox. For example:



4. If two-factor authentication is enabled on your GitHub account, a personal access token is required. In that case, click the **Authorize with a GitHub personal access token** link. See the official GitHub personal access token creation instructions for help. Only the *repo* scope of permissions is needed. Otherwise, click the **Authorize using OAuth** button.

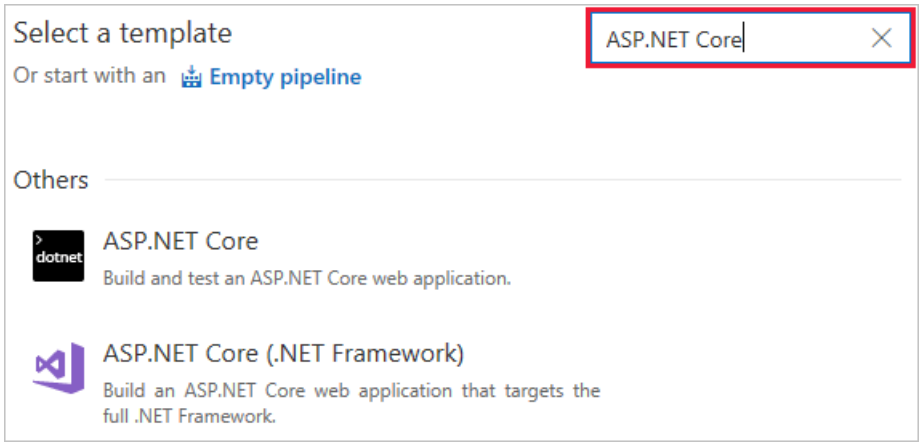
5. When prompted, sign in to your GitHub account. Then select Authorize to grant access to your Azure DevOps organization. If successful, a new service endpoint is created.

6. Click the ellipsis button next to the **Repository** button. Select the *<GitHub_username>/simple-feed-reader* repository from the list. Click the **Select** button.

7. Select the *master* branch from the **Default branch for manual and scheduled builds** drop-down. Click the **Continue** button. The template selection page appears.

Create the build definition

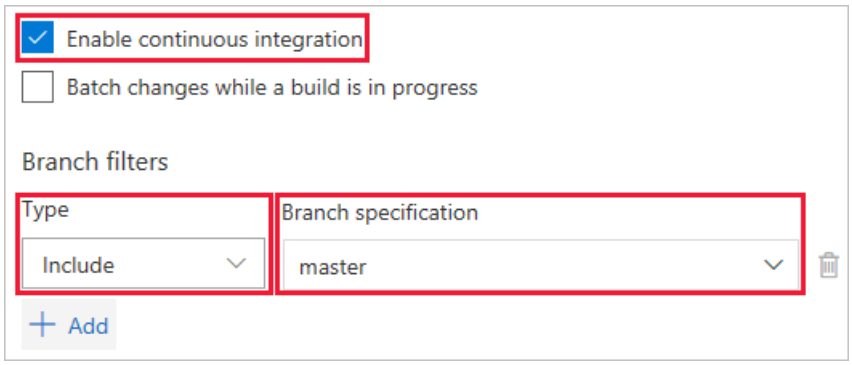
1. From the template selection page, enter *ASP.NET Core* in the search box:



2. The template search results appear. Hover over the **ASP.NET Core** template, and click the **Apply** button.

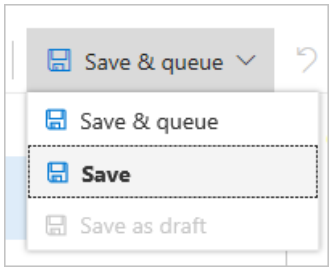
3. The **Tasks** tab of the build definition appears. Click the **Triggers** tab.

4. Check the **Enable continuous integration** box. Under the **Branch filters** section, confirm that the **Type** drop-down is set to *Include*. Set the **Branch specification** drop-down to *master*.

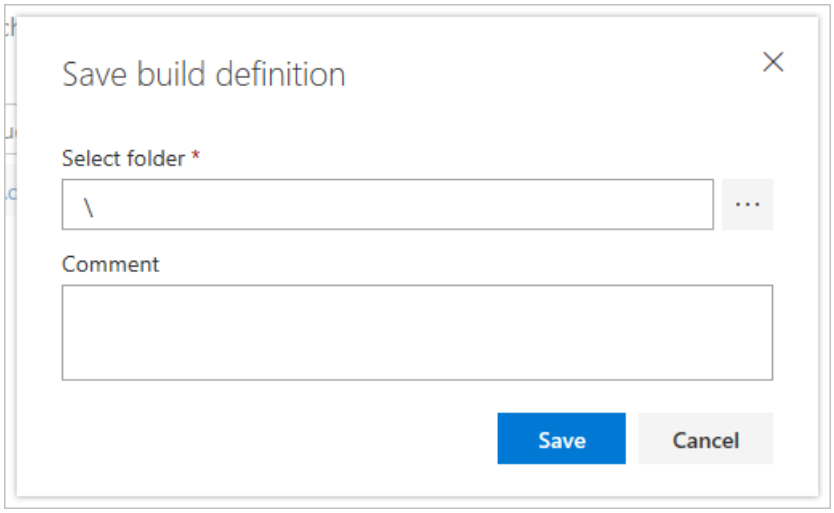


These settings cause a build to trigger when any change is pushed to the *master* branch of the GitHub repository. Continuous integration is tested in the Commit changes to GitHub and automatically deploy to Azure section.

5. Click the **Save & queue** button, and select the **Save** option:



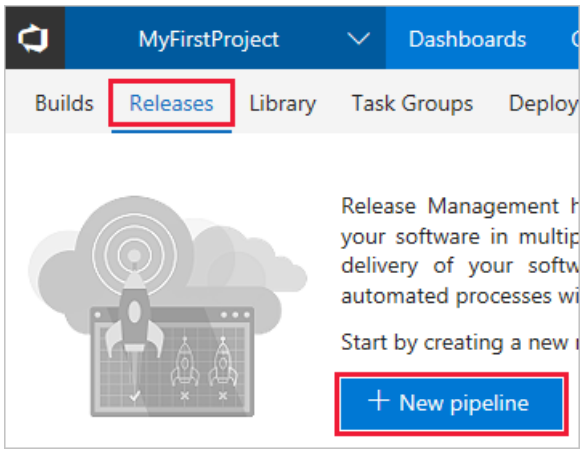
6. The following modal dialog appears:



Use the default folder of \, and click the **Save** button.

Create the release pipeline

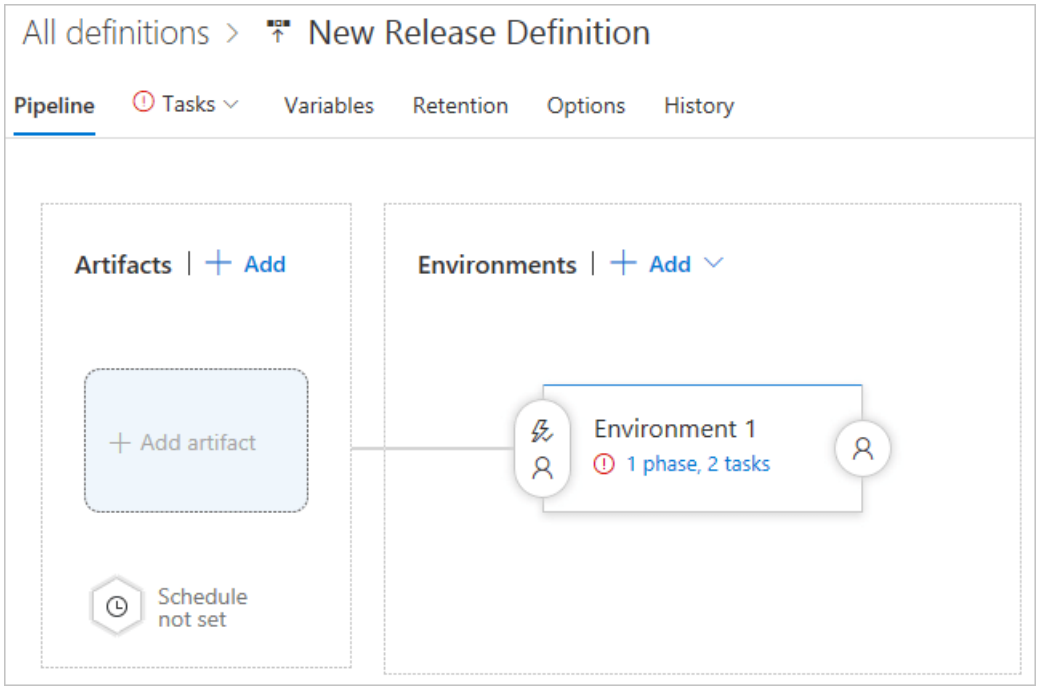
1. Click the **Releases** tab of your team project. Click the **New pipeline** button.



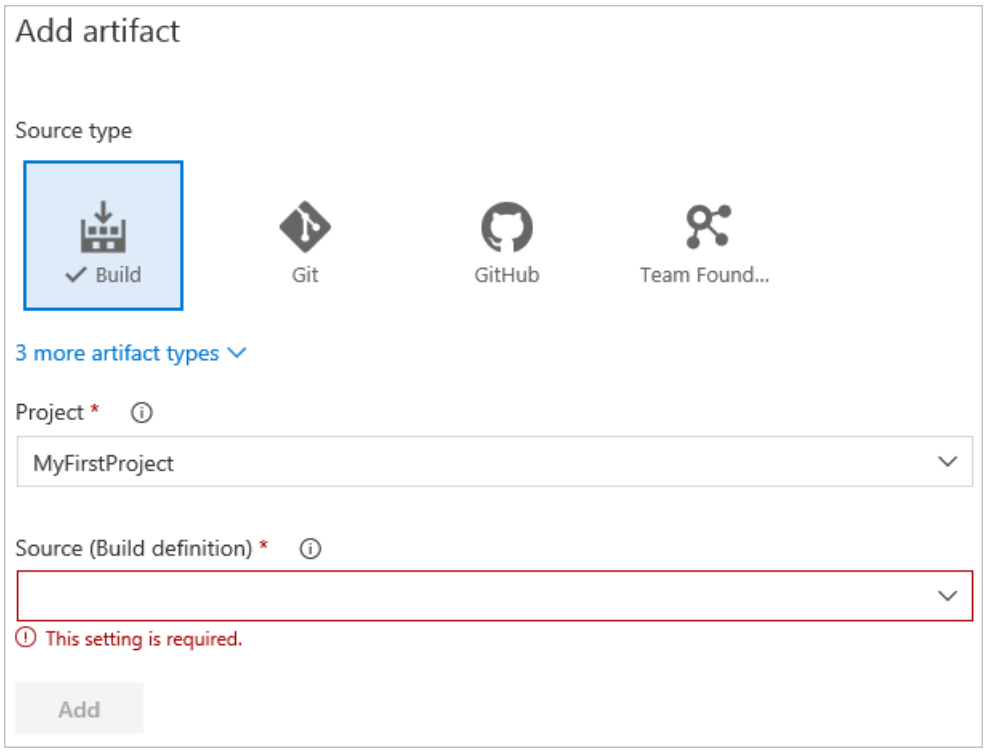
The template selection pane appears.

2. From the template selection page, enter *App Service* in the search box:

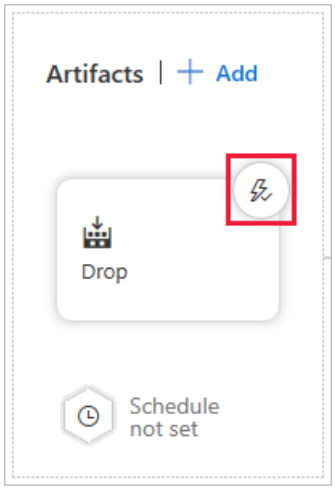
3. The template search results appear. Hover over the **Azure App Service Deployment with Slot** template, and click the **Apply** button. The **Pipeline** tab of the release pipeline appears.



4. Click the **Add** button in the **Artifacts** box. The **Add artifact** panel appears:



5. Select the **Build** tile from the **Source type** section. This type allows for the linking of the release pipeline to the build definition.
6. Select *MyFirstProject* from the **Project** drop-down.
7. Select the build definition name, *MyFirstProject-ASP.NET Core-CI*, from the **Source (Build definition)** drop-down.
8. Select *Latest* from the **Default version** drop-down. This option builds the artifacts produced by the latest run of the build definition.
9. Replace the text in the **Source alias** textbox with *Drop*.
10. Click the **Add** button. The **Artifacts** section updates to display the changes.
11. Click the lightning bolt icon to enable continuous deployments:



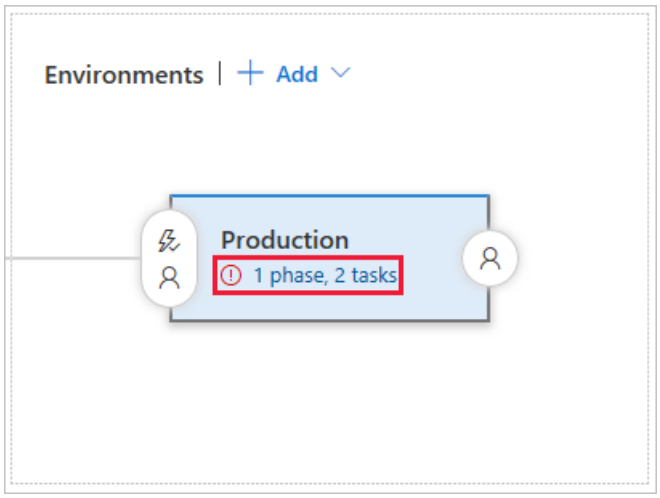
With this option enabled, a deployment occurs each time a new build is available.

12. A **Continuous deployment trigger** panel appears to the right. Click the toggle button to enable the feature. It isn't necessary to enable the **Pull request trigger**.
13. Click the **Add** drop-down in the **Build branch filters** section. Choose the **Build Definition's default branch** option. This filter causes the release to trigger only for a build from the GitHub repository's *master*

branch.

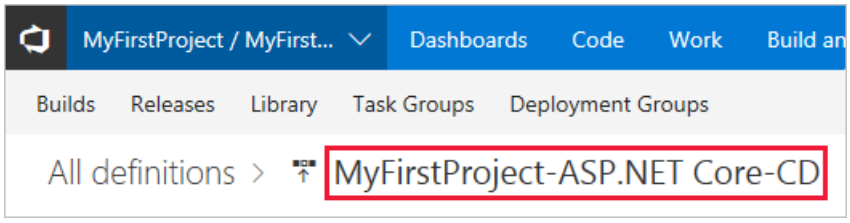
14. Click the **Save** button. Click the **OK** button in the resulting **Save** modal dialog.
15. Click the **Environment 1** box. An **Environment** panel appears to the right. Change the *Environment 1* text in the **Environment name** textbox to *Production*.

16. Click the **1 phase, 2 tasks** link in the **Production** box:



The **Tasks** tab of the environment appears.

17. Click the **Deploy Azure App Service to Slot** task. Its settings appear in a panel to the right.
18. Select the Azure subscription associated with the App Service from the **Azure subscription** drop-down. Once selected, click the **Authorize** button.
19. Select *Web App* from the **App type** drop-down.
20. Select *mywebapp/<unique_number/>* from the **App service name** drop-down.
21. Select *AzureTutorial* from the **Resource group** drop-down.
22. Select *staging* from the **Slot** drop-down.
23. Click the **Save** button.
24. Hover over the default release pipeline name. Click the pencil icon to edit it. Use *MyFirstProject-ASP.NET Core-CD* as the name.



25. Click the **Save** button.

Commit changes to GitHub and automatically deploy to Azure

1. Open *SimpleFeedReader.sln* in Visual Studio.

2. In Solution Explorer, open *Pages\Index.cshtml*. Change `<h2>Simple Feed Reader - V3</h2>` to `<h2>Simple Feed Reader - V4</h2>`.

3. Press **Ctrl**+**Shift**+**B** to build the app.

4. Commit the file to the GitHub repository. Use either the **Changes** page in Visual Studio's *Team Explorer* tab, or execute the following using the local machine's command shell:

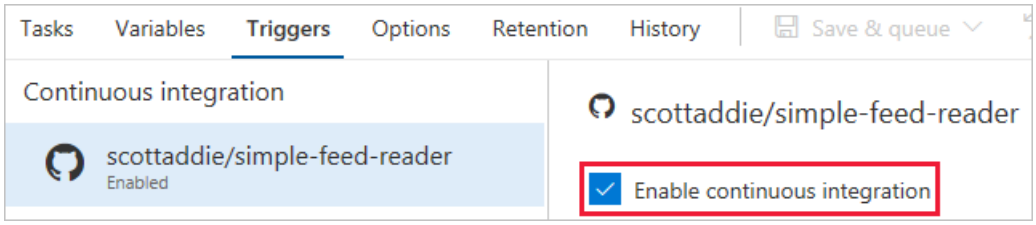
   ```
   git commit -a -m "upgraded to V4"
   ```

5. Push the change in the *master* branch to the *origin* remote of your GitHub repository:

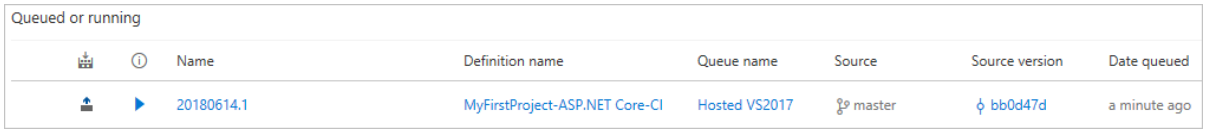
   ```
   git push origin master
   ```

   The commit appears in the GitHub repository's *master* branch:

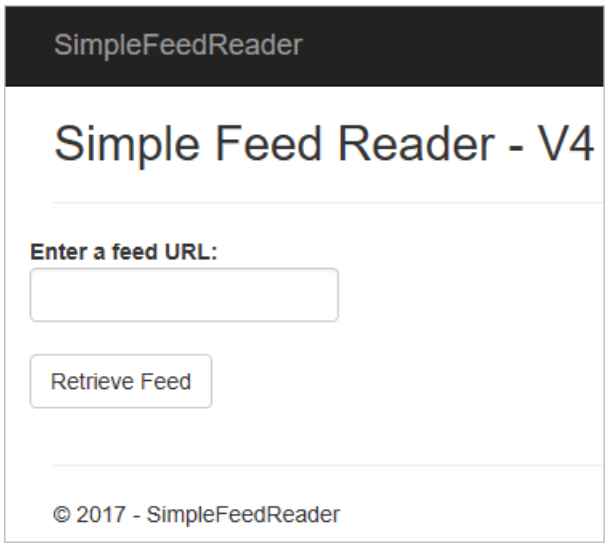
   
   The build is triggered, since continuous integration is enabled in the build definition's **Triggers** tab:

6. Navigate to the **Queued** tab of the **Azure Pipelines** > **Builds** page in Azure DevOps Services. The queued build shows the branch and commit that triggered the build:

7. Once the build succeeds, a deployment to Azure occurs. Navigate to the app in the browser. Notice that the "V4" text appears in the heading:

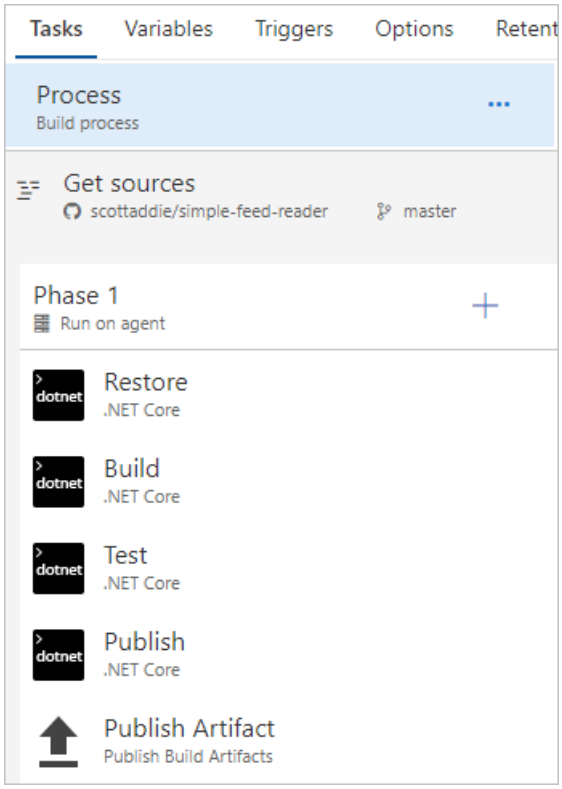


Examine the Azure Pipelines pipeline

Build definition

A build definition was created with the name *MyFirstProject-ASP.NET Core-CI*. Upon completion, the build produces a *.zip* file including the assets to be published. The release pipeline deploys those assets to Azure.

The build definition's **Tasks** tab lists the individual steps being used. There are five build tasks.



1. **Restore** — Executes the `dotnet restore` command to restore the app's NuGet packages. The default package feed used is nuget.org.
2. **Build** — Executes the `dotnet build --configuration release` command to compile the app's code. This `--configuration` option is used to produce an optimized version of the code, which is suitable for deployment to a production environment. Modify the *BuildConfiguration* variable on the build definition's **Variables** tab if, for example, a debug configuration is needed.
3. **Test** — Executes the `dotnet test --configuration release --logger trx --results-directory <local_path_on_build_agent>`

command to run the app's unit tests. Unit tests are executed within any C# project matching the `**/*Tests/*.csproj` glob pattern. Test results are saved in a *.trx* file at the location specified by the `--results-directory` option. If any tests fail, the build fails and isn't deployed.

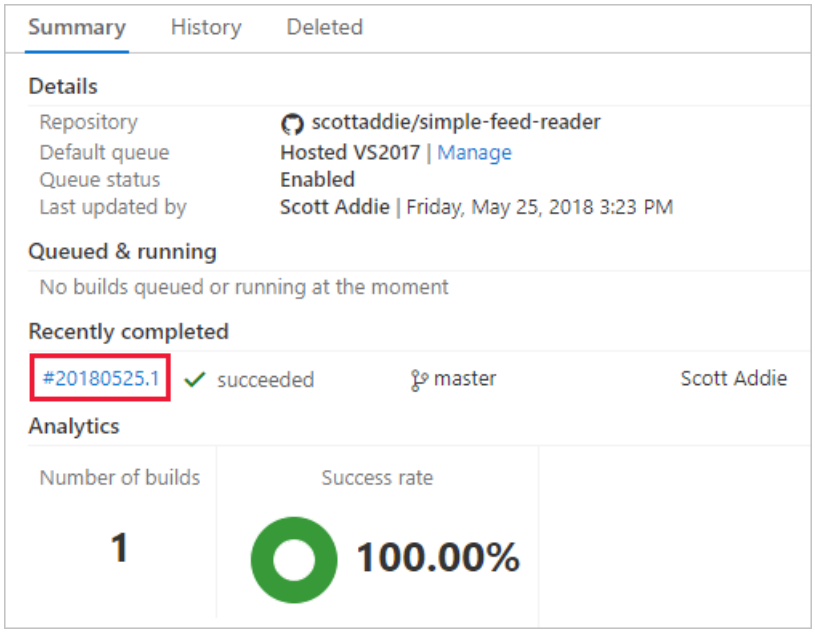
> **NOTE**
>
> To verify the unit tests work, modify *SimpleFeedReader.Tests\Services\NewsServiceTests.cs* to purposefully break one of the tests. For example, change `Assert.True(result.Count > 0);` to `Assert.False(result.Count > 0);` in the `Returns_News_Stories_Given_Valid_Uri` method. Commit and push the change to GitHub. The build is triggered and fails. The build pipeline status changes to **failed**. Revert the change, commit, and push again. The build succeeds.

4. **Publish** — Executes the `dotnet publish --configuration release --output <local_path_on_build_agent>` command to produce a *.zip* file with the artifacts to be deployed. The `--output` option specifies the publish location of the *.zip* file. That location is specified by passing a predefined variable named `$(build.artifactstagingdirectory)`. That variable expands to a local path, such as *c:\agent_work\1\a*, on the build agent.

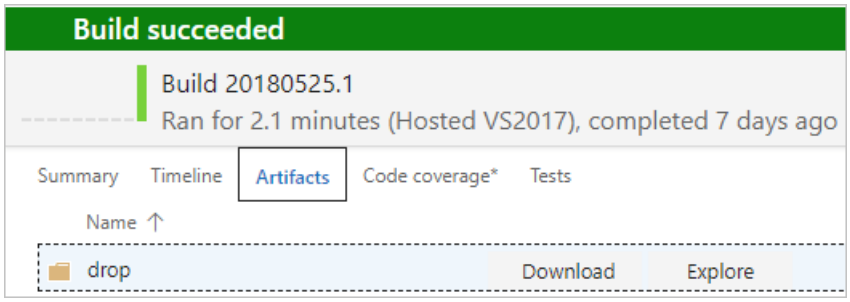
5. **Publish Artifact** — Publishes the *.zip* file produced by the **Publish** task. The task accepts the *.zip* file location as a parameter, which is the predefined variable `$(build.artifactstagingdirectory)`. The *.zip* file is published as a folder named *drop*.

Click the build definition's **Summary** link to view a history of builds with the definition:

On the resulting page, click the link corresponding to the unique build number:



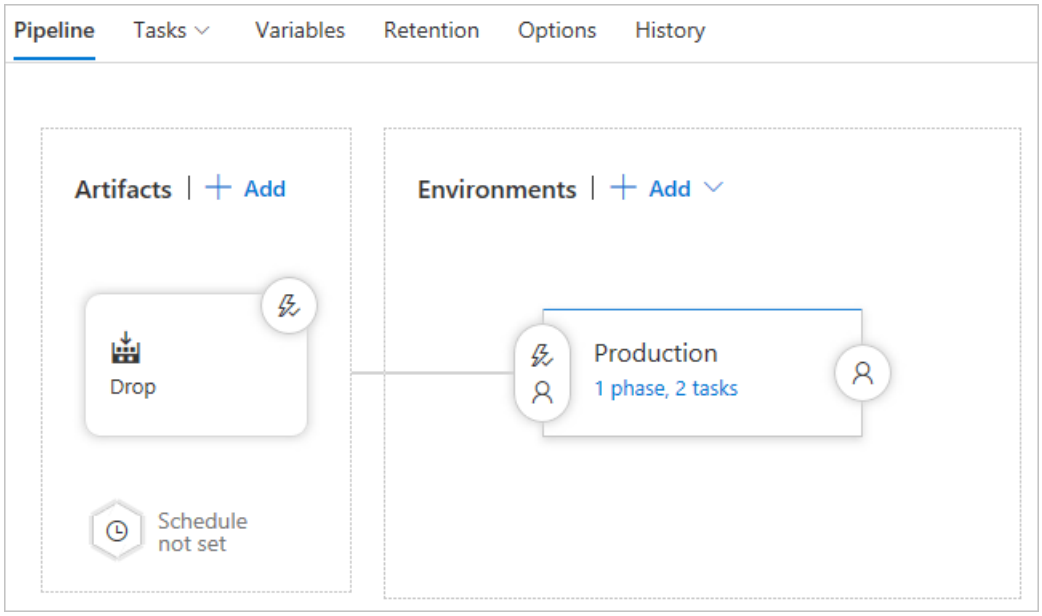
A summary of this specific build is displayed. Click the **Artifacts** tab, and notice the *drop* folder produced by the build is listed:



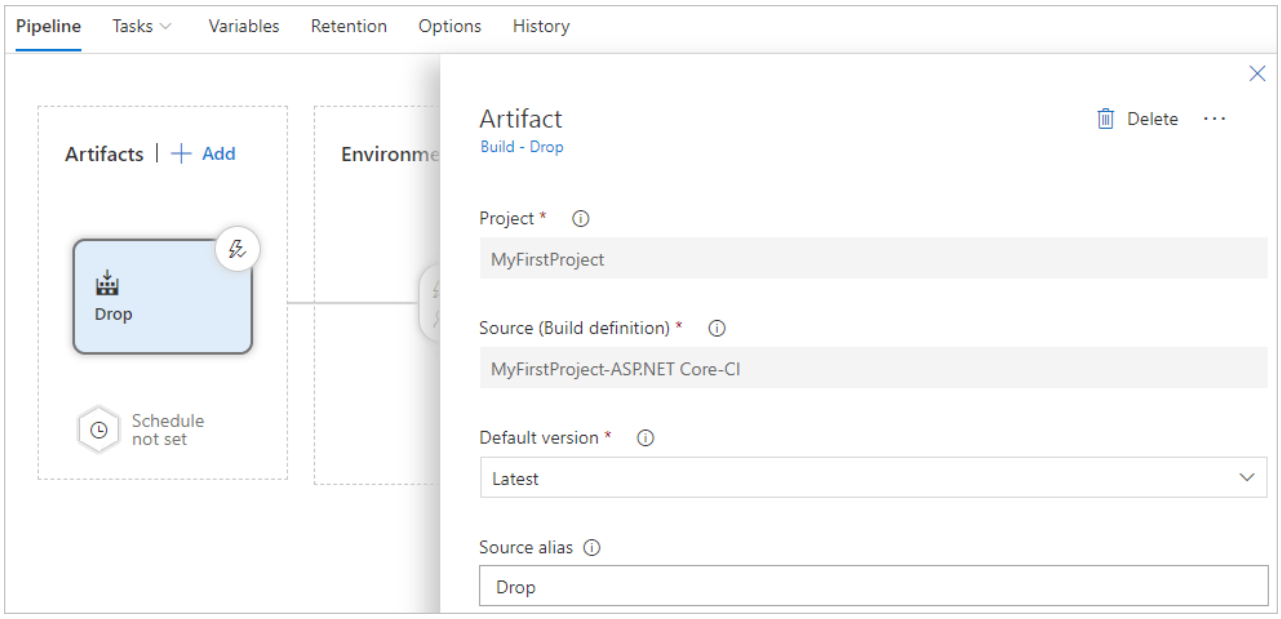
Use the **Download** and **Explore** links to inspect the published artifacts.

Release pipeline

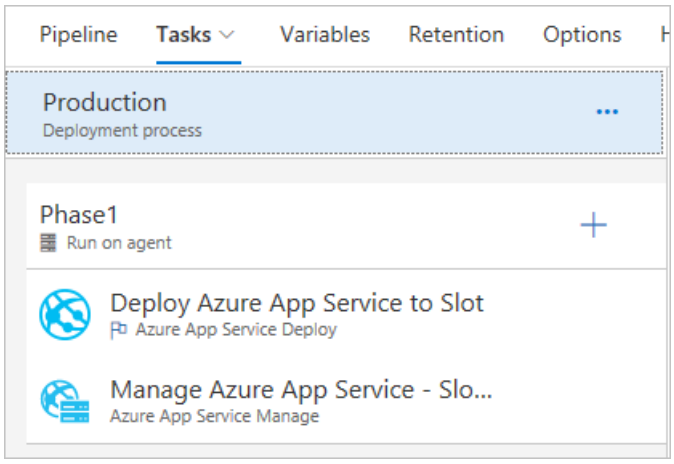
A release pipeline was created with the name *MyFirstProject-ASP.NET Core-CD*.



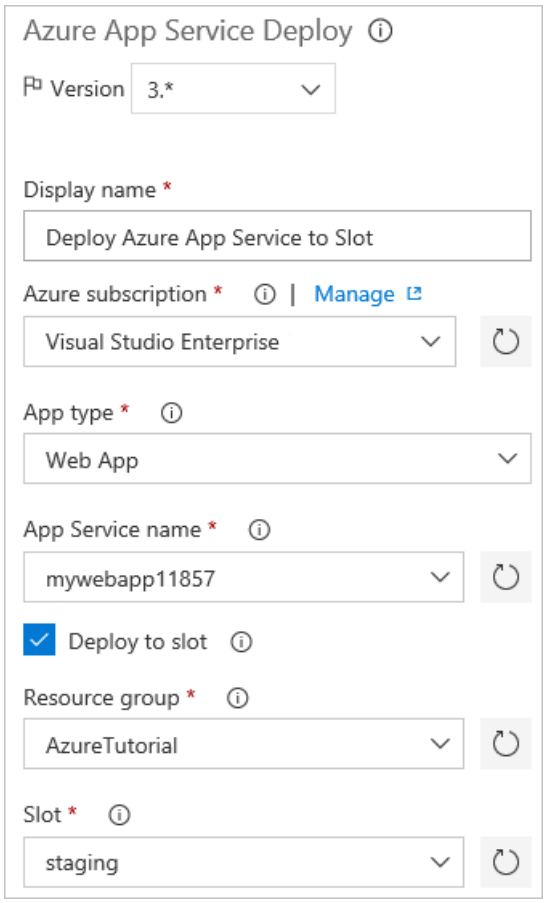
The two major components of the release pipeline are the **Artifacts** and the **Environments**. Clicking the box in the **Artifacts** section reveals the following panel:



The **Source (Build definition)** value represents the build definition to which this release pipeline is linked. The *.zip* file produced by a successful run of the build definition is provided to the *Production* environment for deployment to Azure. Click the *1 phase, 2 tasks* link in the *Production* environment box to view the release pipeline tasks:

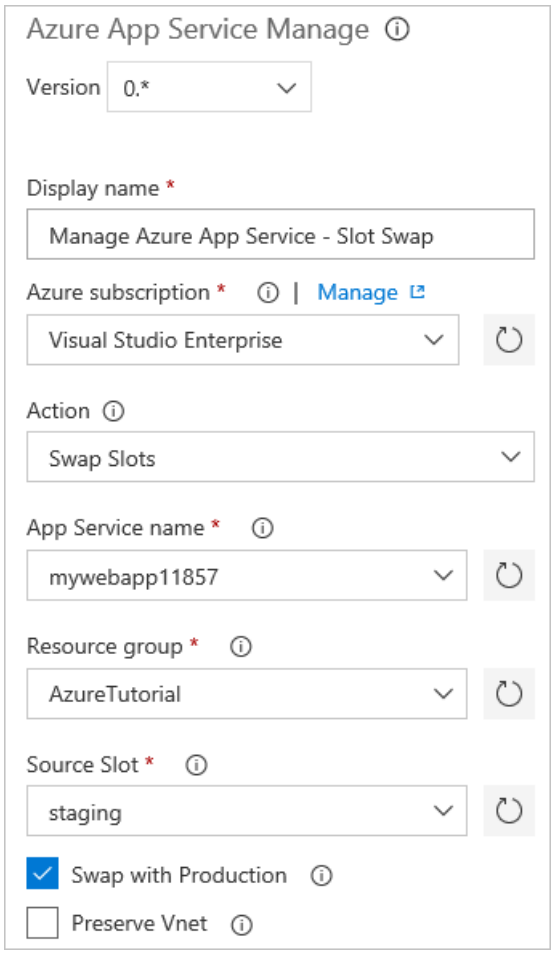


The release pipeline consists of two tasks: *Deploy Azure App Service to Slot* and *Manage Azure App Service - Slot Swap*. Clicking the first task reveals the following task configuration:



The Azure subscription, service type, web app name, resource group, and deployment slot are defined in the deployment task. The **Package or folder** textbox holds the *.zip* file path to be extracted and deployed to the *staging* slot of the *mywebapp<unique_number>* web app.

Clicking the slot swap task reveals the following task configuration:



The subscription, resource group, service type, web app name, and deployment slot details are provided. The **Swap with Production** check box is checked. Consequently, the bits deployed to the *staging* slot are swapped into the production environment.

Additional reading

- Build and .NET Core project
- Deploy a web app with Azure Pipelines

Monitor and debug

9/22/2020 • 4 minutes to read • Edit Online

Having deployed the app and built a DevOps pipeline, it's important to understand how to monitor and troubleshoot the app.

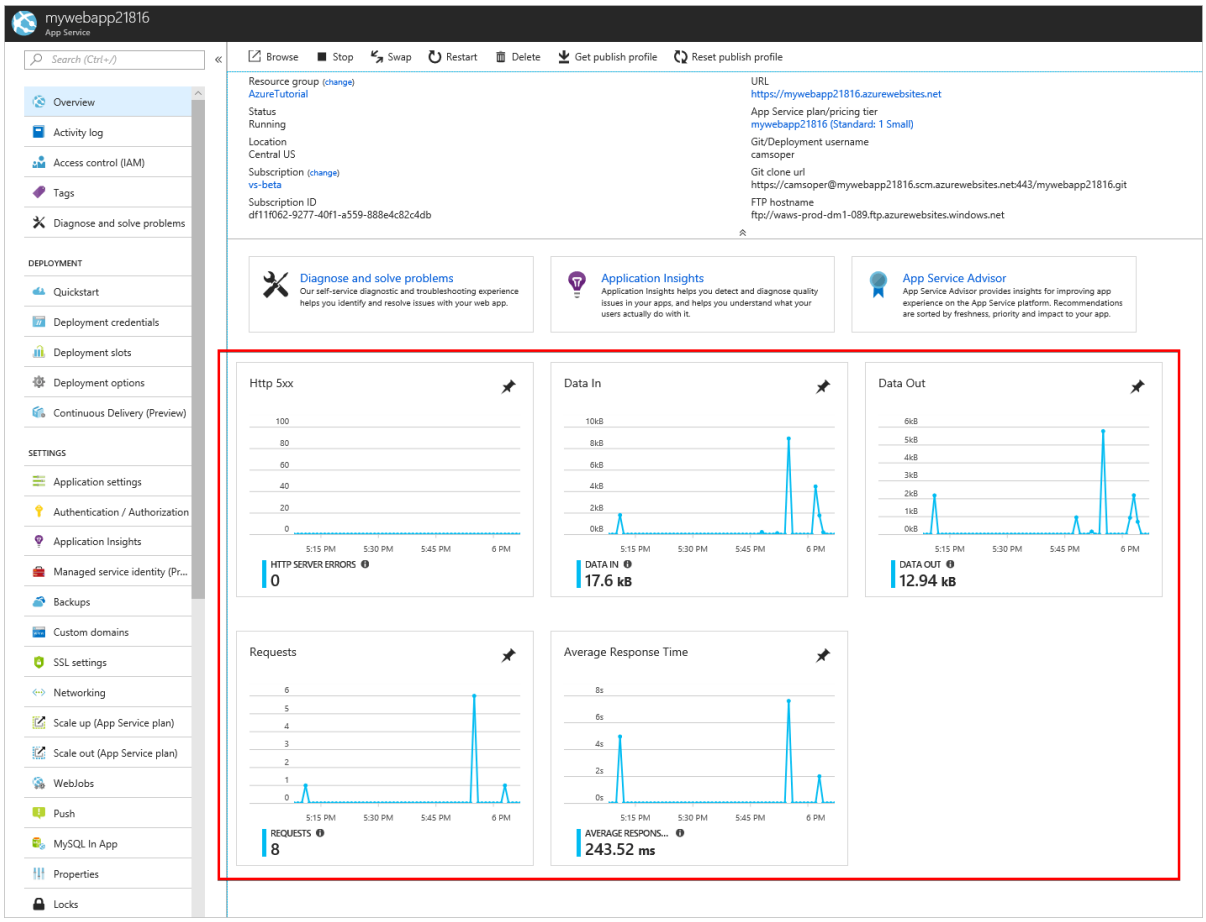
In this section, you'll complete the following tasks:

- Find basic monitoring and troubleshooting data in the Azure portal
- Learn how Azure Monitor provides a deeper look at metrics across all Azure services
- Connect the web app with Application Insights for app profiling
- Turn on logging and learn where to download logs
- Stream logs in real time
- Learn where to set up alerts
- Learn about remote debugging Azure App Service web apps.

Basic monitoring and troubleshooting

App Service web apps are easily monitored in real time. The Azure portal renders metrics in easy-to-understand charts and graphs.

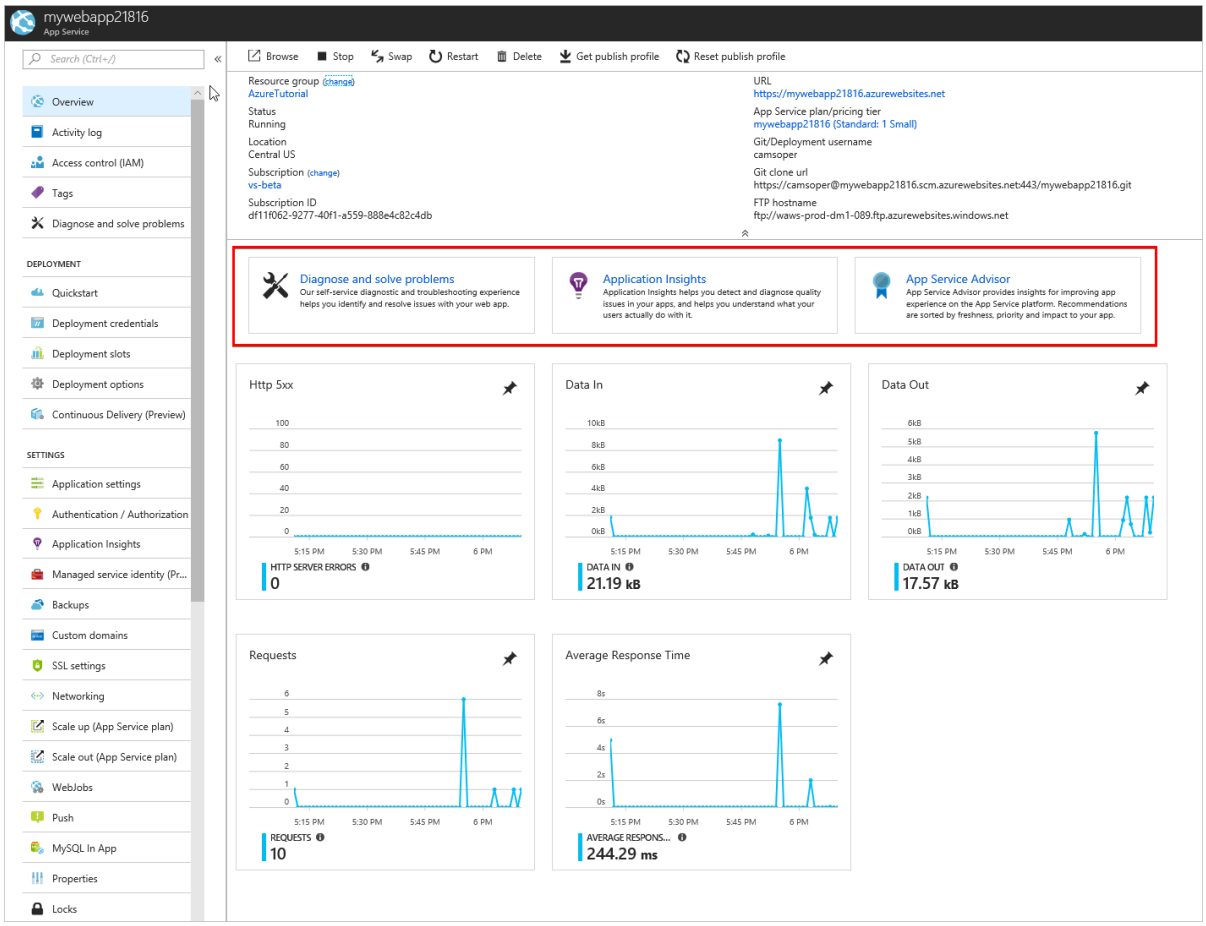
1. Open the Azure portal, and then navigate to the *mywebapp<unique_number>* App Service.
2. The **Overview** tab displays useful "at-a-glance" information, including graphs displaying recent metrics.



- **Http 5xx**: Count of server-side errors, usually exceptions in ASP.NET Core code.

- **Data In**: Data ingress coming into your web app.
- **Data Out**: Data egress from your web app to clients.
- **Requests**: Count of HTTP requests.
- **Average Response Time**: Average time for the web app to respond to HTTP requests.

Several self-service tools for troubleshooting and optimization are also found on this page.



- **Diagnose and solve problems** is a self-service troubleshooter.
- **Application Insights** is for profiling performance and app behavior, and is discussed later in this section.
- **App Service Advisor** makes recommendations to tune your app experience.

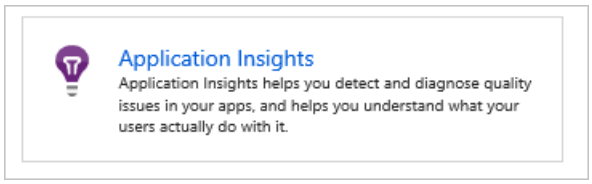
Advanced monitoring

Azure Monitor is the centralized service for monitoring all metrics and setting alerts across Azure services. Within Azure Monitor, administrators can granularly track performance and identify trends. Each Azure service offers its own set of metrics to Azure Monitor.

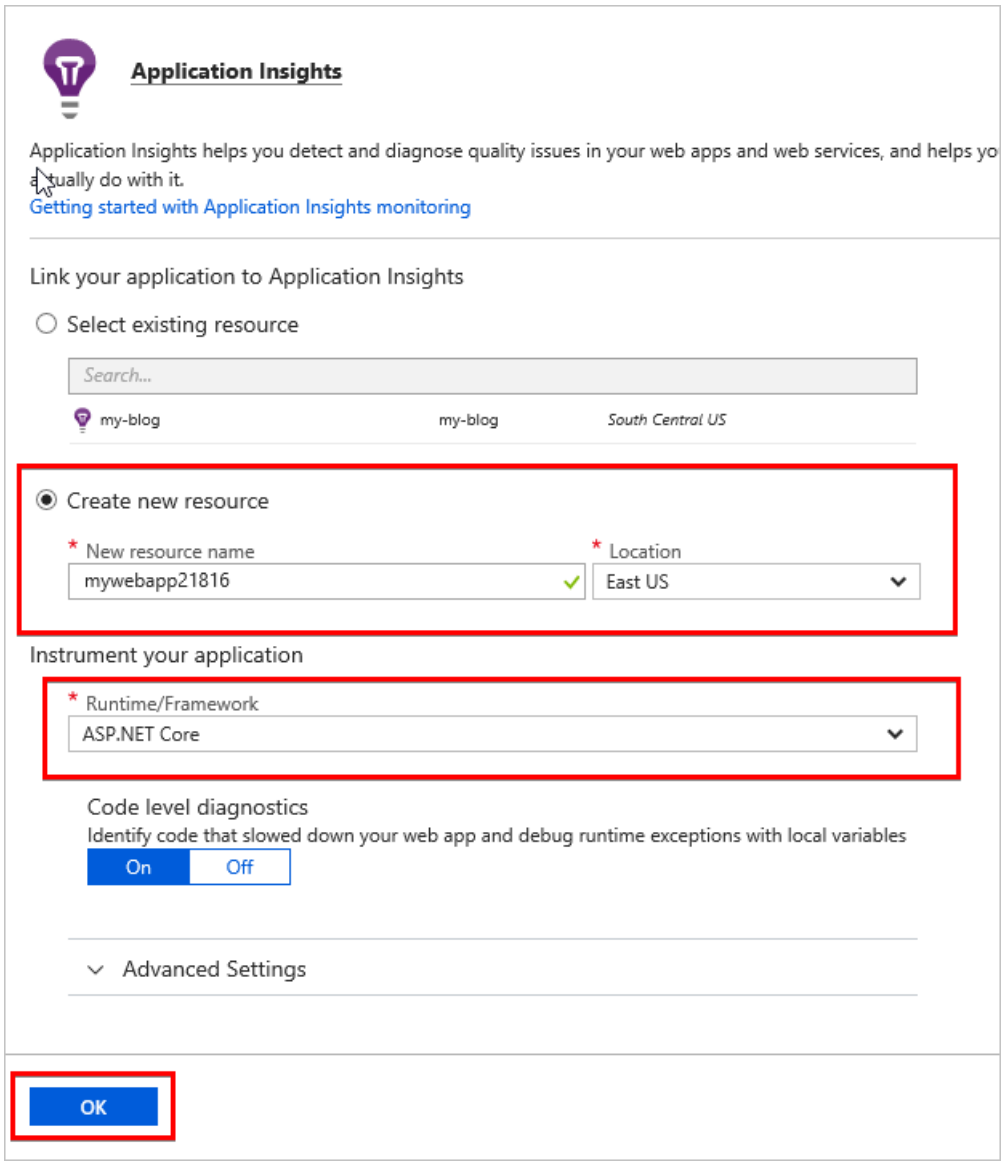
Profile with Application Insights

Application Insights is an Azure service for analyzing the performance and stability of web apps and how users use them. The data from Application Insights is broader and deeper than that of Azure Monitor. The data can provide developers and administrators with key information for improving apps. Application Insights can be added to an Azure App Service resource without code changes.

1. Open the Azure portal, and then navigate to the *mywebapp<unique_number>* App Service.
2. From the **Overview** tab, click the **Application Insights** tile.



3. Select the **Create new resource** radio button. Use the default resource name, and select the location for the Application Insights resource. The location doesn't need to match that of your web app.

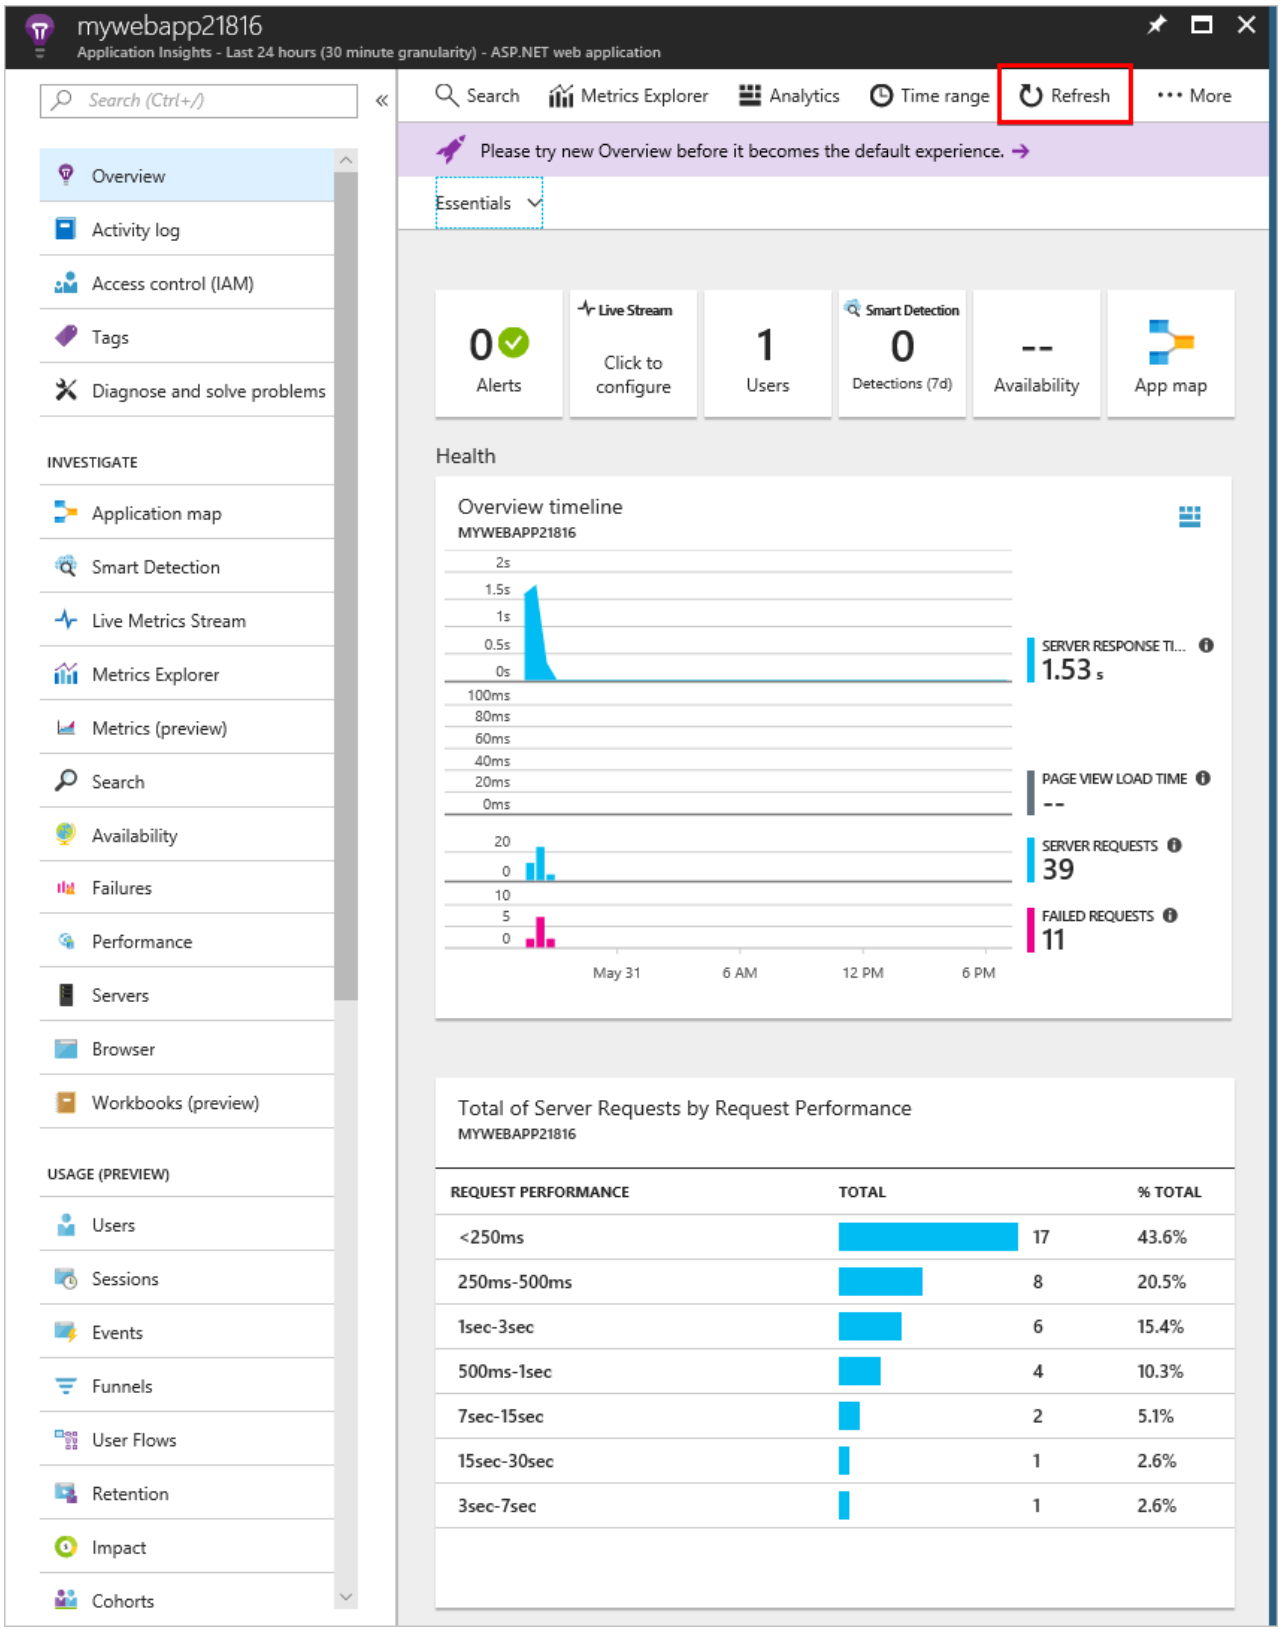


4. For **Runtime/Framework**, select **ASP.NET Core**. Accept the default settings.

5. Select **OK**. If prompted to confirm, select **Continue**.

6. After the resource has been created, click the name of Application Insights resource to navigate directly to the Application Insights page.

As the app is used, data accumulates. Select **Refresh** to reload the blade with new data.

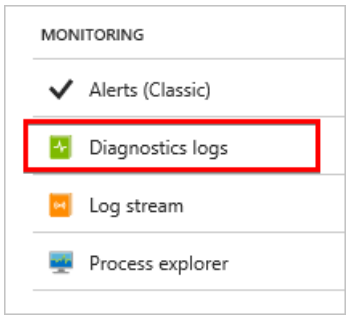


Application Insights provides useful server-side information with no additional configuration. To get the most value from Application Insights, instrument your app with the Application Insights SDK. When properly configured, the service provides end-to-end monitoring across the web server and browser, including client-side performance. For more information, see the Application Insights documentation.

Logging

Web server and app logs are disabled by default in Azure App Service. Enable the logs with the following steps:

1. Open the Azure portal, and navigate to the *mywebapp<unique_number>* App Service.
2. In the menu to the left, scroll down to the **Monitoring** section. Select **Diagnostics logs**.



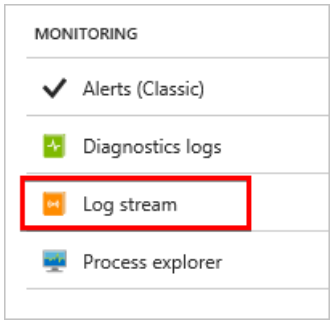
3. Turn on **Application Logging (Filesystem)**. If prompted, click the box to install the extensions to enable app logging in the web app.
4. Set **Web server logging** to **File System**.
5. Enter the **Retention Period** in days. For example, 30.
6. Click **Save**.

ASP.NET Core and web server (App Service) logs are generated for the web app. They can be downloaded using the FTP/FTPS information displayed. The password is the same as the deployment credentials created earlier in this guide. The logs can be streamed directly to your local machine with PowerShell or Azure CLI. Logs can also be viewed in Application Insights.

Log streaming

App and web server logs can be streamed in real time through the portal.

1. Open the Azure portal, and navigate to the *mywebapp<unique_number>* App Service.
2. In the menu to the left, scroll down to the **Monitoring** section and select **Log stream**.



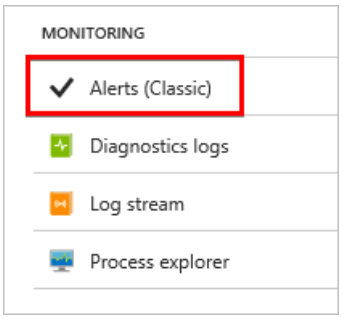
Logs can also be streamed via Azure CLI or Azure PowerShell, including through the Cloud Shell.

Alerts

Azure Monitor also provides real time alerts based on metrics, administrative events, and other criteria.

> *Note: Currently alerting on web app metrics is only available in the Alerts (classic) service.*

The Alerts (classic) service can be found in Azure Monitor or under the **Monitoring** section of the App Service settings.



Live debugging

Azure App Service can be debugged remotely with Visual Studio when logs don't provide enough information. However, remote debugging requires the app to be compiled with debug symbols. Debugging shouldn't be done in production, except as a last resort.

Conclusion

In this section, you completed the following tasks:

- Find basic monitoring and troubleshooting data in the Azure portal
- Learn how Azure Monitor provides a deeper look at metrics across all Azure services
- Connect the web app with Application Insights for app profiling
- Turn on logging and learn where to download logs
- Stream logs in real time
- Learn where to set up alerts
- Learn about remote debugging Azure App Service web apps.

Additional reading

- Troubleshoot ASP.NET Core on Azure App Service and IIS
- Common errors reference for Azure App Service and IIS with ASP.NET Core
- Monitor Azure web app performance with Application Insights
- Enable diagnostics logging for web apps in Azure App Service
- Troubleshoot a web app in Azure App Service using Visual Studio
- Create classic metric alerts in Azure Monitor for Azure services - Azure portal

Next steps

9/22/2020 • 2 minutes to read • Edit Online

In this guide, you created a DevOps pipeline for an ASP.NET Core sample app. Congratulations! We hope you enjoyed learning to publish ASP.NET Core web apps to Azure App Service and automate the continuous integration of changes.

Beyond web hosting and DevOps, Azure has a wide array of Platform-as-a-Service (PaaS) services useful to ASP.NET Core developers. This section gives a brief overview of some of the most commonly used services.

Storage and databases

Redis Cache is high-throughput, low-latency data caching available as a service. It can be used for caching page output, reducing database requests, and providing ASP.NET Core session state across multiple instances of an app.

Azure Storage is Azure's massively scalable cloud storage. Developers can take advantage of Queue Storage for reliable message queuing, and Table Storage is a NoSQL key-value store designed for rapid development using massive, semi-structured data sets.

Azure SQL Database provides familiar relational database functionality as a service using the Microsoft SQL Server Engine.

Cosmos DB globally distributed, multi-model NoSQL database service. Multiple APIs are available, including SQL API (formerly called DocumentDB), Cassandra, and MongoDB.

Identity

Azure Active Directory and Azure Active Directory B2C are both identity services. Azure Active Directory is designed for enterprise scenarios and enables Azure AD B2B (business-to-business) collaboration, while Azure Active Directory B2C is intended business-to-customer scenarios, including social network sign-in.

Mobile

Notification Hubs is a multi-platform, scalable push-notification engine to quickly send millions of messages to apps running on various types of devices.

Web infrastructure

Azure Container Service manages your hosted Kubernetes environment, making it quick and easy to deploy and manage containerized apps without container orchestration expertise.

Azure Search is used to create an enterprise search solution over private, heterogenous content.

Service Fabric is a distributed systems platform that makes it easy to package, deploy, and manage scalable and reliable microservices and containers.

Host ASP.NET Core on Windows with IIS

9/22/2020 • 76 minutes to read • Edit Online

For a tutorial experience on publishing an ASP.NET Core app to an IIS server, see Publish an ASP.NET Core app to IIS.

Install the .NET Core Hosting Bundle

Supported operating systems

The following operating systems are supported:

- Windows 7 or later
- Windows Server 2012 R2 or later

HTTP.sys server (formerly called WebListener) doesn't work in a reverse proxy configuration with IIS. Use the Kestrel server.

For information on hosting in Azure, see Deploy ASP.NET Core apps to Azure App Service.

For troubleshooting guidance, see Troubleshoot and debug ASP.NET Core projects.

Supported platforms

Apps published for 32-bit (x86) or 64-bit (x64) deployment are supported. Deploy a 32-bit app with a 32-bit (x86) .NET Core SDK unless the app:

- Requires the larger virtual memory address space available to a 64-bit app.
- Requires the larger IIS stack size.
- Has 64-bit native dependencies.

Apps published for 32-bit (x86) must have 32-bit enabled for their IIS Application Pools. For more information, see the Create the IIS site section.

Use a 64-bit (x64) .NET Core SDK to publish a 64-bit app. A 64-bit runtime must be present on the host system.

Hosting models

In-process hosting model

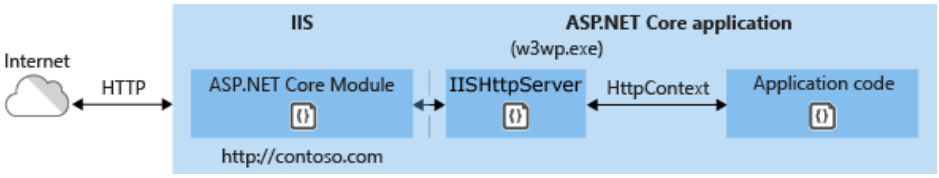
Using in-process hosting, an ASP.NET Core app runs in the same process as its IIS worker process. In-process hosting provides improved performance over out-of-process hosting because requests aren't proxied over the loopback adapter, a network interface that returns outgoing network traffic back to the same machine. IIS handles process management with the Windows Process Activation Service (WAS).

The ASP.NET Core Module:

- Performs app initialization.
  - Loads the CoreCLR.
  - Calls `Program.Main`.
- Handles the lifetime of the IIS native request.

The following diagram illustrates the relationship between IIS, the ASP.NET Core Module, and an app hosted

in-process:



1. A request arrives from the web to the kernel-mode HTTP.sys driver.
2. The driver routes the native request to IIS on the website's configured port, usually 80 (HTTP) or 443 (HTTPS).
3. The ASP.NET Core Module receives the native request and passes it to IIS HTTP Server (`IISHttpServer`). IIS HTTP Server is an in-process server implementation for IIS that converts the request from native to managed.

After the IIS HTTP Server processes the request:

1. The request is sent to the ASP.NET Core middleware pipeline.
2. The middleware pipeline handles the request and passes it on as an `HttpContext` instance to the app's logic.
3. The app's response is passed back to IIS through IIS HTTP Server.
4. IIS sends the response to the client that initiated the request.

In-process hosting is opt-in for existing apps. The ASP.NET Core web templates use the in-process hosting model.

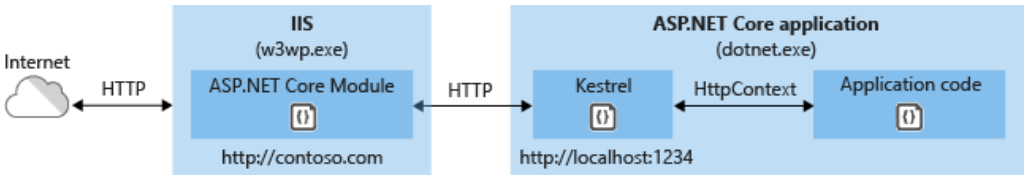
`CreateDefaultBuilder` adds an IServer instance by calling the UseIIS method to boot the CoreCLR and host the app inside of the IIS worker process (*w3wp.exe* or *iisexpress.exe*). Performance tests indicate that hosting a .NET Core app in-process delivers significantly higher request throughput compared to hosting the app out-of-process and proxying requests to Kestrel.

Apps published as a single file executable can't be loaded by the in-process hosting model.

Out-of-process hosting model

Because ASP.NET Core apps run in a process separate from the IIS worker process, the ASP.NET Core Module handles process management. The module starts the process for the ASP.NET Core app when the first request arrives and restarts the app if it shuts down or crashes. This is essentially the same behavior as seen with apps that run in-process that are managed by the Windows Process Activation Service (WAS).

The following diagram illustrates the relationship between IIS, the ASP.NET Core Module, and an app hosted out-of-process:



1. Requests arrive from the web to the kernel-mode HTTP.sys driver.
2. The driver routes the requests to IIS on the website's configured port. The configured port is usually 80 (HTTP) or 443 (HTTPS).
3. The module forwards the requests to Kestrel on a random port for the app. The random port isn't 80 or 443.

The ASP.NET Core Module specifies the port via an environment variable at startup. The UseIISIntegration extension configures the server to listen on `http://localhost:{PORT}`. Additional checks are performed, and requests that don't originate from the module are rejected. The module doesn't support HTTPS forwarding.

Requests are forwarded over HTTP even if received by IIS over HTTPS.

After Kestrel picks up the request from the module, the request is forwarded into the ASP.NET Core middleware pipeline. The middleware pipeline handles the request and passes it on as an `HttpContext` instance to the app's logic. Middleware added by IIS Integration updates the scheme, remote IP, and pathbase to account for forwarding the request to Kestrel. The app's response is passed back to IIS, which forwards it back to the HTTP client that initiated the request.

For ASP.NET Core Module configuration guidance, see ASP.NET Core Module.

For more information on hosting, see Host in ASP.NET Core.

Application configuration

Enable the IISIntegration components

When building a host in `CreateHostBuilder` (*Program.cs*), call CreateDefaultBuilder to enable IIS integration:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        ...
```

For more information on `CreateDefaultBuilder`, see .NET Generic Host.

IIS options

In-process hosting model

To configure IIS Server options, include a service configuration for IISServerOptions in ConfigureServices. The following example disables AutomaticAuthentication:

```
services.Configure<IISServerOptions>(options =>
{
    options.AutomaticAuthentication = false;
});
```

OPTION	DEFAULT	SETTING
`AutomaticAuthentication`	`true`	If `true`, IIS Server sets the `HttpContext.User` authenticated by Windows Authentication. If `false`, the server only provides an identity for `HttpContext.User` and responds to challenges when explicitly requested by the `AuthenticationScheme`. Windows Authentication must be enabled in IIS for `AutomaticAuthentication` to function. For more information, see Windows Authentication.
`AuthenticationDisplayName`	`null`	Sets the display name shown to users on login pages.
`AllowSynchronousIO`	`false`	Whether synchronous I/O is allowed for the `HttpContext.Request` and the `HttpContext.Response`.

OPTION	DEFAULT	SETTING
`MaxRequestBodySize`	`30000000`	Gets or sets the max request body size for the `HttpRequest`. Note that IIS itself has the limit `maxAllowedContentLength` which will be processed before the `MaxRequestBodySize` set in the `IISServerOptions`. Changing the `MaxRequestBodySize` won't affect the `maxAllowedContentLength`. To increase `maxAllowedContentLength`, add an entry in the *web.config* to set `maxAllowedContentLength` to a higher value. For more details, see Configuration.

Out-of-process hosting model

To configure IIS options, include a service configuration for IISOptions in ConfigureServices. The following example prevents the app from populating `HttpContext.Connection.ClientCertificate`:

```
services.Configure<IISOptions>(options =>
{
    options.ForwardClientCertificate = false;
});
```

OPTION	DEFAULT	SETTING
`AutomaticAuthentication`	`true`	If `true`, IIS Integration Middleware sets the `HttpContext.User` authenticated by Windows Authentication. If `false`, the middleware only provides an identity for `HttpContext.User` and responds to challenges when explicitly requested by the `AuthenticationScheme`. Windows Authentication must be enabled in IIS for `AutomaticAuthentication` to function. For more information, see the Windows Authentication topic.
`AuthenticationDisplayName`	`null`	Sets the display name shown to users on login pages.
`ForwardClientCertificate`	`true`	If `true` and the `MS-ASPNETCORE-CLIENTCERT` request header is present, the `HttpContext.Connection.ClientCertificate` is populated.

Proxy server and load balancer scenarios

The IIS Integration Middleware and the ASP.NET Core Module are configured to forward the:

- Scheme (HTTP/HTTPS).
- Remote IP address where the request originated.

The IIS Integration Middleware configures Forwarded Headers Middleware.

Additional configuration might be required for apps hosted behind additional proxy servers and load balancers. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

web.config file

The *web.config* file configures the ASP.NET Core Module. Creating, transforming, and publishing the *web.config* file is handled by an MSBuild target (`_TransformWebConfig`) when the project is published. This target is present in the Web SDK targets (`Microsoft.NET.Sdk.Web`). The SDK is set at the top of the project file:

```
<Project Sdk="Microsoft.NET.Sdk.Web">
```

If a *web.config* file isn't present in the project, the file is created with the correct *processPath* and *arguments* to configure the ASP.NET Core Module and moved to published output.

If a *web.config* file is present in the project, the file is transformed with the correct *processPath* and *arguments* to configure the ASP.NET Core Module and moved to published output. The transformation doesn't modify IIS configuration settings in the file.

The *web.config* file may provide additional IIS configuration settings that control active IIS modules. For information on IIS modules that are capable of processing requests with ASP.NET Core apps, see the IIS modules topic.

To prevent the Web SDK from transforming the *web.config* file, use the **<IsTransformWebConfigDisabled>** property in the project file:

```
<PropertyGroup>
  <IsTransformWebConfigDisabled>true</IsTransformWebConfigDisabled>
</PropertyGroup>
```

When disabling the Web SDK from transforming the file, the *processPath* and *arguments* should be manually set by the developer. For more information, see ASP.NET Core Module.

web.config file location

In order to set up the ASP.NET Core Module correctly, the *web.config* file must be present at the content root path (typically the app base path) of the deployed app. This is the same location as the website physical path provided to IIS. The *web.config* file is required at the root of the app to enable the publishing of multiple apps using Web Deploy.

Sensitive files exist on the app's physical path, such as *<assembly>.runtimeconfig.json*, *<assembly>.xml* (XML Documentation comments), and *<assembly>.deps.json*. When the *web.config* file is present and the site starts normally, IIS doesn't serve these sensitive files if they're requested. If the *web.config* file is missing, incorrectly named, or unable to configure the site for normal startup, IIS may serve sensitive files publicly.

The *web.config* file must be present in the deployment at all times, correctly named, and able to configure the site for normal start up. Never remove the *web.config* file from a production deployment.

Transform web.config

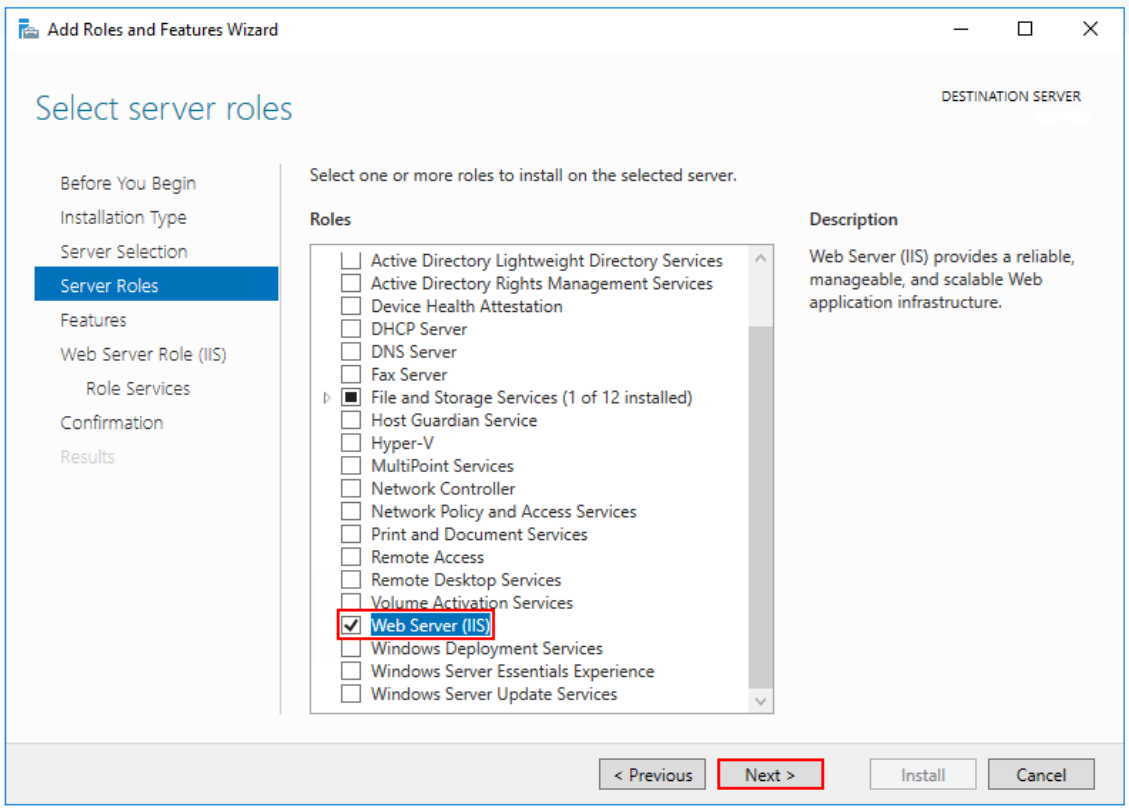
If you need to transform *web.config* on publish, see Transform web.config. You might need to transform *web.config* on publish to set environment variables based on the configuration, profile, or environment.

IIS configuration

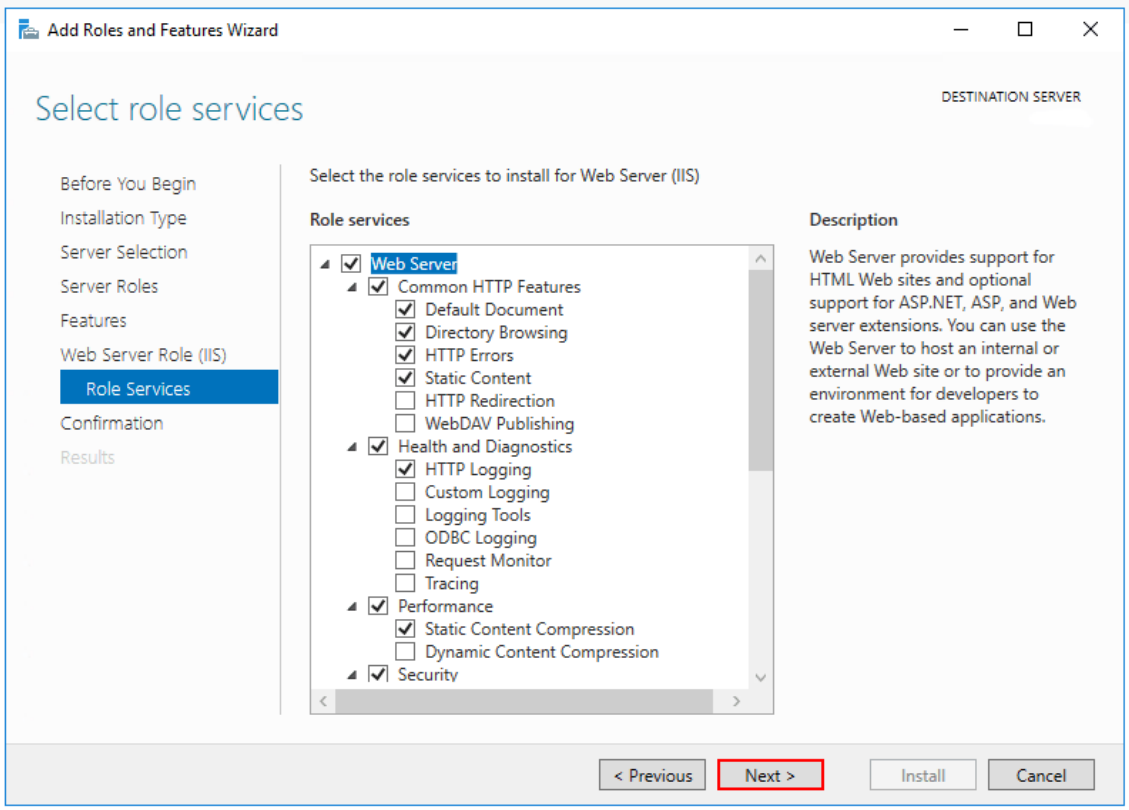
Windows Server operating systems

Enable the **Web Server (IIS)** server role and establish role services.

1. Use the **Add Roles and Features** wizard from the **Manage** menu or the link in **Server Manager**. On the **Server Roles** step, check the box for **Web Server (IIS)**.



2. After the **Features** step, the **Role services** step loads for Web Server (IIS). Select the IIS role services desired or accept the default role services provided.



Windows Authentication (Optional)

To enable Windows Authentication, expand the following nodes: **Web Server** > **Security**. Select the **Windows Authentication** feature. For more information, see Windows Authentication

<windowsAuthentication> and Configure Windows authentication.

WebSockets (Optional)
WebSockets is supported with ASP.NET Core 1.1 or later. To enable WebSockets, expand the following nodes: **Web Server** > **Application Development**. Select the **WebSocket Protocol** feature. For more information, see WebSockets.

3. Proceed through the **Confirmation** step to install the web server role and services. A server/IIS restart isn't required after installing the **Web Server (IIS)** role.

Windows desktop operating systems

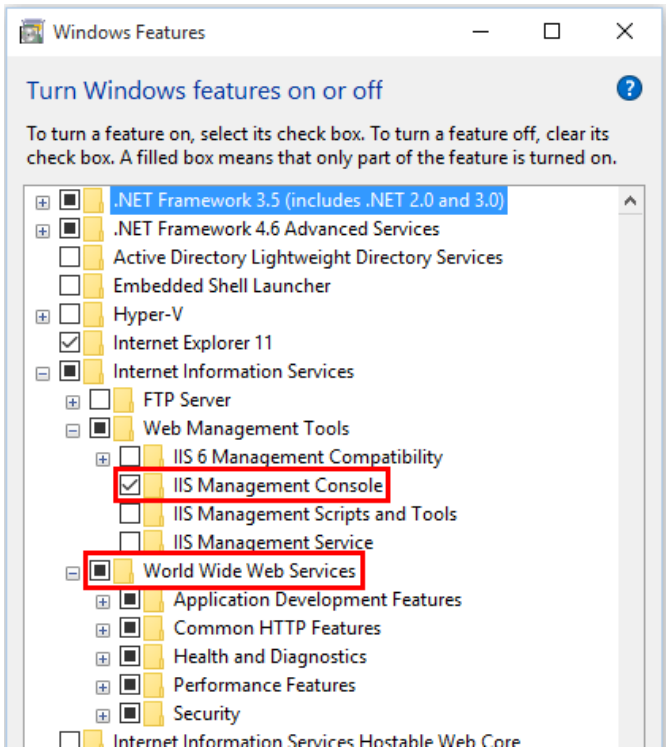
Enable the **IIS Management Console** and **World Wide Web Services**.

1. Navigate to **Control Panel** > **Programs** > **Programs and Features** > **Turn Windows features on or off** (left side of the screen).
2. Open the **Internet Information Services** node. Open the **Web Management Tools** node.
3. Check the box for **IIS Management Console**.
4. Check the box for **World Wide Web Services**.
5. Accept the default features for **World Wide Web Services** or customize the IIS features.

   Windows Authentication (Optional)
   To enable Windows Authentication, expand the following nodes: **World Wide Web Services** > **Security**. Select the **Windows Authentication** feature. For more information, see Windows Authentication <windowsAuthentication> and Configure Windows authentication.

   WebSockets (Optional)
   WebSockets is supported with ASP.NET Core 1.1 or later. To enable WebSockets, expand the following nodes: **World Wide Web Services** > **Application Development Features**. Select the **WebSocket Protocol** feature. For more information, see WebSockets.

6. If the IIS installation requires a restart, restart the system.



Install the .NET Core Hosting Bundle

Install the *.NET Core Hosting Bundle* on the hosting system. The bundle installs the .NET Core Runtime, .NET Core Library, and the ASP.NET Core Module. The module allows ASP.NET Core apps to run behind IIS.

> **IMPORTANT**
>
> If the Hosting Bundle is installed before IIS, the bundle installation must be repaired. Run the Hosting Bundle installer again after installing IIS.
>
> If the Hosting Bundle is installed after installing the 64-bit (x64) version of .NET Core, SDKs might appear to be missing (No .NET Core SDKs were detected). To resolve the problem, see Troubleshoot and debug ASP.NET Core projects.

Direct download (current version)

Download the installer using the following link:

Current .NET Core Hosting Bundle installer (direct download)

Earlier versions of the installer

To obtain an earlier version of the installer:

1. Navigate to the Download .NET Core page.
2. Select the desired .NET Core version.
3. In the **Run apps - Runtime** column, find the row of the .NET Core runtime version desired.
4. Download the installer using the **Hosting Bundle** link.

> **WARNING**
>
> Some installers contain release versions that have reached their end of life (EOL) and are no longer supported by Microsoft. For more information, see the support policy.

Install the Hosting Bundle

1. Run the installer on the server. The following parameters are available when running the installer from an administrator command shell:

   - `OPT_NO_ANCM=1`: Skip installing the ASP.NET Core Module.
   - `OPT_NO_RUNTIME=1`: Skip installing the .NET Core runtime. Used when the server only hosts self-contained deployments (SCD).
   - `OPT_NO_SHAREDFX=1`: Skip installing the ASP.NET Shared Framework (ASP.NET runtime). Used when the server only hosts self-contained deployments (SCD).
   - `OPT_NO_X86=1`: Skip installing x86 runtimes. Use this parameter when you know that you won't be hosting 32-bit apps. If there's any chance that you will host both 32-bit and 64-bit apps in the future, don't use this parameter and install both runtimes.
   - `OPT_NO_SHARED_CONFIG_CHECK=1`: Disable the check for using an IIS Shared Configuration when the shared configuration (*applicationHost.config*) is on the same machine as the IIS installation. *Only available for ASP.NET Core 2.2 or later Hosting Bundler installers.* For more information, see ASP.NET Core Module.

2. Restart the system or execute the following commands in a command shell:

   ```
   net stop was /y
   net start w3svc
   ```

   Restarting IIS picks up a change to the system PATH, which is an environment variable, made by the installer.

ASP.NET Core doesn't adopt roll-forward behavior for patch releases of shared framework packages. After upgrading the shared framework by installing a new hosting bundle, restart the system or execute the following commands in a command shell:

```
net stop was /y
net start w3svc
```

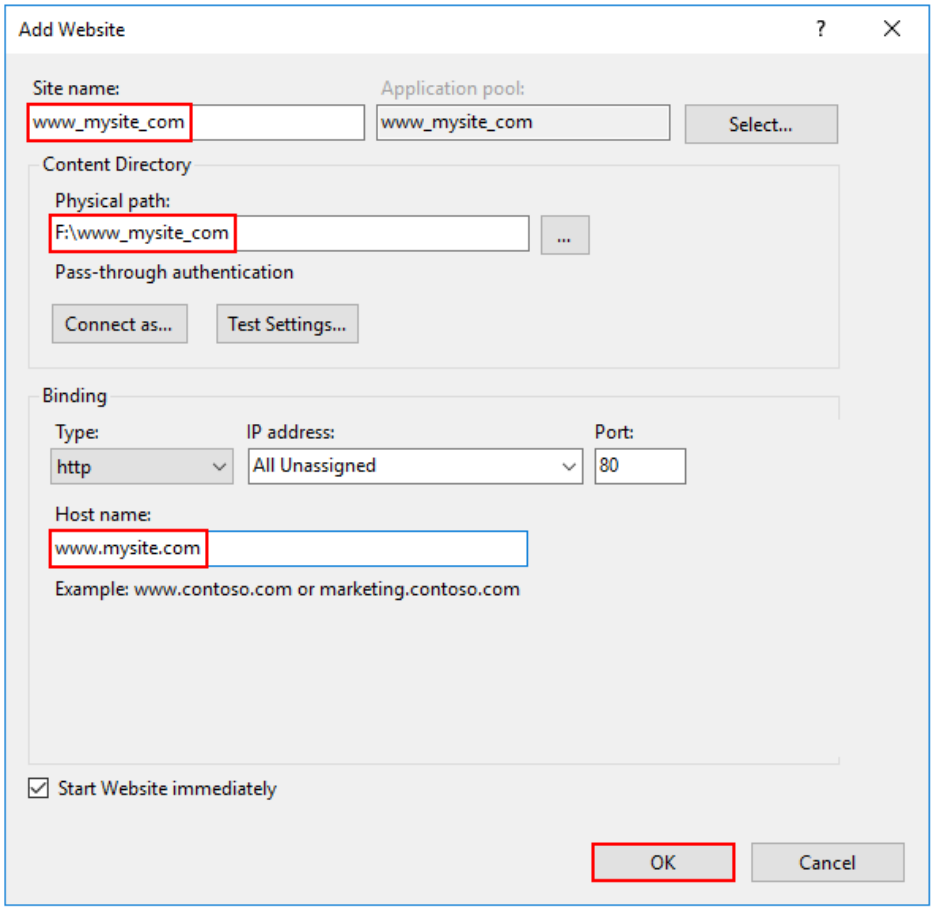
> **NOTE**
> For information on IIS Shared Configuration, see ASP.NET Core Module with IIS Shared Configuration.

Install Web Deploy when publishing with Visual Studio

When deploying apps to servers with Web Deploy, install the latest version of Web Deploy on the server. To install Web Deploy, use the Web Platform Installer (WebPI) or obtain an installer directly from the Microsoft Download Center. The preferred method is to use WebPI. WebPI offers a standalone setup and a configuration for hosting providers.

Create the IIS site

1. On the hosting system, create a folder to contain the app's published folders and files. In a following step, the folder's path is provided to IIS as the physical path to the app. For more information on an app's deployment folder and file layout, see ASP.NET Core directory structure.
2. In IIS Manager, open the server's node in the **Connections** panel. Right-click the **Sites** folder. Select **Add Website** from the contextual menu.
3. Provide a **Site name** and set the **Physical path** to the app's deployment folder. Provide the **Binding** configuration and create the website by selecting **OK**:



> **WARNING**
> Top-level wildcard bindings (`http://*:80/` and `http://+:80`) should **not** be used. Top-level wildcard bindings can open up your app to security vulnerabilities. This applies to both strong and weak wildcards. Use explicit host names rather than wildcards. Subdomain wildcard binding (for example, `*.mysub.com`) doesn't have this security risk if you control the entire parent domain (as opposed to `*.com` , which is vulnerable). See rfc7230 section-5.4 for more information.

4. Under the server's node, select **Application Pools**.
5. Right-click the site's app pool and select **Basic Settings** from the contextual menu.
6. In the **Edit Application Pool** window, set the **.NET CLR version** to **No Managed Code**:

   ASP.NET Core runs in a separate process and manages the runtime. ASP.NET Core doesn't rely on loading the desktop CLR (.NET CLR). The Core Common Language Runtime (CoreCLR) for .NET Core is booted to host the app in the worker process. Setting the **.NET CLR version** to **No Managed Code** is optional but recommended.

7. *ASP.NET Core 2.2 or later*:

   - For a 32-bit (x86) self-contained deployment published with a 32-bit SDK that uses the in-process hosting model, enable the Application Pool for 32-bit. In IIS Manager, navigate to **Application Pools** in the **Connections** sidebar. Select the app's Application Pool. In the **Actions** sidebar, select **Advanced Settings**. Set **Enable 32-Bit Applications** to `True`.
   - For a 64-bit (x64) self-contained deployment that uses the in-process hosting model, disable the app pool for 32-bit (x86) processes. In IIS Manager, navigate to **Application Pools** in the **Connections** sidebar. Select the app's Application Pool. In the **Actions** sidebar, select **Advanced Settings**. Set **Enable 32-Bit Applications** to `False`.

8. Confirm the process model identity has the proper permissions.

   If the default identity of the app pool (**Process Model** > **Identity**) is changed from **ApplicationPoolIdentity** to another identity, verify that the new identity has the required permissions to access the app's folder, database, and other required resources. For example, the app pool requires read and write access to folders where the app reads and writes files.

Windows Authentication configuration (Optional)

For more information, see Configure Windows authentication.

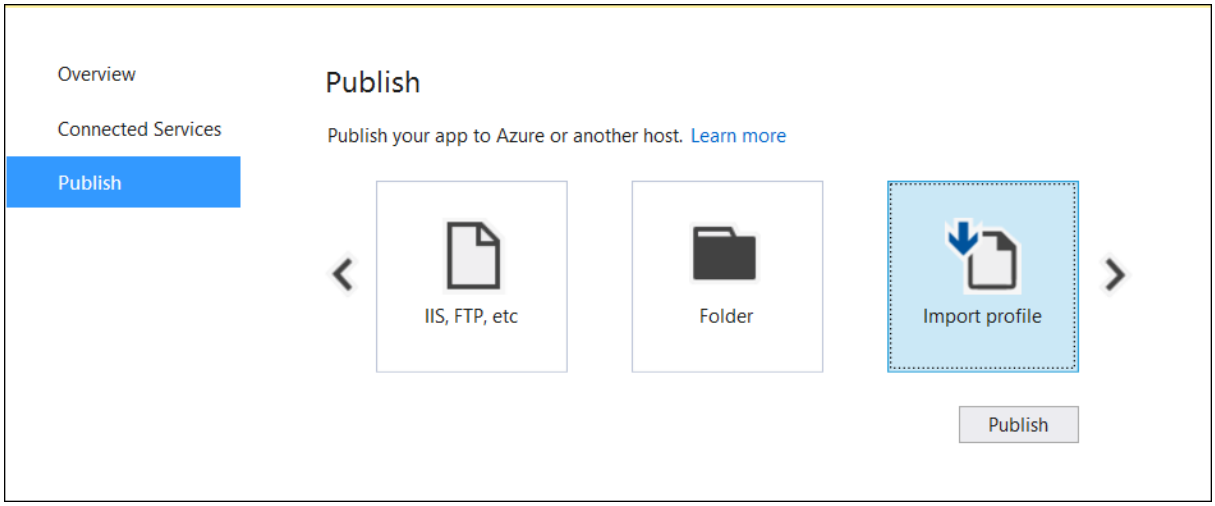
Deploy the app

Deploy the app to the IIS **Physical path** folder that was established in the Create the IIS site section. Web

Deploy is the recommended mechanism for deployment, but several options exist for moving the app from the project's *publish* folder to the hosting system's deployment folder.

Web Deploy with Visual Studio

See the Visual Studio publish profiles for ASP.NET Core app deployment topic to learn how to create a publish profile for use with Web Deploy. If the hosting provider provides a Publish Profile or support for creating one, download their profile and import it using the Visual Studio **Publish** dialog:



Web Deploy outside of Visual Studio

Web Deploy can also be used outside of Visual Studio from the command line. For more information, see Web Deployment Tool.

Alternatives to Web Deploy

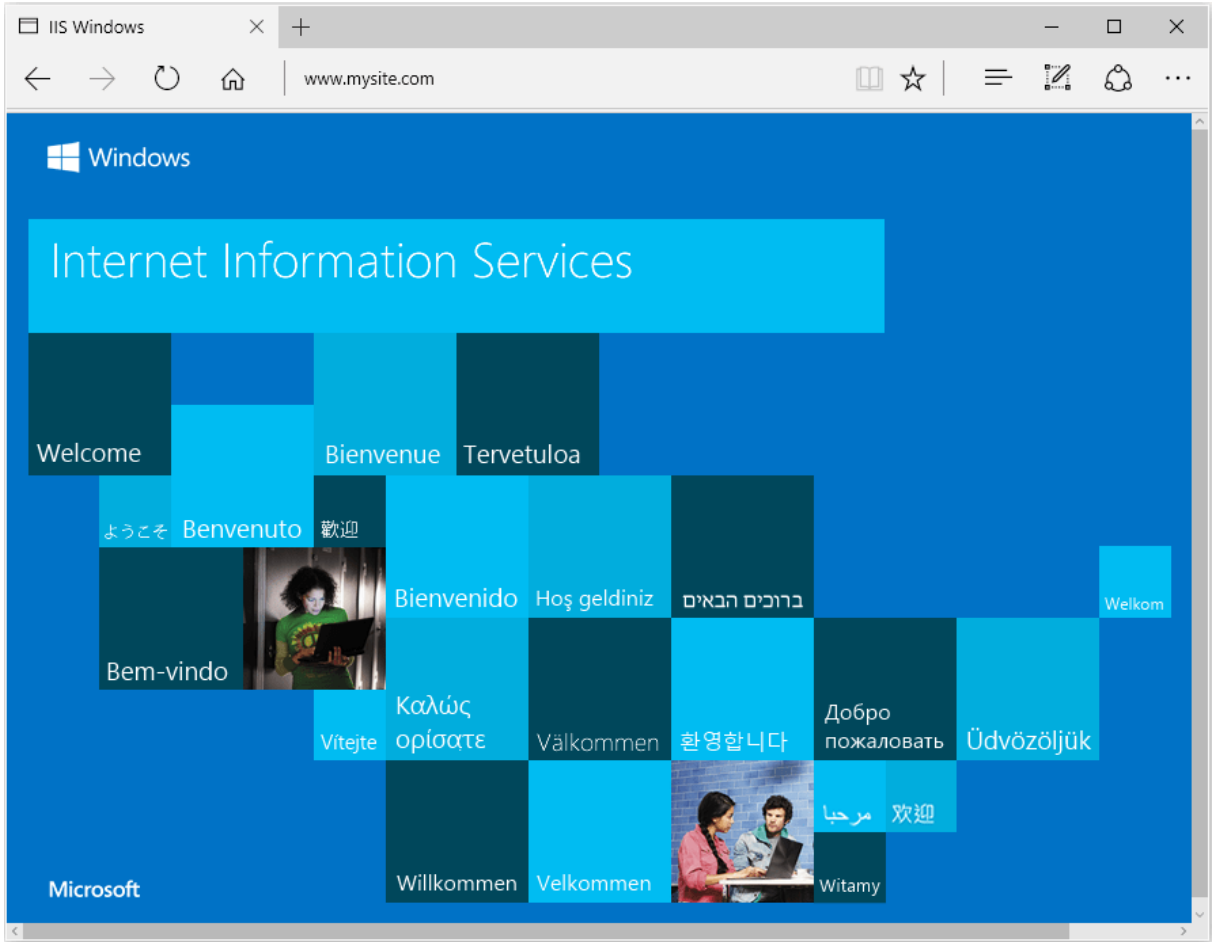
Use any of several methods to move the app to the hosting system, such as manual copy, Xcopy, Robocopy, or PowerShell.

For more information on ASP.NET Core deployment to IIS, see the Deployment resources for IIS administrators section.

Browse the website

After the app is deployed to the hosting system, make a request to one of the app's public endpoints.

In the following example, the site is bound to an IIS **Host name** of `www.mysite.com` on **Port** `80`. A request is made to `http://www.mysite.com`:



Locked deployment files

Files in the deployment folder are locked when the app is running. Locked files can't be overwritten during deployment. To release locked files in a deployment, stop the app pool using **one** of the following approaches:

- Use Web Deploy and reference `Microsoft.NET.Sdk.Web` in the project file. An *app_offline.htm* file is placed at the root of the web app directory. When the file is present, the ASP.NET Core Module gracefully shuts down the app and serves the *app_offline.htm* file during the deployment. For more information, see the ASP.NET Core Module configuration reference.
- Manually stop the app pool in the IIS Manager on the server.
- Use PowerShell to drop *app_offline.htm* (requires PowerShell 5 or later):

```
$pathToApp = 'PATH_TO_APP'

# Stop the AppPool
New-Item -Path $pathToApp app_offline.htm

# Provide script commands here to deploy the app

# Restart the AppPool
Remove-Item -Path $pathToApp app_offline.htm
```

Data protection

The ASP.NET Core Data Protection stack is used by several ASP.NET Core middlewares, including middleware used in authentication. Even if Data Protection APIs aren't called by user code, data protection should be configured with a deployment script or in user code to create a persistent cryptographic key store. If data

protection isn't configured, the keys are held in memory and discarded when the app restarts.

If the key ring is stored in memory when the app restarts:

- All cookie-based authentication tokens are invalidated.
- Users are required to sign in again on their next request.
- Any data protected with the key ring can no longer be decrypted. This may include CSRF tokens and ASP.NET Core MVC TempData cookies.

To configure data protection under IIS to persist the key ring, use **one** of the following approaches:

- **Create Data Protection Registry Keys**

  Data protection keys used by ASP.NET Core apps are stored in the registry external to the apps. To persist the keys for a given app, create registry keys for the app pool.

  For standalone, non-webfarm IIS installations, the Data Protection Provision-AutoGenKeys.ps1 PowerShell script can be used for each app pool used with an ASP.NET Core app. This script creates a registry key in the HKLM registry that's accessible only to the worker process account of the app's app pool. Keys are encrypted at rest using DPAPI with a machine-wide key.

  In web farm scenarios, an app can be configured to use a UNC path to store its data protection key ring. By default, the data protection keys aren't encrypted. Ensure that the file permissions for the network share are limited to the Windows account the app runs under. An X509 certificate can be used to protect keys at rest. Consider a mechanism to allow users to upload certificates: Place certificates into the user's trusted certificate store and ensure they're available on all machines where the user's app runs. See Configure ASP.NET Core Data Protection for details.

- **Configure the IIS Application Pool to load the user profile**

  This setting is in the **Process Model** section under the **Advanced Settings** for the app pool. Set **Load User Profile** to `True`. When set to `True`, keys are stored in the user profile directory and protected using DPAPI with a key specific to the user account. Keys are persisted to the *%LOCALAPPDATA%/ASP.NET/DataProtection-Keys* folder.

  The app pool's setProfileEnvironment attribute must also be enabled. The default value of `setProfileEnvironment` is `true`. In some scenarios (for example, Windows OS), `setProfileEnvironment` is set to `false`. If keys aren't stored in the user profile directory as expected:

  1. Navigate to the *%windir%/system32/inetsrv/config* folder.
  2. Open the *applicationHost.config* file.
  3. Locate the `<system.applicationHost><applicationPools><applicationPoolDefaults><processModel>` element.
  4. Confirm that the `setProfileEnvironment` attribute isn't present, which defaults the value to `true`, or explicitly set the attribute's value to `true`.

- **Use the file system as a key ring store**

  Adjust the app code to use the file system as a key ring store. Use an X509 certificate to protect the key ring and ensure the certificate is a trusted certificate. If the certificate is self-signed, place the certificate in the Trusted Root store.

  When using IIS in a web farm:

  - Use a file share that all machines can access.
  - Deploy an X509 certificate to each machine. Configure data protection in code.

- **Set a machine-wide policy for data protection**

  The data protection system has limited support for setting a default machine-wide policy for all apps

that consume the Data Protection APIs. For more information, see ASP.NET Core Data Protection.

Virtual Directories

IIS Virtual Directories aren't supported with ASP.NET Core apps. An app can be hosted as a sub-application.

Sub-applications

An ASP.NET Core app can be hosted as an IIS sub-application (sub-app). The sub-app's path becomes part of the root app's URL.

Static asset links within the sub-app should use tilde-slash (`~/`) notation. Tilde-slash notation triggers a Tag Helper to prepend the sub-app's pathbase to the rendered relative link. For a sub-app at `/subapp_path`, an image linked with `src="~/image.png"` is rendered as `src="/subapp_path/image.png"`. The root app's Static File Middleware doesn't process the static file request. The request is processed by the sub-app's Static File Middleware.

If a static asset's `src` attribute is set to an absolute path (for example, `src="/image.png"`), the link is rendered without the sub-app's pathbase. The root app's Static File Middleware attempts to serve the asset from the root app's web root, which results in a *404 - Not Found* response unless the static asset is available from the root app.

To host an ASP.NET Core app as a sub-app under another ASP.NET Core app:

1. Establish an app pool for the sub-app. Set the **.NET CLR Version** to **No Managed Code** because the Core Common Language Runtime (CoreCLR) for .NET Core is booted to host the app in the worker process, not the desktop CLR (.NET CLR).
2. Add the root site in IIS Manager with the sub-app in a folder under the root site.
3. Right-click the sub-app folder in IIS Manager and select **Convert to Application**.
4. In the **Add Application** dialog, use the **Select** button for the **Application Pool** to assign the app pool that you created for the sub-app. Select **OK**.

The assignment of a separate app pool to the sub-app is a requirement when using the in-process hosting model.

For more information on the in-process hosting model and configuring the ASP.NET Core Module, see ASP.NET Core Module.

Configuration of IIS with web.config

IIS configuration is influenced by the `<system.webServer>` section of *web.config* for IIS scenarios that are functional for ASP.NET Core apps with the ASP.NET Core Module. For example, IIS configuration is functional for dynamic compression. If IIS is configured at the server level to use dynamic compression, the `<urlCompression>` element in the app's *web.config* file can disable it for an ASP.NET Core app.

For more information, see the following topics:

- Configuration reference for <system.webServer>
- ASP.NET Core Module
- IIS modules with ASP.NET Core

To set environment variables for individual apps running in isolated app pools (supported for IIS 10.0 or later), see the *AppCmd.exe command* section of the Environment Variables <environmentVariables> topic in the IIS reference documentation.

Configuration sections of web.config

Configuration sections of ASP.NET 4.x apps in *web.config* aren't used by ASP.NET Core apps for configuration:

- `<system.web>`
- `<appSettings>`
- `<connectionStrings>`
- `<location>`

ASP.NET Core apps are configured using other configuration providers. For more information, see Configuration.

Application Pools

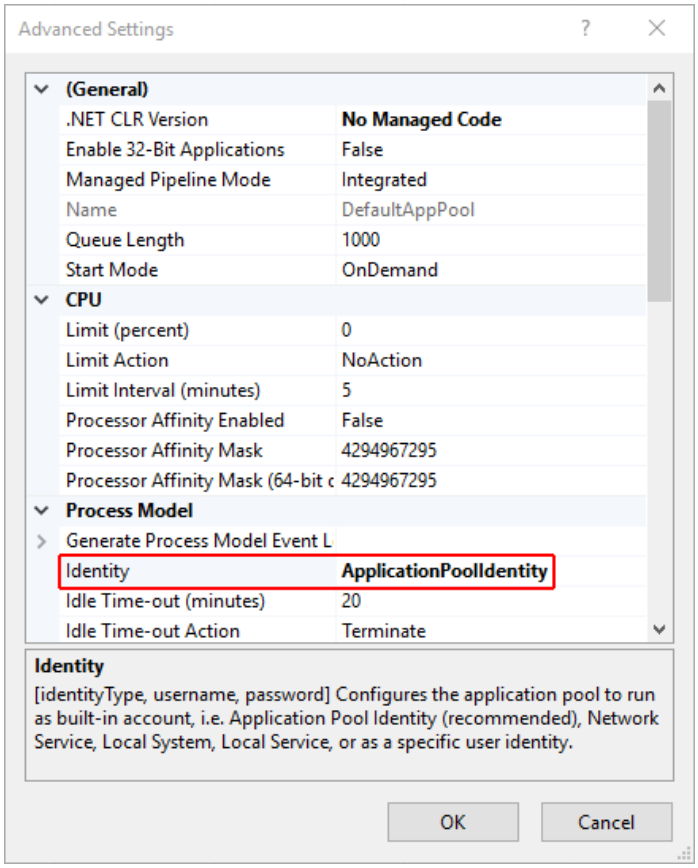
App pool isolation is determined by the hosting model:

- In-process hosting: Apps are required to run in separate app pools.
- Out-of-process hosting: We recommend isolating the apps from each other by running each app in its own app pool.

The IIS **Add Website** dialog defaults to a single app pool per app. When a **Site name** is provided, the text is automatically transferred to the **Application pool** textbox. A new app pool is created using the site name when the site is added.

Application Pool Identity

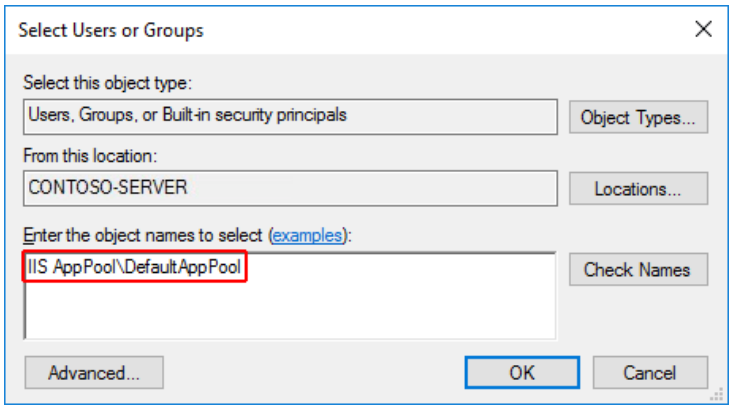
An app pool identity account allows an app to run under a unique account without having to create and manage domains or local accounts. On IIS 8.0 or later, the IIS Admin Worker Process (WAS) creates a virtual account with the name of the new app pool and runs the app pool's worker processes under this account by default. In the IIS Management Console under **Advanced Settings** for the app pool, ensure that the **Identity** is set to use **ApplicationPoolIdentity**:



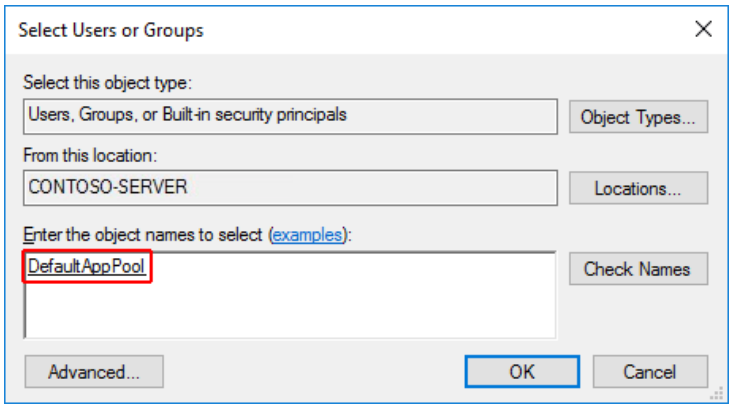
The IIS management process creates a secure identifier with the name of the app pool in the Windows Security System. Resources can be secured using this identity. However, this identity isn't a real user account and doesn't show up in the Windows User Management Console.

If the IIS worker process requires elevated access to the app, modify the Access Control List (ACL) for the directory containing the app:

1. Open Windows Explorer and navigate to the directory.
2. Right-click on the directory and select **Properties**.
3. Under the **Security** tab, select the **Edit** button and then the **Add** button.
4. Select the **Locations** button and make sure the system is selected.
5. Enter **IIS AppPool\<app_pool_name>** in **Enter the object names to select** area. Select the **Check Names** button. For the *DefaultAppPool* check the names using **IIS AppPool\DefaultAppPool**. When the **Check Names** button is selected, a value of **DefaultAppPool** is indicated in the object names area. It isn't possible to enter the app pool name directly into the object names area. Use the **IIS AppPool\<app_pool_name>** format when checking for the object name.



6. Select **OK**.



7. Read & execute permissions should be granted by default. Provide additional permissions as needed.

Access can also be granted at a command prompt using the **ICACLS** tool. Using the *DefaultAppPool* as an example, the following command is used:

```
ICACLS C:\sites\MyWebApp /grant "IIS AppPool\DefaultAppPool":F
```

For more information, see the icacls topic.

HTTP/2 support

HTTP/2 is supported with ASP.NET Core in the following IIS deployment scenarios:

- In-process
  - Windows Server 2016/Windows 10 or later; IIS 10 or later
  - TLS 1.2 or later connection
- Out-of-process
  - Windows Server 2016/Windows 10 or later; IIS 10 or later
  - Public-facing edge server connections use HTTP/2, but the reverse proxy connection to the Kestrel server uses HTTP/1.1.
  - TLS 1.2 or later connection

For an in-process deployment when an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/2`. For an out-of-process deployment when an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/1.1`.

For more information on the in-process and out-of-process hosting models, see ASP.NET Core Module.

HTTP/2 is enabled by default. Connections fall back to HTTP/1.1 if an HTTP/2 connection isn't established. For more information on HTTP/2 configuration with IIS deployments, see HTTP/2 on IIS.

CORS preflight requests

This section only applies to ASP.NET Core apps that target the .NET Framework.

For an ASP.NET Core app that targets the .NET Framework, OPTIONS requests aren't passed to the app by default in IIS. To learn how to configure the app's IIS handlers in *web.config* to pass OPTIONS requests, see Enable cross-origin requests in ASP.NET Web API 2: How CORS Works.

Application Initialization Module and Idle Timeout

When hosted in IIS by the ASP.NET Core Module version 2:

- Application Initialization Module: App's hosted in-process or out-of-process can be configured to start automatically on a worker process restart or server restart.
- Idle Timeout: App's hosted in-process can be configured not to timeout during periods of inactivity.

Application Initialization Module

Applies to apps hosted in-process and out-of-process.

IIS Application Initialization is an IIS feature that sends an HTTP request to the app when the app pool starts or is recycled. The request triggers the app to start. By default, IIS issues a request to the app's root URL (`/`) to initialize the app (see the additional resources for more details on configuration).

Confirm that the IIS Application Initialization role feature in enabled:

On Windows 7 or later desktop systems when using IIS locally:

1. Navigate to **Control Panel** > **Programs** > **Programs and Features** > **Turn Windows features on or off** (left side of the screen).
2. Open **Internet Information Services** > **World Wide Web Services** > **Application Development Features**.
3. Select the check box for **Application Initialization**.

On Windows Server 2008 R2 or later:

1. Open the **Add Roles and Features Wizard**.
2. In the **Select role services** panel, open the **Application Development** node.

3. Select the check box for **Application Initialization**.

Use either of the following approaches to enable the Application Initialization Module for the site:

- Using IIS Manager:

  1. Select **Application Pools** in the **Connections** panel.
  2. Right-click the app's app pool in the list and select **Advanced Settings**.
  3. The default **Start Mode** is **OnDemand**. Set the **Start Mode** to **AlwaysRunning**. Select **OK**.
  4. Open the **Sites** node in the **Connections** panel.
  5. Right-click the app and select **Manage Website** > **Advanced Settings**.
  6. The default **Preload Enabled** setting is **False**. Set **Preload Enabled** to **True**. Select **OK**.

- Using *web.config*, add the `<applicationInitialization>` element with `doAppInitAfterRestart` set to `true` to the `<system.webServer>` elements in the app's *web.config* file:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <location path="." inheritInChildApplications="false">
    <system.webServer>
      <applicationInitialization doAppInitAfterRestart="true" />
    </system.webServer>
  </location>
</configuration>
```

Idle Timeout

Only applies to apps hosted in-process.

To prevent the app from idling, set the app pool's idle timeout using IIS Manager:

1. Select **Application Pools** in the **Connections** panel.
2. Right-click the app's app pool in the list and select **Advanced Settings**.
3. The default **Idle Time-out (minutes)** is **20** minutes. Set the **Idle Time-out (minutes)** to **0** (zero). Select **OK**.
4. Recycle the worker process.

To prevent apps hosted out-of-process from timing out, use either of the following approaches:

- Ping the app from an external service in order to keep it running.
- If the app only hosts background services, avoid IIS hosting and use a Windows Service to host the ASP.NET Core app.

Application Initialization Module and Idle Timeout additional resources

Install the .NET Core Hosting Bundle

Supported operating systems

The following operating systems are supported:

- Windows 7 or later
- Windows Server 2008 R2 or later

HTTP.sys server (formerly called WebListener) doesn't work in a reverse proxy configuration with IIS. Use the Kestrel server.

For information on hosting in Azure, see Deploy ASP.NET Core apps to Azure App Service.

For troubleshooting guidance, see Troubleshoot and debug ASP.NET Core projects.

Supported platforms

Apps published for 32-bit (x86) or 64-bit (x64) deployment are supported. Deploy a 32-bit app with a 32-bit (x86) .NET Core SDK unless the app:

- Requires the larger virtual memory address space available to a 64-bit app.
- Requires the larger IIS stack size.
- Has 64-bit native dependencies.

Use a 64-bit (x64) .NET Core SDK to publish a 64-bit app. A 64-bit runtime must be present on the host system.

Hosting models

In-process hosting model

Using in-process hosting, an ASP.NET Core app runs in the same process as its IIS worker process. In-process hosting provides improved performance over out-of-process hosting because:

- Requests aren't proxied over the loopback adapter. A loopback adapter is a network interface that returns outgoing network traffic back to the same machine.

IIS handles process management with the Windows Process Activation Service (WAS).

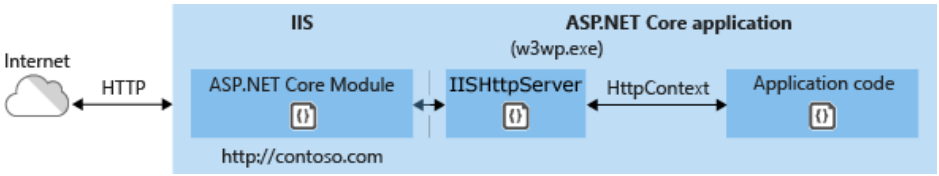
The ASP.NET Core Module:

- Performs app initialization.
  - Loads the CoreCLR.

    - Calls `Program.Main`.
- Handles the lifetime of the IIS native request.

The in-process hosting model isn't supported for ASP.NET Core apps that target the .NET Framework.

The following diagram illustrates the relationship between IIS, the ASP.NET Core Module, and an app hosted in-process:



A request arrives from the web to the kernel-mode HTTP.sys driver. The driver routes the native request to IIS on the website's configured port, usually 80 (HTTP) or 443 (HTTPS). The ASP.NET Core Module receives the native request and passes it to IIS HTTP Server (`IISHttpServer`). IIS HTTP Server is an in-process server implementation for IIS that converts the request from native to managed.

After the IIS HTTP Server processes the request, the request is pushed into the ASP.NET Core middleware pipeline. The middleware pipeline handles the request and passes it on as an `HttpContext` instance to the app's logic. The app's response is passed back to IIS through IIS HTTP Server. IIS sends the response to the client that initiated the request.

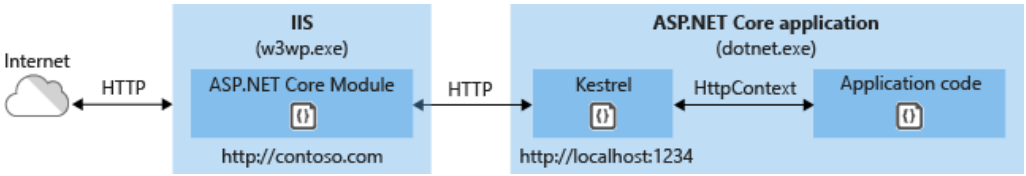
In-process hosting is opt-in for existing apps, but dotnet new templates default to the in-process hosting model for all IIS and IIS Express scenarios.

`CreateDefaultBuilder` adds an IServer instance by calling the UseIIS method to boot the CoreCLR and host the app inside of the IIS worker process (*w3wp.exe* or *iisexpress.exe*). Performance tests indicate that hosting a .NET Core app in-process delivers significantly higher request throughput compared to hosting the app out-of-process and proxying requests to Kestrel server.

Out-of-process hosting model

Because ASP.NET Core apps run in a process separate from the IIS worker process, the ASP.NET Core Module handles process management. The module starts the process for the ASP.NET Core app when the first request arrives and restarts the app if it shuts down or crashes. This is essentially the same behavior as seen with apps that run in-process that are managed by the Windows Process Activation Service (WAS).

The following diagram illustrates the relationship between IIS, the ASP.NET Core Module, and an app hosted out-of-process:



Requests arrive from the web to the kernel-mode HTTP.sys driver. The driver routes the requests to IIS on the website's configured port, usually 80 (HTTP) or 443 (HTTPS). The module forwards the requests to Kestrel on a random port for the app, which isn't port 80 or 443.

The module specifies the port via an environment variable at startup, and the UseIISIntegration extension configures the server to listen on `http://localhost:{PORT}`. Additional checks are performed, and requests that don't originate from the module are rejected. The module doesn't support HTTPS forwarding, so requests are forwarded over HTTP even if received by IIS over HTTPS.

After Kestrel picks up the request from the module, the request is pushed into the ASP.NET Core middleware pipeline. The middleware pipeline handles the request and passes it on as an `HttpContext` instance to the app's logic. Middleware added by IIS Integration updates the scheme, remote IP, and pathbase to account for

forwarding the request to Kestrel. The app's response is passed back to IIS, which pushes it back out to the HTTP client that initiated the request.

For ASP.NET Core Module configuration guidance, see ASP.NET Core Module.

For more information on hosting, see Host in ASP.NET Core.

Application configuration

Enable the IISIntegration components

When building a host in `CreateWebHostBuilder` (*Program.cs*), call CreateDefaultBuilder to enable IIS integration:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        ...
```

For more information on `CreateDefaultBuilder`, see ASP.NET Core Web Host.

IIS options

In-process hosting model

To configure IIS Server options, include a service configuration for IISServerOptions in ConfigureServices. The following example disables AutomaticAuthentication:

```
services.Configure<IISServerOptions>(options =>
{
    options.AutomaticAuthentication = false;
});
```

OPTION	DEFAULT	SETTING
`AutomaticAuthentication`	`true`	If `true`, IIS Server sets the `HttpContext.User` authenticated by Windows Authentication. If `false`, the server only provides an identity for `HttpContext.User` and responds to challenges when explicitly requested by the `AuthenticationScheme`. Windows Authentication must be enabled in IIS for `AutomaticAuthentication` to function. For more information, see Windows Authentication.
`AuthenticationDisplayName`	`null`	Sets the display name shown to users on login pages.

Out-of-process hosting model

To configure IIS options, include a service configuration for IISOptions in ConfigureServices. The following example prevents the app from populating `HttpContext.Connection.ClientCertificate`:

```
services.Configure<IISOptions>(options =>
{
    options.ForwardClientCertificate = false;
});
```

OPTION	DEFAULT	SETTING
`AutomaticAuthentication`	`true`	If `true`, IIS Integration Middleware sets the `HttpContext.User` authenticated by Windows Authentication. If `false`, the middleware only provides an identity for `HttpContext.User` and responds to challenges when explicitly requested by the `AuthenticationScheme`. Windows Authentication must be enabled in IIS for `AutomaticAuthentication` to function. For more information, see the Windows Authentication topic.
`AuthenticationDisplayName`	`null`	Sets the display name shown to users on login pages.
`ForwardClientCertificate`	`true`	If `true` and the `MS-ASPNETCORE-CLIENTCERT` request header is present, the `HttpContext.Connection.ClientCertificate` is populated.

Proxy server and load balancer scenarios

The IIS Integration Middleware, which configures Forwarded Headers Middleware, and the ASP.NET Core Module are configured to forward the scheme (HTTP/HTTPS) and the remote IP address where the request originated. Additional configuration might be required for apps hosted behind additional proxy servers and load balancers. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

web.config file

The *web.config* file configures the ASP.NET Core Module. Creating, transforming, and publishing the *web.config* file is handled by an MSBuild target (`_TransformWebConfig`) when the project is published. This target is present in the Web SDK targets (`Microsoft.NET.Sdk.Web`). The SDK is set at the top of the project file:

```
<Project Sdk="Microsoft.NET.Sdk.Web">
```

If a *web.config* file isn't present in the project, the file is created with the correct *processPath* and *arguments* to configure the ASP.NET Core Module and moved to published output.

If a *web.config* file is present in the project, the file is transformed with the correct *processPath* and *arguments* to configure the ASP.NET Core Module and moved to published output. The transformation doesn't modify IIS configuration settings in the file.

The *web.config* file may provide additional IIS configuration settings that control active IIS modules. For information on IIS modules that are capable of processing requests with ASP.NET Core apps, see the IIS modules topic.

To prevent the Web SDK from transforming the *web.config* file, use the **<IsTransformWebConfigDisabled>** property in the project file:

```
<PropertyGroup>
  <IsTransformWebConfigDisabled>true</IsTransformWebConfigDisabled>
</PropertyGroup>
```

When disabling the Web SDK from transforming the file, the *processPath* and *arguments* should be manually set by the developer. For more information, see ASP.NET Core Module.

web.config file location

In order to set up the ASP.NET Core Module correctly, the *web.config* file must be present at the content root path (typically the app base path) of the deployed app. This is the same location as the website physical path provided to IIS. The *web.config* file is required at the root of the app to enable the publishing of multiple apps using Web Deploy.

Sensitive files exist on the app's physical path, such as *<assembly>.runtimeconfig.json*, *<assembly>.xml* (XML Documentation comments), and *<assembly>.deps.json*. When the *web.config* file is present and the site starts normally, IIS doesn't serve these sensitive files if they're requested. If the *web.config* file is missing, incorrectly named, or unable to configure the site for normal startup, IIS may serve sensitive files publicly.

The *web.config* file must be present in the deployment at all times, correctly named, and able to configure the site for normal start up. Never remove the *web.config* file from a production deployment.

Transform web.config

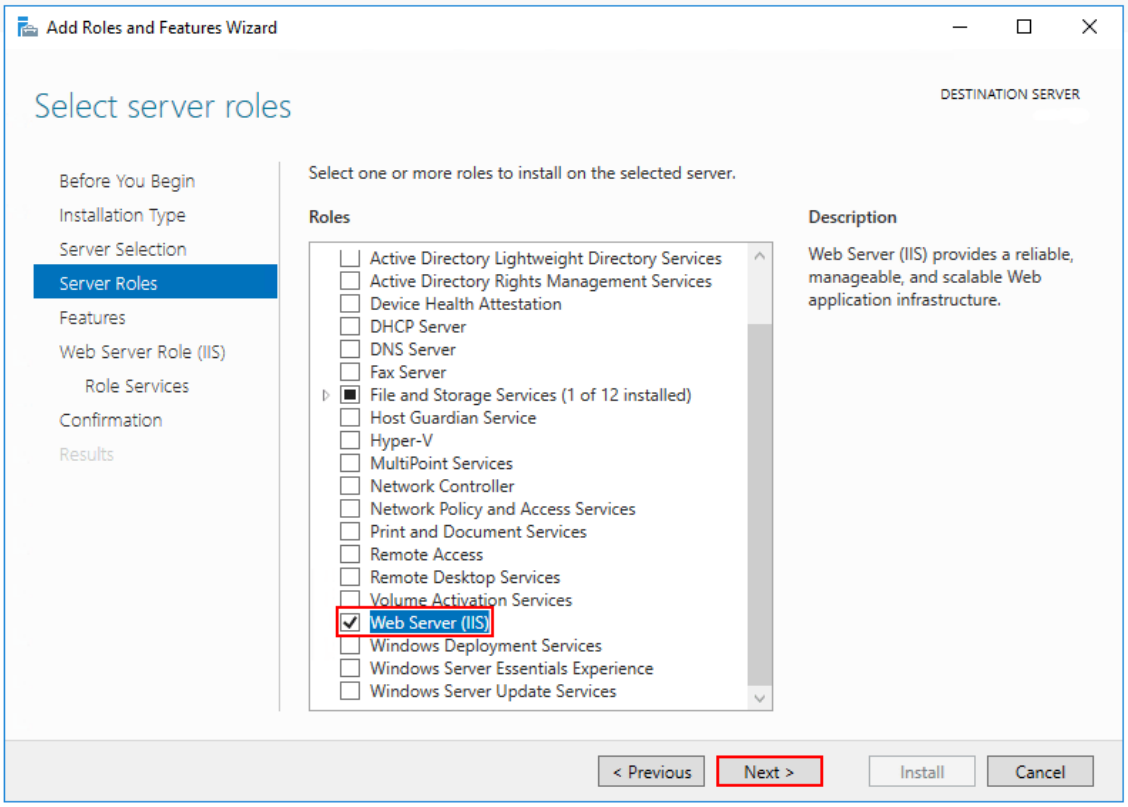
If you need to transform *web.config* on publish (for example, set environment variables based on the configuration, profile, or environment), see Transform web.config.

IIS configuration

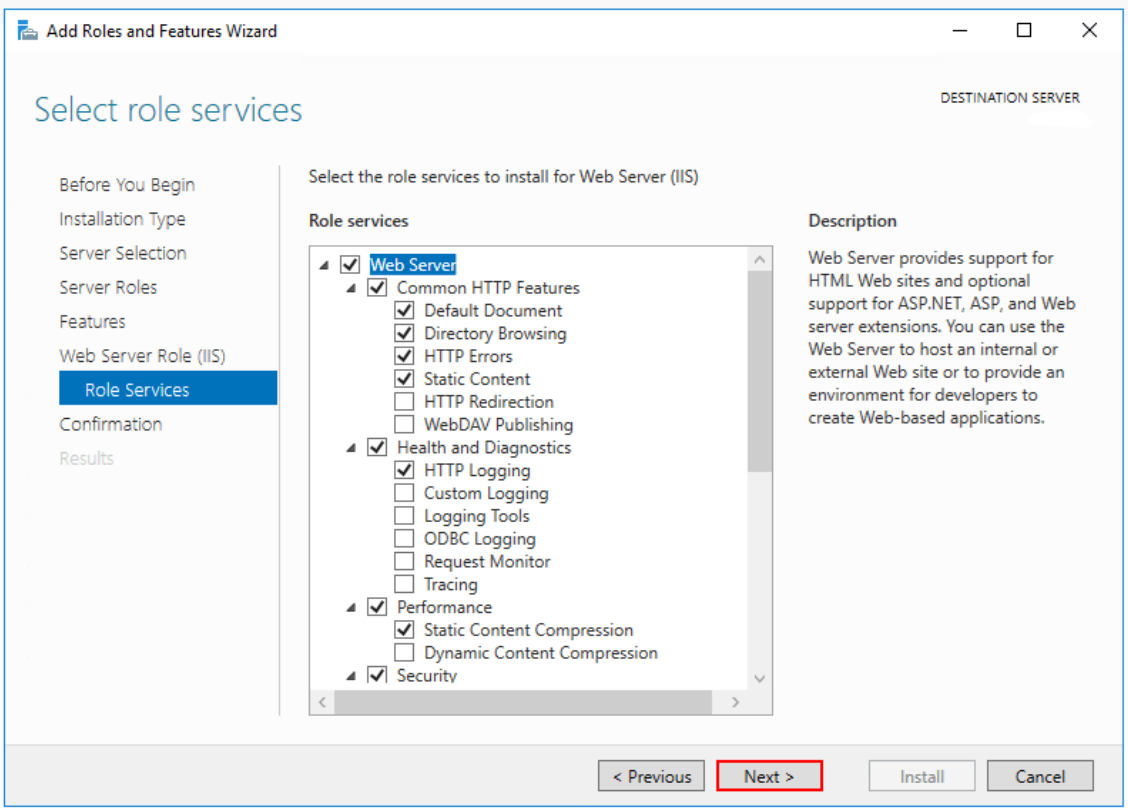
Windows Server operating systems

Enable the **Web Server (IIS)** server role and establish role services.

1. Use the **Add Roles and Features** wizard from the **Manage** menu or the link in **Server Manager**. On the **Server Roles** step, check the box for **Web Server (IIS)**.



2. After the **Features** step, the **Role services** step loads for Web Server (IIS). Select the IIS role services desired or accept the default role services provided.



Windows Authentication (Optional)

To enable Windows Authentication, expand the following nodes: **Web Server** > **Security**. Select the **Windows Authentication** feature. For more information, see Windows Authentication <windowsAuthentication> and Configure Windows authentication.

WebSockets (Optional)

WebSockets is supported with ASP.NET Core 1.1 or later. To enable WebSockets, expand the following nodes: **Web Server** > **Application Development**. Select the **WebSocket Protocol** feature. For

more information, see WebSockets.

3. Proceed through the **Confirmation** step to install the web server role and services. A server/IIS restart isn't required after installing the **Web Server (IIS)** role.

Windows desktop operating systems

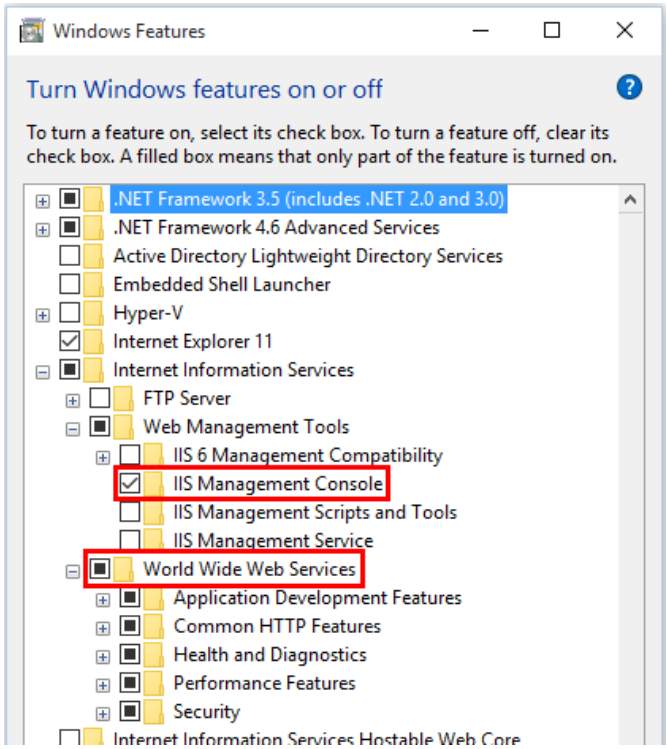
Enable the **IIS Management Console** and **World Wide Web Services**.

1. Navigate to **Control Panel** > **Programs** > **Programs and Features** > **Turn Windows features on or off** (left side of the screen).
2. Open the **Internet Information Services** node. Open the **Web Management Tools** node.
3. Check the box for **IIS Management Console**.
4. Check the box for **World Wide Web Services**.
5. Accept the default features for **World Wide Web Services** or customize the IIS features.

   Windows Authentication (Optional)
   To enable Windows Authentication, expand the following nodes: **World Wide Web Services** > **Security**. Select the **Windows Authentication** feature. For more information, see Windows Authentication <windowsAuthentication> and Configure Windows authentication.

   WebSockets (Optional)
   WebSockets is supported with ASP.NET Core 1.1 or later. To enable WebSockets, expand the following nodes: **World Wide Web Services** > **Application Development Features**. Select the **WebSocket Protocol** feature. For more information, see WebSockets.

6. If the IIS installation requires a restart, restart the system.



Install the .NET Core Hosting Bundle

Install the *.NET Core Hosting Bundle* on the hosting system. The bundle installs the .NET Core Runtime, .NET Core Library, and the ASP.NET Core Module. The module allows ASP.NET Core apps to run behind IIS.

> **IMPORTANT**
>
> If the Hosting Bundle is installed before IIS, the bundle installation must be repaired. Run the Hosting Bundle installer again after installing IIS.
>
> If the Hosting Bundle is installed after installing the 64-bit (x64) version of .NET Core, SDKs might appear to be missing (No .NET Core SDKs were detected). To resolve the problem, see Troubleshoot and debug ASP.NET Core projects.

Download

1. Navigate to the Download .NET Core page.
2. Select the desired .NET Core version.
3. In the **Run apps - Runtime** column, find the row of the .NET Core runtime version desired.
4. Download the installer using the **Hosting Bundle** link.

> **WARNING**
>
> Some installers contain release versions that have reached their end of life (EOL) and are no longer supported by Microsoft. For more information, see the support policy.

Install the Hosting Bundle

1. Run the installer on the server. The following parameters are available when running the installer from an administrator command shell:

   - `OPT_NO_ANCM=1`: Skip installing the ASP.NET Core Module.
   - `OPT_NO_RUNTIME=1`: Skip installing the .NET Core runtime. Used when the server only hosts self-contained deployments (SCD).
   - `OPT_NO_SHAREDFX=1`: Skip installing the ASP.NET Shared Framework (ASP.NET runtime). Used when the server only hosts self-contained deployments (SCD).
   - `OPT_NO_X86=1`: Skip installing x86 runtimes. Use this parameter when you know that you won't be hosting 32-bit apps. If there's any chance that you will host both 32-bit and 64-bit apps in the future, don't use this parameter and install both runtimes.
   - `OPT_NO_SHARED_CONFIG_CHECK=1`: Disable the check for using an IIS Shared Configuration when the shared configuration (*applicationHost.config*) is on the same machine as the IIS installation. *Only available for ASP.NET Core 2.2 or later Hosting Bundler installers.* For more information, see ASP.NET Core Module.

2. Restart the system or execute the following commands in a command shell:

   ```
   net stop was /y
   net start w3svc
   ```

   Restarting IIS picks up a change to the system PATH, which is an environment variable, made by the installer.

It isn't necessary to manually stop individual sites in IIS when installing the Hosting Bundle. Hosted apps (IIS sites) restart when IIS restarts. Apps start up again when they receive their first request, including from the Application Initialization Module.

ASP.NET Core adopts roll-forward behavior for patch releases of shared framework packages. When apps hosted by IIS restart with IIS, the apps load with the latest patch releases of their referenced packages when they receive their first request. If IIS isn't restarted, apps restart and exhibit roll-forward behavior when their worker processes are recycled and they receive their first request.

> **NOTE**
>
> For information on IIS Shared Configuration, see ASP.NET Core Module with IIS Shared Configuration.

Install Web Deploy when publishing with Visual Studio

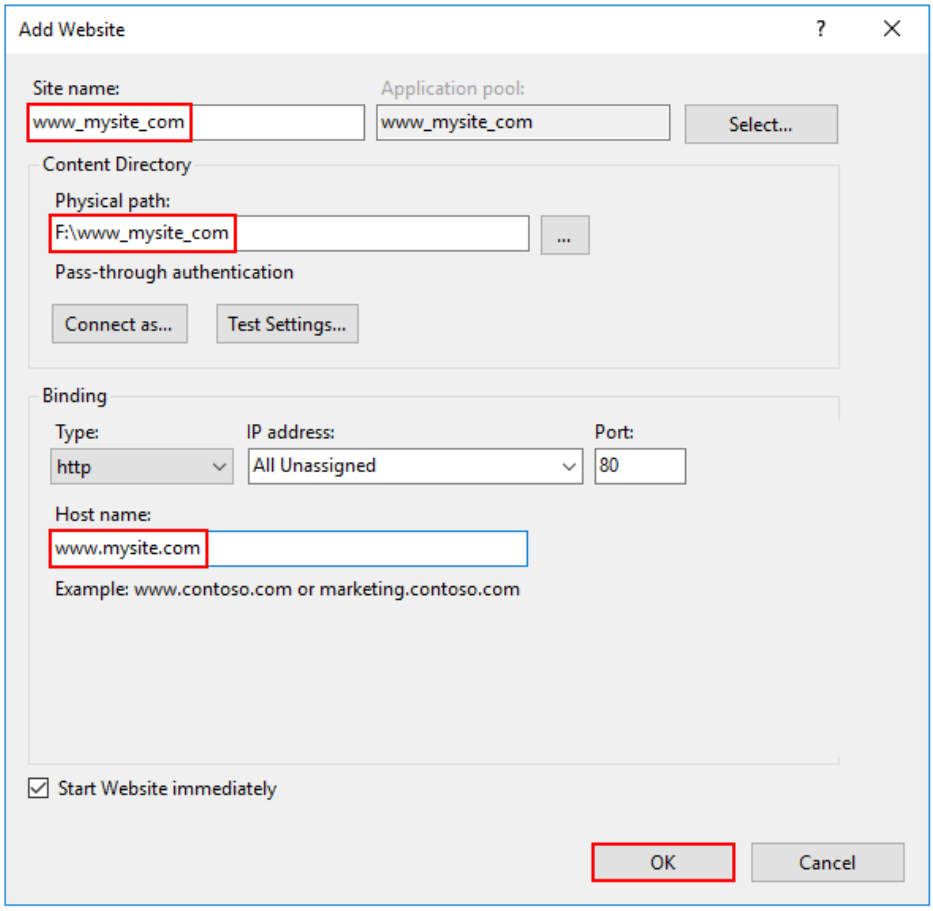
When deploying apps to servers with Web Deploy, install the latest version of Web Deploy on the server. To install Web Deploy, use the Web Platform Installer (WebPI) or obtain an installer directly from the Microsoft Download Center. The preferred method is to use WebPI. WebPI offers a standalone setup and a configuration for hosting providers.

Create the IIS site

1. On the hosting system, create a folder to contain the app's published folders and files. In a following step, the folder's path is provided to IIS as the physical path to the app. For more information on an app's deployment folder and file layout, see ASP.NET Core directory structure.

2. In IIS Manager, open the server's node in the **Connections** panel. Right-click the **Sites** folder. Select **Add Website** from the contextual menu.

3. Provide a **Site name** and set the **Physical path** to the app's deployment folder. Provide the **Binding** configuration and create the website by selecting **OK**:



> **WARNING**
>
> Top-level wildcard bindings (`http://*:80/` and `http://+:80`) should **not** be used. Top-level wildcard bindings can open up your app to security vulnerabilities. This applies to both strong and weak wildcards. Use explicit host names rather than wildcards. Subdomain wildcard binding (for example, `*.mysub.com`) doesn't have this security risk if you control the entire parent domain (as opposed to `*.com` , which is vulnerable). See rfc7230 section-5.4 for more information.

4. Under the server's node, select **Application Pools**.
5. Right-click the site's app pool and select **Basic Settings** from the contextual menu.
6. In the **Edit Application Pool** window, set the **.NET CLR version** to **No Managed Code**:

   ASP.NET Core runs in a separate process and manages the runtime. ASP.NET Core doesn't rely on loading the desktop CLR (.NET CLR)—the Core Common Language Runtime (CoreCLR) for .NET Core is booted to host the app in the worker process. Setting the **.NET CLR version** to **No Managed Code** is optional but recommended.

7. *ASP.NET Core 2.2 or later*: For a 64-bit (x64) self-contained deployment that uses the in-process hosting model, disable the app pool for 32-bit (x86) processes.

   In the **Actions** sidebar of IIS Manager > **Application Pools**, select **Set Application Pool Defaults** or **Advanced Settings**. Locate **Enable 32-Bit Applications** and set the value to `False` . This setting doesn't affect apps deployed for out-of-process hosting.

8. Confirm the process model identity has the proper permissions.

   If the default identity of the app pool (**Process Model** > **Identity**) is changed from **ApplicationPoolIdentity** to another identity, verify that the new identity has the required permissions to access the app's folder, database, and other required resources. For example, the app pool requires read and write access to folders where the app reads and writes files.

Windows Authentication configuration (Optional)

For more information, see Configure Windows authentication.

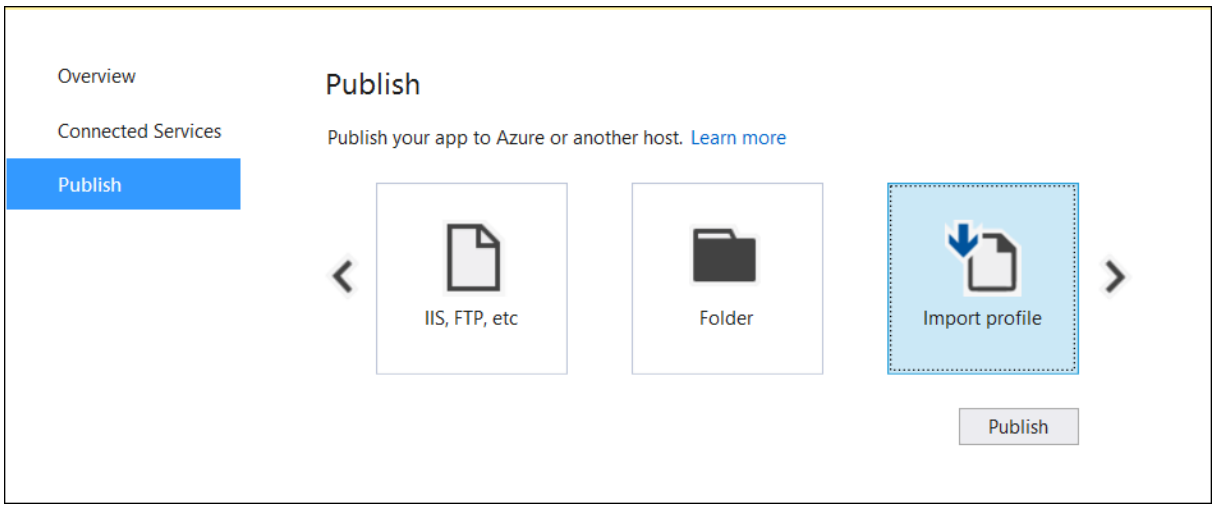
Deploy the app

Deploy the app to the IIS **Physical path** folder that was established in the Create the IIS site section. Web Deploy is the recommended mechanism for deployment, but several options exist for moving the app from the project's *publish* folder to the hosting system's deployment folder.

Web Deploy with Visual Studio

See the Visual Studio publish profiles for ASP.NET Core app deployment topic to learn how to create a publish

profile for use with Web Deploy. If the hosting provider provides a Publish Profile or support for creating one, download their profile and import it using the Visual Studio **Publish** dialog:



Web Deploy outside of Visual Studio

Web Deploy can also be used outside of Visual Studio from the command line. For more information, see Web Deployment Tool.

Alternatives to Web Deploy

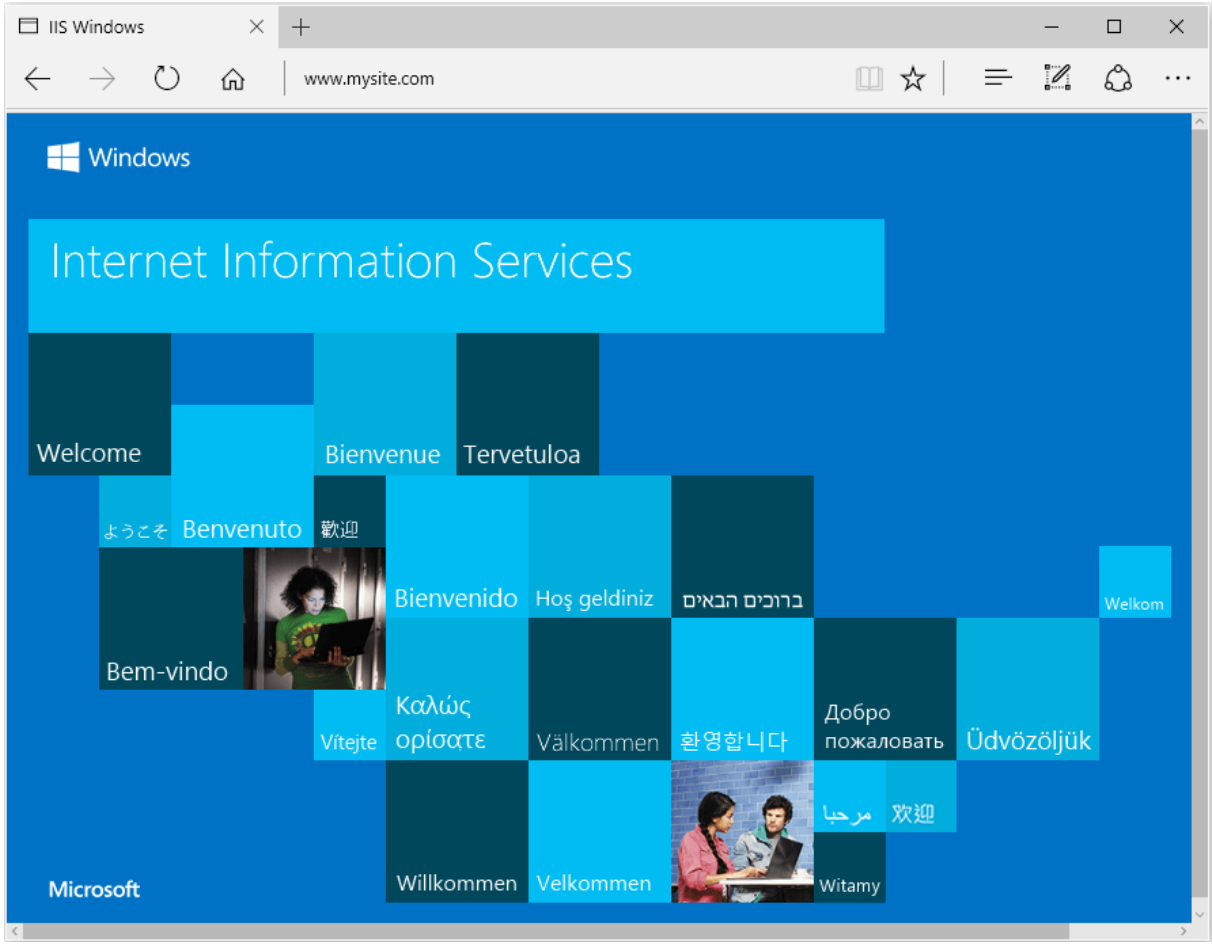
Use any of several methods to move the app to the hosting system, such as manual copy, Xcopy, Robocopy, or PowerShell.

For more information on ASP.NET Core deployment to IIS, see the Deployment resources for IIS administrators section.

Browse the website

After the app is deployed to the hosting system, make a request to one of the app's public endpoints.

In the following example, the site is bound to an IIS **Host name** of `www.mysite.com` on **Port** `80`. A request is made to `http://www.mysite.com`:



Locked deployment files

Files in the deployment folder are locked when the app is running. Locked files can't be overwritten during deployment. To release locked files in a deployment, stop the app pool using **one** of the following approaches:

- Use Web Deploy and reference `Microsoft.NET.Sdk.Web` in the project file. An *app_offline.htm* file is placed at the root of the web app directory. When the file is present, the ASP.NET Core Module gracefully shuts down the app and serves the *app_offline.htm* file during the deployment. For more information, see the ASP.NET Core Module configuration reference.
- Manually stop the app pool in the IIS Manager on the server.
- Use PowerShell to drop *app_offline.htm* (requires PowerShell 5 or later):

```
$pathToApp = 'PATH_TO_APP'

# Stop the AppPool
New-Item -Path $pathToApp app_offline.htm

# Provide script commands here to deploy the app

# Restart the AppPool
Remove-Item -Path $pathToApp app_offline.htm
```

Data protection

The ASP.NET Core Data Protection stack is used by several ASP.NET Core middlewares, including middleware used in authentication. Even if Data Protection APIs aren't called by user code, data protection should be configured with a deployment script or in user code to create a persistent cryptographic key store. If data

protection isn't configured, the keys are held in memory and discarded when the app restarts.

If the key ring is stored in memory when the app restarts:

- All cookie-based authentication tokens are invalidated.
- Users are required to sign in again on their next request.
- Any data protected with the key ring can no longer be decrypted. This may include CSRF tokens and ASP.NET Core MVC TempData cookies.

To configure data protection under IIS to persist the key ring, use **one** of the following approaches:

- **Create Data Protection Registry Keys**

  Data protection keys used by ASP.NET Core apps are stored in the registry external to the apps. To persist the keys for a given app, create registry keys for the app pool.

  For standalone, non-webfarm IIS installations, the Data Protection Provision-AutoGenKeys.ps1 PowerShell script can be used for each app pool used with an ASP.NET Core app. This script creates a registry key in the HKLM registry that's accessible only to the worker process account of the app's app pool. Keys are encrypted at rest using DPAPI with a machine-wide key.

  In web farm scenarios, an app can be configured to use a UNC path to store its data protection key ring. By default, the data protection keys aren't encrypted. Ensure that the file permissions for the network share are limited to the Windows account the app runs under. An X509 certificate can be used to protect keys at rest. Consider a mechanism to allow users to upload certificates: Place certificates into the user's trusted certificate store and ensure they're available on all machines where the user's app runs. See Configure ASP.NET Core Data Protection for details.

- **Configure the IIS Application Pool to load the user profile**

  This setting is in the **Process Model** section under the **Advanced Settings** for the app pool. Set **Load User Profile** to `True`. When set to `True`, keys are stored in the user profile directory and protected using DPAPI with a key specific to the user account. Keys are persisted to the *%LOCALAPPDATA%/ASP.NET/DataProtection-Keys* folder.

  The app pool's setProfileEnvironment attribute must also be enabled. The default value of `setProfileEnvironment` is `true`. In some scenarios (for example, Windows OS), `setProfileEnvironment` is set to `false`. If keys aren't stored in the user profile directory as expected:

  1. Navigate to the *%windir%/system32/inetsrv/config* folder.
  2. Open the *applicationHost.config* file.
  3. Locate the `<system.applicationHost><applicationPools><applicationPoolDefaults><processModel>` element.
  4. Confirm that the `setProfileEnvironment` attribute isn't present, which defaults the value to `true`, or explicitly set the attribute's value to `true`.

- **Use the file system as a key ring store**

  Adjust the app code to use the file system as a key ring store. Use an X509 certificate to protect the key ring and ensure the certificate is a trusted certificate. If the certificate is self-signed, place the certificate in the Trusted Root store.

  When using IIS in a web farm:

  - Use a file share that all machines can access.
  - Deploy an X509 certificate to each machine. Configure data protection in code.

- **Set a machine-wide policy for data protection**

  The data protection system has limited support for setting a default machine-wide policy for all apps

that consume the Data Protection APIs. For more information, see ASP.NET Core Data Protection.

Virtual Directories

IIS Virtual Directories aren't supported with ASP.NET Core apps. An app can be hosted as a sub-application.

Sub-applications

An ASP.NET Core app can be hosted as an IIS sub-application (sub-app). The sub-app's path becomes part of the root app's URL.

Static asset links within the sub-app should use tilde-slash (`~/`) notation. Tilde-slash notation triggers a Tag Helper to prepend the sub-app's pathbase to the rendered relative link. For a sub-app at `/subapp_path`, an image linked with `src="~/image.png"` is rendered as `src="/subapp_path/image.png"`. The root app's Static File Middleware doesn't process the static file request. The request is processed by the sub-app's Static File Middleware.

If a static asset's `src` attribute is set to an absolute path (for example, `src="/image.png"`), the link is rendered without the sub-app's pathbase. The root app's Static File Middleware attempts to serve the asset from the root app's web root, which results in a *404 - Not Found* response unless the static asset is available from the root app.

To host an ASP.NET Core app as a sub-app under another ASP.NET Core app:

1. Establish an app pool for the sub-app. Set the **.NET CLR Version** to **No Managed Code** because the Core Common Language Runtime (CoreCLR) for .NET Core is booted to host the app in the worker process, not the desktop CLR (.NET CLR).
2. Add the root site in IIS Manager with the sub-app in a folder under the root site.
3. Right-click the sub-app folder in IIS Manager and select **Convert to Application**.
4. In the **Add Application** dialog, use the **Select** button for the **Application Pool** to assign the app pool that you created for the sub-app. Select **OK**.

The assignment of a separate app pool to the sub-app is a requirement when using the in-process hosting model.

For more information on the in-process hosting model and configuring the ASP.NET Core Module, see ASP.NET Core Module.

Configuration of IIS with web.config

IIS configuration is influenced by the `<system.webServer>` section of *web.config* for IIS scenarios that are functional for ASP.NET Core apps with the ASP.NET Core Module. For example, IIS configuration is functional for dynamic compression. If IIS is configured at the server level to use dynamic compression, the `<urlCompression>` element in the app's *web.config* file can disable it for an ASP.NET Core app.

For more information, see the following topics:

- Configuration reference for <system.webServer>
- ASP.NET Core Module
- IIS modules with ASP.NET Core

To set environment variables for individual apps running in isolated app pools (supported for IIS 10.0 or later), see the *AppCmd.exe command* section of the Environment Variables <environmentVariables> topic in the IIS reference documentation.

Configuration sections of web.config

Configuration sections of ASP.NET 4.x apps in *web.config* aren't used by ASP.NET Core apps for configuration:

- `<system.web>`
- `<appSettings>`
- `<connectionStrings>`
- `<location>`

ASP.NET Core apps are configured using other configuration providers. For more information, see Configuration.

Application Pools

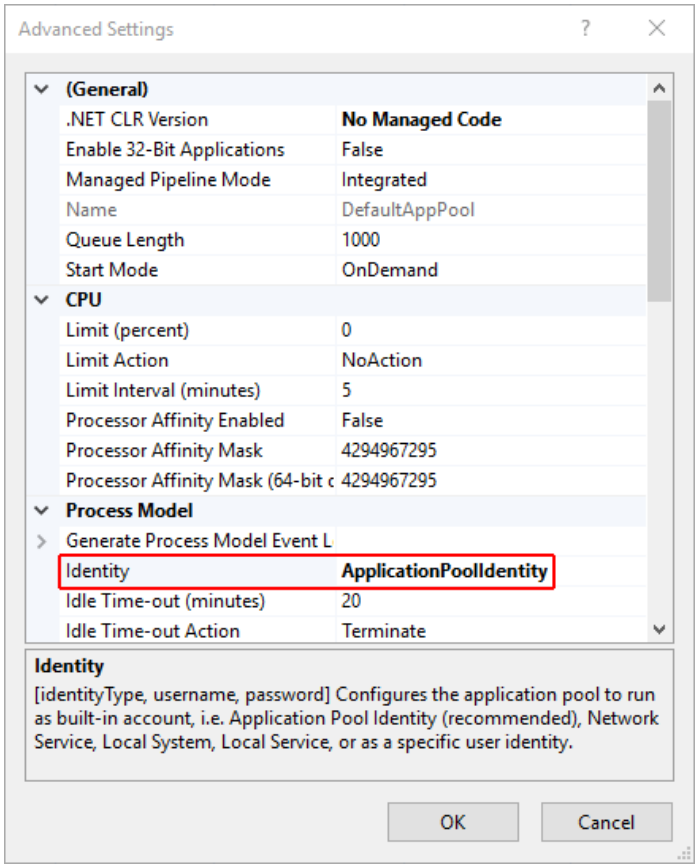
App pool isolation is determined by the hosting model:

- In-process hosting: Apps are required to run in separate app pools.
- Out-of-process hosting: We recommend isolating the apps from each other by running each app in its own app pool.

The IIS **Add Website** dialog defaults to a single app pool per app. When a **Site name** is provided, the text is automatically transferred to the **Application pool** textbox. A new app pool is created using the site name when the site is added.

Application Pool Identity

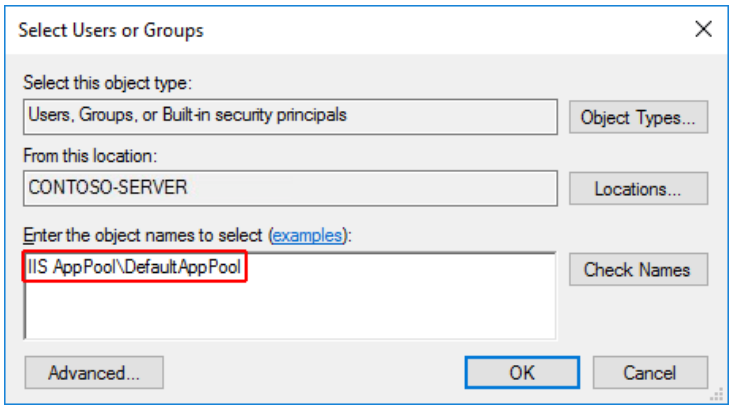
An app pool identity account allows an app to run under a unique account without having to create and manage domains or local accounts. On IIS 8.0 or later, the IIS Admin Worker Process (WAS) creates a virtual account with the name of the new app pool and runs the app pool's worker processes under this account by default. In the IIS Management Console under **Advanced Settings** for the app pool, ensure that the **Identity** is set to use **ApplicationPoolIdentity**:



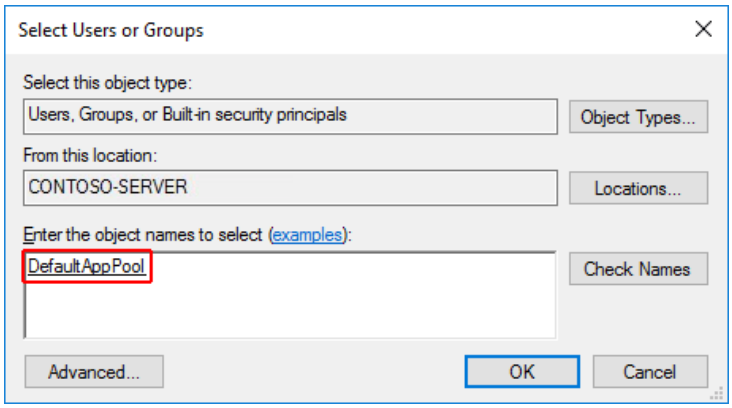
The IIS management process creates a secure identifier with the name of the app pool in the Windows Security System. Resources can be secured using this identity. However, this identity isn't a real user account and doesn't show up in the Windows User Management Console.

If the IIS worker process requires elevated access to the app, modify the Access Control List (ACL) for the directory containing the app:

1. Open Windows Explorer and navigate to the directory.
2. Right-click on the directory and select **Properties**.
3. Under the **Security** tab, select the **Edit** button and then the **Add** button.
4. Select the **Locations** button and make sure the system is selected.
5. Enter **IIS AppPool\<app_pool_name>** in **Enter the object names to select** area. Select the **Check Names** button. For the *DefaultAppPool* check the names using **IIS AppPool\DefaultAppPool**. When the **Check Names** button is selected, a value of **DefaultAppPool** is indicated in the object names area. It isn't possible to enter the app pool name directly into the object names area. Use the **IIS AppPool\<app_pool_name>** format when checking for the object name.



6. Select **OK**.



7. Read & execute permissions should be granted by default. Provide additional permissions as needed.

Access can also be granted at a command prompt using the **ICACLS** tool. Using the *DefaultAppPool* as an example, the following command is used:

```
ICACLS C:\sites\MyWebApp /grant "IIS AppPool\DefaultAppPool":F
```

For more information, see the icacls topic.

HTTP/2 support

HTTP/2 is supported with ASP.NET Core in the following IIS deployment scenarios:

- In-process
  - Windows Server 2016/Windows 10 or later; IIS 10 or later
  - TLS 1.2 or later connection
- Out-of-process
  - Windows Server 2016/Windows 10 or later; IIS 10 or later
  - Public-facing edge server connections use HTTP/2, but the reverse proxy connection to the Kestrel server uses HTTP/1.1.
  - TLS 1.2 or later connection

For an in-process deployment when an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/2`. For an out-of-process deployment when an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/1.1`.

For more information on the in-process and out-of-process hosting models, see ASP.NET Core Module.

HTTP/2 is enabled by default. Connections fall back to HTTP/1.1 if an HTTP/2 connection isn't established. For more information on HTTP/2 configuration with IIS deployments, see HTTP/2 on IIS.

CORS preflight requests

This section only applies to ASP.NET Core apps that target the .NET Framework.

For an ASP.NET Core app that targets the .NET Framework, OPTIONS requests aren't passed to the app by default in IIS. To learn how to configure the app's IIS handlers in *web.config* to pass OPTIONS requests, see Enable cross-origin requests in ASP.NET Web API 2: How CORS Works.

Application Initialization Module and Idle Timeout

When hosted in IIS by the ASP.NET Core Module version 2:

- Application Initialization Module: App's hosted in-process or out-of-process can be configured to start automatically on a worker process restart or server restart.
- Idle Timeout: App's hosted in-process can be configured not to timeout during periods of inactivity.

Application Initialization Module

Applies to apps hosted in-process and out-of-process.

IIS Application Initialization is an IIS feature that sends an HTTP request to the app when the app pool starts or is recycled. The request triggers the app to start. By default, IIS issues a request to the app's root URL (`/`) to initialize the app (see the additional resources for more details on configuration).

Confirm that the IIS Application Initialization role feature in enabled:

On Windows 7 or later desktop systems when using IIS locally:

1. Navigate to **Control Panel** > **Programs** > **Programs and Features** > **Turn Windows features on or off** (left side of the screen).
2. Open **Internet Information Services** > **World Wide Web Services** > **Application Development Features**.
3. Select the check box for **Application Initialization**.

On Windows Server 2008 R2 or later:

1. Open the **Add Roles and Features Wizard**.
2. In the **Select role services** panel, open the **Application Development** node.

3. Select the check box for **Application Initialization**.

Use either of the following approaches to enable the Application Initialization Module for the site:

- Using IIS Manager:

  1. Select **Application Pools** in the **Connections** panel.
  2. Right-click the app's app pool in the list and select **Advanced Settings**.
  3. The default **Start Mode** is **OnDemand**. Set the **Start Mode** to **AlwaysRunning**. Select **OK**.
  4. Open the **Sites** node in the **Connections** panel.
  5. Right-click the app and select **Manage Website** > **Advanced Settings**.
  6. The default **Preload Enabled** setting is **False**. Set **Preload Enabled** to **True**. Select **OK**.

- Using *web.config*, add the `<applicationInitialization>` element with `doAppInitAfterRestart` set to `true` to the `<system.webServer>` elements in the app's *web.config* file:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <location path="." inheritInChildApplications="false">
    <system.webServer>
      <applicationInitialization doAppInitAfterRestart="true" />
    </system.webServer>
  </location>
</configuration>
```

Idle Timeout

Only applies to apps hosted in-process.

To prevent the app from idling, set the app pool's idle timeout using IIS Manager:

1. Select **Application Pools** in the **Connections** panel.
2. Right-click the app's app pool in the list and select **Advanced Settings**.
3. The default **Idle Time-out (minutes)** is **20** minutes. Set the **Idle Time-out (minutes)** to **0** (zero). Select **OK**.
4. Recycle the worker process.

To prevent apps hosted out-of-process from timing out, use either of the following approaches:

- Ping the app from an external service in order to keep it running.
- If the app only hosts background services, avoid IIS hosting and use a Windows Service to host the ASP.NET Core app.

Application Initialization Module and Idle Timeout additional resources

- IIS 8.0 Application Initialization
- Application Initialization <applicationInitialization>.
- Process Model Settings for an Application Pool <processModel>.

For a tutorial experience on publishing an ASP.NET Core app to an IIS server, see Publish an ASP.NET Core app to IIS.

Install the .NET Core Hosting Bundle

Supported operating systems

The following operating systems are supported:

- Windows 7 or later
- Windows Server 2008 R2 or later

HTTP.sys server (formerly called WebListener) doesn't work in a reverse proxy configuration with IIS. Use the Kestrel server.

For information on hosting in Azure, see Deploy ASP.NET Core apps to Azure App Service.

For troubleshooting guidance, see Troubleshoot and debug ASP.NET Core projects.

Supported platforms

Apps published for 32-bit (x86) or 64-bit (x64) deployment are supported. Deploy a 32-bit app with a 32-bit (x86) .NET Core SDK unless the app:

- Requires the larger virtual memory address space available to a 64-bit app.
- Requires the larger IIS stack size.
- Has 64-bit native dependencies.

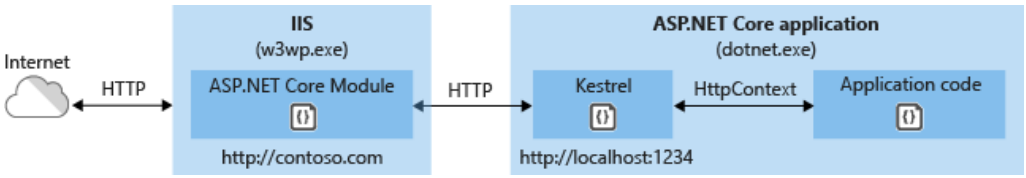
Use a 64-bit (x64) .NET Core SDK to publish a 64-bit app. A 64-bit runtime must be present on the host system.

ASP.NET Core ships with Kestrel server, a default, cross-platform HTTP server.

When using IIS or IIS Express, the app runs in a process separate from the IIS worker process (*out-of-process*) with the Kestrel server.

Because ASP.NET Core apps run in a process separate from the IIS worker process, the module handles process management. The module starts the process for the ASP.NET Core app when the first request arrives and restarts the app if it shuts down or crashes. This is essentially the same behavior as seen with apps that run in-process that are managed by the Windows Process Activation Service (WAS).

The following diagram illustrates the relationship between IIS, the ASP.NET Core Module, and an app hosted out-of-process:



Requests arrive from the web to the kernel-mode HTTP.sys driver. The driver routes the requests to IIS on the website's configured port, usually 80 (HTTP) or 443 (HTTPS). The module forwards the requests to Kestrel on a random port for the app, which isn't port 80 or 443.

The module specifies the port via an environment variable at startup, and the IIS Integration Middleware configures the server to listen on `http://localhost:{port}`. Additional checks are performed, and requests that don't originate from the module are rejected. The module doesn't support HTTPS forwarding, so requests are forwarded over HTTP even if received by IIS over HTTPS.

After Kestrel picks up the request from the module, the request is pushed into the ASP.NET Core middleware pipeline. The middleware pipeline handles the request and passes it on as an `HttpContext` instance to the app's logic. Middleware added by IIS Integration updates the scheme, remote IP, and pathbase to account for forwarding the request to Kestrel. The app's response is passed back to IIS, which pushes it back out to the HTTP client that initiated the request.

`CreateDefaultBuilder` configures Kestrel server as the web server and enables IIS Integration by configuring the base path and port for the ASP.NET Core Module.

The ASP.NET Core Module generates a dynamic port to assign to the backend process. `CreateDefaultBuilder` calls the UseIISIntegration method. `UseIISIntegration` configures Kestrel to listen on the dynamic port at the localhost IP address (`127.0.0.1`). If the dynamic port is 1234, Kestrel listens at `127.0.0.1:1234`. This configuration replaces other URL configurations provided by:

- `UseUrls`
- Kestrel's Listen API
- Configuration (or command-line --urls option)

Calls to `UseUrls` or Kestrel's `Listen` API aren't required when using the module. If `UseUrls` or `Listen` is called, Kestrel listens on the port specified only when running the app without IIS.

For ASP.NET Core Module configuration guidance, see ASP.NET Core Module.

For more information on hosting, see Host in ASP.NET Core.

Application configuration

Enable the IISIntegration components

When building a host in `CreateWebHostBuilder` (*Program.cs*), call CreateDefaultBuilder to enable IIS integration:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        ...
```

For more information on `CreateDefaultBuilder`, see ASP.NET Core Web Host.

IIS options

OPTION	DEFAULT	SETTING

OPTION	DEFAULT	SETTING
`AutomaticAuthentication`	`true`	If `true`, IIS Server sets the `HttpContext.User` authenticated by Windows Authentication. If `false`, the server only provides an identity for `HttpContext.User` and responds to challenges when explicitly requested by the `AuthenticationScheme`. Windows Authentication must be enabled in IIS for `AutomaticAuthentication` to function. For more information, see Windows Authentication.
`AuthenticationDisplayName`	`null`	Sets the display name shown to users on login pages.

To configure IIS options, include a service configuration for IISOptions in ConfigureServices. The following example prevents the app from populating `HttpContext.Connection.ClientCertificate`:

```
services.Configure<IISOptions>(options =>
{
    options.ForwardClientCertificate = false;
});
```

OPTION	DEFAULT	SETTING
`AutomaticAuthentication`	`true`	If `true`, IIS Integration Middleware sets the `HttpContext.User` authenticated by Windows Authentication. If `false`, the middleware only provides an identity for `HttpContext.User` and responds to challenges when explicitly requested by the `AuthenticationScheme`. Windows Authentication must be enabled in IIS for `AutomaticAuthentication` to function. For more information, see the Windows Authentication topic.
`AuthenticationDisplayName`	`null`	Sets the display name shown to users on login pages.
`ForwardClientCertificate`	`true`	If `true` and the `MS-ASPNETCORE-CLIENTCERT` request header is present, the `HttpContext.Connection.ClientCertificate` is populated.

Proxy server and load balancer scenarios

The IIS Integration Middleware, which configures Forwarded Headers Middleware, and the ASP.NET Core Module are configured to forward the scheme (HTTP/HTTPS) and the remote IP address where the request originated. Additional configuration might be required for apps hosted behind additional proxy servers and load balancers. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

web.config file

The *web.config* file configures the ASP.NET Core Module. Creating, transforming, and publishing the *web.config* file is handled by an MSBuild target (`_TransformWebConfig`) when the project is published. This target is present in the Web SDK targets (`Microsoft.NET.Sdk.Web`). The SDK is set at the top of the project file:

```
<Project Sdk="Microsoft.NET.Sdk.Web">
```

If a *web.config* file isn't present in the project, the file is created with the correct *processPath* and *arguments* to configure the ASP.NET Core Module and moved to published output.

If a *web.config* file is present in the project, the file is transformed with the correct *processPath* and *arguments* to configure the ASP.NET Core Module and moved to published output. The transformation doesn't modify IIS configuration settings in the file.

The *web.config* file may provide additional IIS configuration settings that control active IIS modules. For information on IIS modules that are capable of processing requests with ASP.NET Core apps, see the IIS modules topic.

To prevent the Web SDK from transforming the *web.config* file, use the **<IsTransformWebConfigDisabled>** property in the project file:

```
<PropertyGroup>
  <IsTransformWebConfigDisabled>true</IsTransformWebConfigDisabled>
</PropertyGroup>
```

When disabling the Web SDK from transforming the file, the *processPath* and *arguments* should be manually set by the developer. For more information, see ASP.NET Core Module.

web.config file location

In order to set up the ASP.NET Core Module correctly, the *web.config* file must be present at the content root path (typically the app base path) of the deployed app. This is the same location as the website physical path provided to IIS. The *web.config* file is required at the root of the app to enable the publishing of multiple apps using Web Deploy.

Sensitive files exist on the app's physical path, such as *<assembly>.runtimeconfig.json*, *<assembly>.xml* (XML Documentation comments), and *<assembly>.deps.json*. When the *web.config* file is present and the site starts normally, IIS doesn't serve these sensitive files if they're requested. If the *web.config* file is missing, incorrectly named, or unable to configure the site for normal startup, IIS may serve sensitive files publicly.

The *web.config* file must be present in the deployment at all times, correctly named, and able to configure the site for normal start up. Never remove the *web.config* file from a production deployment.

Transform web.config

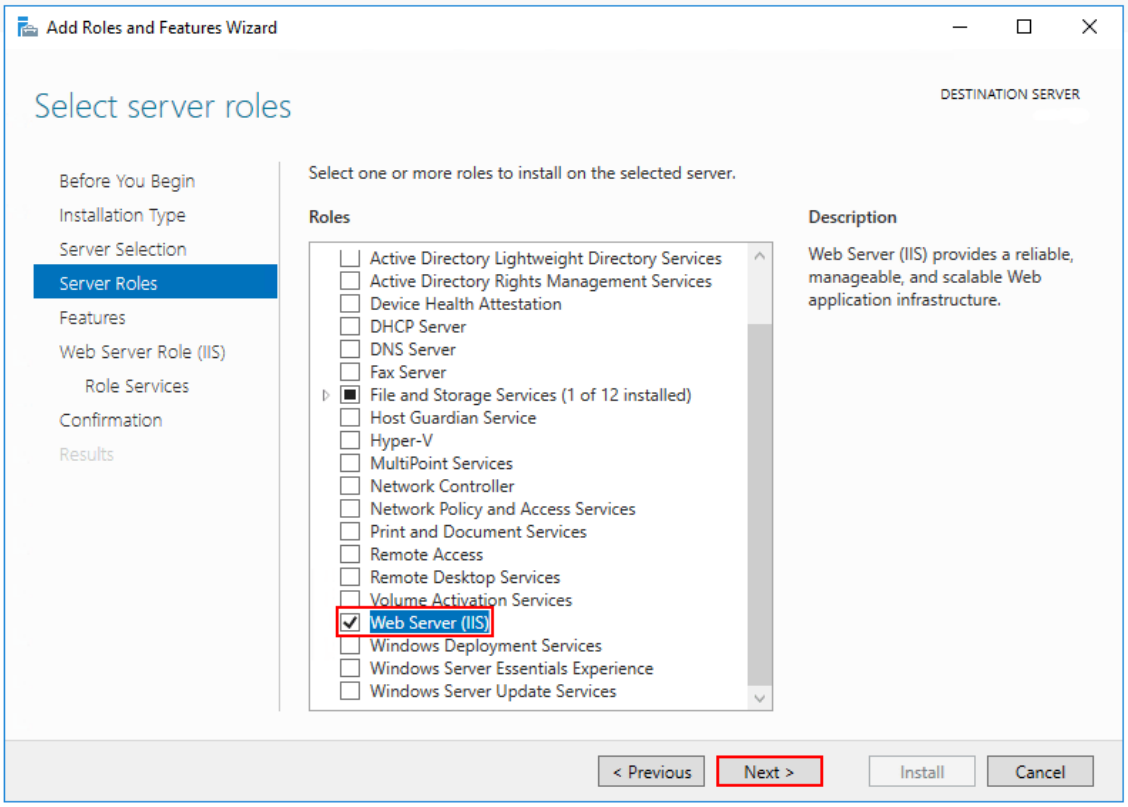
If you need to transform *web.config* on publish (for example, set environment variables based on the configuration, profile, or environment), see Transform web.config.

IIS configuration

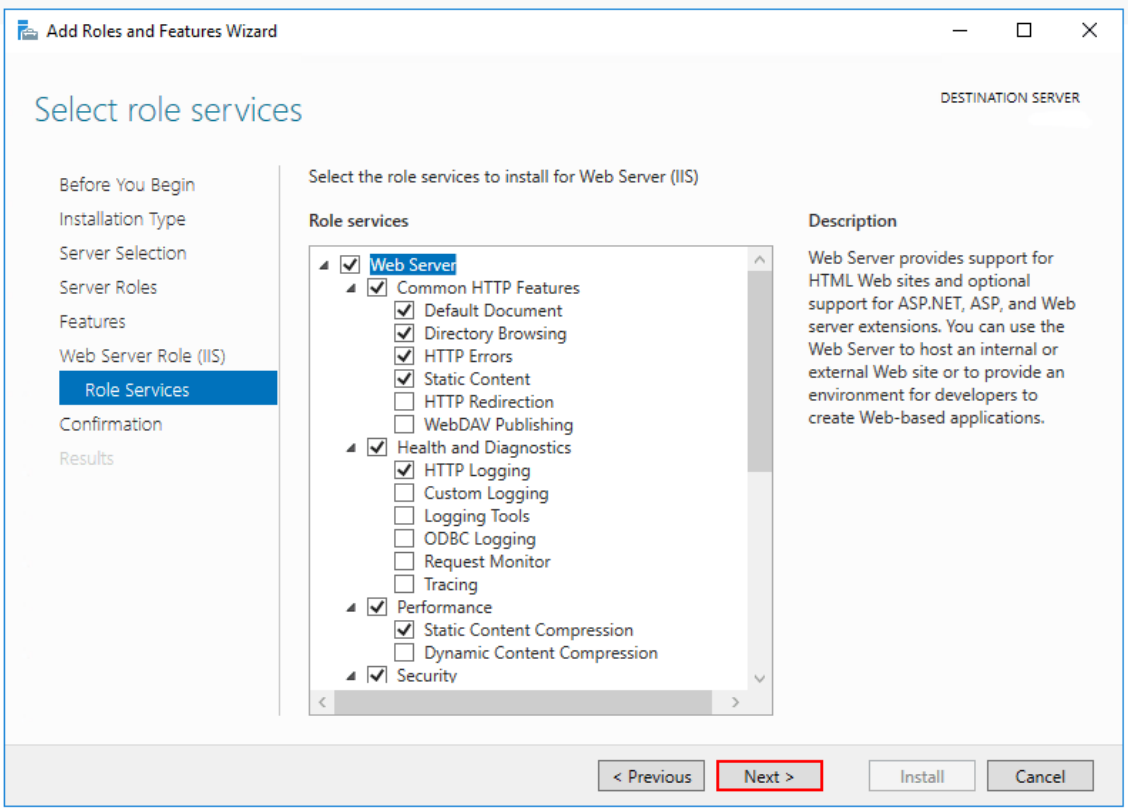
Windows Server operating systems

Enable the **Web Server (IIS)** server role and establish role services.

1. Use the **Add Roles and Features** wizard from the **Manage** menu or the link in **Server Manager**. On the **Server Roles** step, check the box for **Web Server (IIS)**.



2. After the **Features** step, the **Role services** step loads for Web Server (IIS). Select the IIS role services desired or accept the default role services provided.



Windows Authentication (Optional)

To enable Windows Authentication, expand the following nodes: **Web Server** > **Security**. Select the **Windows Authentication** feature. For more information, see Windows Authentication <windowsAuthentication> and Configure Windows authentication.

WebSockets (Optional)

WebSockets is supported with ASP.NET Core 1.1 or later. To enable WebSockets, expand the following nodes: **Web Server** > **Application Development**. Select the **WebSocket Protocol** feature. For

more information, see WebSockets.

3. Proceed through the **Confirmation** step to install the web server role and services. A server/IIS restart isn't required after installing the **Web Server (IIS)** role.

Windows desktop operating systems

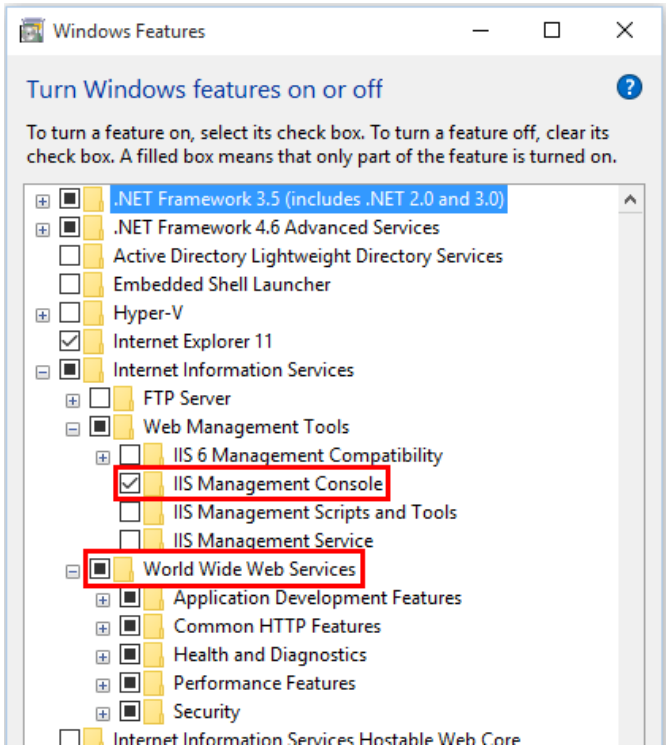
Enable the **IIS Management Console** and **World Wide Web Services**.

1. Navigate to **Control Panel** > **Programs** > **Programs and Features** > **Turn Windows features on or off** (left side of the screen).
2. Open the **Internet Information Services** node. Open the **Web Management Tools** node.
3. Check the box for **IIS Management Console**.
4. Check the box for **World Wide Web Services**.
5. Accept the default features for **World Wide Web Services** or customize the IIS features.

   Windows Authentication (Optional)
   To enable Windows Authentication, expand the following nodes: **World Wide Web Services** > **Security**. Select the **Windows Authentication** feature. For more information, see Windows Authentication <windowsAuthentication> and Configure Windows authentication.

   WebSockets (Optional)
   WebSockets is supported with ASP.NET Core 1.1 or later. To enable WebSockets, expand the following nodes: **World Wide Web Services** > **Application Development Features**. Select the **WebSocket Protocol** feature. For more information, see WebSockets.

6. If the IIS installation requires a restart, restart the system.



Install the .NET Core Hosting Bundle

Install the *.NET Core Hosting Bundle* on the hosting system. The bundle installs the .NET Core Runtime, .NET Core Library, and the ASP.NET Core Module. The module allows ASP.NET Core apps to run behind IIS.

> **IMPORTANT**
>
> If the Hosting Bundle is installed before IIS, the bundle installation must be repaired. Run the Hosting Bundle installer again after installing IIS.
>
> If the Hosting Bundle is installed after installing the 64-bit (x64) version of .NET Core, SDKs might appear to be missing (No .NET Core SDKs were detected). To resolve the problem, see Troubleshoot and debug ASP.NET Core projects.

Download

1. Navigate to the Download .NET Core page.
2. Select the desired .NET Core version.
3. In the **Run apps - Runtime** column, find the row of the .NET Core runtime version desired.
4. Download the installer using the **Hosting Bundle** link.

> **WARNING**
>
> Some installers contain release versions that have reached their end of life (EOL) and are no longer supported by Microsoft. For more information, see the support policy.

Install the Hosting Bundle

1. Run the installer on the server. The following parameters are available when running the installer from an administrator command shell:

   - `OPT_NO_ANCM=1`: Skip installing the ASP.NET Core Module.
   - `OPT_NO_RUNTIME=1`: Skip installing the .NET Core runtime. Used when the server only hosts self-contained deployments (SCD).
   - `OPT_NO_SHAREDFX=1`: Skip installing the ASP.NET Shared Framework (ASP.NET runtime). Used when the server only hosts self-contained deployments (SCD).
   - `OPT_NO_X86=1`: Skip installing x86 runtimes. Use this parameter when you know that you won't be hosting 32-bit apps. If there's any chance that you will host both 32-bit and 64-bit apps in the future, don't use this parameter and install both runtimes.
   - `OPT_NO_SHARED_CONFIG_CHECK=1`: Disable the check for using an IIS Shared Configuration when the shared configuration (*applicationHost.config*) is on the same machine as the IIS installation. *Only available for ASP.NET Core 2.2 or later Hosting Bundler installers.* For more information, see ASP.NET Core Module.

2. Restart the system or execute the following commands in a command shell:

   ```
   net stop was /y
   net start w3svc
   ```

   Restarting IIS picks up a change to the system PATH, which is an environment variable, made by the installer.

It isn't necessary to manually stop individual sites in IIS when installing the Hosting Bundle. Hosted apps (IIS sites) restart when IIS restarts. Apps start up again when they receive their first request, including from the Application Initialization Module.

ASP.NET Core adopts roll-forward behavior for patch releases of shared framework packages. When apps hosted by IIS restart with IIS, the apps load with the latest patch releases of their referenced packages when they receive their first request. If IIS isn't restarted, apps restart and exhibit roll-forward behavior when their worker processes are recycled and they receive their first request.

> **NOTE**
>
> For information on IIS Shared Configuration, see ASP.NET Core Module with IIS Shared Configuration.

Install Web Deploy when publishing with Visual Studio

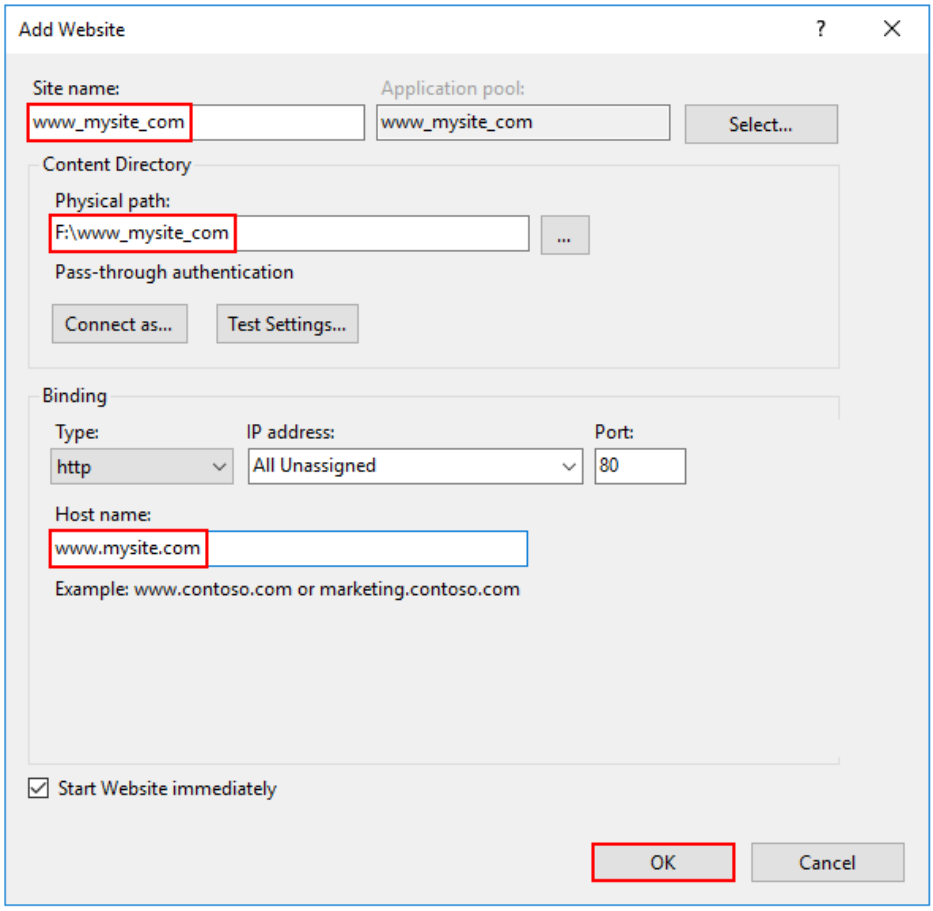
When deploying apps to servers with Web Deploy, install the latest version of Web Deploy on the server. To install Web Deploy, use the Web Platform Installer (WebPI) or obtain an installer directly from the Microsoft Download Center. The preferred method is to use WebPI. WebPI offers a standalone setup and a configuration for hosting providers.

Create the IIS site

1. On the hosting system, create a folder to contain the app's published folders and files. In a following step, the folder's path is provided to IIS as the physical path to the app. For more information on an app's deployment folder and file layout, see ASP.NET Core directory structure.

2. In IIS Manager, open the server's node in the **Connections** panel. Right-click the **Sites** folder. Select **Add Website** from the contextual menu.

3. Provide a **Site name** and set the **Physical path** to the app's deployment folder. Provide the **Binding** configuration and create the website by selecting **OK**:



> **WARNING**
>
> Top-level wildcard bindings (`http://*:80/` and `http://+:80`) should **not** be used. Top-level wildcard bindings can open up your app to security vulnerabilities. This applies to both strong and weak wildcards. Use explicit host names rather than wildcards. Subdomain wildcard binding (for example, `*.mysub.com`) doesn't have this security risk if you control the entire parent domain (as opposed to `*.com` , which is vulnerable). See rfc7230 section-5.4 for more information.

4. Under the server's node, select **Application Pools**.
5. Right-click the site's app pool and select **Basic Settings** from the contextual menu.
6. In the **Edit Application Pool** window, set the **.NET CLR version** to **No Managed Code**:

   ASP.NET Core runs in a separate process and manages the runtime. ASP.NET Core doesn't rely on loading the desktop CLR (.NET CLR)—the Core Common Language Runtime (CoreCLR) for .NET Core is booted to host the app in the worker process. Setting the **.NET CLR version** to **No Managed Code** is optional but recommended.

7. *ASP.NET Core 2.2 or later*: For a 64-bit (x64) self-contained deployment that uses the in-process hosting model, disable the app pool for 32-bit (x86) processes.

   In the **Actions** sidebar of IIS Manager > **Application Pools**, select **Set Application Pool Defaults** or **Advanced Settings**. Locate **Enable 32-Bit Applications** and set the value to `False` . This setting doesn't affect apps deployed for out-of-process hosting.

8. Confirm the process model identity has the proper permissions.

   If the default identity of the app pool (**Process Model** > **Identity**) is changed from **ApplicationPoolIdentity** to another identity, verify that the new identity has the required permissions to access the app's folder, database, and other required resources. For example, the app pool requires read and write access to folders where the app reads and writes files.

Windows Authentication configuration (Optional)

For more information, see Configure Windows authentication.

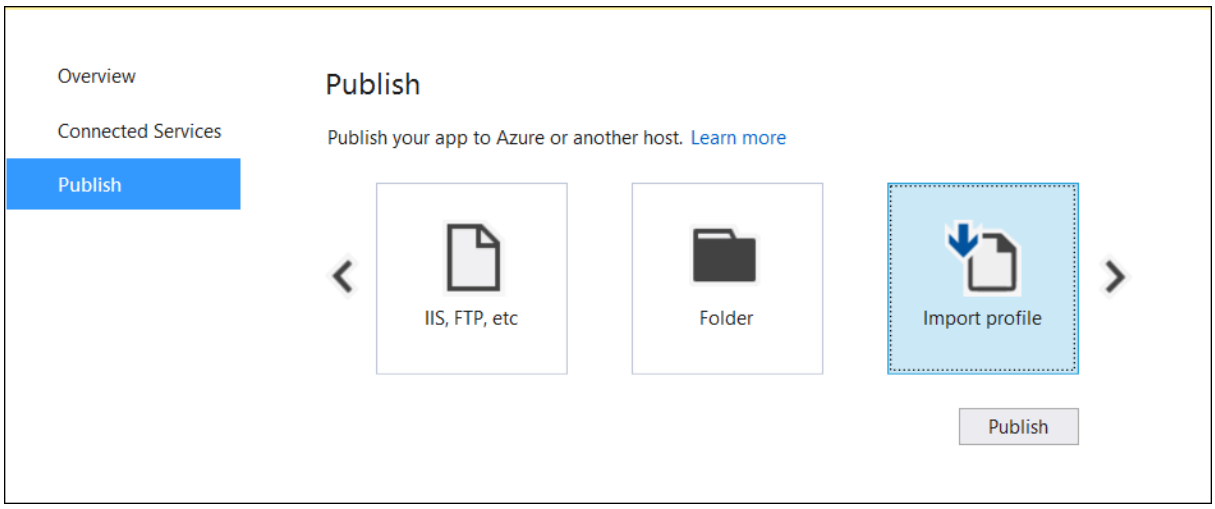
Deploy the app

Deploy the app to the IIS **Physical path** folder that was established in the Create the IIS site section. Web Deploy is the recommended mechanism for deployment, but several options exist for moving the app from the project's *publish* folder to the hosting system's deployment folder.

Web Deploy with Visual Studio

See the Visual Studio publish profiles for ASP.NET Core app deployment topic to learn how to create a publish

profile for use with Web Deploy. If the hosting provider provides a Publish Profile or support for creating one, download their profile and import it using the Visual Studio **Publish** dialog:



Web Deploy outside of Visual Studio

Web Deploy can also be used outside of Visual Studio from the command line. For more information, see Web Deployment Tool.

Alternatives to Web Deploy

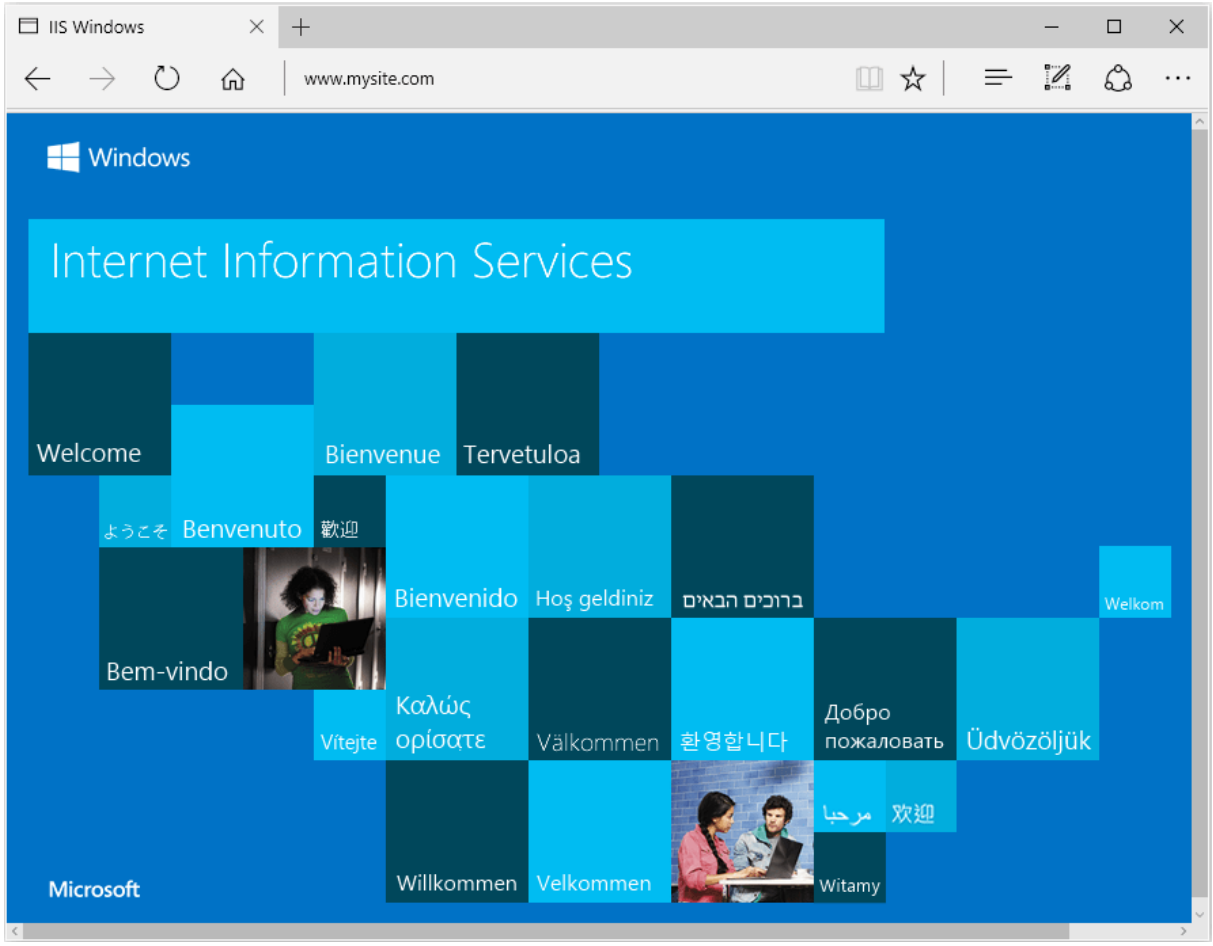
Use any of several methods to move the app to the hosting system, such as manual copy, Xcopy, Robocopy, or PowerShell.

For more information on ASP.NET Core deployment to IIS, see the Deployment resources for IIS administrators section.

Browse the website

After the app is deployed to the hosting system, make a request to one of the app's public endpoints.

In the following example, the site is bound to an IIS **Host name** of `www.mysite.com` on **Port** `80`. A request is made to `http://www.mysite.com`:



Locked deployment files

Files in the deployment folder are locked when the app is running. Locked files can't be overwritten during deployment. To release locked files in a deployment, stop the app pool using **one** of the following approaches:

- Use Web Deploy and reference `Microsoft.NET.Sdk.Web` in the project file. An *app_offline.htm* file is placed at the root of the web app directory. When the file is present, the ASP.NET Core Module gracefully shuts down the app and serves the *app_offline.htm* file during the deployment. For more information, see the ASP.NET Core Module configuration reference.
- Manually stop the app pool in the IIS Manager on the server.
- Use PowerShell to drop *app_offline.htm* (requires PowerShell 5 or later):

```
$pathToApp = 'PATH_TO_APP'

# Stop the AppPool
New-Item -Path $pathToApp app_offline.htm

# Provide script commands here to deploy the app

# Restart the AppPool
Remove-Item -Path $pathToApp app_offline.htm
```

Data protection

The ASP.NET Core Data Protection stack is used by several ASP.NET Core middlewares, including middleware used in authentication. Even if Data Protection APIs aren't called by user code, data protection should be configured with a deployment script or in user code to create a persistent cryptographic key store. If data

protection isn't configured, the keys are held in memory and discarded when the app restarts.

If the key ring is stored in memory when the app restarts:

- All cookie-based authentication tokens are invalidated.
- Users are required to sign in again on their next request.
- Any data protected with the key ring can no longer be decrypted. This may include CSRF tokens and ASP.NET Core MVC TempData cookies.

To configure data protection under IIS to persist the key ring, use **one** of the following approaches:

- **Create Data Protection Registry Keys**

  Data protection keys used by ASP.NET Core apps are stored in the registry external to the apps. To persist the keys for a given app, create registry keys for the app pool.

  For standalone, non-webfarm IIS installations, the Data Protection Provision-AutoGenKeys.ps1 PowerShell script can be used for each app pool used with an ASP.NET Core app. This script creates a registry key in the HKLM registry that's accessible only to the worker process account of the app's app pool. Keys are encrypted at rest using DPAPI with a machine-wide key.

  In web farm scenarios, an app can be configured to use a UNC path to store its data protection key ring. By default, the data protection keys aren't encrypted. Ensure that the file permissions for the network share are limited to the Windows account the app runs under. An X509 certificate can be used to protect keys at rest. Consider a mechanism to allow users to upload certificates: Place certificates into the user's trusted certificate store and ensure they're available on all machines where the user's app runs. See Configure ASP.NET Core Data Protection for details.

- **Configure the IIS Application Pool to load the user profile**

  This setting is in the **Process Model** section under the **Advanced Settings** for the app pool. Set **Load User Profile** to `True`. When set to `True`, keys are stored in the user profile directory and protected using DPAPI with a key specific to the user account. Keys are persisted to the *%LOCALAPPDATA%/ASP.NET/DataProtection-Keys* folder.

  The app pool's setProfileEnvironment attribute must also be enabled. The default value of `setProfileEnvironment` is `true`. In some scenarios (for example, Windows OS), `setProfileEnvironment` is set to `false`. If keys aren't stored in the user profile directory as expected:

  1. Navigate to the *%windir%/system32/inetsrv/config* folder.
  2. Open the *applicationHost.config* file.
  3. Locate the `<system.applicationHost><applicationPools><applicationPoolDefaults><processModel>` element.
  4. Confirm that the `setProfileEnvironment` attribute isn't present, which defaults the value to `true`, or explicitly set the attribute's value to `true`.

- **Use the file system as a key ring store**

  Adjust the app code to use the file system as a key ring store. Use an X509 certificate to protect the key ring and ensure the certificate is a trusted certificate. If the certificate is self-signed, place the certificate in the Trusted Root store.

  When using IIS in a web farm:

  - Use a file share that all machines can access.
  - Deploy an X509 certificate to each machine. Configure data protection in code.

- **Set a machine-wide policy for data protection**

  The data protection system has limited support for setting a default machine-wide policy for all apps

that consume the Data Protection APIs. For more information, see ASP.NET Core Data Protection.

Virtual Directories

IIS Virtual Directories aren't supported with ASP.NET Core apps. An app can be hosted as a sub-application.

Sub-applications

An ASP.NET Core app can be hosted as an IIS sub-application (sub-app). The sub-app's path becomes part of the root app's URL.

A sub-app shouldn't include the ASP.NET Core Module as a handler. If the module is added as a handler in a sub-app's *web.config* file, a *500.19 Internal Server Error* referencing the faulty config file is received when attempting to browse the sub-app.

The following example shows a published *web.config* file for an ASP.NET Core sub-app:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <system.webServer>
    <aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout" />
  </system.webServer>
</configuration>
```

When hosting a non-ASP.NET Core sub-app underneath an ASP.NET Core app, explicitly remove the inherited handler in the sub-app's *web.config* file:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <system.webServer>
    <handlers>
      <remove name="aspNetCore" />
    </handlers>
    <aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout" />
  </system.webServer>
</configuration>
```

Static asset links within the sub-app should use tilde-slash (`~/`) notation. Tilde-slash notation triggers a Tag Helper to prepend the sub-app's pathbase to the rendered relative link. For a sub-app at `/subapp_path` , an image linked with `src="~/image.png"` is rendered as `src="/subapp_path/image.png"` . The root app's Static File Middleware doesn't process the static file request. The request is processed by the sub-app's Static File Middleware.

If a static asset's `src` attribute is set to an absolute path (for example, `src="/image.png"`), the link is rendered without the sub-app's pathbase. The root app's Static File Middleware attempts to serve the asset from the root app's web root, which results in a *404 - Not Found* response unless the static asset is available from the root app.

To host an ASP.NET Core app as a sub-app under another ASP.NET Core app:

1. Establish an app pool for the sub-app. Set the **.NET CLR Version** to **No Managed Code** because the Core Common Language Runtime (CoreCLR) for .NET Core is booted to host the app in the worker process, not the desktop CLR (.NET CLR).

2. Add the root site in IIS Manager with the sub-app in a folder under the root site.
3. Right-click the sub-app folder in IIS Manager and select **Convert to Application**.
4. In the **Add Application** dialog, use the **Select** button for the **Application Pool** to assign the app pool that you created for the sub-app. Select **OK**.

The assignment of a separate app pool to the sub-app is a requirement when using the in-process hosting model.

For more information on the in-process hosting model and configuring the ASP.NET Core Module, see ASP.NET Core Module.

Configuration of IIS with web.config

IIS configuration is influenced by the `<system.webServer>` section of *web.config* for IIS scenarios that are functional for ASP.NET Core apps with the ASP.NET Core Module. For example, IIS configuration is functional for dynamic compression. If IIS is configured at the server level to use dynamic compression, the `<urlCompression>` element in the app's *web.config* file can disable it for an ASP.NET Core app.

For more information, see the following topics:

- Configuration reference for <system.webServer>
- ASP.NET Core Module
- IIS modules with ASP.NET Core

To set environment variables for individual apps running in isolated app pools (supported for IIS 10.0 or later), see the *AppCmd.exe command* section of the Environment Variables <environmentVariables> topic in the IIS reference documentation.

Configuration sections of web.config

Configuration sections of ASP.NET 4.x apps in *web.config* aren't used by ASP.NET Core apps for configuration:

- `<system.web>`
- `<appSettings>`
- `<connectionStrings>`
- `<location>`

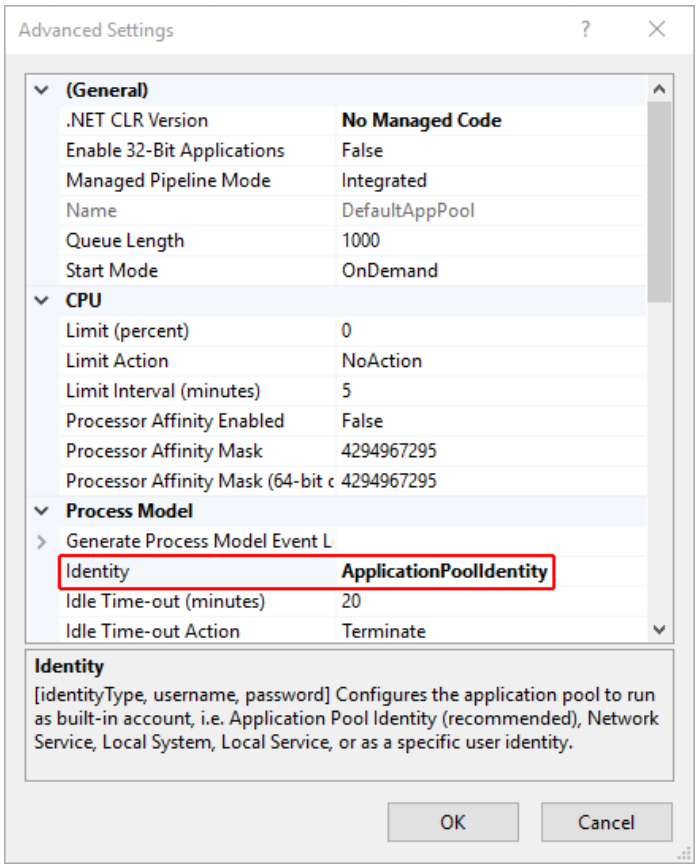
ASP.NET Core apps are configured using other configuration providers. For more information, see Configuration.

Application Pools

When hosting multiple websites on a server, we recommend isolating the apps from each other by running each app in its own app pool. The IIS **Add Website** dialog defaults to this configuration. When a **Site name** is provided, the text is automatically transferred to the **Application pool** textbox. A new app pool is created using the site name when the site is added.

Application Pool Identity

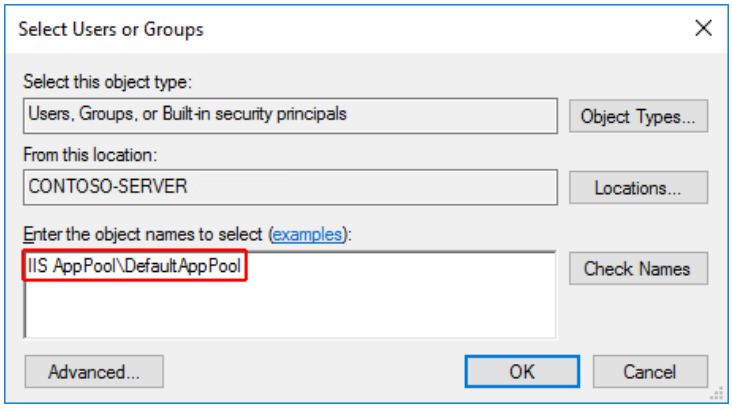
An app pool identity account allows an app to run under a unique account without having to create and manage domains or local accounts. On IIS 8.0 or later, the IIS Admin Worker Process (WAS) creates a virtual account with the name of the new app pool and runs the app pool's worker processes under this account by default. In the IIS Management Console under **Advanced Settings** for the app pool, ensure that the **Identity** is set to use **ApplicationPoolIdentity**:



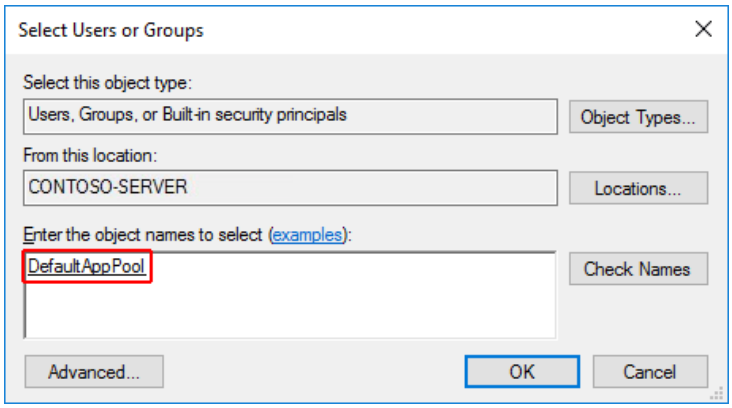
The IIS management process creates a secure identifier with the name of the app pool in the Windows Security System. Resources can be secured using this identity. However, this identity isn't a real user account and doesn't show up in the Windows User Management Console.

If the IIS worker process requires elevated access to the app, modify the Access Control List (ACL) for the directory containing the app:

1. Open Windows Explorer and navigate to the directory.
2. Right-click on the directory and select **Properties**.
3. Under the **Security** tab, select the **Edit** button and then the **Add** button.
4. Select the **Locations** button and make sure the system is selected.
5. Enter **IIS AppPool\<app_pool_name>** in **Enter the object names to select** area. Select the **Check Names** button. For the *DefaultAppPool* check the names using **IIS AppPool\DefaultAppPool**. When the **Check Names** button is selected, a value of **DefaultAppPool** is indicated in the object names area. It isn't possible to enter the app pool name directly into the object names area. Use the **IIS AppPool\<app_pool_name>** format when checking for the object name.



6. Select **OK**.



7. Read & execute permissions should be granted by default. Provide additional permissions as needed.

Access can also be granted at a command prompt using the **ICACLS** tool. Using the *DefaultAppPool* as an example, the following command is used:

```
ICACLS C:\sites\MyWebApp /grant "IIS AppPool\DefaultAppPool":F
```

For more information, see the icacls topic.

HTTP/2 support

HTTP/2 is supported for out-of-process deployments that meet the following base requirements:

- Windows Server 2016/Windows 10 or later; IIS 10 or later
- Public-facing edge server connections use HTTP/2, but the reverse proxy connection to the Kestrel server uses HTTP/1.1.
- Target framework: Not applicable to out-of-process deployments, since the HTTP/2 connection is handled entirely by IIS.
- TLS 1.2 or later connection

If an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/1.1`.

HTTP/2 is enabled by default. Connections fall back to HTTP/1.1 if an HTTP/2 connection isn't established. For more information on HTTP/2 configuration with IIS deployments, see HTTP/2 on IIS.

CORS preflight requests

This section only applies to ASP.NET Core apps that target the .NET Framework.

For an ASP.NET Core app that targets the .NET Framework, OPTIONS requests aren't passed to the app by default in IIS. To learn how to configure the app's IIS handlers in *web.config* to pass OPTIONS requests, see Enable cross-origin requests in ASP.NET Web API 2: How CORS Works.

Publish an ASP.NET Core app to IIS

9/22/2020 • 5 minutes to read • Edit Online

This tutorial shows how to host an ASP.NET Core app on an IIS server.

This tutorial covers the following subjects:

- Install the .NET Core Hosting Bundle on Windows Server.
- Create an IIS site in IIS Manager.
- Deploy an ASP.NET Core app.

Prerequisites

- .NET Core SDK installed on the development machine.
- Windows Server configured with the **Web Server (IIS)** server role. If your server isn't configured to host websites with IIS, follow the guidance in the *IIS configuration* section of the Host ASP.NET Core on Windows with IIS article and then return to this tutorial.

> **WARNING**
>
> **IIS configuration and website security involve concepts that aren't covered by this tutorial.** Consult the IIS guidance in the Microsoft IIS documentation and the ASP.NET Core article on hosting with IIS before hosting production apps on IIS.
>
> Important scenarios for IIS hosting not covered by this tutorial include:
>
> - Creation of a registry hive for ASP.NET Core Data Protection
> - Configuration of the app pool's Access Control List (ACL)
> - To focus on IIS deployment concepts, this tutorial deploys an app without HTTPS security configured in IIS. For more information on hosting an app enabled for HTTPS protocol, see the security topics in the Additional resources section of this article. Further guidance for hosting ASP.NET Core apps is provided in the Host ASP.NET Core on Windows with IIS article.

Install the .NET Core Hosting Bundle

Install the *.NET Core Hosting Bundle* on the IIS server. The bundle installs the .NET Core Runtime, .NET Core Library, and the ASP.NET Core Module. The module allows ASP.NET Core apps to run behind IIS.

Download the installer using the following link:

Current .NET Core Hosting Bundle installer (direct download)

1. Run the installer on the IIS server.
2. Restart the server or execute **net stop was /y** followed by **net start w3svc** in a command shell.

Create the IIS site

1. On the IIS server, create a folder to contain the app's published folders and files. In a following step, the folder's path is provided to IIS as the physical path to the app.
2. In IIS Manager, open the server's node in the **Connections** panel. Right-click the **Sites** folder. Select **Add Website** from the contextual menu.

3. Provide a **Site name** and set the **Physical path** to the app's deployment folder that you created. Provide the **Binding** configuration and create the website by selecting **OK**.

Create an ASP.NET Core Razor Pages app

Follow the Get started with ASP.NET Core tutorial to create a Razor Pages app.

Publish and deploy the app

Publish an app means to produce a compiled app that can be hosted by a server. *Deploy an app* means to move the published app to a hosting system. The publish step is handled by the .NET Core SDK, while the deployment step can be handled by a variety of approaches. This tutorial adopts the *folder* deployment approach, where:

- The app is published to a folder.
- The folder's contents are moved to the IIS site's folder (the **Physical path** to the site in IIS Manager).

- Visual Studio
- .NET Core CLI
- Visual Studio for Mac

1. Right-click on the project in **Solution Explorer** and select **Publish**.
2. In the **Pick a publish target** dialog, select the **Folder** publish option.
3. Set the **Folder or File Share** path.
   - If you created a folder for the IIS site that's available on the development machine as a network share, provide the path to the share. The current user must have write access to publish to the share.
   - If you're unable to deploy directly to the IIS site folder on the IIS server, publish to a folder on removeable media and physically move the published app to the IIS site folder on the server, which is the site's **Physical path** in IIS Manager. Move the contents of the *bin/Release/{TARGET FRAMEWORK}/publish* folder to the IIS site folder on the server, which is the site's **Physical path** in IIS Manager.

Browse the website

The app is accessible in a browser after it receives the first request. Make a request to the app at the endpoint binding that you established in IIS Manager for the site.

Next steps

In this tutorial, you learned how to:

- Install the .NET Core Hosting Bundle on Windows Server.
- Create an IIS site in IIS Manager.
- Deploy an ASP.NET Core app.

To learn more about hosting ASP.NET Core apps on IIS, see the IIS Overview article:

Host ASP.NET Core on Windows with IIS

ASP.NET Core Module

9/22/2020 • 40 minutes to read • Edit Online

By Tom Dykstra, Rick Strahl, Chris Ross, Rick Anderson, Sourabh Shirhatti, and Justin Kotalik

The ASP.NET Core Module is a native IIS module that plugs into the IIS pipeline to either:

- Host an ASP.NET Core app inside of the IIS worker process (`w3wp.exe`), called the in-process hosting model.
- Forward web requests to a backend ASP.NET Core app running the Kestrel server, called the out-of-process hosting model.

Supported Windows versions:

- Windows 7 or later
- Windows Server 2012 R2 or later

When hosting in-process, the module uses an in-process server implementation for IIS, called IIS HTTP Server (`IISHttpServer`).

When hosting out-of-process, the module only works with Kestrel. The module doesn't function with HTTP.sys.

Hosting models

In-process hosting model

ASP.NET Core apps default to the in-process hosting model.

The following characteristics apply when hosting in-process:

- IIS HTTP Server (`IISHttpServer`) is used instead of Kestrel server. For in-process, CreateDefaultBuilder calls UseIIS to:
  - Register the `IISHttpServer`.
  - Configure the port and base path the server should listen on when running behind the ASP.NET Core Module.
  - Configure the host to capture startup errors.
- The requestTimeout attribute doesn't apply to in-process hosting.
- Sharing an app pool among apps isn't supported. Use one app pool per app.
- When using Web Deploy or manually placing an app_offline.htm file in the deployment, the app might not shut down immediately if there's an open connection. For example, a websocket connection may delay app shut down.
- The architecture (bitness) of the app and installed runtime (x64 or x86) must match the architecture of the app pool.
- Client disconnects are detected. The HttpContext.RequestAborted cancellation token is cancelled when the client disconnects.
- In ASP.NET Core 2.2.1 or earlier, GetCurrentDirectory returns the worker directory of the process started by IIS rather than the app's directory (for example,

C:\Windows\System32\inetsrv for *w3wp.exe*).

For sample code that sets the app's current directory, see the CurrentDirectoryHelpers class. Call the `SetCurrentDirectory` method. Subsequent calls to GetCurrentDirectory provide the app's directory.

- When hosting in-process, AuthenticateAsync isn't called internally to initialize a user. Therefore, an IClaimsTransformation implementation used to transform claims after every authentication isn't activated by default. When transforming claims with an IClaimsTransformation implementation, call AddAuthentication to add authentication services:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddTransient<IClaimsTransformation, ClaimsTransformer>();
    services.AddAuthentication(IISServerDefaults.AuthenticationScheme);
}

public void Configure(IApplicationBuilder app)
{
    app.UseAuthentication();
}
```

  - Web Package (single-file) deployments aren't supported.

Out-of-process hosting model

To configure an app for out-of-process hosting, set the value of the `<AspNetCoreHostingModel>` property to `OutOfProcess` in the project file (*.csproj*):

```
<PropertyGroup>
  <AspNetCoreHostingModel>OutOfProcess</AspNetCoreHostingModel>
</PropertyGroup>
```

In-process hosting is set with `InProcess`, which is the default value.

The value of `<AspNetCoreHostingModel>` is case insensitive, so `inprocess` and `outofprocess` are valid values.

Kestrel server is used instead of IIS HTTP Server (`IISHttpServer`).

For out-of-process, CreateDefaultBuilder calls UseIISIntegration to:

- Configure the port and base path the server should listen on when running behind the ASP.NET Core Module.
- Configure the host to capture startup errors.

Hosting model changes

If the `hostingModel` setting is changed in the *web.config* file (explained in the Configuration with web.config section), the module recycles the worker process for IIS.

For IIS Express, the module doesn't recycle the worker process but instead triggers a graceful shutdown of the current IIS Express process. The next request to the app spawns a new IIS Express process.

Process name

`Process.GetCurrentProcess().ProcessName` reports `w3wp` / `iisexpress` (in-process) or `dotnet` (out-of-process).

Many native modules, such as Windows Authentication, remain active. To learn more about IIS modules active with the ASP.NET Core Module, see IIS modules with ASP.NET Core.

The ASP.NET Core Module can also:

- Set environment variables for the worker process.
- Log stdout output to file storage for troubleshooting startup issues.
- Forward Windows authentication tokens.

How to install and use the ASP.NET Core Module

For instructions on how to install the ASP.NET Core Module, see Install the .NET Core Hosting Bundle.

Configuration with web.config

The ASP.NET Core Module is configured with the `aspNetCore` section of the `system.webServer` node in the site's *web.config* file.

The following *web.config* file is published for a framework-dependent deployment and configures the ASP.NET Core Module to handle site requests:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <location path="." inheritInChildApplications="false">
    <system.webServer>
      <handlers>
        <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModuleV2"
resourceType="Unspecified" />
      </handlers>
      <aspNetCore processPath="dotnet"
                  arguments=".\MyApp.dll"
                  stdoutLogEnabled="false"
                  stdoutLogFile=".\logs\stdout"
                  hostingModel="inprocess" />
    </system.webServer>
  </location>
</configuration>
```

The following *web.config* is published for a self-contained deployment:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <location path="." inheritInChildApplications="false">
    <system.webServer>
      <handlers>
        <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModuleV2"
resourceType="Unspecified" />
      </handlers>
      <aspNetCore processPath=".\MyApp.exe"
                  stdoutLogEnabled="false"
                  stdoutLogFile=".\logs\stdout"
                  hostingModel="inprocess" />
    </system.webServer>
  </location>
</configuration>
```

The InheritInChildApplications property is set to `false` to indicate that the settings

specified within the <location> element aren't inherited by apps that reside in a subdirectory of the app.

When an app is deployed to Azure App Service, the `stdoutLogFile` path is set to `\\?\%home%\LogFiles\stdout`. The path saves stdout logs to the *LogFiles* folder, which is a location automatically created by the service.

For information on IIS sub-application configuration, see Host ASP.NET Core on Windows with IIS.

Attributes of the aspNetCore element

ATTRIBUTE	DESCRIPTION	DEFAULT
`arguments`	Optional string attribute. Arguments to the executable specified in **processPath**.	
`disableStartUpErrorPage`	Optional Boolean attribute. If true, the **502.5 - Process Failure** page is suppressed, and the 502 status code page configured in the *web.config* takes precedence.	`false`
`forwardWindowsAuthToken`	Optional Boolean attribute. If true, the token is forwarded to the child process listening on %ASPNETCORE_PORT% as a header 'MS-ASPNETCORE-WINAUTHTOKEN' per request. It's the responsibility of that process to call CloseHandle on this token per request.	`true`
`hostingModel`	Optional string attribute. Specifies the hosting model as in-process (`InProcess` / `inprocess`) or out-of-process (`OutOfProcess` / `outofprocess`).	`InProcess` `inprocess`

ATTRIBUTE	DESCRIPTION	DEFAULT
`processesPerApplication`	Optional integer attribute. Specifies the number of instances of the process specified in the **processPath** setting that can be spun up per app. †For in-process hosting, the value is limited to `1`. Setting `processesPerApplication` is discouraged. This attribute will be removed in a future release.	Default: `1` Min: `1` Max: `100` †
`processPath`	Required string attribute. Path to the executable that launches a process listening for HTTP requests. Relative paths are supported. If the path begins with `.`, the path is considered to be relative to the site root.	
`rapidFailsPerMinute`	Optional integer attribute. Specifies the number of times the process specified in **processPath** is allowed to crash per minute. If this limit is exceeded, the module stops launching the process for the remainder of the minute. Not supported with in-process hosting.	Default: `10` Min: `0` Max: `100`

ATTRIBUTE	DESCRIPTION	DEFAULT
`requestTimeout`	Optional timespan attribute. Specifies the duration for which the ASP.NET Core Module waits for a response from the process listening on %ASPNETCORE_PORT%. In versions of the ASP.NET Core Module that shipped with the release of ASP.NET Core 2.1 or later, the `requestTimeout` is specified in hours, minutes, and seconds. Doesn't apply to in-process hosting. For in-process hosting, the module waits for the app to process the request. Valid values for minutes and seconds segments of the string are in the range 0-59. Use of **60** in the value for minutes or seconds results in a *500 - Internal Server Error*.	Default: `00:02:00` Min: `00:00:00` Max: `360:00:00`
`shutdownTimeLimit`	Optional integer attribute. Duration in seconds that the module waits for the executable to gracefully shutdown when the *app_offline.htm* file is detected.	Default: `10` Min: `0` Max: `600`

ATTRIBUTE	DESCRIPTION	DEFAULT
`startupTimeLimit`	Optional integer attribute. Duration in seconds that the module waits for the executable to start a process listening on the port. If this time limit is exceeded, the module kills the process. When hosting *in-process*: The process is **not** restarted and does **not** use the **rapidFailsPerMinute** setting. When hosting *out-of-process*: The module attempts to relaunch the process when it receives a new request and continues to attempt to restart the process on subsequent incoming requests unless the app fails to start **rapidFailsPerMinute** number of times in the last rolling minute. A value of 0 (zero) is **not** considered an infinite timeout.	Default: `120` Min: `0` Max: `3600`
`stdoutLogEnabled`	Optional Boolean attribute. If true, **stdout** and **stderr** for the process specified in **processPath** are redirected to the file specified in **stdoutLogFile**.	`false`

ATTRIBUTE	DESCRIPTION	DEFAULT
`stdoutLogFile`	Optional string attribute. Specifies the relative or absolute file path for which **stdout** and **stderr** from the process specified in **processPath** are logged. Relative paths are relative to the root of the site. Any path starting with `.` are relative to the site root and all other paths are treated as absolute paths. Any folders provided in the path are created by the module when the log file is created. Using underscore delimiters, a timestamp, process ID, and file extension (*.log*) are added to the last segment of the **stdoutLogFile** path. If `.\logs\stdout` is supplied as a value, an example stdout log is saved as *stdout_20180205194132_1934.log* in the *logs* folder when saved on 2/5/2018 at 19:41:32 with a process ID of 1934.	`aspnetcore-stdout`

Set environment variables

Environment variables can be specified for the process in the `processPath` attribute. Specify an environment variable with the `<environmentVariable>` child element of an `<environmentVariables>` collection element. Environment variables set in this section take precedence over system environment variables.

The following example sets two environment variables in *web.config*. `ASPNETCORE_ENVIRONMENT` configures the app's environment to `Development`. A developer may temporarily set this value in the *web.config* file in order to force the Developer Exception Page to load when debugging an app exception. `CONFIG_DIR` is an example of a user-defined environment variable, where the developer has written code that reads the value on startup to form a path for loading the app's configuration file.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout"
      hostingModel="inprocess">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
    <environmentVariable name="CONFIG_DIR" value="f:\application_config" />
  </environmentVariables>
</aspNetCore>
```

NOTE

An alternative to setting the environment directly in *web.config* is to include the `<EnvironmentName>` property in the publish profile (.pubxml) or project file. This approach sets the environment in *web.config* when the project is published:

```
<PropertyGroup>
  <EnvironmentName>Development</EnvironmentName>
</PropertyGroup>
```

WARNING

Only set the `ASPNETCORE_ENVIRONMENT` environment variable to `Development` on staging and testing servers that aren't accessible to untrusted networks, such as the Internet.

app_offline.htm

If a file with the name *app_offline.htm* is detected in the root directory of an app, the ASP.NET Core Module attempts to gracefully shutdown the app and stop processing incoming requests. If the app is still running after the number of seconds defined in `shutdownTimeLimit`, the ASP.NET Core Module kills the running process.

While the *app_offline.htm* file is present, the ASP.NET Core Module responds to requests by sending back the contents of the *app_offline.htm* file. When the *app_offline.htm* file is removed, the next request starts the app.

When using the out-of-process hosting model, the app might not shut down immediately if there's an open connection. For example, a websocket connection may delay app shut down.

Start-up error page

Both in-process and out-of-process hosting produce custom error pages when they fail to start the app.

If the ASP.NET Core Module fails to find either the in-process or out-of-process request handler, a *500.0 - In-Process/Out-Of-Process Handler Load Failure* status code page appears.

For in-process hosting if the ASP.NET Core Module fails to start the app, a *500.30 - Start Failure* status code page appears.

For out-of-process hosting if the ASP.NET Core Module fails to launch the backend process or the backend process starts but fails to listen on the configured port, a *502.5 - Process Failure* status code page appears.

To suppress this page and revert to the default IIS 5xx status code page, use the `disableStartUpErrorPage` attribute. For more information on configuring custom error messages, see HTTP Errors <httpErrors>.

Log creation and redirection

The ASP.NET Core Module redirects stdout and stderr console output to disk if the `stdoutLogEnabled` and `stdoutLogFile` attributes of the `aspNetCore` element are set. Any

folders in the `stdoutLogFile` path are created by the module when the log file is created. The app pool must have write access to the location where the logs are written (use `IIS AppPool\<app_pool_name>` to provide write permission).

Logs aren't rotated, unless process recycling/restart occurs. It's the responsibility of the hoster to limit the disk space the logs consume.

Using the stdout log is only recommended for troubleshooting app startup issues when hosting on IIS or when using development-time support for IIS with Visual Studio, not while debugging locally and running the app with IIS Express.

Don't use the stdout log for general app logging purposes. For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

A timestamp and file extension are added automatically when the log file is created. The log file name is composed by appending the timestamp, process ID, and file extension (*.log*) to the last segment of the `stdoutLogFile` path (typically *stdout*) delimited by underscores. If the `stdoutLogFile` path ends with *stdout*, a log for an app with a PID of 1934 created on 2/5/2018 at 19:42:32 has the file name *stdout_20180205194132_1934.log*.

If `stdoutLogEnabled` is false, errors that occur on app startup are captured and emitted to the event log up to 30 KB. After startup, all additional logs are discarded.

The following sample `aspNetCore` element configures stdout logging at the relative path `.\log\`. Confirm that the AppPool user identity has permission to write to the path provided.

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="true"
    stdoutLogFile=".\logs\stdout"
    hostingModel="inprocess">
</aspNetCore>
```

When publishing an app for Azure App Service deployment, the Web SDK sets the `stdoutLogFile` value to `\\?\%home%\LogFiles\stdout`. The `%home` environment variable is predefined for apps hosted by Azure App Service.

To create logging filter rules, see the Configuration and Log filtering sections of the ASP.NET Core logging documentation.

For more information on path formats, see File path formats on Windows systems.

Enhanced diagnostic logs

The ASP.NET Core Module is configurable to provide enhanced diagnostics logs. Add the `<handlerSettings>` element to the `<aspNetCore>` element in *web.config*. Setting the `debugLevel` to `TRACE` exposes a higher fidelity of diagnostic information:

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="false"
    stdoutLogFile="\\?\%home%\LogFiles\stdout"
    hostingModel="inprocess">
  <handlerSettings>
    <handlerSetting name="debugFile" value=".\logs\aspnetcore-debug.log" />
    <handlerSetting name="debugLevel" value="FILE,TRACE" />
  </handlerSettings>
</aspNetCore>
```

Any folders in the path (*logs* in the preceding example) are created by the module when the log file is created. The app pool must have write access to the location where the logs are written (use `IIS AppPool\<app_pool_name>` to provide write permission).

Debug level (`debugLevel`) values can include both the level and the location.

Levels (in order from least to most verbose):

- ERROR
- WARNING
- INFO
- TRACE

Locations (multiple locations are permitted):

- CONSOLE
- EVENTLOG
- FILE

The handler settings can also be provided via environment variables:

- `ASPNETCORE_MODULE_DEBUG_FILE`: Path to the debug log file. (Default: *aspnetcore-debug.log*)
- `ASPNETCORE_MODULE_DEBUG`: Debug level setting.

> **WARNING**
> Do **not** leave debug logging enabled in the deployment for longer than required to troubleshoot an issue. The size of the log isn't limited. Leaving the debug log enabled can exhaust the available disk space and crash the server or app service.

See Configuration with web.config for an example of the `aspNetCore` element in the *web.config* file.

Modify the stack size

Only applies when using the in-process hosting model.

Configure the managed stack size using the `stackSize` setting in bytes in *web.config*. The default size is `1048576` bytes (1 MB).

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="false"
    stdoutLogFile="\\?\%home%\LogFiles\stdout"
    hostingModel="inprocess">
  <handlerSettings>
    <handlerSetting name="stackSize" value="2097152" />
  </handlerSettings>
</aspNetCore>
```

Proxy configuration uses HTTP protocol and a pairing token

Only applies to out-of-process hosting.

The proxy created between the ASP.NET Core Module and Kestrel uses the HTTP protocol. There's no risk of eavesdropping the traffic between the module and Kestrel from a location off of the server.

A pairing token is used to guarantee that the requests received by Kestrel were proxied by IIS and didn't come from some other source. The pairing token is created and set into an environment variable (`ASPNETCORE_TOKEN`) by the module. The pairing token is also set into a header (`MS-ASPNETCORE-TOKEN`) on every proxied request. IIS Middleware checks each request it receives to confirm that the pairing token header value matches the environment variable value. If the token values are mismatched, the request is logged and rejected. The pairing token environment variable and the traffic between the module and Kestrel aren't accessible from a location off of the server. Without knowing the pairing token value, an attacker can't submit requests that bypass the check in the IIS Middleware.

ASP.NET Core Module with an IIS Shared Configuration

The ASP.NET Core Module installer runs with the privileges of the **TrustedInstaller** account. Because the local system account doesn't have modify permission for the share path used by the IIS Shared Configuration, the installer throws an access denied error when attempting to configure the module settings in the *applicationHost.config* file on the share.

When using an IIS Shared Configuration on the same machine as the IIS installation, run the ASP.NET Core Hosting Bundle installer with the `OPT_NO_SHARED_CONFIG_CHECK` parameter set to `1`:

```
dotnet-hosting-{VERSION}.exe OPT_NO_SHARED_CONFIG_CHECK=1
```

When the path to the shared configuration isn't on the same machine as the IIS installation, follow these steps:

1. Disable the IIS Shared Configuration.
2. Run the installer.
3. Export the updated *applicationHost.config* file to the share.
4. Re-enable the IIS Shared Configuration.

Module version and Hosting Bundle installer logs

To determine the version of the installed ASP.NET Core Module:

1. On the hosting system, navigate to *%windir%\System32\inetsrv*.
2. Locate the *aspnetcore.dll* file.
3. Right-click the file and select **Properties** from the contextual menu.
4. Select the **Details** tab. The **File version** and **Product version** represent the installed version of the module.

The Hosting Bundle installer logs for the module are found at *C:\Users\%UserName%\AppData\Local\Temp*. The file is named *dd_DotNetCoreWinSvrHosting__ <timestamp>_000_AspNetCoreModule_x64.log*.

Module, schema, and configuration file locations

Module

IIS (x86/amd64):

- %windir%\System32\inetsrv\aspnetcore.dll
- %windir%\SysWOW64\inetsrv\aspnetcore.dll
- %ProgramFiles%\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll
- %ProgramFiles(x86)%\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll

IIS Express (x86/amd64):

- %ProgramFiles%\IIS Express\aspnetcore.dll
- %ProgramFiles(x86)%\IIS Express\aspnetcore.dll
- %ProgramFiles%\IIS Express\Asp.Net Core Module\V2\aspnetcorev2.dll
- %ProgramFiles(x86)%\IIS Express\Asp.Net Core Module\V2\aspnetcorev2.dll

Schema

IIS

- %windir%\System32\inetsrv\config\schema\aspnetcore_schema.xml
- %windir%\System32\inetsrv\config\schema\aspnetcore_schema_v2.xml

IIS Express

- %ProgramFiles%\IIS Express\config\schema\aspnetcore_schema.xml
- %ProgramFiles%\IIS Express\config\schema\aspnetcore_schema_v2.xml

Configuration

IIS

- %windir%\System32\inetsrv\config\applicationHost.config

IIS Express

- Visual Studio: {APPLICATION ROOT}\.vs\config\applicationHost.config
- *iisexpress.exe* CLI: %USERPROFILE%\Documents\IISExpress\config\applicationhost.config

The files can be found by searching for *aspnetcore* in the *applicationHost.config* file.

The ASP.NET Core Module is a native IIS module that plugs into the IIS pipeline to either:

- Host an ASP.NET Core app inside of the IIS worker process (`w3wp.exe`), called the in-process hosting model.
- Forward web requests to a backend ASP.NET Core app running the Kestrel server, called the out-of-process hosting model.

Supported Windows versions:

- Windows 7 or later
- Windows Server 2008 R2 or later

When hosting in-process, the module uses an in-process server implementation for IIS, called IIS HTTP Server (`IISHttpServer`).

When hosting out-of-process, the module only works with Kestrel. The module doesn't function with HTTP.sys.

Hosting models

In-process hosting model

To configure an app for in-process hosting, add the `<AspNetCoreHostingModel>` property to the app's project file with a value of `InProcess` (out-of-process hosting is set with `OutOfProcess`):

```
<PropertyGroup>
  <AspNetCoreHostingModel>InProcess</AspNetCoreHostingModel>
</PropertyGroup>
```

The in-process hosting model isn't supported for ASP.NET Core apps that target the .NET Framework.

The value of `<AspNetCoreHostingModel>` is case insensitive, so `inprocess` and `outofprocess` are valid values.

If the `<AspNetCoreHostingModel>` property isn't present in the file, the default value is `OutOfProcess`.

The following characteristics apply when hosting in-process:

- IIS HTTP Server (`IISHttpServer`) is used instead of Kestrel server. For in-process, CreateDefaultBuilder calls UseIIS to:
  - Register the `IISHttpServer`.
  - Configure the port and base path the server should listen on when running behind the ASP.NET Core Module.
  - Configure the host to capture startup errors.
- The requestTimeout attribute doesn't apply to in-process hosting.
- Sharing an app pool among apps isn't supported. Use one app pool per app.
- When using Web Deploy or manually placing an app_offline.htm file in the deployment, the app might not shut down immediately if there's an open connection. For example, a websocket connection may delay app shut down.
- The architecture (bitness) of the app and installed runtime (x64 or x86) must match the architecture of the app pool.

- Client disconnects are detected. The HttpContext.RequestAborted cancellation token is cancelled when the client disconnects.
- In ASP.NET Core 2.2.1 or earlier, GetCurrentDirectory returns the worker directory of the process started by IIS rather than the app's directory (for example, *C:\Windows\System32\inetsrv* for *w3wp.exe*).

  For sample code that sets the app's current directory, see the CurrentDirectoryHelpers class. Call the `SetCurrentDirectory` method. Subsequent calls to GetCurrentDirectory provide the app's directory.
- When hosting in-process, AuthenticateAsync isn't called internally to initialize a user. Therefore, an IClaimsTransformation implementation used to transform claims after every authentication isn't activated by default. When transforming claims with an IClaimsTransformation implementation, call AddAuthentication to add authentication services:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddTransient<IClaimsTransformation, ClaimsTransformer>();
    services.AddAuthentication(IISServerDefaults.AuthenticationScheme);
}

public void Configure(IApplicationBuilder app)
{
    app.UseAuthentication();
}
```

Out-of-process hosting model

To configure an app for out-of-process hosting, use either of the following approaches in the project file:

- Don't specify the `<AspNetCoreHostingModel>` property. If the `<AspNetCoreHostingModel>` property isn't present in the file, the default value is `OutOfProcess`.
- Set the value of the `<AspNetCoreHostingModel>` property to `OutOfProcess` (in-process hosting is set with `InProcess`):

```
<PropertyGroup>
  <AspNetCoreHostingModel>OutOfProcess</AspNetCoreHostingModel>
</PropertyGroup>
```

The value is case insensitive, so `inprocess` and `outofprocess` are valid values.

Kestrel server is used instead of IIS HTTP Server (`IISHttpServer`).

For out-of-process, CreateDefaultBuilder calls UseIISIntegration to:

- Configure the port and base path the server should listen on when running behind the ASP.NET Core Module.
- Configure the host to capture startup errors.

Hosting model changes

If the `hostingModel` setting is changed in the *web.config* file (explained in the Configuration with web.config section), the module recycles the worker process for IIS.

For IIS Express, the module doesn't recycle the worker process but instead triggers a graceful shutdown of the current IIS Express process. The next request to the app spawns

a new IIS Express process.

Process name

`Process.GetCurrentProcess().ProcessName` reports `w3wp` / `iisexpress` (in-process) or `dotnet` (out-of-process).

Many native modules, such as Windows Authentication, remain active. To learn more about IIS modules active with the ASP.NET Core Module, see IIS modules with ASP.NET Core.

The ASP.NET Core Module can also:

- Set environment variables for the worker process.
- Log stdout output to file storage for troubleshooting startup issues.
- Forward Windows authentication tokens.

How to install and use the ASP.NET Core Module

For instructions on how to install the ASP.NET Core Module, see Install the .NET Core Hosting Bundle.

Configuration with web.config

The ASP.NET Core Module is configured with the `aspNetCore` section of the `system.webServer` node in the site's *web.config* file.

The following *web.config* file is published for a framework-dependent deployment and configures the ASP.NET Core Module to handle site requests:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <location path="." inheritInChildApplications="false">
    <system.webServer>
      <handlers>
        <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModuleV2"
resourceType="Unspecified" />
      </handlers>
      <aspNetCore processPath="dotnet"
                  arguments=".\MyApp.dll"
                  stdoutLogEnabled="false"
                  stdoutLogFile=".\logs\stdout"
                  hostingModel="inprocess" />
    </system.webServer>
  </location>
</configuration>
```

The following *web.config* is published for a self-contained deployment:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <location path="." inheritInChildApplications="false">
    <system.webServer>
      <handlers>
        <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModuleV2"
resourceType="Unspecified" />
      </handlers>
      <aspNetCore processPath=".\MyApp.exe"
                  stdoutLogEnabled="false"
                  stdoutLogFile=".\logs\stdout"
                  hostingModel="inprocess" />
    </system.webServer>
  </location>
</configuration>
```

The InheritInChildApplications property is set to `false` to indicate that the settings specified within the <location> element aren't inherited by apps that reside in a subdirectory of the app.

When an app is deployed to Azure App Service, the `stdoutLogFile` path is set to `\\?\%home%\LogFiles\stdout`. The path saves stdout logs to the *LogFiles* folder, which is a location automatically created by the service.

For information on IIS sub-application configuration, see Host ASP.NET Core on Windows with IIS.

Attributes of the aspNetCore element

ATTRIBUTE	DESCRIPTION	DEFAULT
`arguments`	Optional string attribute. Arguments to the executable specified in **processPath**.	
`disableStartUpErrorPage`	Optional Boolean attribute. If true, the **502.5 - Process Failure** page is suppressed, and the 502 status code page configured in the *web.config* takes precedence.	`false`

ATTRIBUTE	DESCRIPTION	DEFAULT
`forwardWindowsAuthToken`	Optional Boolean attribute. If true, the token is forwarded to the child process listening on %ASPNETCORE_PORT% as a header 'MS-ASPNETCORE-WINAUTHTOKEN' per request. It's the responsibility of that process to call CloseHandle on this token per request.	`true`
`hostingModel`	Optional string attribute. Specifies the hosting model as in-process (`InProcess` / `inprocess`) or out-of-process (`OutOfProcess` / `outofprocess`).	`OutOfProcess` `outofprocess`
`processesPerApplication`	Optional integer attribute. Specifies the number of instances of the process specified in the **processPath** setting that can be spun up per app. †For in-process hosting, the value is limited to `1` . Setting `processesPerApplication` is discouraged. This attribute will be removed in a future release.	Default: `1` Min: `1` Max: `100` †
`processPath`	Required string attribute. Path to the executable that launches a process listening for HTTP requests. Relative paths are supported. If the path begins with `.` , the path is considered to be relative to the site root.	

ATTRIBUTE	DESCRIPTION	DEFAULT
`rapidFailsPerMinute`	Optional integer attribute. Specifies the number of times the process specified in **processPath** is allowed to crash per minute. If this limit is exceeded, the module stops launching the process for the remainder of the minute. Not supported with in-process hosting.	Default: `10` Min: `0` Max: `100`
`requestTimeout`	Optional timespan attribute. Specifies the duration for which the ASP.NET Core Module waits for a response from the process listening on %ASPNETCORE_PORT%. In versions of the ASP.NET Core Module that shipped with the release of ASP.NET Core 2.1 or later, the `requestTimeout` is specified in hours, minutes, and seconds. Doesn't apply to in-process hosting. For in-process hosting, the module waits for the app to process the request. Valid values for minutes and seconds segments of the string are in the range 0-59. Use of **60** in the value for minutes or seconds results in a *500 - Internal Server Error*.	Default: `00:02:00` Min: `00:00:00` Max: `360:00:00`
`shutdownTimeLimit`	Optional integer attribute. Duration in seconds that the module waits for the executable to gracefully shutdown when the *app_offline.htm* file is detected.	Default: `10` Min: `0` Max: `600`

ATTRIBUTE	DESCRIPTION	DEFAULT
`startupTimeLimit`	Optional integer attribute. Duration in seconds that the module waits for the executable to start a process listening on the port. If this time limit is exceeded, the module kills the process. When hosting *in-process*: The process is **not** restarted and does **not** use the **rapidFailsPerMinute** setting. When hosting *out-of-process*: The module attempts to relaunch the process when it receives a new request and continues to attempt to restart the process on subsequent incoming requests unless the app fails to start **rapidFailsPerMinute** number of times in the last rolling minute. A value of 0 (zero) is **not** considered an infinite timeout.	Default: `120` Min: `0` Max: `3600`
`stdoutLogEnabled`	Optional Boolean attribute. If true, **stdout** and **stderr** for the process specified in **processPath** are redirected to the file specified in **stdoutLogFile**.	`false`

ATTRIBUTE	DESCRIPTION	DEFAULT
`stdoutLogFile`	Optional string attribute. Specifies the relative or absolute file path for which **stdout** and **stderr** from the process specified in **processPath** are logged. Relative paths are relative to the root of the site. Any path starting with `.` are relative to the site root and all other paths are treated as absolute paths. Any folders provided in the path are created by the module when the log file is created. Using underscore delimiters, a timestamp, process ID, and file extension (*.log*) are added to the last segment of the **stdoutLogFile** path. If `.\logs\stdout` is supplied as a value, an example stdout log is saved as *stdout_20180205194132_1934.log* in the *logs* folder when saved on 2/5/2018 at 19:41:32 with a process ID of 1934.	`aspnetcore-stdout`

Setting environment variables

Environment variables can be specified for the process in the `processPath` attribute. Specify an environment variable with the `<environmentVariable>` child element of an `<environmentVariables>` collection element. Environment variables set in this section take precedence over system environment variables.

The following example sets two environment variables. `ASPNETCORE_ENVIRONMENT` configures the app's environment to `Development`. A developer may temporarily set this value in the *web.config* file in order to force the Developer Exception Page to load when debugging an app exception. `CONFIG_DIR` is an example of a user-defined environment variable, where the developer has written code that reads the value on startup to form a path for loading the app's configuration file.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout"
      hostingModel="inprocess">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
    <environmentVariable name="CONFIG_DIR" value="f:\application_config" />
  </environmentVariables>
</aspNetCore>
```

NOTE

An alternative to setting the environment directly in *web.config* is to include the `<EnvironmentName>` property in the publish profile (.pubxml) or project file. This approach sets the environment in *web.config* when the project is published:

```
<PropertyGroup>
  <EnvironmentName>Development</EnvironmentName>
</PropertyGroup>
```

WARNING

Only set the `ASPNETCORE_ENVIRONMENT` environment variable to `Development` on staging and testing servers that aren't accessible to untrusted networks, such as the Internet.

app_offline.htm

If a file with the name *app_offline.htm* is detected in the root directory of an app, the ASP.NET Core Module attempts to gracefully shutdown the app and stop processing incoming requests. If the app is still running after the number of seconds defined in `shutdownTimeLimit`, the ASP.NET Core Module kills the running process.

While the *app_offline.htm* file is present, the ASP.NET Core Module responds to requests by sending back the contents of the *app_offline.htm* file. When the *app_offline.htm* file is removed, the next request starts the app.

When using the out-of-process hosting model, the app might not shut down immediately if there's an open connection. For example, a websocket connection may delay app shut down.

Start-up error page

Both in-process and out-of-process hosting produce custom error pages when they fail to start the app.

If the ASP.NET Core Module fails to find either the in-process or out-of-process request handler, a *500.0 - In-Process/Out-Of-Process Handler Load Failure* status code page appears.

For in-process hosting if the ASP.NET Core Module fails to start the app, a *500.30 - Start Failure* status code page appears.

For out-of-process hosting if the ASP.NET Core Module fails to launch the backend process or the backend process starts but fails to listen on the configured port, a *502.5 - Process Failure* status code page appears.

To suppress this page and revert to the default IIS 5xx status code page, use the `disableStartUpErrorPage` attribute. For more information on configuring custom error messages, see HTTP Errors <httpErrors>.

Log creation and redirection

The ASP.NET Core Module redirects stdout and stderr console output to disk if the `stdoutLogEnabled` and `stdoutLogFile` attributes of the `aspNetCore` element are set. Any

folders in the `stdoutLogFile` path are created by the module when the log file is created. The app pool must have write access to the location where the logs are written (use `IIS AppPool\<app_pool_name>` to provide write permission).

Logs aren't rotated, unless process recycling/restart occurs. It's the responsibility of the hoster to limit the disk space the logs consume.

Using the stdout log is only recommended for troubleshooting app startup issues when hosting on IIS or when using development-time support for IIS with Visual Studio, not while debugging locally and running the app with IIS Express.

Don't use the stdout log for general app logging purposes. For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

A timestamp and file extension are added automatically when the log file is created. The log file name is composed by appending the timestamp, process ID, and file extension (*.log*) to the last segment of the `stdoutLogFile` path (typically *stdout*) delimited by underscores. If the `stdoutLogFile` path ends with *stdout*, a log for an app with a PID of 1934 created on 2/5/2018 at 19:42:32 has the file name *stdout_20180205194132_1934.log*.

If `stdoutLogEnabled` is false, errors that occur on app startup are captured and emitted to the event log up to 30 KB. After startup, all additional logs are discarded.

The following sample `aspNetCore` element configures stdout logging at the relative path `.\log\`. Confirm that the AppPool user identity has permission to write to the path provided.

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="true"
    stdoutLogFile=".\logs\stdout"
    hostingModel="inprocess">
</aspNetCore>
```

When publishing an app for Azure App Service deployment, the Web SDK sets the `stdoutLogFile` value to `\\?\%home%\LogFiles\stdout`. The `%home` environment variable is predefined for apps hosted by Azure App Service.

For more information on path formats, see File path formats on Windows systems.

Enhanced diagnostic logs

The ASP.NET Core Module is configurable to provide enhanced diagnostics logs. Add the `<handlerSettings>` element to the `<aspNetCore>` element in *web.config*. Setting the `debugLevel` to `TRACE` exposes a higher fidelity of diagnostic information:

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="false"
    stdoutLogFile="\\?\%home%\LogFiles\stdout"
    hostingModel="inprocess">
  <handlerSettings>
    <handlerSetting name="debugFile" value=".\logs\aspnetcore-debug.log" />
    <handlerSetting name="debugLevel" value="FILE,TRACE" />
  </handlerSettings>
</aspNetCore>
```

Folders in the path provided to the `<handlerSetting>` value (*logs* in the preceding example) aren't created by the module automatically and should pre-exist in the deployment. The app pool must have write access to the location where the logs are written (use `IIS AppPool\<app_pool_name>` to provide write permission).

Debug level (`debugLevel`) values can include both the level and the location.

Levels (in order from least to most verbose):

- ERROR
- WARNING
- INFO
- TRACE

Locations (multiple locations are permitted):

- CONSOLE
- EVENTLOG
- FILE

The handler settings can also be provided via environment variables:

- `ASPNETCORE_MODULE_DEBUG_FILE`: Path to the debug log file. (Default: *aspnetcore-debug.log*)
- `ASPNETCORE_MODULE_DEBUG`: Debug level setting.

> **WARNING**
> Do **not** leave debug logging enabled in the deployment for longer than required to troubleshoot an issue. The size of the log isn't limited. Leaving the debug log enabled can exhaust the available disk space and crash the server or app service.

See Configuration with web.config for an example of the `aspNetCore` element in the *web.config* file.

Proxy configuration uses HTTP protocol and a pairing token

Only applies to out-of-process hosting.

The proxy created between the ASP.NET Core Module and Kestrel uses the HTTP protocol. There's no risk of eavesdropping the traffic between the module and Kestrel from a location off of the server.

A pairing token is used to guarantee that the requests received by Kestrel were proxied by

IIS and didn't come from some other source. The pairing token is created and set into an environment variable (`ASPNETCORE_TOKEN`) by the module. The pairing token is also set into a header (`MS-ASPNETCORE-TOKEN`) on every proxied request. IIS Middleware checks each request it receives to confirm that the pairing token header value matches the environment variable value. If the token values are mismatched, the request is logged and rejected. The pairing token environment variable and the traffic between the module and Kestrel aren't accessible from a location off of the server. Without knowing the pairing token value, an attacker can't submit requests that bypass the check in the IIS Middleware.

ASP.NET Core Module with an IIS Shared Configuration

The ASP.NET Core Module installer runs with the privileges of the **TrustedInstaller** account. Because the local system account doesn't have modify permission for the share path used by the IIS Shared Configuration, the installer throws an access denied error when attempting to configure the module settings in the *applicationHost.config* file on the share.

When using an IIS Shared Configuration on the same machine as the IIS installation, run the ASP.NET Core Hosting Bundle installer with the `OPT_NO_SHARED_CONFIG_CHECK` parameter set to `1`:

```
dotnet-hosting-{VERSION}.exe OPT_NO_SHARED_CONFIG_CHECK=1
```

When the path to the shared configuration isn't on the same machine as the IIS installation, follow these steps:

1. Disable the IIS Shared Configuration.
2. Run the installer.
3. Export the updated *applicationHost.config* file to the share.
4. Re-enable the IIS Shared Configuration.

Module version and Hosting Bundle installer logs

To determine the version of the installed ASP.NET Core Module:

1. On the hosting system, navigate to *%windir%\System32\inetsrv*.
2. Locate the *aspnetcore.dll* file.
3. Right-click the file and select **Properties** from the contextual menu.
4. Select the **Details** tab. The **File version** and **Product version** represent the installed version of the module.

The Hosting Bundle installer logs for the module are found at *C:\Users\%UserName%\AppData\Local\Temp*. The file is named *dd_DotNetCoreWinSvrHosting__<timestamp>_000_AspNetCoreModule_x64.log*.

Module, schema, and configuration file locations

Module

IIS (x86/amd64):

- %windir%\System32\inetsrv\aspnetcore.dll
- %windir%\SysWOW64\inetsrv\aspnetcore.dll

- %ProgramFiles%\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll
- %ProgramFiles(x86)%\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll

IIS Express (x86/amd64):

- %ProgramFiles%\IIS Express\aspnetcore.dll
- %ProgramFiles(x86)%\IIS Express\aspnetcore.dll
- %ProgramFiles%\IIS Express\Asp.Net Core Module\V2\aspnetcorev2.dll
- %ProgramFiles(x86)%\IIS Express\Asp.Net Core Module\V2\aspnetcorev2.dll

Schema

IIS

- %windir%\System32\inetsrv\config\schema\aspnetcore_schema.xml
- %windir%\System32\inetsrv\config\schema\aspnetcore_schema_v2.xml

IIS Express

- %ProgramFiles%\IIS Express\config\schema\aspnetcore_schema.xml
- %ProgramFiles%\IIS Express\config\schema\aspnetcore_schema_v2.xml

Configuration

IIS

- %windir%\System32\inetsrv\config\applicationHost.config

IIS Express

- Visual Studio: {APPLICATION ROOT}\.vs\config\applicationHost.config
- *iisexpress.exe* CLI: %USERPROFILE%\Documents\IISExpress\config\applicationhost.config

The files can be found by searching for *aspnetcore* in the *applicationHost.config* file.

The ASP.NET Core Module is a native IIS module that plugs into the IIS pipeline to forward web requests to backend ASP.NET Core apps.

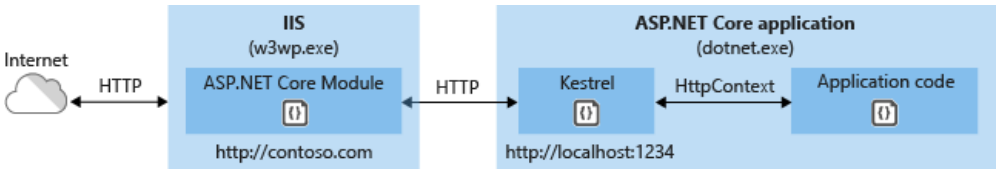
Supported Windows versions:

- Windows 7 or later
- Windows Server 2008 R2 or later

The module only works with Kestrel. The module is incompatible with HTTP.sys.

Because ASP.NET Core apps run in a process separate from the IIS worker process, the module also handles process management. The module starts the process for the ASP.NET Core app when the first request arrives and restarts the app if it crashes. This is essentially the same behavior as seen with ASP.NET 4.x apps that run in-process in IIS that are managed by the Windows Process Activation Service (WAS).

The following diagram illustrates the relationship between IIS, the ASP.NET Core Module, and an app:



Requests arrive from the web to the kernel-mode HTTP.sys driver. The driver routes the requests to IIS on the website's configured port, usually 80 (HTTP) or 443 (HTTPS). The module forwards the requests to Kestrel on a random port for the app, which isn't port 80 or 443.

The module specifies the port via an environment variable at startup, and the IIS Integration Middleware configures the server to listen on `http://localhost:{port}`. Additional checks are performed, and requests that don't originate from the module are rejected. The module doesn't support HTTPS forwarding, so requests are forwarded over HTTP even if received by IIS over HTTPS.

After Kestrel picks up the request from the module, the request is pushed into the ASP.NET Core middleware pipeline. The middleware pipeline handles the request and passes it on as an `HttpContext` instance to the app's logic. Middleware added by IIS Integration updates the scheme, remote IP, and pathbase to account for forwarding the request to Kestrel. The app's response is passed back to IIS, which pushes it back out to the HTTP client that initiated the request.

Many native modules, such as Windows Authentication, remain active. To learn more about IIS modules active with the ASP.NET Core Module, see IIS modules with ASP.NET Core.

The ASP.NET Core Module can also:

- Set environment variables for the worker process.
- Log stdout output to file storage for troubleshooting startup issues.
- Forward Windows authentication tokens.

How to install and use the ASP.NET Core Module

For instructions on how to install the ASP.NET Core Module, see Install the .NET Core Hosting Bundle.

Configuration with web.config

The ASP.NET Core Module is configured with the `aspNetCore` section of the `system.webServer` node in the site's *web.config* file.

The following *web.config* file is published for a framework-dependent deployment and configures the ASP.NET Core Module to handle site requests:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <system.webServer>
    <handlers>
      <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModule"
resourceType="Unspecified" />
    </handlers>
    <aspNetCore processPath="dotnet"
                arguments=".\MyApp.dll"
                stdoutLogEnabled="false"
                stdoutLogFile=".\logs\stdout" />
  </system.webServer>
</configuration>
```

The following *web.config* is published for a self-contained deployment:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <system.webServer>
    <handlers>
      <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModule"
resourceType="Unspecified" />
    </handlers>
    <aspNetCore processPath=".\MyApp.exe"
                stdoutLogEnabled="false"
                stdoutLogFile=".\logs\stdout" />
  </system.webServer>
</configuration>
```

When an app is deployed to Azure App Service, the `stdoutLogFile` path is set to `\\?\%home%\LogFiles\stdout`. The path saves stdout logs to the *LogFiles* folder, which is a location automatically created by the service.

For information on IIS sub-application configuration, see Host ASP.NET Core on Windows with IIS.

Attributes of the aspNetCore element

ATTRIBUTE	DESCRIPTION	DEFAULT
`arguments`	Optional string attribute. Arguments to the executable specified in **processPath**.	
`disableStartUpErrorPage`	Optional Boolean attribute. If true, the **502.5 - Process Failure** page is suppressed, and the 502 status code page configured in the *web.config* takes precedence.	`false`

ATTRIBUTE	DESCRIPTION	DEFAULT
`forwardWindowsAuthToken`	Optional Boolean attribute. If true, the token is forwarded to the child process listening on %ASPNETCORE_PORT% as a header 'MS-ASPNETCORE-WINAUTHTOKEN' per request. It's the responsibility of that process to call CloseHandle on this token per request.	`true`
`processesPerApplication`	Optional integer attribute. Specifies the number of instances of the process specified in the **processPath** setting that can be spun up per app. Setting `processesPerApplication` is discouraged. This attribute will be removed in a future release.	Default: `1` Min: `1` Max: `100`
`processPath`	Required string attribute. Path to the executable that launches a process listening for HTTP requests. Relative paths are supported. If the path begins with `.`, the path is considered to be relative to the site root.	
`rapidFailsPerMinute`	Optional integer attribute. Specifies the number of times the process specified in **processPath** is allowed to crash per minute. If this limit is exceeded, the module stops launching the process for the remainder of the minute.	Default: `10` Min: `0` Max: `100`

ATTRIBUTE	DESCRIPTION	DEFAULT
`requestTimeout`	Optional timespan attribute. Specifies the duration for which the ASP.NET Core Module waits for a response from the process listening on %ASPNETCORE_PORT%. In versions of the ASP.NET Core Module that shipped with the release of ASP.NET Core 2.1 or later, the `requestTimeout` is specified in hours, minutes, and seconds.	Default: `00:02:00` Min: `00:00:00` Max: `360:00:00`
`shutdownTimeLimit`	Optional integer attribute. Duration in seconds that the module waits for the executable to gracefully shutdown when the *app_offline.htm* file is detected.	Default: `10` Min: `0` Max: `600`
`startupTimeLimit`	Optional integer attribute. Duration in seconds that the module waits for the executable to start a process listening on the port. If this time limit is exceeded, the module kills the process. The module attempts to relaunch the process when it receives a new request and continues to attempt to restart the process on subsequent incoming requests unless the app fails to start **rapidFailsPerMinute** number of times in the last rolling minute. A value of 0 (zero) is **not** considered an infinite timeout.	Default: `120` Min: `0` Max: `3600`

ATTRIBUTE	DESCRIPTION	DEFAULT
`stdoutLogEnabled`	Optional Boolean attribute. If true, **stdout** and **stderr** for the process specified in **processPath** are redirected to the file specified in **stdoutLogFile**.	`false`
`stdoutLogFile`	Optional string attribute. Specifies the relative or absolute file path for which **stdout** and **stderr** from the process specified in **processPath** are logged. Relative paths are relative to the root of the site. Any path starting with `.` are relative to the site root and all other paths are treated as absolute paths. Any folders provided in the path must exist in order for the module to create the log file. Using underscore delimiters, a timestamp, process ID, and file extension (*.log*) are added to the last segment of the **stdoutLogFile** path. If `.\logs\stdout` is supplied as a value, an example stdout log is saved as *stdout_20180205194132_1934.log* in the *logs* folder when saved on 2/5/2018 at 19:41:32 with a process ID of 1934.	`aspnetcore-stdout`

Setting environment variables

Environment variables can be specified for the process in the `processPath` attribute. Specify an environment variable with the `<environmentVariable>` child element of an `<environmentVariables>` collection element.

> **WARNING**
>
> Environment variables set in this section conflict with system environment variables set with the same name. If an environment variable is set in both the *web.config* file and at the system level in Windows, the value from the *web.config* file becomes appended to the system environment variable value (for example, `ASPNETCORE_ENVIRONMENT: Development;Development`), which prevents the app from starting.

The following example sets two environment variables. `ASPNETCORE_ENVIRONMENT` configures the app's environment to `Development`. A developer may temporarily set this value in the *web.config* file in order to force the Developer Exception Page to load when debugging an app exception. `CONFIG_DIR` is an example of a user-defined environment variable, where the developer has written code that reads the value on startup to form a path for loading the app's configuration file.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile="\\?\%home%\LogFiles\stdout">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
    <environmentVariable name="CONFIG_DIR" value="f:\application_config" />
  </environmentVariables>
</aspNetCore>
```

WARNING

Only set the `ASPNETCORE_ENVIRONMENT` environment variable to `Development` on staging and testing servers that aren't accessible to untrusted networks, such as the Internet.

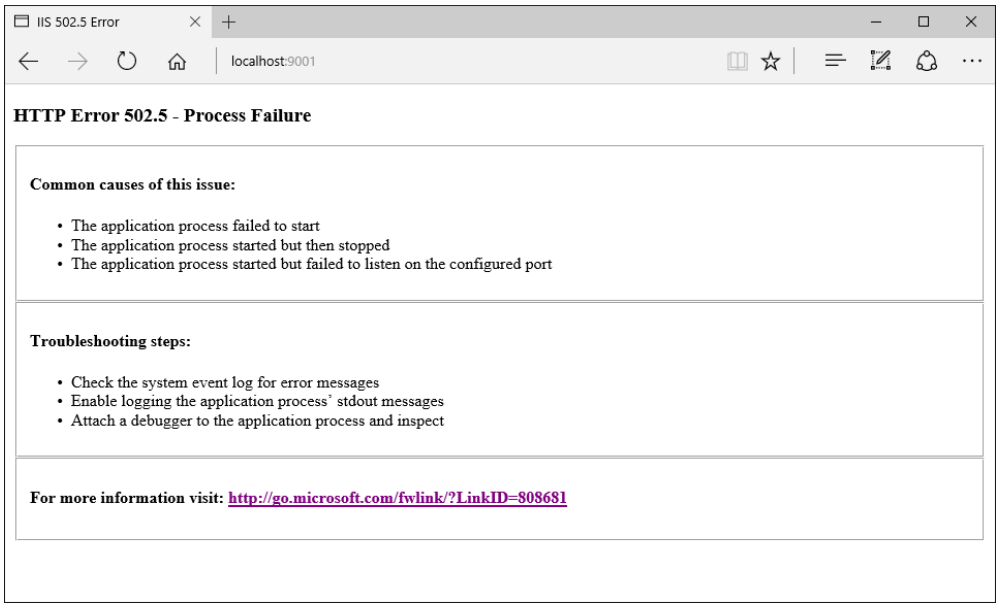
app_offline.htm

If a file with the name *app_offline.htm* is detected in the root directory of an app, the ASP.NET Core Module attempts to gracefully shutdown the app and stop processing incoming requests. If the app is still running after the number of seconds defined in `shutdownTimeLimit`, the ASP.NET Core Module kills the running process.

While the *app_offline.htm* file is present, the ASP.NET Core Module responds to requests by sending back the contents of the *app_offline.htm* file. When the *app_offline.htm* file is removed, the next request starts the app.

Start-up error page

If the ASP.NET Core Module fails to launch the backend process or the backend process starts but fails to listen on the configured port, a *502.5 - Process Failure* status code page appears. To suppress this page and revert to the default IIS 502 status code page, use the `disableStartUpErrorPage` attribute. For more information on configuring custom error messages, see HTTP Errors <httpErrors>.



Log creation and redirection

The ASP.NET Core Module redirects stdout and stderr console output to disk if the `stdoutLogEnabled` and `stdoutLogFile` attributes of the `aspNetCore` element are set. Any folders in the `stdoutLogFile` path are created by the module when the log file is created. The app pool must have write access to the location where the logs are written (use `IIS AppPool\<app_pool_name>` to provide write permission).

Logs aren't rotated, unless process recycling/restart occurs. It's the responsibility of the hoster to limit the disk space the logs consume.

Using the stdout log is only recommended for troubleshooting app startup issues when hosting on IIS or when using development-time support for IIS with Visual Studio, not while debugging locally and running the app with IIS Express.

Don't use the stdout log for general app logging purposes. For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

A timestamp and file extension are added automatically when the log file is created. The log file name is composed by appending the timestamp, process ID, and file extension (*.log*) to the last segment of the `stdoutLogFile` path (typically *stdout*) delimited by underscores. If the `stdoutLogFile` path ends with *stdout*, a log for an app with a PID of 1934 created on 2/5/2018 at 19:42:32 has the file name *stdout_20180205194132_1934.log*.

The following sample `aspNetCore` element configures stdout logging at the relative path `.\log\`. Confirm that the AppPool user identity has permission to write to the path provided.

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="true"
    stdoutLogFile=".\logs\stdout">
</aspNetCore>
```

When publishing an app for Azure App Service deployment, the Web SDK sets the `stdoutLogFile` value to `\\?\%home%\LogFiles\stdout`. The `%home` environment variable is

predefined for apps hosted by Azure App Service.

To create logging filter rules, see the Configuration and Log filtering sections of the ASP.NET Core logging documentation.

For more information on path formats, see File path formats on Windows systems.

Proxy configuration uses HTTP protocol and a pairing token

The proxy created between the ASP.NET Core Module and Kestrel uses the HTTP protocol. There's no risk of eavesdropping the traffic between the module and Kestrel from a location off of the server.

A pairing token is used to guarantee that the requests received by Kestrel were proxied by IIS and didn't come from some other source. The pairing token is created and set into an environment variable (`ASPNETCORE_TOKEN`) by the module. The pairing token is also set into a header (`MS-ASPNETCORE-TOKEN`) on every proxied request. IIS Middleware checks each request it receives to confirm that the pairing token header value matches the environment variable value. If the token values are mismatched, the request is logged and rejected. The pairing token environment variable and the traffic between the module and Kestrel aren't accessible from a location off of the server. Without knowing the pairing token value, an attacker can't submit requests that bypass the check in the IIS Middleware.

ASP.NET Core Module with an IIS Shared Configuration

The ASP.NET Core Module installer runs with the privileges of the **TrustedInstaller** account. Because the local system account doesn't have modify permission for the share path used by the IIS Shared Configuration, the installer throws an access denied error when attempting to configure the module settings in the *applicationHost.config* file on the share.

When using an IIS Shared Configuration, follow these steps:

1. Disable the IIS Shared Configuration.
2. Run the installer.
3. Export the updated *applicationHost.config* file to the share.
4. Re-enable the IIS Shared Configuration.

Module version and Hosting Bundle installer logs

To determine the version of the installed ASP.NET Core Module:

1. On the hosting system, navigate to *%windir%\System32\inetsrv*.
2. Locate the *aspnetcore.dll* file.
3. Right-click the file and select **Properties** from the contextual menu.
4. Select the **Details** tab. The **File version** and **Product version** represent the installed version of the module.

The Hosting Bundle installer logs for the module are found at *C:\Users\%UserName%\AppData\Local\Temp*. The file is named *dd_DotNetCoreWinSvrHosting__<timestamp>_000_AspNetCoreModule_x64.log*.

Module, schema, and configuration file locations

Module

IIS (x86/amd64):

- %windir%\System32\inetsrv\aspnetcore.dll
- %windir%\SysWOW64\inetsrv\aspnetcore.dll

IIS Express (x86/amd64):

- %ProgramFiles%\IIS Express\aspnetcore.dll
- %ProgramFiles(x86)%\IIS Express\aspnetcore.dll

Schema

IIS

- %windir%\System32\inetsrv\config\schema\aspnetcore_schema.xml

IIS Express

- %ProgramFiles%\IIS Express\config\schema\aspnetcore_schema.xml

Configuration

IIS

- %windir%\System32\inetsrv\config\applicationHost.config

IIS Express

- Visual Studio: {APPLICATION ROOT}\.vs\config\applicationHost.config
- *iisexpress.exe* CLI: %USERPROFILE%\Documents\IISExpress\config\applicationhost.config

The files can be found by searching for *aspnetcore* in the *applicationHost.config* file.

Additional resources

Development-time IIS support in Visual Studio for ASP.NET Core

9/22/2020 • 8 minutes to read • Edit Online

By Sourabh Shirhatti

This article describes Visual Studio support for debugging ASP.NET Core apps running with IIS on Windows Server. This topic walks through enabling this scenario and setting up a project.

Prerequisites

- Visual Studio for Windows
- **ASP.NET and web development** workload
- **.NET Core cross-platform development** workload
- X.509 security certificate (for HTTPS support)

Enable IIS

1. In Windows, navigate to **Control Panel** > **Programs** > **Programs and Features** > **Turn Windows features on or off** (left side of the screen).
2. Select the **Internet Information Services** check box. Select **OK**.

The IIS installation may require a system restart.

Configure IIS

IIS must have a website configured with the following:

- **Host name**: Typically, the **Default Web Site** is used with a **Host name** of `localhost`. However, any valid IIS website with a unique host name works.
- **Site Binding**
  - For apps that require HTTPS, create a binding to port 443 with a certificate. Typically, the **IIS Express Development Certificate** is used, but any valid certificate works.
  - For apps that use HTTP, confirm the existence of a binding to post 80 or create a binding to port 80 for a new site.
  - Use a single binding for either HTTP or HTTPS. **Binding to both HTTP and HTTPS ports simultaneously isn't supported.**

Enable development-time IIS support in Visual Studio

1. Launch the Visual Studio installer.
2. Select **Modify** for the Visual Studio installation that you plan to use for IIS development-time support.
3. For the **ASP.NET and web development** workload, locate and install the **Development time IIS support** component.

   The component is listed in the **Optional** section under **Development time IIS support** in the **Installation details** panel to the right of the workloads. The component installs the ASP.NET Core Module, which is a native IIS module required to run ASP.NET Core apps with IIS.

Configure the project

HTTPS redirection

For a new project that requires HTTPS, select the check box to **Configure for HTTPS** in the **Create a new ASP.NET Core Web Application** window. Selecting the check box adds HTTPS Redirection and HSTS Middleware to the app when it's created.

For an existing project that requires HTTPS, use HTTPS Redirection and HSTS Middleware in `Startup.Configure`. For more information, see Enforce HTTPS in ASP.NET Core.

For a project that uses HTTP, HTTPS Redirection and HSTS Middleware aren't added to the app. No app configuration is required.

IIS launch profile

Create a new launch profile to add development-time IIS support:

1. Right-click the project in **Solution Explorer**. Select **Properties**. Open the **Debug** tab.
2. For **Profile**, select the **New** button. Name the profile "IIS" in the popup window. Select **OK** to create the profile.
3. For the **Launch** setting, select **IIS** from the list.
4. Select the check box for **Launch browser** and provide the endpoint URL.

   When the app requires HTTPS, use an HTTPS endpoint (`https://`). For HTTP, use an HTTP (`http://`) endpoint.

   Provide the same host name and port as the IIS configuration specified earlier uses, typically `localhost`.

   Provide the name of the app at the end of the URL.

   For example, `https://localhost/WebApplication1` (HTTPS) or `http://localhost/WebApplication1` (HTTP) are valid endpoint URLs.
5. In the **Environment variables** section, select the **Add** button. Provide an environment variable with a **Name** of `ASPNETCORE_ENVIRONMENT` and a **Value** of `Development`.
6. In the **Web Server Settings** area, set the **App URL** to the same value used for the **Launch browser** endpoint URL.
7. For the **Hosting Model** setting in Visual Studio 2019 or later, select **Default** to use the hosting model used by the project. If the project sets the `<AspNetCoreHostingModel>` property in its project file, the value of the property (`InProcess` or `OutOfProcess`) is used. If the property isn't present, the default hosting model of the app is used, which is in-process. If the app requires an explicit hosting model setting different from the app's normal hosting model, set the **Hosting Model** to either `In Process` or `Out Of Process` as needed.
8. Save the profile.

When not using Visual Studio, manually add a launch profile to the launchSettings.json file in the *Properties* folder. The following example configures the profile to use the HTTPS protocol:

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iis": {
      "applicationUrl": "https://localhost/WebApplication1",
      "sslPort": 0
    }
  },
  "profiles": {
    "IIS": {
      "commandName": "IIS",
      "launchBrowser": true,
      "launchUrl": "https://localhost/WebApplication1",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    }
  }
}
```

Confirm that the `applicationUrl` and `launchUrl` endpoints match and use the same protocol as the IIS binding configuration, either HTTP or HTTPS.

Run the project

Run Visual Studio as an administrator:

- Confirm that the build configuration drop-down list is set to **Debug**.
- Set the Start Debugging button to the **IIS** profile and select the button to start the app.

Visual Studio may prompt a restart if not running as an administrator. If prompted, restart Visual Studio.

If an untrusted development certificate is used, the browser may require you to create an exception for the untrusted certificate.

> **NOTE**
> Debugging a Release build configuration with Just My Code and compiler optimizations results in a degraded experience. For example, break points aren't hit.

- Enforce HTTPS in ASP.NET Core

This article describes Visual Studio support for debugging ASP.NET Core apps running with IIS on Windows Server. This topic walks through enabling this scenario and setting up a project.

Prerequisites

- Visual Studio for Windows
- **ASP.NET and web development** workload
- **.NET Core cross-platform development** workload
- X.509 security certificate (for HTTPS support)

Enable IIS

1. In Windows, navigate to **Control Panel** > **Programs** > **Programs and Features** > **Turn Windows features on or off** (left side of the screen).
2. Select the **Internet Information Services** check box. Select **OK**.

The IIS installation may require a system restart.

Configure IIS

IIS must have a website configured with the following:

- **Host name**: Typically, the **Default Web Site** is used with a **Host name** of `localhost`. However, any valid IIS website with a unique host name works.
- **Site Binding**
  - For apps that require HTTPS, create a binding to port 443 with a certificate. Typically, the **IIS Express Development Certificate** is used, but any valid certificate works.
  - For apps that use HTTP, confirm the existence of a binding to post 80 or create a binding to port 80 for a new site.
  - Use a single binding for either HTTP or HTTPS. **Binding to both HTTP and HTTPS ports simultaneously isn't supported.**

Enable development-time IIS support in Visual Studio

1. Launch the Visual Studio installer.
2. Select **Modify** for the Visual Studio installation that you plan to use for IIS development-time support.
3. For the **ASP.NET and web development** workload, locate and install the **Development time IIS support** component.

   The component is listed in the **Optional** section under **Development time IIS support** in the **Installation details** panel to the right of the workloads. The component installs the ASP.NET Core Module, which is a native IIS module required to run ASP.NET Core apps with IIS.

Configure the project

HTTPS redirection

For a new project that requires HTTPS, select the check box to **Configure for HTTPS** in the **Create a new ASP.NET Core Web Application** window. Selecting the check box adds HTTPS Redirection and HSTS Middleware to the app when it's created.

For an existing project that requires HTTPS, use HTTPS Redirection and HSTS Middleware in `Startup.Configure`. For more information, see Enforce HTTPS in ASP.NET Core.

For a project that uses HTTP, HTTPS Redirection and HSTS Middleware aren't added to the app. No app configuration is required.

IIS launch profile

Create a new launch profile to add development-time IIS support:

1. Right-click the project in **Solution Explorer**. Select **Properties**. Open the **Debug** tab.
2. For **Profile**, select the **New** button. Name the profile "IIS" in the popup window. Select **OK** to create the profile.

3. For the **Launch** setting, select **IIS** from the list.
4. Select the check box for **Launch browser** and provide the endpoint URL.

   When the app requires HTTPS, use an HTTPS endpoint (`https://`). For HTTP, use an HTTP (`http://`) endpoint.

   Provide the same host name and port as the IIS configuration specified earlier uses, typically `localhost`.

   Provide the name of the app at the end of the URL.

   For example, `https://localhost/WebApplication1` (HTTPS) or `http://localhost/WebApplication1` (HTTP) are valid endpoint URLs.
5. In the **Environment variables** section, select the **Add** button. Provide an environment variable with a **Name** of `ASPNETCORE_ENVIRONMENT` and a **Value** of `Development`.
6. In the **Web Server Settings** area, set the **App URL** to the same value used for the **Launch browser** endpoint URL.
7. For the **Hosting Model** setting in Visual Studio 2019 or later, select **Default** to use the hosting model used by the project. If the project sets the `<AspNetCoreHostingModel>` property in its project file, the value of the property (`InProcess` or `OutOfProcess`) is used. If the property isn't present, the default hosting model of the app is used, which is out-of-process. If the app requires an explicit hosting model setting different from the app's normal hosting model, set the **Hosting Model** to either `In Process` or `Out Of Process` as needed.
8. Save the profile.

When not using Visual Studio, manually add a launch profile to the launchSettings.json file in the *Properties* folder. The following example configures the profile to use the HTTPS protocol:

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iis": {
      "applicationUrl": "https://localhost/WebApplication1",
      "sslPort": 0
    }
  },
  "profiles": {
    "IIS": {
      "commandName": "IIS",
      "launchBrowser": true,
      "launchUrl": "https://localhost/WebApplication1",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    }
  }
}
```

Confirm that the `applicationUrl` and `launchUrl` endpoints match and use the same protocol as the IIS binding configuration, either HTTP or HTTPS.

Run the project

Run Visual Studio as an administrator:

- Confirm that the build configuration drop-down list is set to **Debug**.

- Set the Start Debugging button to the **IIS** profile and select the button to start the app.

Visual Studio may prompt a restart if not running as an administrator. If prompted, restart Visual Studio.

If an untrusted development certificate is used, the browser may require you to create an exception for the untrusted certificate.

> **NOTE**
>
> Debugging a Release build configuration with Just My Code and compiler optimizations results in a degraded experience. For example, break points aren't hit.

IIS modules with ASP.NET Core

9/22/2020 • 5 minutes to read • Edit Online

Some of the native IIS modules and all of the IIS managed modules aren't able to process requests for ASP.NET Core apps. In many cases, ASP.NET Core offers an alternative to the scenarios addressed by IIS native and managed modules.

Native modules

The table indicates native IIS modules that are functional with ASP.NET Core apps and the ASP.NET Core Module.

MODULE	FUNCTIONAL WITH ASP.NET CORE APPS	ASP.NET CORE OPTION
Anonymous Authentication `AnonymousAuthenticationModule`	Yes	
Basic Authentication `BasicAuthenticationModule`	Yes	
Client Certification Mapping Authentication `CertificateMappingAuthenticationModule`	Yes	
CGI `CgiModule`	No	
Configuration Validation `ConfigurationValidationModule`	Yes	
HTTP Errors `CustomErrorModule`	No	Status Code Pages Middleware
Custom Logging `CustomLoggingModule`	Yes	
Default Document `DefaultDocumentModule`	No	Default Files Middleware
Digest Authentication `DigestAuthenticationModule`	Yes	
Directory Browsing `DirectoryListingModule`	No	Directory Browsing Middleware
Dynamic Compression `DynamicCompressionModule`	Yes	Response Compression Middleware
Failed Requests Tracing `FailedRequestsTracingModule`	Yes	ASP.NET Core Logging

MODULE	FUNCTIONAL WITH ASP.NET CORE APPS	ASP.NET CORE OPTION
File Caching `FileCacheModule`	No	Response Caching Middleware
HTTP Caching `HttpCacheModule`	No	Response Caching Middleware
HTTP Logging `HttpLoggingModule`	Yes	ASP.NET Core Logging
HTTP Redirection `HttpRedirectionModule`	Yes	URL Rewriting Middleware
HTTP Tracing `TracingModule`	Yes	
IIS Client Certificate Mapping Authentication `IISCertificateMappingAuthenticationModule`	Yes	
IP and Domain Restrictions `IpRestrictionModule`	Yes	
ISAPI Filters `IsapiFilterModule`	Yes	Middleware
ISAPI `IsapiModule`	Yes	Middleware
Protocol Support `ProtocolSupportModule`	Yes	
Request Filtering `RequestFilteringModule`	Yes	URL Rewriting Middleware `IRule`
Request Monitor `RequestMonitorModule`	Yes	
URL Rewriting† `RewriteModule`	Yes	URL Rewriting Middleware
Server-Side Includes `ServerSideIncludeModule`	No	
Static Compression `StaticCompressionModule`	No	Response Compression Middleware
Static Content `StaticFileModule`	No	Static File Middleware
Token Caching `TokenCacheModule`	Yes	

MODULE	FUNCTIONAL WITH ASP.NET CORE APPS	ASP.NET CORE OPTION
URI Caching `UriCacheModule`	Yes	
URL Authorization `UrlAuthorizationModule`	Yes	ASP.NET Core Identity
Windows Authentication `WindowsAuthenticationModule`	Yes	

†The URL Rewrite Module's `isFile` and `isDirectory` match types don't work with ASP.NET Core apps due to the changes in directory structure.

Managed modules

Managed modules are *not* functional with hosted ASP.NET Core apps when the app pool's .NET CLR version is set to **No Managed Code**. ASP.NET Core offers middleware alternatives in several cases.

MODULE	ASP.NET CORE OPTION
AnonymousIdentification	
DefaultAuthentication	
FileAuthorization	
FormsAuthentication	Cookie Authentication Middleware
OutputCache	Response Caching Middleware
Profile	
RoleManager	
ScriptModule-4.0	
Session	Session Middleware
UrlAuthorization	
UrlMappingsModule	URL Rewriting Middleware
UrlRoutingModule-4.0	ASP.NET Core Identity
WindowsAuthentication	

IIS Manager application changes

When using IIS Manager to configure settings, the *web.config* file of the app is changed. If deploying an app and including *web.config*, any changes made with IIS Manager are overwritten by the deployed *web.config* file. If changes are made to the server's *web.config* file, copy the updated *web.config* file on the server to the local

project immediately.

Disabling IIS modules

If an IIS module is configured at the server level that must be disabled for an app, an addition to the app's *web.config* file can disable the module. Either leave the module in place and deactivate it using a configuration setting (if available) or remove the module from the app.

Module deactivation

Many modules offer a configuration setting that allows them to be disabled without removing the module from the app. This is the simplest and quickest way to deactivate a module. For example, the HTTP Redirection Module can be disabled with the `<httpRedirect>` element in *web.config*:

```
<configuration>
  <system.webServer>
    <httpRedirect enabled="false" />
  </system.webServer>
</configuration>
```

For more information on disabling modules with configuration settings, follow the links in the *Child Elements* section of IIS <system.webServer>.

Module removal

If opting to remove a module with a setting in *web.config*, unlock the module and unlock the `<modules>` section of *web.config* first:

1. Unlock the module at the server level. Select the IIS server in the IIS Manager **Connections** sidebar. Open the **Modules** in the **IIS** area. Select the module in the list. In the **Actions** sidebar on the right, select **Unlock**. If the action entry for the module appears as **Lock**, the module is already unlocked, and no action is required. Unlock as many modules as you plan to remove from *web.config* later.

2. Deploy the app without a `<modules>` section in *web.config*. If an app is deployed with a *web.config* containing the `<modules>` section without having unlocked the section first in the IIS Manager, the Configuration Manager throws an exception when attempting to unlock the section. Therefore, deploy the app without a `<modules>` section.

3. Unlock the `<modules>` section of *web.config*. In the **Connections** sidebar, select the website in **Sites**. In the **Management** area, open the **Configuration Editor**. Use the navigation controls to select the `system.webServer/modules` section. In the **Actions** sidebar on the right, select to **Unlock** the section. If the action entry for the module section appears as **Lock Section**, the module section is already unlocked, and no action is required.

4. Add a `<modules>` section to the app's local *web.config* file with a `<remove>` element to remove the module from the app. Add multiple `<remove>` elements to remove multiple modules. If *web.config* changes are made on the server, immediately make the same changes to the project's *web.config* file locally. Removing a module using this approach doesn't affect the use of the module with other apps on the server.

   ```
   <configuration>
    <system.webServer>
      <modules>
        <remove name="MODULE_NAME" />
      </modules>
    </system.webServer>
   </configuration>
   ```

In order to add or remove modules for IIS Express using *web.config*, modify *applicationHost.config* to unlock the `<modules>` section:

1. Open *{APPLICATION ROOT}\.vs\config\applicationhost.config*.
2. Locate the `<section>` element for IIS modules and change `overrideModeDefault` from `Deny` to `Allow`:

   ```
   <section name="modules"
            allowDefinition="MachineToApplication"
            overrideModeDefault="Allow" />
   ```

3. Locate the `<location path="" overrideMode="Allow"><system.webServer><modules>` section. For any modules that you wish to remove, set `lockItem` from `true` to `false`. In the following example, the CGI Module is unlocked:

   ```
   <add name="CgiModule" lockItem="false" />
   ```

4. After the `<modules>` section and individual modules are unlocked, you're free to add or remove IIS modules using the app's *web.config* file for running the app on IIS Express.

An IIS module can also be removed with *Appcmd.exe*. Provide the `MODULE_NAME` and `APPLICATION_NAME` in the command:

```
Appcmd.exe delete module MODULE_NAME /app.name:APPLICATION_NAME
```

For example, remove the `DynamicCompressionModule` from the Default Web Site:

```
%windir%\system32\inetsrv\appcmd.exe delete module DynamicCompressionModule /app.name:"Default Web Site"
```

Minimum module configuration

The only modules required to run an ASP.NET Core app are the Anonymous Authentication Module and the ASP.NET Core Module.

The URI Caching Module (`UriCacheModule`) allows IIS to cache website configuration at the URL level. Without this module, IIS must read and parse configuration on every request, even when the same URL is repeatedly requested. Parsing the configuration every request results in a significant performance penalty. *Although the URI Caching Module isn't strictly required for a hosted ASP.NET Core app to run, we recommend that the URI Caching Module be enabled for all ASP.NET Core deployments.*

The HTTP Caching Module (`HttpCacheModule`) implements the IIS output cache and also the logic for caching items in the HTTP.sys cache. Without this module, content is no longer cached in kernel mode, and cache profiles are ignored. Removing the HTTP Caching Module usually has adverse effects on performance and resource usage. *Although the HTTP Caching Module isn't strictly required for a hosted ASP.NET Core app to run, we recommend that the HTTP Caching Module be enabled for all ASP.NET Core deployments.*

Troubleshoot ASP.NET Core on Azure App Service and IIS

9/22/2020 • 59 minutes to read • Edit Online

By Justin Kotalik

This article provides information on common app startup errors and instructions on how to diagnose errors when an app is deployed to Azure App Service or IIS:

App startup errors
Explains common startup HTTP status code scenarios.

Troubleshoot on Azure App Service
Provides troubleshooting advice for apps deployed to Azure App Service.

Troubleshoot on IIS
Provides troubleshooting advice for apps deployed to IIS or running on IIS Express locally. The guidance applies to both Windows Server and Windows desktop deployments.

Clear package caches
Explains what to do when incoherent packages break an app when performing major upgrades or changing package versions.

Additional resources
Lists additional troubleshooting topics.

App startup errors

In Visual Studio, an ASP.NET Core project defaults to IIS Express hosting during debugging. A *502.5 - Process Failure* or a *500.30 - Start Failure* that occurs when debugging locally can be diagnosed using the advice in this topic.

403.14 Forbidden

The app fails to start. The following error is logged:

```
The Web server is configured to not list the contents of this directory.
```

The error is usually caused by a broken deployment on the hosting system, which includes any of the following scenarios:

- The app is deployed to the wrong folder on the hosting system.
- The deployment process failed to move all of the app's files and folders to the deployment folder on the hosting system.
- The *web.config* file is missing from the deployment, or the *web.config* file contents are malformed.

Perform the following steps:

1. Delete all of the files and folders from the deployment folder on the hosting system.
2. Redeploy the contents of the app's *publish* folder to the hosting system using your normal method of deployment, such as Visual Studio, PowerShell, or manual deployment:

- Confirm that the *web.config* file is present in the deployment and that its contents are correct.
- When hosting on Azure App Service, confirm that the app is deployed to the `D:\home\site\wwwroot` folder.
- When the app is hosted by IIS, confirm that the app is deployed to the IIS **Physical path** shown in **IIS Manager**'s **Basic Settings**.

3. Confirm that all of the app's files and folders are deployed by comparing the deployment on the hosting system to the contents of the project's *publish* folder.

For more information on the layout of a published ASP.NET Core app, see ASP.NET Core directory structure. For more information on the *web.config* file, see ASP.NET Core Module.

500 Internal Server Error

The app starts, but an error prevents the server from fulfilling the request.

This error occurs within the app's code during startup or while creating a response. The response may contain no content, or the response may appear as a *500 Internal Server Error* in the browser. The Application Event Log usually states that the app started normally. From the server's perspective, that's correct. The app did start, but it can't generate a valid response. Run the app at a command prompt on the server or enable the ASP.NET Core Module stdout log to troubleshoot the problem.

500.0 In-Process Handler Load Failure

The worker process fails. The app doesn't start.

An unknown error occurred loading ASP.NET Core Module components. Take one of the following actions:

- Contact Microsoft Support (select **Developer Tools** then **ASP.NET Core**).
- Ask a question on Stack Overflow.
- File an issue on our GitHub repository.

500.30 In-Process Startup Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the .NET Core CLR in-process, but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

Common failure conditions:

- The app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine.
- Using Azure Key Vault, lack of permissions to the Key Vault. Check the access policies in the targeted Key Vault to ensure that the correct permissions are granted.

500.31 ANCM Failed to Find Native Dependencies

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the .NET Core runtime in-process, but it fails to start. The most common cause of this startup failure is when the `Microsoft.NETCore.App` or `Microsoft.AspNetCore.App` runtime isn't installed. If the app is deployed to target ASP.NET Core 3.0 and that version doesn't exist on the machine, this error occurs. An example error message follows:

```
The specified framework 'Microsoft.NETCore.App', version '3.0.0' was not found.
  - The following frameworks were found:
      2.2.1 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview5-27626-15 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27713-13 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27714-15 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27723-08 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
```

The error message lists all the installed .NET Core versions and the version requested by the app. To fix this error, either:

- Install the appropriate version of .NET Core on the machine.
- Change the app to target a version of .NET Core that's present on the machine.
- Publish the app as a self-contained deployment.

When running in development (the `ASPNETCORE_ENVIRONMENT` environment variable is set to `Development`), the specific error is written to the HTTP response. The cause of a process startup failure is also found in the Application Event Log.

500.32 ANCM Failed to Load dll

The worker process fails. The app doesn't start.

The most common cause for this error is that the app is published for an incompatible processor architecture. If the worker process is running as a 32-bit app and the app was published to target 64-bit, this error occurs.

To fix this error, either:

- Republish the app for the same processor architecture as the worker process.
- Publish the app as a framework-dependent deployment.

500.33 ANCM Request Handler Load Failure

The worker process fails. The app doesn't start.

The app didn't reference the `Microsoft.AspNetCore.App` framework. Only apps targeting the `Microsoft.AspNetCore.App` framework can be hosted by the ASP.NET Core Module.

To fix this error, confirm that the app is targeting the `Microsoft.AspNetCore.App` framework. Check the `.runtimeconfig.json` to verify the framework targeted by the app.

500.34 ANCM Mixed Hosting Models Not Supported

The worker process can't run both an in-process app and an out-of-process app in the same process.

To fix this error, run apps in separate IIS application pools.

500.35 ANCM Multiple In-Process Applications in same Process

The worker process can't run multiple in-process apps in the same process.

To fix this error, run apps in separate IIS application pools.

500.36 ANCM Out-Of-Process Handler Load Failure

The out-of-process request handler, *aspnetcorev2_outofprocess.dll*, isn't next to the *aspnetcorev2.dll* file. This indicates a corrupted installation of the ASP.NET Core Module.

To fix this error, repair the installation of the .NET Core Hosting Bundle (for IIS) or Visual Studio (for IIS Express).

500.37 ANCM Failed to Start Within Startup Time Limit

ANCM failed to start within the provided startup time limit. By default, the timeout is 120 seconds.

This error can occur when starting a large number of apps on the same machine. Check for CPU/Memory usage spikes on the server during startup. You may need to stagger the startup process of multiple apps.

500.38 ANCM Application DLL Not Found

ANCM failed to locate the application DLL, which should be next to the executable.

This error occurs when hosting an app packaged as a single-file executable using the in-process hosting model. The in-process model requires that the ANCM load the .NET Core app into the existing IIS process. This scenario isn't supported by the single-file deployment model. Use **one** of the following approaches in the app's project file to fix this error:

1. Disable single-file publishing by setting the `PublishSingleFile` MSBuild property to `false`.
2. Switch to the out-of-process hosting model by setting the `AspNetCoreHostingModel` MSBuild property to `OutOfProcess`.

502.5 Process Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the worker process but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

A common failure condition is the app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and referenced by a metapackage such as `Microsoft.AspNetCore.App`. The metapackage reference can specify a minimum required version. For more information, see The shared framework.

The *502.5 Process Failure* error page is returned when a hosting or app misconfiguration causes the worker process to fail:

Failed to start application (ErrorCode '0x800700c1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/6/ROOT/', ErrorCode '0x800700c1'.
```

The app failed to start because the app's assembly (*.dll*) couldn't be loaded.

This error occurs when there's a bitness mismatch between the published app and the w3wp/iisexpress process.

Confirm that the app pool's 32-bit setting is correct:

1. Select the app pool in IIS Manager's **Application Pools**.
2. Select **Advanced Settings** under **Edit Application Pool** in the **Actions** panel.
3. Set **Enable 32-Bit Applications**:
   - If deploying a 32-bit (x86) app, set the value to `True`.
   - If deploying a 64-bit (x64) app, set the value to `False`.

Confirm that there isn't a conflict between a `<Platform>` MSBuild property in the project file and the published bitness of the app.

Connection reset

If an error occurs after the headers are sent, it's too late for the server to send a **500 Internal Server Error** when an error occurs. This often happens when an error occurs during the serialization of complex objects for a response. This type of error appears as a *connection reset* error on the client. Application logging can help troubleshoot these types of errors.

Default startup limits

The ASP.NET Core Module is configured with a default *startupTimeLimit* of 120 seconds. When left at the default value, an app may take up to two minutes to start before the module logs a process failure. For information on configuring the module, see Attributes of the aspNetCore element.

Troubleshoot on Azure App Service

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

Application Event Log (Azure App Service)

To access the Application Event Log, use the **Diagnose and solve problems** blade in the Azure portal:

1. In the Azure portal, open the app in **App Services**.
2. Select **Diagnose and solve problems**.
3. Select the **Diagnostic Tools** heading.
4. Under **Support Tools**, select the **Application Events** button.
5. Examine the latest error provided by the *IIS AspNetCoreModule* or *IIS AspNetCoreModule V2* entry in the **Source** column.

An alternative to using the **Diagnose and solve problems** blade is to examine the Application Event Log file directly using Kudu:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the **LogFiles** folder.
4. Select the pencil icon next to the *eventlog.xml* file.
5. Examine the log. Scroll to the bottom of the log to see the most recent events.

Run the app in the Kudu console

Many startup errors don't produce useful information in the Application Event Log. You can run the app in the Kudu Remote Execution Console to discover the error:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.

Test a 32-bit (x86) app

Current release

1. `cd d:\home\site\wwwroot`
2. Run the app:

- If the app is a framework-dependent deployment:

```
dotnet .\{ASSEMBLY NAME}.dll
```

- If the app is a self-contained deployment:

```
{ASSEMBLY NAME}.exe
```

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x86) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x32` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

Test a 64-bit (x64) app

Current release

- If the app is a 64-bit (x64) framework-dependent deployment:
  1. `cd D:\Program Files\dotnet`
  2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`
- If the app is a self-contained deployment:
  1. `cd D:\home\site\wwwroot`
  2. Run the app: `{ASSEMBLY NAME}.exe`

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x64) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x64` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

ASP.NET Core Module stdout log (Azure App Service)

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created. Only use stdout logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

The ASP.NET Core Module stdout log often records useful error messages not found in the Application Event Log. To enable and view stdout logs:

1. In the Azure Portal, navigate to the web app.
2. In the **App Service** blade, enter **kudu** in the search box.
3. Select **Advanced Tools** > **Go**.

4. Select **Debug console** > **CMD**.
5. Navigate to *site/wwwroot*
6. Select the pencil icon to edit the *web.config* file.
7. In the `<aspNetCore />` element, set `stdoutLogEnabled="true"` and select **Save**.

Disable stdout logging when troubleshooting is complete by setting `stdoutLogEnabled="false"`.

For more information, see ASP.NET Core Module.

ASP.NET Core Module debug log (Azure App Service)

The ASP.NET Core Module debug log provides additional, deeper logging from the ASP.NET Core Module. To enable and view stdout logs:

1. To enable the enhanced diagnostic log, perform either of the following:
   - Follow the instructions in Enhanced diagnostic logs to configure the app for an enhanced diagnostic logging. Redeploy the app.
   - Add the `<handlerSettings>` shown in Enhanced diagnostic logs to the live app's *web.config* file using the Kudu console:
     a. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
     b. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
     c. Open the folders to the path **site** > **wwwroot**. Edit the *web.config* file by selecting the pencil button. Add the `<handlerSettings>` section as shown in Enhanced diagnostic logs. Select the **Save** button.
2. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
3. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
4. Open the folders to the path **site** > **wwwroot**. If you didn't supply a path for the *aspnetcore-debug.log* file, the file appears in the list. If you supplied a path, navigate to the location of the log file.
5. Open the log file with the pencil button next to the file name.

Disable debug logging when troubleshooting is complete:

To disable the enhanced debug log, perform either of the following:

- Remove the `<handlerSettings>` from the *web.config* file locally and redeploy the app.
- Use the Kudu console to edit the *web.config* file and remove the `<handlerSettings>` section. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
> Failure to disable the debug log can lead to app or server failure. There's no limit on log file size. Only use debug logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Slow or hanging app (Azure App Service)

When an app responds slowly or hangs on a request, see the following articles:

- Troubleshoot slow web app performance issues in Azure App Service
- Use Crash Diagnoser Site Extension to Capture Dump for Intermittent Exception issues or performance issues on Azure Web App

Monitoring blades

Monitoring blades provide an alternative troubleshooting experience to the methods described earlier in the topic. These blades can be used to diagnose 500-series errors.

Confirm that the ASP.NET Core Extensions are installed. If the extensions aren't installed, install them manually:

1. In the **DEVELOPMENT TOOLS** blade section, select the **Extensions** blade.
2. The **ASP.NET Core Extensions** should appear in the list.
3. If the extensions aren't installed, select the **Add** button.
4. Choose the **ASP.NET Core Extensions** from the list.
5. Select **OK** to accept the legal terms.
6. Select **OK** on the **Add extension** blade.
7. An informational pop-up message indicates when the extensions are successfully installed.

If stdout logging isn't enabled, follow these steps:

1. In the Azure portal, select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the folders to the path **site** > **wwwroot** and scroll down to reveal the *web.config* file at the bottom of the list.
4. Click the pencil icon next to the *web.config* file.
5. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
6. Select **Save** to save the updated *web.config* file.

Proceed to activate diagnostic logging:

1. In the Azure portal, select the **Diagnostics logs** blade.
2. Select the **On** switch for **Application Logging (Filesystem)** and **Detailed error messages**. Select the **Save** button at the top of the blade.
3. To include failed request tracing, also known as Failed Request Event Buffering (FREB) logging, select the **On** switch for **Failed request tracing**.
4. Select the **Log stream** blade, which is listed immediately under the **Diagnostics logs** blade in the portal.
5. Make a request to the app.
6. Within the log stream data, the cause of the error is indicated.

Be sure to disable stdout logging when troubleshooting is complete.

To view the failed request tracing logs (FREB logs):

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Select **Failed Request Tracing Logs** from the **SUPPORT TOOLS** area of the sidebar.

See Failed request traces section of the Enable diagnostics logging for web apps in Azure App Service topic and the Application performance FAQs for Web Apps in Azure: How do I turn on failed request tracing? for more information.

For more information, see Enable diagnostics logging for web apps in Azure App Service.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Troubleshoot on IIS

Application Event Log (IIS)

Access the Application Event Log:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.
2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app. Errors have a value of *IIS AspNetCore Module* or *IIS Express AspNetCore Module* in the *Source* column.

Run the app at a command prompt

Many startup errors don't produce useful information in the Application Event Log. You can find the cause of some errors by running the app at a command prompt on the hosting system.

Framework-dependent deployment

If the app is a framework-dependent deployment:

1. At a command prompt, navigate to the deployment folder and run the app by executing the app's assembly with *dotnet.exe*. In the following command, substitute the name of the app's assembly for <assembly_name>: `dotnet .\<assembly_name>.dll`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

Self-contained deployment

If the app is a self-contained deployment:

1. At a command prompt, navigate to the deployment folder and run the app's executable. In the following command, substitute the name of the app's assembly for <assembly_name>: `<assembly_name>.exe`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

ASP.NET Core Module stdout log (IIS)

To enable and view stdout logs:

1. Navigate to the site's deployment folder on the hosting system.
2. If the *logs* folder isn't present, create the folder. For instructions on how to enable MSBuild to

create the *logs* folder in the deployment automatically, see the Directory structure topic.

3. Edit the *web.config* file. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to point to the *logs* folder (for example, `.\logs\stdout`). `stdout` in the path is the log file name prefix. A timestamp, process id, and file extension are added automatically when the log is created. Using `stdout` as the file name prefix, a typical log file is named *stdout_20180205184032_5412.log*.
4. Ensure your application pool's identity has write permissions to the *logs* folder.
5. Save the updated *web.config* file.
6. Make a request to the app.
7. Navigate to the *logs* folder. Find and open the most recent stdout log.
8. Study the log for errors.

Disable stdout logging when troubleshooting is complete:

1. Edit the *web.config* file.
2. Set **stdoutLogEnabled** to `false`.
3. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

ASP.NET Core Module debug log (IIS)

Add the following handler settings to the app's *web.config* file to enable ASP.NET Core Module debug log:

```
<aspNetCore ...>
  <handlerSettings>
    <handlerSetting name="debugLevel" value="file" />
    <handlerSetting name="debugFile" value="c:\temp\ancm.log" />
  </handlerSettings>
</aspNetCore>
```

Confirm that the path specified for the log exists and that the app pool's identity has write permissions to the location.

For more information, see ASP.NET Core Module.

Enable the Developer Exception Page

The `ASPNETCORE_ENVIRONMENT` environment variable can be added to web.config to run the app in the Development environment. As long as the environment isn't overridden in app startup by `UseEnvironment` on the host builder, setting the environment variable allows the Developer Exception Page to appear when the app is run.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout"
      hostingModel="InProcess">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
  </environmentVariables>
</aspNetCore>
```

Setting the environment variable for `ASPNETCORE_ENVIRONMENT` is only recommended for use on staging and testing servers that aren't exposed to the Internet. Remove the environment variable from the *web.config* file after troubleshooting. For information on setting environment variables in *web.config*, see environmentVariables child element of aspNetCore.

Obtain data from an app

If an app is capable of responding to requests, obtain request, connection, and additional data from the app using terminal inline middleware. For more information and sample code, see Troubleshoot and debug ASP.NET Core projects.

Slow or hanging app (IIS)

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`. The app pool must have write access to the folder.
2. Run the EnableDumps PowerShell script:
   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\EnableDumps w3wp.exe c:\dumps
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\EnableDumps dotnet.exe c:\dumps
     ```

3. Run the app under the conditions that cause the crash to occur.
4. After the crash has occurred, run the DisableDumps PowerShell script:
   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\DisableDumps w3wp.exe
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\DisableDumps dotnet.exe
     ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> **WARNING**
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App hangs, fails during startup, or runs normally

When an app *hangs* (stops responding but doesn't crash), fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.
2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

This article provides information on common app startup errors and instructions on how to diagnose errors when an app is deployed to Azure App Service or IIS:

App startup errors
Explains common startup HTTP status code scenarios.

Troubleshoot on Azure App Service
Provides troubleshooting advice for apps deployed to Azure App Service.

Troubleshoot on IIS
Provides troubleshooting advice for apps deployed to IIS or running on IIS Express locally. The guidance applies to both Windows Server and Windows desktop deployments.

Clear package caches
Explains what to do when incoherent packages break an app when performing major upgrades or changing package versions.

Additional resources
Lists additional troubleshooting topics.

App startup errors

In Visual Studio, an ASP.NET Core project defaults to IIS Express hosting during debugging. A *502.5 - Process Failure* or a *500.30 - Start Failure* that occurs when debugging locally can be diagnosed using the advice in this topic.

403.14 Forbidden

The app fails to start. The following error is logged:

```
The Web server is configured to not list the contents of this directory.
```

The error is usually caused by a broken deployment on the hosting system, which includes any of the following scenarios:

- The app is deployed to the wrong folder on the hosting system.
- The deployment process failed to move all of the app's files and folders to the deployment folder on the hosting system.
- The *web.config* file is missing from the deployment, or the *web.config* file contents are malformed.

Perform the following steps:

1. Delete all of the files and folders from the deployment folder on the hosting system.
2. Redeploy the contents of the app's *publish* folder to the hosting system using your normal method of deployment, such as Visual Studio, PowerShell, or manual deployment:
   - Confirm that the *web.config* file is present in the deployment and that its contents are correct.
   - When hosting on Azure App Service, confirm that the app is deployed to the `D:\home\site\wwwroot` folder.

- When the app is hosted by IIS, confirm that the app is deployed to the IIS **Physical path** shown in **IIS Manager**'s **Basic Settings**.

3. Confirm that all of the app's files and folders are deployed by comparing the deployment on the hosting system to the contents of the project's *publish* folder.

For more information on the layout of a published ASP.NET Core app, see ASP.NET Core directory structure. For more information on the *web.config* file, see ASP.NET Core Module.

500 Internal Server Error

The app starts, but an error prevents the server from fulfilling the request.

This error occurs within the app's code during startup or while creating a response. The response may contain no content, or the response may appear as a *500 Internal Server Error* in the browser. The Application Event Log usually states that the app started normally. From the server's perspective, that's correct. The app did start, but it can't generate a valid response. Run the app at a command prompt on the server or enable the ASP.NET Core Module stdout log to troubleshoot the problem.

500.0 In-Process Handler Load Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module fails to find the .NET Core CLR and find the in-process request handler (*aspnetcorev2_inprocess.dll*). Check that:

- The app targets either the Microsoft.AspNetCore.Server.IIS NuGet package or the Microsoft.AspNetCore.App metapackage.
- The version of the ASP.NET Core shared framework that the app targets is installed on the target machine.

500.0 Out-Of-Process Handler Load Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module fails to find the out-of-process hosting request handler. Make sure the *aspnetcorev2_outofprocess.dll* is present in a subfolder next to *aspnetcorev2.dll*.

502.5 Process Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the worker process but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

A common failure condition is the app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and referenced by a metapackage such as `Microsoft.AspNetCore.App`. The metapackage reference can specify a minimum required version. For more information, see The shared framework.

The *502.5 Process Failure* error page is returned when a hosting or app misconfiguration causes the worker process to fail:

Failed to start application (ErrorCode '0x800700c1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/6/ROOT/', ErrorCode '0x800700c1'.
```

The app failed to start because the app's assembly (*.dll*) couldn't be loaded.

This error occurs when there's a bitness mismatch between the published app and the w3wp/iisexpress process.

Confirm that the app pool's 32-bit setting is correct:

1. Select the app pool in IIS Manager's **Application Pools**.
2. Select **Advanced Settings** under **Edit Application Pool** in the **Actions** panel.
3. Set **Enable 32-Bit Applications**:
   - If deploying a 32-bit (x86) app, set the value to `True`.
   - If deploying a 64-bit (x64) app, set the value to `False`.

Confirm that there isn't a conflict between a `<Platform>` MSBuild property in the project file and the published bitness of the app.

Connection reset

If an error occurs after the headers are sent, it's too late for the server to send a **500 Internal Server Error** when an error occurs. This often happens when an error occurs during the serialization of complex objects for a response. This type of error appears as a *connection reset* error on the client. Application logging can help troubleshoot these types of errors.

Default startup limits

The ASP.NET Core Module is configured with a default *startupTimeLimit* of 120 seconds. When left at the default value, an app may take up to two minutes to start before the module logs a process failure. For information on configuring the module, see Attributes of the aspNetCore element.

Troubleshoot on Azure App Service

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

Application Event Log (Azure App Service)

To access the Application Event Log, use the **Diagnose and solve problems** blade in the Azure portal:

1. In the Azure portal, open the app in **App Services**.
2. Select **Diagnose and solve problems**.
3. Select the **Diagnostic Tools** heading.
4. Under **Support Tools**, select the **Application Events** button.
5. Examine the latest error provided by the *IIS AspNetCoreModule* or *IIS AspNetCoreModule V2* entry in the **Source** column.

An alternative to using the **Diagnose and solve problems** blade is to examine the Application Event Log file directly using Kudu:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the **LogFiles** folder.

4. Select the pencil icon next to the *eventlog.xml* file.
5. Examine the log. Scroll to the bottom of the log to see the most recent events.

Run the app in the Kudu console

Many startup errors don't produce useful information in the Application Event Log. You can run the app in the Kudu Remote Execution Console to discover the error:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go →** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.

Test a 32-bit (x86) app

Current release

1. `cd d:\home\site\wwwroot`
2. Run the app:
   - If the app is a framework-dependent deployment:

     ```
     dotnet .\{ASSEMBLY NAME}.dll
     ```

   - If the app is a self-contained deployment:

     ```
     {ASSEMBLY NAME}.exe
     ```

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x86) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x32` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

Test a 64-bit (x64) app

Current release

- If the app is a 64-bit (x64) framework-dependent deployment:
  1. `cd D:\Program Files\dotnet`
  2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`
- If the app is a self-contained deployment:
  1. `cd D:\home\site\wwwroot`
  2. Run the app: `{ASSEMBLY NAME}.exe`

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x64) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x64` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

ASP.NET Core Module stdout log (Azure App Service)

The ASP.NET Core Module stdout log often records useful error messages not found in the Application Event Log. To enable and view stdout logs:

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Under **SELECT PROBLEM CATEGORY**, select the **Web App Down** button.
3. Under **Suggested Solutions** > **Enable Stdout Log Redirection**, select the button to **Open Kudu Console to edit Web.Config**.
4. In the Kudu **Diagnostic Console**, open the folders to the path **site** > **wwwroot**. Scroll down to reveal the *web.config* file at the bottom of the list.
5. Click the pencil icon next to the *web.config* file.
6. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
7. Select **Save** to save the updated *web.config* file.
8. Make a request to the app.
9. Return to the Azure portal. Select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
10. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
11. Select the **LogFiles** folder.
12. Inspect the **Modified** column and select the pencil icon to edit the stdout log with the latest modification date.
13. When the log file opens, the error is displayed.

Disable stdout logging when troubleshooting is complete:

1. In the Kudu **Diagnostic Console**, return to the path **site** > **wwwroot** to reveal the *web.config* file. Open the **web.config** file again by selecting the pencil icon.
2. Set **stdoutLogEnabled** to `false`.
3. Select **Save** to save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created. Only use stdout logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

ASP.NET Core Module debug log (Azure App Service)

The ASP.NET Core Module debug log provides additional, deeper logging from the ASP.NET Core Module. To enable and view stdout logs:

1. To enable the enhanced diagnostic log, perform either of the following:
   - Follow the instructions in Enhanced diagnostic logs to configure the app for an enhanced diagnostic logging. Redeploy the app.
   - Add the `<handlerSettings>` shown in Enhanced diagnostic logs to the live app's *web.config* file using the Kudu console:
     a. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
     b. Using the navigation bar at the top of the page, open **Debug console** and select

CMD.

c. Open the folders to the path **site** > **wwwroot**. Edit the *web.config* file by selecting the pencil button. Add the `<handlerSettings>` section as shown in Enhanced diagnostic logs. Select the **Save** button.

2. Open **Advanced Tools** in the **Development Tools** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
3. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
4. Open the folders to the path **site** > **wwwroot**. If you didn't supply a path for the *aspnetcore-debug.log* file, the file appears in the list. If you supplied a path, navigate to the location of the log file.
5. Open the log file with the pencil button next to the file name.

Disable debug logging when troubleshooting is complete:

To disable the enhanced debug log, perform either of the following:

- Remove the `<handlerSettings>` from the *web.config* file locally and redeploy the app.
- Use the Kudu console to edit the *web.config* file and remove the `<handlerSettings>` section. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
> Failure to disable the debug log can lead to app or server failure. There's no limit on log file size. Only use debug logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Slow or hanging app (Azure App Service)

When an app responds slowly or hangs on a request, see the following articles:

- Troubleshoot slow web app performance issues in Azure App Service
- Use Crash Diagnoser Site Extension to Capture Dump for Intermittent Exception issues or performance issues on Azure Web App

Monitoring blades

Monitoring blades provide an alternative troubleshooting experience to the methods described earlier in the topic. These blades can be used to diagnose 500-series errors.

Confirm that the ASP.NET Core Extensions are installed. If the extensions aren't installed, install them manually:

1. In the **DEVELOPMENT TOOLS** blade section, select the **Extensions** blade.
2. The **ASP.NET Core Extensions** should appear in the list.
3. If the extensions aren't installed, select the **Add** button.
4. Choose the **ASP.NET Core Extensions** from the list.
5. Select **OK** to accept the legal terms.
6. Select **OK** on the **Add extension** blade.
7. An informational pop-up message indicates when the extensions are successfully installed.

If stdout logging isn't enabled, follow these steps:

1. In the Azure portal, select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select

the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the folders to the path **site** > **wwwroot** and scroll down to reveal the *web.config* file at the bottom of the list.
4. Click the pencil icon next to the *web.config* file.
5. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
6. Select **Save** to save the updated *web.config* file.

Proceed to activate diagnostic logging:

1. In the Azure portal, select the **Diagnostics logs** blade.
2. Select the **On** switch for **Application Logging (Filesystem)** and **Detailed error messages**. Select the **Save** button at the top of the blade.
3. To include failed request tracing, also known as Failed Request Event Buffering (FREB) logging, select the **On** switch for **Failed request tracing**.
4. Select the **Log stream** blade, which is listed immediately under the **Diagnostics logs** blade in the portal.
5. Make a request to the app.
6. Within the log stream data, the cause of the error is indicated.

Be sure to disable stdout logging when troubleshooting is complete.

To view the failed request tracing logs (FREB logs):

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Select **Failed Request Tracing Logs** from the **SUPPORT TOOLS** area of the sidebar.

See Failed request traces section of the Enable diagnostics logging for web apps in Azure App Service topic and the Application performance FAQs for Web Apps in Azure: How do I turn on failed request tracing? for more information.

For more information, see Enable diagnostics logging for web apps in Azure App Service.

> **WARNING**
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Troubleshoot on IIS

Application Event Log (IIS)

Access the Application Event Log:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.
2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app. Errors have a value of *IIS AspNetCore Module* or *IIS Express AspNetCore Module* in the *Source* column.

Run the app at a command prompt

Many startup errors don't produce useful information in the Application Event Log. You can find the cause of some errors by running the app at a command prompt on the hosting system.

Framework-dependent deployment

If the app is a framework-dependent deployment:

1. At a command prompt, navigate to the deployment folder and run the app by executing the app's assembly with *dotnet.exe*. In the following command, substitute the name of the app's assembly for <assembly_name>: `dotnet .\<assembly_name>.dll`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

Self-contained deployment

If the app is a self-contained deployment:

1. At a command prompt, navigate to the deployment folder and run the app's executable. In the following command, substitute the name of the app's assembly for <assembly_name>: `<assembly_name>.exe`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

ASP.NET Core Module stdout log (IIS)

To enable and view stdout logs:

1. Navigate to the site's deployment folder on the hosting system.
2. If the *logs* folder isn't present, create the folder. For instructions on how to enable MSBuild to create the *logs* folder in the deployment automatically, see the Directory structure topic.
3. Edit the *web.config* file. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to point to the *logs* folder (for example, `.\logs\stdout`). `stdout` in the path is the log file name prefix. A timestamp, process id, and file extension are added automatically when the log is created. Using `stdout` as the file name prefix, a typical log file is named *stdout_20180205184032_5412.log*.
4. Ensure your application pool's identity has write permissions to the *logs* folder.
5. Save the updated *web.config* file.
6. Make a request to the app.
7. Navigate to the *logs* folder. Find and open the most recent stdout log.
8. Study the log for errors.

Disable stdout logging when troubleshooting is complete:

1. Edit the *web.config* file.
2. Set **stdoutLogEnabled** to `false`.
3. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

ASP.NET Core Module debug log (IIS)

Add the following handler settings to the app's *web.config* file to enable ASP.NET Core Module debug log:

```
<aspNetCore ...>
  <handlerSettings>
    <handlerSetting name="debugLevel" value="file" />
    <handlerSetting name="debugFile" value="c:\temp\ancm.log" />
  </handlerSettings>
</aspNetCore>
```

Confirm that the path specified for the log exists and that the app pool's identity has write permissions to the location.

For more information, see ASP.NET Core Module.

Enable the Developer Exception Page

The `ASPNETCORE_ENVIRONMENT` environment variable can be added to web.config to run the app in the Development environment. As long as the environment isn't overridden in app startup by `UseEnvironment` on the host builder, setting the environment variable allows the Developer Exception Page to appear when the app is run.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout"
      hostingModel="InProcess">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
  </environmentVariables>
</aspNetCore>
```

Setting the environment variable for `ASPNETCORE_ENVIRONMENT` is only recommended for use on staging and testing servers that aren't exposed to the Internet. Remove the environment variable from the *web.config* file after troubleshooting. For information on setting environment variables in *web.config*, see environmentVariables child element of aspNetCore.

Obtain data from an app

If an app is capable of responding to requests, obtain request, connection, and additional data from the app using terminal inline middleware. For more information and sample code, see Troubleshoot and debug ASP.NET Core projects.

Slow or hanging app (IIS)

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`. The app pool must have write access to the folder.
2. Run the EnableDumps PowerShell script:
   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\EnableDumps w3wp.exe c:\dumps
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\EnableDumps dotnet.exe c:\dumps
     ```

3. Run the app under the conditions that cause the crash to occur.
4. After the crash has occurred, run the DisableDumps PowerShell script:
   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\DisableDumps w3wp.exe
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\DisableDumps dotnet.exe
     ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> **WARNING**
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App hangs, fails during startup, or runs normally

When an app *hangs* (stops responding but doesn't crash), fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.
2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.

3. Restore and rebuild the project.

4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

This article provides information on common app startup errors and instructions on how to diagnose errors when an app is deployed to Azure App Service or IIS:

App startup errors
Explains common startup HTTP status code scenarios.

Troubleshoot on Azure App Service
Provides troubleshooting advice for apps deployed to Azure App Service.

Troubleshoot on IIS
Provides troubleshooting advice for apps deployed to IIS or running on IIS Express locally. The guidance applies to both Windows Server and Windows desktop deployments.

Clear package caches
Explains what to do when incoherent packages break an app when performing major upgrades or changing package versions.

Additional resources
Lists additional troubleshooting topics.

App startup errors

In Visual Studio, an ASP.NET Core project defaults to IIS Express hosting during debugging. A *502.5 Process Failure* that occurs when debugging locally can be diagnosed using the advice in this topic.

403.14 Forbidden

The app fails to start. The following error is logged:

```
The Web server is configured to not list the contents of this directory.
```

The error is usually caused by a broken deployment on the hosting system, which includes any of the following scenarios:

- The app is deployed to the wrong folder on the hosting system.
- The deployment process failed to move all of the app's files and folders to the deployment folder on the hosting system.
- The *web.config* file is missing from the deployment, or the *web.config* file contents are malformed.

Perform the following steps:

1. Delete all of the files and folders from the deployment folder on the hosting system.
2. Redeploy the contents of the app's *publish* folder to the hosting system using your normal method of deployment, such as Visual Studio, PowerShell, or manual deployment:
   - Confirm that the *web.config* file is present in the deployment and that its contents are correct.
   - When hosting on Azure App Service, confirm that the app is deployed to the `D:\home\site\wwwroot` folder.
   - When the app is hosted by IIS, confirm that the app is deployed to the IIS **Physical path** shown in **IIS Manager**'s **Basic Settings**.
3. Confirm that all of the app's files and folders are deployed by comparing the deployment on the hosting system to the contents of the project's *publish* folder.

For more information on the layout of a published ASP.NET Core app, see ASP.NET Core directory structure. For more information on the *web.config* file, see ASP.NET Core Module.

500 Internal Server Error

The app starts, but an error prevents the server from fulfilling the request.

This error occurs within the app's code during startup or while creating a response. The response may contain no content, or the response may appear as a *500 Internal Server Error* in the browser. The Application Event Log usually states that the app started normally. From the server's perspective, that's correct. The app did start, but it can't generate a valid response. Run the app at a command prompt on the server or enable the ASP.NET Core Module stdout log to troubleshoot the problem.

502.5 Process Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the worker process but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

A common failure condition is the app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and referenced by a metapackage such as

`Microsoft.AspNetCore.App`. The metapackage reference can specify a minimum required version. For more information, see The shared framework.

The *502.5 Process Failure* error page is returned when a hosting or app misconfiguration causes the worker process to fail:

Failed to start application (ErrorCode '0x800700c1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/6/ROOT/', ErrorCode '0x800700c1'.
```

The app failed to start because the app's assembly (*.dll*) couldn't be loaded.

This error occurs when there's a bitness mismatch between the published app and the w3wp/iisexpress process.

Confirm that the app pool's 32-bit setting is correct:

1. Select the app pool in IIS Manager's **Application Pools**.
2. Select **Advanced Settings** under **Edit Application Pool** in the **Actions** panel.
3. Set **Enable 32-Bit Applications**:
   - If deploying a 32-bit (x86) app, set the value to `True`.
   - If deploying a 64-bit (x64) app, set the value to `False`.

Confirm that there isn't a conflict between a `<Platform>` MSBuild property in the project file and the published bitness of the app.

Connection reset

If an error occurs after the headers are sent, it's too late for the server to send a **500 Internal Server Error** when an error occurs. This often happens when an error occurs during the serialization of complex objects for a response. This type of error appears as a *connection reset* error on the client. Application logging can help troubleshoot these types of errors.

Default startup limits

The ASP.NET Core Module is configured with a default *startupTimeLimit* of 120 seconds. When left at the default value, an app may take up to two minutes to start before the module logs a process failure. For information on configuring the module, see Attributes of the aspNetCore element.

Troubleshoot on Azure App Service

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

Application Event Log (Azure App Service)

To access the Application Event Log, use the **Diagnose and solve problems** blade in the Azure portal:

1. In the Azure portal, open the app in **App Services**.
2. Select **Diagnose and solve problems**.
3. Select the **Diagnostic Tools** heading.

4. Under **Support Tools**, select the **Application Events** button.
5. Examine the latest error provided by the *IIS AspNetCoreModule* or *IIS AspNetCoreModule V2* entry in the **Source** column.

An alternative to using the **Diagnose and solve problems** blade is to examine the Application Event Log file directly using Kudu:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go →** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the **LogFiles** folder.
4. Select the pencil icon next to the *eventlog.xml* file.
5. Examine the log. Scroll to the bottom of the log to see the most recent events.

Run the app in the Kudu console

Many startup errors don't produce useful information in the Application Event Log. You can run the app in the Kudu Remote Execution Console to discover the error:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go →** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.

Test a 32-bit (x86) app

Current release

1. `cd d:\home\site\wwwroot`
2. Run the app:
   - If the app is a framework-dependent deployment:

     ```
     dotnet .\{ASSEMBLY NAME}.dll
     ```

   - If the app is a self-contained deployment:

     ```
     {ASSEMBLY NAME}.exe
     ```

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x86) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x32` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

Test a 64-bit (x64) app

Current release

- If the app is a 64-bit (x64) framework-dependent deployment:
  1. `cd D:\Program Files\dotnet`
  2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`
- If the app is a self-contained deployment:
  1. `cd D:\home\site\wwwroot`

2. Run the app: `{ASSEMBLY NAME}.exe`

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x64) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x64` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

ASP.NET Core Module stdout log (Azure App Service)

The ASP.NET Core Module stdout log often records useful error messages not found in the Application Event Log. To enable and view stdout logs:

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Under **SELECT PROBLEM CATEGORY**, select the **Web App Down** button.
3. Under **Suggested Solutions** > **Enable Stdout Log Redirection**, select the button to **Open Kudu Console to edit Web.Config**.
4. In the Kudu **Diagnostic Console**, open the folders to the path **site** > **wwwroot**. Scroll down to reveal the *web.config* file at the bottom of the list.
5. Click the pencil icon next to the *web.config* file.
6. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
7. Select **Save** to save the updated *web.config* file.
8. Make a request to the app.
9. Return to the Azure portal. Select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
10. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
11. Select the **LogFiles** folder.
12. Inspect the **Modified** column and select the pencil icon to edit the stdout log with the latest modification date.
13. When the log file opens, the error is displayed.

Disable stdout logging when troubleshooting is complete:

1. In the Kudu **Diagnostic Console**, return to the path **site** > **wwwroot** to reveal the *web.config* file. Open the **web.config** file again by selecting the pencil icon.
2. Set **stdoutLogEnabled** to `false`.
3. Select **Save** to save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created. Only use stdout logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Slow or hanging app (Azure App Service)

When an app responds slowly or hangs on a request, see the following articles:

- Troubleshoot slow web app performance issues in Azure App Service
- Use Crash Diagnoser Site Extension to Capture Dump for Intermittent Exception issues or performance issues on Azure Web App

Monitoring blades

Monitoring blades provide an alternative troubleshooting experience to the methods described earlier in the topic. These blades can be used to diagnose 500-series errors.

Confirm that the ASP.NET Core Extensions are installed. If the extensions aren't installed, install them manually:

1. In the **DEVELOPMENT TOOLS** blade section, select the **Extensions** blade.
2. The **ASP.NET Core Extensions** should appear in the list.
3. If the extensions aren't installed, select the **Add** button.
4. Choose the **ASP.NET Core Extensions** from the list.
5. Select **OK** to accept the legal terms.
6. Select **OK** on the **Add extension** blade.
7. An informational pop-up message indicates when the extensions are successfully installed.

If stdout logging isn't enabled, follow these steps:

1. In the Azure portal, select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go→** button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the folders to the path **site** > **wwwroot** and scroll down to reveal the *web.config* file at the bottom of the list.
4. Click the pencil icon next to the *web.config* file.
5. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
6. Select **Save** to save the updated *web.config* file.

Proceed to activate diagnostic logging:

1. In the Azure portal, select the **Diagnostics logs** blade.
2. Select the **On** switch for **Application Logging (Filesystem)** and **Detailed error messages**. Select the **Save** button at the top of the blade.
3. To include failed request tracing, also known as Failed Request Event Buffering (FREB) logging, select the **On** switch for **Failed request tracing**.
4. Select the **Log stream** blade, which is listed immediately under the **Diagnostics logs** blade in the portal.
5. Make a request to the app.
6. Within the log stream data, the cause of the error is indicated.

Be sure to disable stdout logging when troubleshooting is complete.

To view the failed request tracing logs (FREB logs):

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Select **Failed Request Tracing Logs** from the **SUPPORT TOOLS** area of the sidebar.

See Failed request traces section of the Enable diagnostics logging for web apps in Azure App Service topic and the Application performance FAQs for Web Apps in Azure: How do I turn on failed

request tracing? for more information.

For more information, see Enable diagnostics logging for web apps in Azure App Service.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Troubleshoot on IIS

Application Event Log (IIS)

Access the Application Event Log:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.
2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app. Errors have a value of *IIS AspNetCore Module* or *IIS Express AspNetCore Module* in the *Source* column.

Run the app at a command prompt

Many startup errors don't produce useful information in the Application Event Log. You can find the cause of some errors by running the app at a command prompt on the hosting system.

Framework-dependent deployment

If the app is a framework-dependent deployment:

1. At a command prompt, navigate to the deployment folder and run the app by executing the app's assembly with *dotnet.exe*. In the following command, substitute the name of the app's assembly for <assembly_name>: `dotnet .\<assembly_name>.dll`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

Self-contained deployment

If the app is a self-contained deployment:

1. At a command prompt, navigate to the deployment folder and run the app's executable. In the following command, substitute the name of the app's assembly for <assembly_name>: `<assembly_name>.exe`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

ASP.NET Core Module stdout log (IIS)

To enable and view stdout logs:

1. Navigate to the site's deployment folder on the hosting system.

2. If the *logs* folder isn't present, create the folder. For instructions on how to enable MSBuild to create the *logs* folder in the deployment automatically, see the Directory structure topic.
3. Edit the *web.config* file. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to point to the *logs* folder (for example, `.\logs\stdout`). `stdout` in the path is the log file name prefix. A timestamp, process id, and file extension are added automatically when the log is created. Using `stdout` as the file name prefix, a typical log file is named *stdout_20180205184032_5412.log*.
4. Ensure your application pool's identity has write permissions to the *logs* folder.
5. Save the updated *web.config* file.
6. Make a request to the app.
7. Navigate to the *logs* folder. Find and open the most recent stdout log.
8. Study the log for errors.

Disable stdout logging when troubleshooting is complete:

1. Edit the *web.config* file.
2. Set **stdoutLogEnabled** to `false`.
3. Save the file.

For more information, see ASP.NET Core Module.

> **WARNING**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Enable the Developer Exception Page

The `ASPNETCORE_ENVIRONMENT` environment variable can be added to web.config to run the app in the Development environment. As long as the environment isn't overridden in app startup by `UseEnvironment` on the host builder, setting the environment variable allows the Developer Exception Page to appear when the app is run.

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development" />
  </environmentVariables>
</aspNetCore>
```

Setting the environment variable for `ASPNETCORE_ENVIRONMENT` is only recommended for use on staging and testing servers that aren't exposed to the Internet. Remove the environment variable from the *web.config* file after troubleshooting. For information on setting environment variables in *web.config*, see environmentVariables child element of aspNetCore.

Obtain data from an app

If an app is capable of responding to requests, obtain request, connection, and additional data from the app using terminal inline middleware. For more information and sample code, see Troubleshoot and debug ASP.NET Core projects.

Slow or hanging app (IIS)

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`. The app pool must have write access to the folder.
2. Run the EnableDumps PowerShell script:
   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\EnableDumps w3wp.exe c:\dumps
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\EnableDumps dotnet.exe c:\dumps
     ```

3. Run the app under the conditions that cause the crash to occur.
4. After the crash has occurred, run the DisableDumps PowerShell script:
   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     .\DisableDumps w3wp.exe
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     .\DisableDumps dotnet.exe
     ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> **WARNING**
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App hangs, fails during startup, or runs normally

When an app *hangs* (stops responding but doesn't crash), fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.
2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

Common errors reference for Azure App Service and IIS with ASP.NET Core

9/22/2020 • 22 minutes to read • Edit Online

This topic describes common errors and provides troubleshooting advice for specific errors when hosting ASP.NET Core apps on Azure Apps Service and IIS.

For general troubleshooting guidance, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

Collect the following information:

- Browser behavior (status code and error message)
- Application Event Log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS
    1. Select **Start** on the **Windows** menu, type *Event Viewer*, and press **Enter**.
    2. After the **Event Viewer** opens, expand **Windows Logs** > **Application** in the sidebar.
- ASP.NET Core Module stdout and debug log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS: Follow the instructions in the Log creation and redirection and Enhanced diagnostic logs sections of the ASP.NET Core Module topic.

Compare error information to the following common errors. If a match is found, follow the troubleshooting advice.

The list of errors in this topic isn't exhaustive. If you encounter an error not listed here, open a new issue using the **Content feedback** button at the bottom of this topic with detailed instructions on how to reproduce the error.

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

OS upgrade removed the 32-bit ASP.NET Core Module

Application Log: The Module DLL **C:\WINDOWS\system32\inetsrv\aspnetcore.dll** failed to load. The data is the error.

Troubleshooting:

Non-OS files in the **C:\Windows\SysWOW64\inetsrv** directory aren't preserved during an OS upgrade. If the ASP.NET Core Module is installed prior to an OS upgrade and then any app pool is run in 32-bit mode after an OS upgrade, this issue is encountered. After an OS upgrade, repair the ASP.NET Core Module. See Install the .NET Core Hosting bundle. Select **Repair** when the installer is run.

Missing site extension, 32-bit (x86) and 64-bit (x64) site extensions

installed, or wrong process bitness set

Applies to apps hosted by Azure App Services.

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found. Failed to start application '/LM/W3SVC/1416782824/ROOT', ErrorCode '0x8000ffff'.
- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.
- **ASP.NET Core Module Debug Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Failed HRESULT returned: 0x8000ffff. Could not find inprocess request handler. It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.

Troubleshooting:

- If running the app on a preview runtime, install either the 32-bit (x86) **or** 64-bit (x64) site extension that matches the bitness of the app and the app's runtime version. **Don't install both extensions or multiple runtime versions of the extension.**
  - ASP.NET Core {RUNTIME VERSION} (x86) Runtime
  - ASP.NET Core {RUNTIME VERSION} (x64) Runtime

  Restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and both the 32-bit (x86) and 64-bit (x64) site extensions are installed, uninstall the site extension that doesn't match the bitness of the app. After removing the site extension, restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and the site extension's bitness matches that of the app, confirm that the preview site extension's *runtime version* matches the app's runtime version.
- Confirm that the app's **Platform** in **Application Settings** matches the bitness of the app.

For more information, see Deploy ASP.NET Core apps to Azure App Service.

An x86 app is deployed but the app pool isn't enabled for 32-bit apps

- **Browser:** HTTP Error 500.30 - ANCM In-Process Start Failure
- **Application Log:** Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' hit unexpected managed exception, exception code = '0xe0434352'. Please check the stderr logs for more information. Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' failed to load clr and managed application. CLR worker thread exited prematurely
- **ASP.NET Core Module stdout Log:** The log file is created but empty.
- **ASP.NET Core Module Debug Log:** Failed HRESULT returned: 0x8007023e

This scenario is trapped by the SDK when publishing a self-contained app. The SDK produces an error if the

RID doesn't match the platform target (for example, `win10-x64` RID with `<PlatformTarget>x86</PlatformTarget>` in the project file).

Troubleshooting:

For an x86 framework-dependent deployment (`<PlatformTarget>x86</PlatformTarget>`), enable the IIS app pool for 32-bit apps. In IIS Manager, open the app pool's **Advanced Settings** and set **Enable 32-Bit Applications** to **True**.

Platform conflicts with RID

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"C:{PATH}{ASSEMBLY}.{exe|dll}" ', ErrorCode = '0x80004005 : ff.
- **ASP.NET Core Module stdout Log:** Unhandled Exception: System.BadImageFormatException: Could not load file or assembly '{ASSEMBLY}.dll'. An attempt was made to load a program with an incorrect format.

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- If this exception occurs for an Azure Apps deployment when upgrading an app and deploying newer assemblies, manually delete all files from the prior deployment. Lingering incompatible assemblies can result in a `System.BadImageFormatException` exception when deploying an upgraded app.

URI endpoint wrong or stopped website

- **Browser:** ERR_CONNECTION_REFUSED --**OR**-- Unable to connect
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

- Confirm the correct URI endpoint for the app is in use. Check the bindings.
- Confirm that the IIS website isn't in the *Stopped* state.

CoreWebEngine or W3SVC server features disabled

OS Exception: The IIS 7.0 CoreWebEngine and W3SVC features must be installed to use the ASP.NET Core Module.

Troubleshooting:

Confirm that the proper role and features are enabled. See IIS Configuration.

Incorrect website physical path or app missing

- **Browser:** 403 Forbidden - Access is denied --**OR**-- 403.14 Forbidden - The Web server is configured to not list the contents of this directory.

- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

Check the IIS website **Basic Settings** and the physical app folder. Confirm that the app is in the folder at the IIS website **Physical path**.

Incorrect role, ASP.NET Core Module not installed, or incorrect permissions

- **Browser:** 500.19 Internal Server Error - The requested page cannot be accessed because the related configuration data for the page is invalid. --**OR**-- This page can't be displayed
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

- Confirm that the proper role is enabled. See IIS Configuration.
- Open **Programs & Features** or **Apps & features** and confirm that **Windows Server Hosting** is installed. If **Windows Server Hosting** isn't present in the list of installed programs, download and install the .NET Core Hosting Bundle.

  Current .NET Core Hosting Bundle installer (direct download)

  For more information, see Install the .NET Core Hosting Bundle.
- Make sure that the **Application Pool** > **Process Model** > **Identity** is set to **ApplicationPoolIdentity** or the custom identity has the correct permissions to access the app's deployment folder.
- If you uninstalled the ASP.NET Core Hosting Bundle and installed an earlier version of the hosting bundle, the *applicationHost.config* file doesn't include a section for the ASP.NET Core Module. Open *applicationHost.config* at *%windir%/System32/inetsrv/config* and find the `<configuration><configSections><sectionGroup name="system.webServer">` section group. If the section for the ASP.NET Core Module is missing from the section group, add the section element:

  ```
  <section name="aspNetCore" overrideModeDefault="Allow" />
  ```

  Alternatively, install the latest version of the ASP.NET Core Hosting Bundle. The latest version is backwards-compatible with supported ASP.NET Core apps.

Incorrect processPath, missing PATH variable, Hosting Bundle not installed, system/IIS not restarted, VC++ Redistributable not installed, or dotnet.exe access violation

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:

{PATH}' failed to start process with commandline '"{...}" ', ErrorCode = '0x80070002 : 0. Application '{PATH}' wasn't able to start. Executable was not found at '{PATH}'. Failed to start application '/LM/W3SVC/2/ROOT', ErrorCode '0x8007023e'.

- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** Event Log: 'Application '{PATH}' wasn't able to start. Executable was not found at '{PATH}'. Failed HRESULT returned: 0x8007023e

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Check the *processPath* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's `dotnet` for a framework-dependent deployment (FDD) or `.\{ASSEMBLY}.exe` for a self-contained deployment (SCD).
- For an FDD, *dotnet.exe* might not be accessible via the PATH settings. Confirm that *C:\Program Files\dotnet* exists in the System PATH settings.
- For an FDD, *dotnet.exe* might not be accessible for the user identity of the app pool. Confirm that the app pool user identity has access to the *C:\Program Files\dotnet* directory. Confirm that there are no deny rules configured for the app pool user identity on the *C:\Program Files\dotnet* and app directories.
- An FDD may have been deployed and .NET Core installed without restarting IIS. Either restart the server or restart IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.
- An FDD may have been deployed without installing the .NET Core runtime on the hosting system. If the .NET Core runtime hasn't been installed, run the **.NET Core Hosting Bundle installer** on the system.

  Current .NET Core Hosting Bundle installer (direct download)

  For more information, see Install the .NET Core Hosting Bundle.

  If a specific runtime is required, download the runtime from the .NET Download Archives and install it on the system. Complete the installation by restarting the system or restarting IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.

Incorrect arguments of <aspNetCore> element

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Could not find inprocess request handler. Captured output from invoking hostfxr: Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409 Failed to start application '/LM/W3SVC/3/ROOT', ErrorCode '0x8000ffff'.
- **ASP.NET Core Module stdout Log:** Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409
- **ASP.NET Core Module Debug Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Failed HRESULT returned: 0x8000ffff Could not find inprocess request handler. Captured output from invoking hostfxr: Did you mean to run dotnet SDK

commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409 Failed HRESULT returned: 0x8000ffff

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Examine the *arguments* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's either (a) `.\{ASSEMBLY}.dll` for a framework-dependent deployment (FDD); or (b) not present, an empty string (`arguments=""`), or a list of the app's arguments (`arguments="{ARGUMENT_1}, {ARGUMENT_2}, ... {ARGUMENT_X}"`) for a self-contained deployment (SCD).

Missing .NET Core shared framework

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}' was not found.

Failed to start application '/LM/W3SVC/5/ROOT', ErrorCode '0x8000ffff'.

- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}' was not found.
- **ASP.NET Core Module Debug Log:** Failed HRESULT returned: 0x8000ffff

Troubleshooting:

For a framework-dependent deployment (FDD), confirm that the correct runtime installed on the system.

Stopped Application Pool

- **Browser:** 503 Service Unavailable
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

Confirm that the Application Pool isn't in the *Stopped* state.

Sub-application includes a <handlers> section

- **Browser:** HTTP Error 500.19 - Internal Server Error
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.
- **ASP.NET Core Module Debug Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.

Troubleshooting:

Confirm that the sub-app's *web.config* file doesn't include a `<handlers>` section or that the sub-app doesn't inherit the parent app's handlers.

The parent app's `<system.webServer>` section of *web.config* is placed inside of a `<location>` element. The InheritInChildApplications property is set to `false` to indicate that the settings specified within the <location> element aren't inherited by apps that reside in a subdirectory of the parent app. For more information, see ASP.NET Core Module.

stdout log path incorrect

- **Browser:** The app responds normally.
- **Application Log:** Could not start stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070005 returned at {PATH}\aspnetcoremodulev2\commonlib\fileoutputmanager.cpp:84. Could not stop stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070002 returned at {PATH}. Could not start stdout redirection in {PATH}\aspnetcorev2_inprocess.dll.
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module debug Log:** Could not start stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070005 returned at {PATH}\aspnetcoremodulev2\commonlib\fileoutputmanager.cpp:84. Could not stop stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070002 returned at {PATH}. Could not start stdout redirection in {PATH}\aspnetcorev2_inprocess.dll.

Troubleshooting:

- The `stdoutLogFile` path specified in the `<aspNetCore>` element of *web.config* doesn't exist. For more information, see ASP.NET Core Module: Log creation and redirection.
- The app pool user doesn't have write access to the stdout log path.

Application configuration general issue

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure --**OR**-- HTTP Error 500.30 - ANCM In-Process Start Failure
- **Application Log:** Variable
- **ASP.NET Core Module stdout Log:** The log file is created but empty or created with normal entries until the point of the app failing.
- **ASP.NET Core Module Debug Log:** Variable

Troubleshooting:

The process failed to start, most likely due to an app configuration or programming issue.

For more information, see the following topics:

- Troubleshoot ASP.NET Core on Azure App Service and IIS
- Troubleshoot and debug ASP.NET Core projects

This topic describes common errors and provides troubleshooting advice for specific errors when hosting ASP.NET Core apps on Azure Apps Service and IIS.

For general troubleshooting guidance, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

Collect the following information:

- Browser behavior (status code and error message)
- Application Event Log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS
    1. Select **Start** on the **Windows** menu, type *Event Viewer*, and press **Enter**.
    2. After the **Event Viewer** opens, expand **Windows Logs** > **Application** in the sidebar.
- ASP.NET Core Module stdout and debug log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS: Follow the instructions in the Log creation and redirection and Enhanced diagnostic logs sections of the ASP.NET Core Module topic.

Compare error information to the following common errors. If a match is found, follow the troubleshooting advice.

The list of errors in this topic isn't exhaustive. If you encounter an error not listed here, open a new issue using the **Content feedback** button at the bottom of this topic with detailed instructions on how to reproduce the error.

> **IMPORTANT**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

OS upgrade removed the 32-bit ASP.NET Core Module

Application Log: The Module DLL **C:\WINDOWS\system32\inetsrv\aspnetcore.dll** failed to load. The data is the error.

Troubleshooting:

Non-OS files in the **C:\Windows\SysWOW64\inetsrv** directory aren't preserved during an OS upgrade. If the ASP.NET Core Module is installed prior to an OS upgrade and then any app pool is run in 32-bit mode after an OS upgrade, this issue is encountered. After an OS upgrade, repair the ASP.NET Core Module. See Install the .NET Core Hosting bundle. Select **Repair** when the installer is run.

Missing site extension, 32-bit (x86) and 64-bit (x64) site extensions installed, or wrong process bitness set

Applies to apps hosted by Azure App Services.

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found. Failed to start application

'/LM/W3SVC/1416782824/ROOT', ErrorCode '0x8000ffff'.

- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.

Troubleshooting:

- If running the app on a preview runtime, install either the 32-bit (x86) **or** 64-bit (x64) site extension that matches the bitness of the app and the app's runtime version. **Don't install both extensions or multiple runtime versions of the extension.**
  - ASP.NET Core {RUNTIME VERSION} (x86) Runtime
  - ASP.NET Core {RUNTIME VERSION} (x64) Runtime

  Restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and both the 32-bit (x86) and 64-bit (x64) site extensions are installed, uninstall the site extension that doesn't match the bitness of the app. After removing the site extension, restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and the site extension's bitness matches that of the app, confirm that the preview site extension's *runtime version* matches the app's runtime version.
- Confirm that the app's **Platform** in **Application Settings** matches the bitness of the app.

For more information, see Deploy ASP.NET Core apps to Azure App Service.

An x86 app is deployed but the app pool isn't enabled for 32-bit apps

- **Browser:** HTTP Error 500.30 - ANCM In-Process Start Failure
- **Application Log:** Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' hit unexpected managed exception, exception code = '0xe0434352'. Please check the stderr logs for more information. Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' failed to load clr and managed application. CLR worker thread exited prematurely
- **ASP.NET Core Module stdout Log:** The log file is created but empty.

This scenario is trapped by the SDK when publishing a self-contained app. The SDK produces an error if the RID doesn't match the platform target (for example, `win10-x64` RID with `<PlatformTarget>x86</PlatformTarget>` in the project file).

Troubleshooting:

For an x86 framework-dependent deployment (`<PlatformTarget>x86</PlatformTarget>`), enable the IIS app pool for 32-bit apps. In IIS Manager, open the app pool's **Advanced Settings** and set **Enable 32-Bit Applications** to **True**.

Platform conflicts with RID

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"C:{PATH}{ASSEMBLY}.{exe|dll}" ', ErrorCode = '0x80004005 : ff.
- **ASP.NET Core Module stdout Log:** Unhandled Exception: System.BadImageFormatException: Could not load file or assembly '{ASSEMBLY}.dll'. An attempt was made to load a program with an incorrect

format.

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- If this exception occurs for an Azure Apps deployment when upgrading an app and deploying newer assemblies, manually delete all files from the prior deployment. Lingering incompatible assemblies can result in a `System.BadImageFormatException` exception when deploying an upgraded app.

URI endpoint wrong or stopped website

- **Browser:** ERR_CONNECTION_REFUSED --**OR**-- Unable to connect
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

- Confirm the correct URI endpoint for the app is in use. Check the bindings.
- Confirm that the IIS website isn't in the *Stopped* state.

CoreWebEngine or W3SVC server features disabled

OS Exception: The IIS 7.0 CoreWebEngine and W3SVC features must be installed to use the ASP.NET Core Module.

Troubleshooting:

Confirm that the proper role and features are enabled. See IIS Configuration.

Incorrect website physical path or app missing

- **Browser:** 403 Forbidden - Access is denied --**OR**-- 403.14 Forbidden - The Web server is configured to not list the contents of this directory.
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

Check the IIS website **Basic Settings** and the physical app folder. Confirm that the app is in the folder at the IIS website **Physical path**.

Incorrect role, ASP.NET Core Module not installed, or incorrect permissions

- **Browser:** 500.19 Internal Server Error - The requested page cannot be accessed because the related configuration data for the page is invalid. --**OR**-- This page can't be displayed
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

- Confirm that the proper role is enabled. See IIS Configuration.
- Open **Programs & Features** or **Apps & features** and confirm that **Windows Server Hosting** is installed. If **Windows Server Hosting** isn't present in the list of installed programs, download and install the .NET Core Hosting Bundle.

  Current .NET Core Hosting Bundle installer (direct download)

  For more information, see Install the .NET Core Hosting Bundle.
- Make sure that the **Application Pool** > **Process Model** > **Identity** is set to **ApplicationPoolIdentity** or the custom identity has the correct permissions to access the app's deployment folder.
- If you uninstalled the ASP.NET Core Hosting Bundle and installed an earlier version of the hosting bundle, the *applicationHost.config* file doesn't include a section for the ASP.NET Core Module. Open *applicationHost.config* at *%windir%/System32/inetsrv/config* and find the `<configuration><configSections><sectionGroup name="system.webServer">` section group. If the section for the ASP.NET Core Module is missing from the section group, add the section element:

  ```
  <section name="aspNetCore" overrideModeDefault="Allow" />
  ```

  Alternatively, install the latest version of the ASP.NET Core Hosting Bundle. The latest version is backwards-compatible with supported ASP.NET Core apps.

Incorrect processPath, missing PATH variable, Hosting Bundle not installed, system/IIS not restarted, VC++ Redistributable not installed, or dotnet.exe access violation

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"{...}" ', ErrorCode = '0x80070002 : 0.
- **ASP.NET Core Module stdout Log:** The log file is created but empty.

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Check the *processPath* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's `dotnet` for a framework-dependent deployment (FDD) or `.\{ASSEMBLY}.exe` for a self-contained deployment (SCD).
- For an FDD, *dotnet.exe* might not be accessible via the PATH settings. Confirm that *C:\Program Files\dotnet* exists in the System PATH settings.
- For an FDD, *dotnet.exe* might not be accessible for the user identity of the app pool. Confirm that the app pool user identity has access to the *C:\Program Files\dotnet* directory. Confirm that there are no deny rules configured for the app pool user identity on the *C:\Program Files\dotnet* and app directories.
- An FDD may have been deployed and .NET Core installed without restarting IIS. Either restart the server or restart IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.
- An FDD may have been deployed without installing the .NET Core runtime on the hosting system. If the .NET Core runtime hasn't been installed, run the **.NET Core Hosting Bundle installer** on the system.

Current .NET Core Hosting Bundle installer (direct download)

For more information, see Install the .NET Core Hosting Bundle.

If a specific runtime is required, download the runtime from the .NET Download Archives and install it on the system. Complete the installation by restarting the system or restarting IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.

Incorrect arguments of <aspNetCore> element

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"dotnet" .{ASSEMBLY}.dll', ErrorCode = '0x80004005 : 80008081.
- **ASP.NET Core Module stdout Log:** The application to execute does not exist: 'PATH{ASSEMBLY}.dll'

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Examine the *arguments* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's either (a) `.\{ASSEMBLY}.dll` for a framework-dependent deployment (FDD); or (b) not present, an empty string (`arguments=""`), or a list of the app's arguments (`arguments="{ARGUMENT_1}, {ARGUMENT_2}, ... {ARGUMENT_X}"`) for a self-contained deployment (SCD).

Troubleshooting:

For a framework-dependent deployment (FDD), confirm that the correct runtime installed on the system.

Stopped Application Pool

- **Browser:** 503 Service Unavailable
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

Confirm that the Application Pool isn't in the *Stopped* state.

Sub-application includes a <handlers> section

- **Browser:** HTTP Error 500.19 - Internal Server Error
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.

Troubleshooting:

Confirm that the sub-app's *web.config* file doesn't include a `<handlers>` section.

stdout log path incorrect

- **Browser:** The app responds normally.

- **Application Log:** Warning: Could not create stdoutLogFile \?{PATH}\path_doesnt_exist\stdout_{PROCESS ID}_{TIMESTAMP}.log, ErrorCode = -2147024893.
- **ASP.NET Core Module stdout Log:** The log file isn't created.

Troubleshooting:

- The `stdoutLogFile` path specified in the `<aspNetCore>` element of *web.config* doesn't exist. For more information, see ASP.NET Core Module: Log creation and redirection.
- The app pool user doesn't have write access to the stdout log path.

Application configuration general issue

- **Browser:** HTTP Error 502.5 - Process Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' created process with commandline '"C:{PATH}{ASSEMBLY}.{exe|dll}" ' but either crashed or did not respond or did not listen on the given port '{PORT}', ErrorCode = '{ERROR CODE}'
- **ASP.NET Core Module stdout Log:** The log file is created but empty.

Troubleshooting:

The process failed to start, most likely due to an app configuration or programming issue.

For more information, see the following topics:

- Troubleshoot ASP.NET Core on Azure App Service and IIS
- Troubleshoot and debug ASP.NET Core projects

Transform web.config

9/22/2020 • 2 minutes to read • Edit Online

By Vijay Ramakrishnan

Transformations to the *web.config* file can be applied automatically when an app is published based on:

- Build configuration
- Profile
- Environment
- Custom

These transformations occur for either of the following *web.config* generation scenarios:

- Generated automatically by the `Microsoft.NET.Sdk.Web` SDK.
- Provided by the developer in the content root of the app.

Build configuration

Build configuration transforms are run first.

Include a *web.{CONFIGURATION}.config* file for each build configuration (Debug|Release) requiring a *web.config* transformation.

In the following example, a configuration-specific environment variable is set in *web.Release.config*:

```
<?xml version="1.0"?>
<configuration xmlns:xdt="http://schemas.microsoft.com/XML-Document-Transform">
  <location>
    <system.webServer>
      <aspNetCore>
        <environmentVariables xdt:Transform="InsertIfMissing">
          <environmentVariable name="Configuration_Specific"
                               value="Configuration_Specific_Value"
                               xdt:Locator="Match(name)"
                               xdt:Transform="InsertIfMissing" />
        </environmentVariables>
      </aspNetCore>
    </system.webServer>
  </location>
</configuration>
```

The transform is applied when the configuration is set to *Release*:

```
dotnet publish --configuration Release
```

The MSBuild property for the configuration is `$(Configuration)`.

Profile

Profile transformations are run second, after Build configuration transforms.

Include a *web.{PROFILE}.config* file for each profile configuration requiring a *web.config* transformation.

In the following example, a profile-specific environment variable is set in *web.FolderProfile.config* for a folder publish profile:

```
<?xml version="1.0"?>
<configuration xmlns:xdt="http://schemas.microsoft.com/XML-Document-Transform">
  <location>
    <system.webServer>
      <aspNetCore>
        <environmentVariables xdt:Transform="InsertIfMissing">
          <environmentVariable name="Profile_Specific"
                               value="Profile_Specific_Value"
                               xdt:Locator="Match(name)"
                               xdt:Transform="InsertIfMissing" />
        </environmentVariables>
      </aspNetCore>
    </system.webServer>
  </location>
</configuration>
```

The transform is applied when the profile is *FolderProfile*:

```
dotnet publish --configuration Release /p:PublishProfile=FolderProfile
```

The MSBuild property for the profile name is `$(PublishProfile)`.

If no profile is passed, the default profile name is **FileSystem** and *web.FileSystem.config* is applied if the file is present in the app's content root.

Environment

Environment transformations are run third, after Build configuration and Profile transforms.

Include a *web.{ENVIRONMENT}.config* file for each environment requiring a *web.config* transformation.

In the following example, a environment-specific environment variable is set in *web.Production.config* for the Production environment:

```
<?xml version="1.0"?>
<configuration xmlns:xdt="http://schemas.microsoft.com/XML-Document-Transform">
  <location>
    <system.webServer>
      <aspNetCore>
        <environmentVariables xdt:Transform="InsertIfMissing">
          <environmentVariable name="Environment_Specific"
                               value="Environment_Specific_Value"
                               xdt:Locator="Match(name)"
                               xdt:Transform="InsertIfMissing" />
        </environmentVariables>
      </aspNetCore>
    </system.webServer>
  </location>
</configuration>
```

The transform is applied when the environment is *Production*:

```
dotnet publish --configuration Release /p:EnvironmentName=Production
```

The MSBuild property for the environment is `$(EnvironmentName)`.

When publishing from Visual Studio and using a publish profile, see Visual Studio publish profiles (.pubxml) for ASP.NET Core app deployment.

The `ASPNETCORE_ENVIRONMENT` environment variable is automatically added to the *web.config* file when the environment name is specified.

Custom

Custom transformations are run last, after Build configuration, Profile, and Environment transforms.

Include a *{CUSTOM_NAME}.transform* file for each custom configuration requiring a *web.config* transformation.

In the following example, a custom transform environment variable is set in *custom.transform*:

```
<?xml version="1.0"?>
<configuration xmlns:xdt="http://schemas.microsoft.com/XML-Document-Transform">
  <location>
    <system.webServer>
      <aspNetCore>
        <environmentVariables xdt:Transform="InsertIfMissing">
          <environmentVariable name="Custom_Specific"
                               value="Custom_Specific_Value"
                               xdt:Locator="Match(name)"
                               xdt:Transform="InsertIfMissing" />
        </environmentVariables>
      </aspNetCore>
    </system.webServer>
  </location>
</configuration>
```

The transform is applied when the `CustomTransformFileName` property is passed to the dotnet publish command:

```
dotnet publish --configuration Release /p:CustomTransformFileName=custom.transform
```

The MSBuild property for the profile name is `$(CustomTransformFileName)`.

Prevent web.config transformation

To prevent transformations of the *web.config* file, set the MSBuild property `$(IsWebConfigTransformDisabled)`:

```
dotnet publish /p:IsWebConfigTransformDisabled=true
```

Kestrel web server implementation in ASP.NET Core

9/22/2020 • 69 minutes to read • Edit Online

By Tom Dykstra, Chris Ross, and Stephen Halter

Kestrel is a cross-platform web server for ASP.NET Core. Kestrel is the web server that's included by default in ASP.NET Core project templates.

Kestrel supports the following scenarios:

- HTTPS
- Opaque upgrade used to enable WebSockets
- Unix sockets for high performance behind Nginx
- HTTP/2 (except on macOS†)

†HTTP/2 will be supported on macOS in a future release.

Kestrel is supported on all platforms and versions that .NET Core supports.

View or download sample code (how to download)

HTTP/2 support

HTTP/2 is available for ASP.NET Core apps if the following base requirements are met:

- Operating system†
  - Windows Server 2016/Windows 10 or later‡
  - Linux with OpenSSL 1.0.2 or later (for example, Ubuntu 16.04 or later)
- Target framework: .NET Core 2.2 or later
- Application-Layer Protocol Negotiation (ALPN) connection
- TLS 1.2 or later connection

†HTTP/2 will be supported on macOS in a future release. ‡Kestrel has limited support for HTTP/2 on Windows Server 2012 R2 and Windows 8.1. Support is limited because the list of supported TLS cipher suites available on these operating systems is limited. A certificate generated using an Elliptic Curve Digital Signature Algorithm (ECDSA) may be required to secure TLS connections.

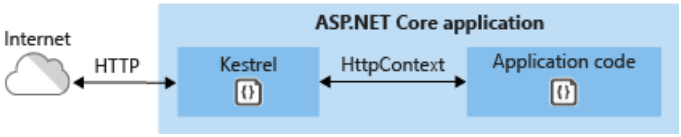
If an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/2`.

HTTP/2 is disabled by default. For more information on configuration, see the Kestrel options and ListenOptions.Protocols sections.

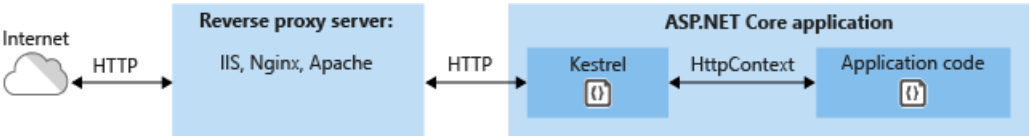
When to use Kestrel with a reverse proxy

Kestrel can be used by itself or with a *reverse proxy server*, such as Internet Information Services (IIS), Nginx, or Apache. A reverse proxy server receives HTTP requests from the network and forwards them to Kestrel.

Kestrel used as an edge (Internet-facing) web server:



Kestrel used in a reverse proxy configuration:



Either configuration, with or without a reverse proxy server, is a supported hosting configuration.

Kestrel used as an edge server without a reverse proxy server doesn't support sharing the same IP and port among multiple processes. When Kestrel is configured to listen on a port, Kestrel handles all of the traffic for that port regardless of requests' `Host` headers. A reverse proxy that can share ports has the ability to forward requests to Kestrel on a unique IP and port.

Even if a reverse proxy server isn't required, using a reverse proxy server might be a good choice.

A reverse proxy:

- Can limit the exposed public surface area of the apps that it hosts.
- Provide an additional layer of configuration and defense.
- Might integrate better with existing infrastructure.
- Simplify load balancing and secure communication (HTTPS) configuration. Only the reverse proxy server requires an X.509 certificate, and that server can communicate with the app's servers on the internal network using plain HTTP.

> **WARNING**
> Hosting in a reverse proxy configuration requires host filtering.

Kestrel in ASP.NET Core apps

ASP.NET Core project templates use Kestrel by default. In *Program.cs*, the ConfigureWebHostDefaults method calls UseKestrel:

```
public static void Main(string[] args)
{
    CreateHostBuilder(args).Build().Run();
}

public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

For more information on building the host, see the *Set up a host* and *Default builder settings* sections of .NET Generic Host.

To provide additional configuration after calling `ConfigureWebHostDefaults`, use

`ConfigureKestrel`:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.ConfigureKestrel(serverOptions =>
            {
                // Set properties and call methods on options
            })
            .UseStartup<Startup>();
        });
```

Kestrel options

The Kestrel web server has constraint configuration options that are especially useful in Internet-facing deployments.

Set constraints on the Limits property of the KestrelServerOptions class. The `Limits` property holds an instance of the KestrelServerLimits class.

The following examples use the Microsoft.AspNetCore.Server.Kestrel.Core namespace:

```
using Microsoft.AspNetCore.Server.Kestrel.Core;
```

In examples shown later in this article, Kestrel options are configured in C# code. Kestrel options can also be set using a configuration provider. For example, the File Configuration Provider can load Kestrel configuration from an *appsettings.json* or *appsettings.{Environment}.json* file:

```
{
  "Kestrel": {
    "Limits": {
      "MaxConcurrentConnections": 100,
      "MaxConcurrentUpgradedConnections": 100
    },
    "DisableStringReuse": true
  }
}
```

> **NOTE**
>
> KestrelServerOptions and endpoint configuration are configurable from configuration providers. Remaining Kestrel configuration must be configured in C# code.

Use **one** of the following approaches:

- Configure Kestrel in `Startup.ConfigureServices`:

  1. Inject an instance of `IConfiguration` into the `Startup` class. The following example assumes that the injected configuration is assigned to the `Configuration` property.

  2. In `Startup.ConfigureServices`, load the `Kestrel` section of configuration into Kestrel's configuration:

```
using Microsoft.Extensions.Configuration

public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.Configure<KestrelServerOptions>(
            Configuration.GetSection("Kestrel"));
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        ...
    }
}
```

- Configure Kestrel when building the host:

  In *Program.cs*, load the `Kestrel` section of configuration into Kestrel's configuration:

  ```
  // using Microsoft.Extensions.DependencyInjection;

  public static IHostBuilder CreateHostBuilder(string[] args) =>
      Host.CreateDefaultBuilder(args)
          .ConfigureServices((context, services) =>
          {
              services.Configure<KestrelServerOptions>(
                  context.Configuration.GetSection("Kestrel"));
          })
          .ConfigureWebHostDefaults(webBuilder =>
          {
              webBuilder.UseStartup<Startup>();
          });
  ```

Both of the preceding approaches work with any configuration provider.

Keep-alive timeout

KeepAliveTimeout

Gets or sets the keep-alive timeout. Defaults to 2 minutes.

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.MaxConcurrentConnections = 100;
    serverOptions.Limits.MaxConcurrentUpgradedConnections = 100;
    serverOptions.Limits.MaxRequestBodySize = 10 * 1024;
    serverOptions.Limits.MinRequestBodyDataRate =
        new MinDataRate(bytesPerSecond: 100,
            gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Limits.MinResponseDataRate =
        new MinDataRate(bytesPerSecond: 100,
            gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Listen(IPAddress.Loopback, 5000);
    serverOptions.Listen(IPAddress.Loopback, 5001,
        listenOptions =>
        {
            listenOptions.UseHttps("testCert.pfx",
                "testPassword");
        });
    serverOptions.Limits.KeepAliveTimeout =
        TimeSpan.FromMinutes(2);
    serverOptions.Limits.RequestHeadersTimeout =
        TimeSpan.FromMinutes(1);
})
```

Maximum client connections

MaxConcurrentConnections MaxConcurrentUpgradedConnections

The maximum number of concurrent open TCP connections can be set for the entire app with the following code:

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.MaxConcurrentConnections = 100;
    serverOptions.Limits.MaxConcurrentUpgradedConnections = 100;
    serverOptions.Limits.MaxRequestBodySize = 10 * 1024;
    serverOptions.Limits.MinRequestBodyDataRate =
        new MinDataRate(bytesPerSecond: 100,
            gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Limits.MinResponseDataRate =
        new MinDataRate(bytesPerSecond: 100,
            gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Listen(IPAddress.Loopback, 5000);
    serverOptions.Listen(IPAddress.Loopback, 5001,
        listenOptions =>
        {
            listenOptions.UseHttps("testCert.pfx",
                "testPassword");
        });
    serverOptions.Limits.KeepAliveTimeout =
        TimeSpan.FromMinutes(2);
    serverOptions.Limits.RequestHeadersTimeout =
        TimeSpan.FromMinutes(1);
})
```

There's a separate limit for connections that have been upgraded from HTTP or HTTPS to another protocol (for example, on a WebSockets request). After a connection is upgraded, it isn't counted against the `MaxConcurrentConnections` limit.

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.MaxConcurrentConnections = 100;
    serverOptions.Limits.MaxConcurrentUpgradedConnections = 100;
    serverOptions.Limits.MaxRequestBodySize = 10 * 1024;
    serverOptions.Limits.MinRequestBodyDataRate =
        new MinDataRate(bytesPerSecond: 100,
            gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Limits.MinResponseDataRate =
        new MinDataRate(bytesPerSecond: 100,
            gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Listen(IPAddress.Loopback, 5000);
    serverOptions.Listen(IPAddress.Loopback, 5001,
        listenOptions =>
        {
            listenOptions.UseHttps("testCert.pfx",
                "testPassword");
        });
    serverOptions.Limits.KeepAliveTimeout =
        TimeSpan.FromMinutes(2);
    serverOptions.Limits.RequestHeadersTimeout =
        TimeSpan.FromMinutes(1);
})
```

The maximum number of connections is unlimited (null) by default.

Maximum request body size

MaxRequestBodySize

The default maximum request body size is 30,000,000 bytes, which is approximately 28.6 MB.

The recommended approach to override the limit in an ASP.NET Core MVC app is to use the RequestSizeLimitAttribute attribute on an action method:

```
[RequestSizeLimit(100000000)]
public IActionResult MyActionMethod()
```

Here's an example that shows how to configure the constraint for the app on every request:

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.MaxConcurrentConnections = 100;
    serverOptions.Limits.MaxConcurrentUpgradedConnections = 100;
    serverOptions.Limits.MaxRequestBodySize = 10 * 1024;
    serverOptions.Limits.MinRequestBodyDataRate =
        new MinDataRate(bytesPerSecond: 100,
            gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Limits.MinResponseDataRate =
        new MinDataRate(bytesPerSecond: 100,
            gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Listen(IPAddress.Loopback, 5000);
    serverOptions.Listen(IPAddress.Loopback, 5001,
        listenOptions =>
        {
            listenOptions.UseHttps("testCert.pfx",
                "testPassword");
        });
    serverOptions.Limits.KeepAliveTimeout =
        TimeSpan.FromMinutes(2);
    serverOptions.Limits.RequestHeadersTimeout =
        TimeSpan.FromMinutes(1);
})
```

Override the setting on a specific request in middleware:

```
app.Run(async (context) =>
{
    context.Features.Get<IHttpMaxRequestBodySizeFeature>()
        .MaxRequestBodySize = 10 * 1024;

    var minRequestRateFeature =
        context.Features.Get<IHttpMinRequestBodyDataRateFeature>();
    var minResponseRateFeature =
        context.Features.Get<IHttpMinResponseDataRateFeature>();

    if (minRequestRateFeature != null)
    {
        minRequestRateFeature.MinDataRate = new MinDataRate(
            bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    }

    if (minResponseRateFeature != null)
    {
        minResponseRateFeature.MinDataRate = new MinDataRate(
            bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    }
```

An exception is thrown if the app configures the limit on a request after the app has started to read the request. There's an `IsReadOnly` property that indicates if the `MaxRequestBodySize` property is in read-only state, meaning it's too late to configure the limit.

When an app is run out-of-process behind the ASP.NET Core Module, Kestrel's request body size limit is disabled because IIS already sets the limit.

Minimum request body data rate

MinRequestBodyDataRate MinResponseDataRate

Kestrel checks every second if data is arriving at the specified rate in bytes/second. If the rate drops below the minimum, the connection is timed out. The grace period is the amount of time that Kestrel gives the client to increase its send rate up to the minimum; the rate isn't checked during that time. The grace period helps avoid dropping connections that are initially sending data at a slow rate due to TCP slow-start.

The default minimum rate is 240 bytes/second with a 5 second grace period.

A minimum rate also applies to the response. The code to set the request limit and the response limit is the same except for having `RequestBody` or `Response` in the property and interface names.

Here's an example that shows how to configure the minimum data rates in *Program.cs*:

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.MaxConcurrentConnections = 100;
    serverOptions.Limits.MaxConcurrentUpgradedConnections = 100;
    serverOptions.Limits.MaxRequestBodySize = 10 * 1024;
    serverOptions.Limits.MinRequestBodyDataRate =
        new MinDataRate(bytesPerSecond: 100,
            gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Limits.MinResponseDataRate =
        new MinDataRate(bytesPerSecond: 100,
            gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Listen(IPAddress.Loopback, 5000);
    serverOptions.Listen(IPAddress.Loopback, 5001,
        listenOptions =>
        {
            listenOptions.UseHttps("testCert.pfx",
                "testPassword");
        });
    serverOptions.Limits.KeepAliveTimeout =
        TimeSpan.FromMinutes(2);
    serverOptions.Limits.RequestHeadersTimeout =
        TimeSpan.FromMinutes(1);
})
```

Override the minimum rate limits per request in middleware:

```
app.Run(async (context) =>
{
    context.Features.Get<IHttpMaxRequestBodySizeFeature>()
        .MaxRequestBodySize = 10 * 1024;

    var minRequestRateFeature =
        context.Features.Get<IHttpMinRequestBodyDataRateFeature>();
    var minResponseRateFeature =
        context.Features.Get<IHttpMinResponseDataRateFeature>();

    if (minRequestRateFeature != null)
    {
        minRequestRateFeature.MinDataRate = new MinDataRate(
            bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    }

    if (minResponseRateFeature != null)
    {
        minResponseRateFeature.MinDataRate = new MinDataRate(
            bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    }
```

The IHttpMinResponseDataRateFeature referenced in the prior sample is not present in `HttpContext.Features` for HTTP/2 requests because modifying rate limits on a per-request basis is generally not supported for HTTP/2 due to the protocol's support for request multiplexing. However, the IHttpMinRequestBodyDataRateFeature is still present `HttpContext.Features` for HTTP/2 requests, because the read rate limit can still be *disabled entirely* on a per-request basis by setting `IHttpMinRequestBodyDataRateFeature.MinDataRate` to `null` even for an HTTP/2 request. Attempting to read `IHttpMinRequestBodyDataRateFeature.MinDataRate` or attempting to set it to a value other than `null` will result in a `NotSupportedException` being thrown given an HTTP/2 request.

Server-wide rate limits configured via `KestrelServerOptions.Limits` still apply to both HTTP/1.x and HTTP/2 connections.

Request headers timeout

RequestHeadersTimeout

Gets or sets the maximum amount of time the server spends receiving request headers. Defaults to 30 seconds.

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.MaxConcurrentConnections = 100;
    serverOptions.Limits.MaxConcurrentUpgradedConnections = 100;
    serverOptions.Limits.MaxRequestBodySize = 10 * 1024;
    serverOptions.Limits.MinRequestBodyDataRate =
        new MinDataRate(bytesPerSecond: 100,
            gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Limits.MinResponseDataRate =
        new MinDataRate(bytesPerSecond: 100,
            gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Listen(IPAddress.Loopback, 5000);
    serverOptions.Listen(IPAddress.Loopback, 5001,
        listenOptions =>
        {
            listenOptions.UseHttps("testCert.pfx",
                "testPassword");
        });
    serverOptions.Limits.KeepAliveTimeout =
        TimeSpan.FromMinutes(2);
    serverOptions.Limits.RequestHeadersTimeout =
        TimeSpan.FromMinutes(1);
})
```

Maximum streams per connection

`Http2.MaxStreamsPerConnection` limits the number of concurrent request streams per HTTP/2 connection. Excess streams are refused.

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.Http2.MaxStreamsPerConnection = 100;
});
```

The default value is 100.

Header table size

The HPACK decoder decompresses HTTP headers for HTTP/2 connections. `Http2.HeaderTableSize` limits the size of the header compression table that the HPACK decoder uses. The value is provided in octets and must be greater than zero (0).

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.Http2.HeaderTableSize = 4096;
});
```

The default value is 4096.

Maximum frame size

`Http2.MaxFrameSize` indicates the maximum allowed size of an HTTP/2 connection frame payload received or sent by the server. The value is provided in octets and must be between 2^14 (16,384) and 2^24-1 (16,777,215).

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.Http2.MaxFrameSize = 16384;
});
```

The default value is 2^14 (16,384).

Maximum request header size

`Http2.MaxRequestHeaderFieldSize` indicates the maximum allowed size in octets of request header values. This limit applies to both name and value in their compressed and uncompressed representations. The value must be greater than zero (0).

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.Http2.MaxRequestHeaderFieldSize = 8192;
});
```

The default value is 8,192.

Initial connection window size

`Http2.InitialConnectionWindowSize` indicates the maximum request body data in bytes the server buffers at one time aggregated across all requests (streams) per connection. Requests are also limited by `Http2.InitialStreamWindowSize`. The value must be greater than or equal to 65,535 and less than 2^31 (2,147,483,648).

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.Http2.InitialConnectionWindowSize = 131072;
});
```

The default value is 128 KB (131,072).

Initial stream window size

`Http2.InitialStreamWindowSize` indicates the maximum request body data in bytes the server buffers at one time per request (stream). Requests are also limited by `Http2.InitialConnectionWindowSize`. The value must be greater than or equal to 65,535 and less than 2^31 (2,147,483,648).

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.Http2.InitialStreamWindowSize = 98304;
});
```

The default value is 96 KB (98,304).

Synchronous I/O

AllowSynchronousIO controls whether synchronous I/O is allowed for the request and response. The default value is `false`.

> **WARNING**
> A large number of blocking synchronous I/O operations can lead to thread pool starvation, which makes the app unresponsive. Only enable `AllowSynchronousIO` when using a library that doesn't support asynchronous I/O.

The following example enables synchronous I/O:

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.AllowSynchronousIO = true;
})
```

For information about other Kestrel options and limits, see:

- KestrelServerOptions
- KestrelServerLimits
- ListenOptions

Endpoint configuration

By default, ASP.NET Core binds to:

- `http://localhost:5000`
- `https://localhost:5001` (when a local development certificate is present)

Specify URLs using the:

- `ASPNETCORE_URLS` environment variable.
- `--urls` command-line argument.
- `urls` host configuration key.
- `UseUrls` extension method.

The value provided using these approaches can be one or more HTTP and HTTPS endpoints (HTTPS if a default cert is available). Configure the value as a semicolon-separated list (for example, `"Urls": "http://localhost:8000;http://localhost:8001"`).

For more information on these approaches, see Server URLs and Override configuration.

A development certificate is created:

- When the .NET Core SDK is installed.
- The dev-certs tool is used to create a certificate.

Some browsers require granting explicit permission to trust the local development certificate.

Project templates configure apps to run on HTTPS by default and include HTTPS redirection and HSTS support.

Call Listen or ListenUnixSocket methods on KestrelServerOptions to configure URL prefixes and ports for Kestrel.

`UseUrls`, the `--urls` command-line argument, `urls` host configuration key, and the `ASPNETCORE_URLS` environment variable also work but have the limitations noted later in this section (a default certificate must be available for HTTPS endpoint configuration).

`KestrelServerOptions` configuration:

ConfigureEndpointDefaults(Action<ListenOptions>)

Specifies a configuration `Action` to run for each specified endpoint. Calling `ConfigureEndpointDefaults` multiple times replaces prior `Action`s with the last `Action` specified.

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.ConfigureEndpointDefaults(listenOptions =>
    {
        // Configure endpoint defaults
    });
});
```

> **NOTE**
> Endpoints created by calling Listen **before** calling ConfigureEndpointDefaults won't have the defaults applied.

ConfigureHttpsDefaults(Action<HttpsConnectionAdapterOptions>)

Specifies a configuration `Action` to run for each HTTPS endpoint. Calling `ConfigureHttpsDefaults` multiple times replaces prior `Action`s with the last `Action` specified.

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.ConfigureHttpsDefaults(listenOptions =>
    {
        // certificate is an X509Certificate2
        listenOptions.ServerCertificate = certificate;
    });
});
```

> **NOTE**
> Endpoints created by calling Listen **before** calling ConfigureHttpsDefaults won't have the defaults applied.

Configure(IConfiguration)

Creates a configuration loader for setting up Kestrel that takes an IConfiguration as input. The configuration must be scoped to the configuration section for Kestrel.

ListenOptions.UseHttps

Configure Kestrel to use HTTPS.

`ListenOptions.UseHttps` extensions:

- `UseHttps`: Configure Kestrel to use HTTPS with the default certificate. Throws an exception if no default certificate is configured.
- `UseHttps(string fileName)`
- `UseHttps(string fileName, string password)`
- `UseHttps(string fileName, string password, Action<HttpsConnectionAdapterOptions> configureOptions)`
- `UseHttps(StoreName storeName, string subject)`

- `UseHttps(StoreName storeName, string subject, bool allowInvalid)`
- `UseHttps(StoreName storeName, string subject, bool allowInvalid, StoreLocation location)`
- `UseHttps(StoreName storeName, string subject, bool allowInvalid, StoreLocation location, Action<HttpsConnectionAdapterOptions> configureOptions)`
- `UseHttps(X509Certificate2 serverCertificate)`
- `UseHttps(X509Certificate2 serverCertificate, Action<HttpsConnectionAdapterOptions> configureOptions)`
- `UseHttps(Action<HttpsConnectionAdapterOptions> configureOptions)`

`ListenOptions.UseHttps` parameters:

- `filename` is the path and file name of a certificate file, relative to the directory that contains the app's content files.
- `password` is the password required to access the X.509 certificate data.
- `configureOptions` is an `Action` to configure the `HttpsConnectionAdapterOptions`. Returns the `ListenOptions`.
- `storeName` is the certificate store from which to load the certificate.
- `subject` is the subject name for the certificate.
- `allowInvalid` indicates if invalid certificates should be considered, such as self-signed certificates.
- `location` is the store location to load the certificate from.
- `serverCertificate` is the X.509 certificate.

In production, HTTPS must be explicitly configured. At a minimum, a default certificate must be provided.

Supported configurations described next:

- No configuration
- Replace the default certificate from configuration
- Change the defaults in code

No configuration

Kestrel listens on `http://localhost:5000` and `https://localhost:5001` (if a default cert is available).

Replace the default certificate from configuration

`CreateDefaultBuilder` calls `Configure(context.Configuration.GetSection("Kestrel"))` by default to load Kestrel configuration. A default HTTPS app settings configuration schema is available for Kestrel. Configure multiple endpoints, including the URLs and the certificates to use, either from a file on disk or from a certificate store.

In the following *appsettings.json* example:

- Set **AllowInvalid** to `true` to permit the use of invalid certificates (for example, self-signed certificates).
- Any HTTPS endpoint that doesn't specify a certificate (**HttpsDefaultCert** in the example that follows) falls back to the cert defined under **Certificates** > **Default** or the development certificate.

```
{
  "Kestrel": {
    "Endpoints": {
      "Http": {
        "Url": "http://localhost:5000"
      },
      "HttpsInlineCertFile": {
        "Url": "https://localhost:5001",
        "Certificate": {
          "Path": "<path to .pfx file>",
          "Password": "<certificate password>"
        }
      },
      "HttpsInlineCertStore": {
        "Url": "https://localhost:5002",
        "Certificate": {
          "Subject": "<subject; required>",
          "Store": "<certificate store; required>",
          "Location": "<location; defaults to CurrentUser>",
          "AllowInvalid": "<true or false; defaults to false>"
        }
      },
      "HttpsDefaultCert": {
        "Url": "https://localhost:5003"
      },
      "Https": {
        "Url": "https://*:5004",
        "Certificate": {
          "Path": "<path to .pfx file>",
          "Password": "<certificate password>"
        }
      }
    },
    "Certificates": {
      "Default": {
        "Path": "<path to .pfx file>",
        "Password": "<certificate password>"
      }
    }
  }
}
```

An alternative to using **Path** and **Password** for any certificate node is to specify the certificate using certificate store fields. For example, the **Certificates** > **Default** certificate can be specified as:

```
"Default": {
  "Subject": "<subject; required>",
  "Store": "<cert store; required>",
  "Location": "<location; defaults to CurrentUser>",
  "AllowInvalid": "<true or false; defaults to false>"
}
```

Schema notes:

- Endpoints names are case-insensitive. For example, `HTTPS` and `Https` are valid.
- The `Url` parameter is required for each endpoint. The format for this parameter is the same as the top-level `Urls` configuration parameter except that it's limited to a single value.
- These endpoints replace those defined in the top-level `Urls` configuration rather than adding to them. Endpoints defined in code via `Listen` are cumulative with the endpoints defined in the configuration section.

- The `Certificate` section is optional. If the `Certificate` section isn't specified, the defaults defined in earlier scenarios are used. If no defaults are available, the server throws an exception and fails to start.
- The `Certificate` section supports both **Path–Password** and **Subject–Store** certificates.
- Any number of endpoints may be defined in this way so long as they don't cause port conflicts.
- `options.Configure(context.Configuration.GetSection("{SECTION}"))` returns a `KestrelConfigurationLoader` with an `.Endpoint(string name, listenOptions => { })` method that can be used to supplement a configured endpoint's settings:

```
webBuilder.UseKestrel((context, serverOptions) =>
{
    serverOptions.Configure(context.Configuration.GetSection("Kestrel"))
        .Endpoint("HTTPS", listenOptions =>
        {
            listenOptions.HttpsOptions.SslProtocols = SslProtocols.Tls12;
        });
});
```

`KestrelServerOptions.ConfigurationLoader` can be directly accessed to continue iterating on the existing loader, such as the one provided by CreateDefaultBuilder.

- The configuration section for each endpoint is available on the options in the `Endpoint` method so that custom settings may be read.
- Multiple configurations may be loaded by calling `options.Configure(context.Configuration.GetSection("{SECTION}"))` again with another section. Only the last configuration is used, unless `Load` is explicitly called on prior instances. The metapackage doesn't call `Load` so that its default configuration section may be replaced.
- `KestrelConfigurationLoader` mirrors the `Listen` family of APIs from `KestrelServerOptions` as `Endpoint` overloads, so code and config endpoints may be configured in the same place. These overloads don't use names and only consume default settings from configuration.

Change the defaults in code

`ConfigureEndpointDefaults` and `ConfigureHttpsDefaults` can be used to change default settings for `ListenOptions` and `HttpsConnectionAdapterOptions`, including overriding the default certificate specified in the prior scenario. `ConfigureEndpointDefaults` and `ConfigureHttpsDefaults` should be called before any endpoints are configured.

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.ConfigureEndpointDefaults(listenOptions =>
    {
        // Configure endpoint defaults
    });

    serverOptions.ConfigureHttpsDefaults(listenOptions =>
    {
        listenOptions.SslProtocols = SslProtocols.Tls12;
    });
});
```

Kestrel support for SNI

Server Name Indication (SNI) can be used to host multiple domains on the same IP address and port. For SNI to function, the client sends the host name for the secure session to the server

during the TLS handshake so that the server can provide the correct certificate. The client uses the furnished certificate for encrypted communication with the server during the secure session that follows the TLS handshake.

Kestrel supports SNI via the `ServerCertificateSelector` callback. The callback is invoked once per connection to allow the app to inspect the host name and select the appropriate certificate.

SNI support requires:

- Running on target framework `netcoreapp2.1` or later. On `net461` or later, the callback is invoked but the `name` is always `null`. The `name` is also `null` if the client doesn't provide the host name parameter in the TLS handshake.
- All websites run on the same Kestrel instance. Kestrel doesn't support sharing an IP address and port across multiple instances without a reverse proxy.

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.ListenAnyIP(5005, listenOptions =>
    {
        listenOptions.UseHttps(httpsOptions =>
        {
            var localhostCert = CertificateLoader.LoadFromStoreCert(
                "localhost", "My", StoreLocation.CurrentUser,
                allowInvalid: true);
            var exampleCert = CertificateLoader.LoadFromStoreCert(
                "example.com", "My", StoreLocation.CurrentUser,
                allowInvalid: true);
            var subExampleCert = CertificateLoader.LoadFromStoreCert(
                "sub.example.com", "My", StoreLocation.CurrentUser,
                allowInvalid: true);
            var certs = new Dictionary<string, X509Certificate2>(
                StringComparer.OrdinalIgnoreCase);
            certs["localhost"] = localhostCert;
            certs["example.com"] = exampleCert;
            certs["sub.example.com"] = subExampleCert;

            httpsOptions.ServerCertificateSelector = (connectionContext, name) =>
            {
                if (name != null && certs.TryGetValue(name, out var cert))
                {
                    return cert;
                }

                return exampleCert;
            };
        });
    });
});
```

Connection logging

Call UseConnectionLogging to emit Debug level logs for byte-level communication on a connection. Connection logging is helpful for troubleshooting problems in low-level communication, such as during TLS encryption and behind proxies. If `UseConnectionLogging` is placed before `UseHttps`, encrypted traffic is logged. If `UseConnectionLogging` is placed after `UseHttps`, decrypted traffic is logged.

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Listen(IPAddress.Any, 8000, listenOptions =>
    {
        listenOptions.UseConnectionLogging();
    });
});
```

Bind to a TCP socket

The Listen method binds to a TCP socket, and an options lambda permits X.509 certificate configuration:

```
public static void Main(string[] args)
{
    CreateHostBuilder(args).Build().Run();
}

public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.ConfigureKestrel(serverOptions =>
            {
                serverOptions.Listen(IPAddress.Loopback, 5000);
                serverOptions.Listen(IPAddress.Loopback, 5001,
                    listenOptions =>
                    {
                        listenOptions.UseHttps("testCert.pfx",
                            "testPassword");
                    });
            })
            .UseStartup<Startup>();
        });
```

The example configures HTTPS for an endpoint with ListenOptions. Use the same API to configure other Kestrel settings for specific endpoints.

On Windows, self-signed certificates can be created using the New-SelfSignedCertificate PowerShell cmdlet. For an unsupported example, see UpdateIISExpressSSLForChrome.ps1.

On macOS, Linux, and Windows, certificates can be created using OpenSSL.

Bind to a Unix socket

Listen on a Unix socket with ListenUnixSocket for improved performance with Nginx, as shown in this example:

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.ListenUnixSocket("/tmp/kestrel-test.sock");
    serverOptions.ListenUnixSocket("/tmp/kestrel-test.sock",
        listenOptions =>
        {
            listenOptions.UseHttps("testCert.pfx",
                "testpassword");
        });
})
```

- In the Nginx configuration file, set the `server` > `location` > `proxy_pass` entry to `http://unix:/tmp/{KESTREL SOCKET}:/;`. `{KESTREL SOCKET}` is the name of the socket provided

to ListenUnixSocket (for example, `kestrel-test.sock` in the preceding example).

- Ensure that the socket is writeable by Nginx (for example, `chmod go+w /tmp/kestrel-test.sock`).

Port 0

When the port number `0` is specified, Kestrel dynamically binds to an available port. The following example shows how to determine which port Kestrel actually bound at runtime:

```
public void Configure(IApplicationBuilder app)
{
    var serverAddressesFeature =
        app.ServerFeatures.Get<IServerAddressesFeature>();

    app.UseStaticFiles();

    app.Run(async (context) =>
    {
        context.Response.ContentType = "text/html";
        await context.Response
            .WriteAsync("<!DOCTYPE html><html lang=\"en\"><head>" +
                "<title></title></head><body><p>Hosted by Kestrel</p>");

        if (serverAddressesFeature != null)
        {
            await context.Response
                .WriteAsync("<p>Listening on the following addresses: " +
                    string.Join(", ", serverAddressesFeature.Addresses) +
                    "</p>");
        }

        await context.Response.WriteAsync("<p>Request URL: " +
            $"{context.Request.GetDisplayUrl()}<p>");
    });
}
```

When the app is run, the console window output indicates the dynamic port where the app can be reached:

```
Listening on the following addresses: http://127.0.0.1:48508
```

Limitations

Configure endpoints with the following approaches:

- UseUrls
- `--urls` command-line argument
- `urls` host configuration key
- `ASPNETCORE_URLS` environment variable

These methods are useful for making code work with servers other than Kestrel. However, be aware of the following limitations:

- HTTPS can't be used with these approaches unless a default certificate is provided in the HTTPS endpoint configuration (for example, using `KestrelServerOptions` configuration or a configuration file as shown earlier in this topic).
- When both the `Listen` and `UseUrls` approaches are used simultaneously, the `Listen` endpoints override the `UseUrls` endpoints.

IIS endpoint configuration

When using IIS, the URL bindings for IIS override bindings are set by either `Listen` or `UseUrls`. For more information, see the ASP.NET Core Module topic.

ListenOptions.Protocols

The `Protocols` property establishes the HTTP protocols (`HttpProtocols`) enabled on a connection endpoint or for the server. Assign a value to the `Protocols` property from the `HttpProtocols` enum.

`HTTPPROTOCOLS` ENUM VALUE	CONNECTION PROTOCOL PERMITTED
`Http1`	HTTP/1.1 only. Can be used with or without TLS.
`Http2`	HTTP/2 only. May be used without TLS only if the client supports a Prior Knowledge mode.
`Http1AndHttp2`	HTTP/1.1 and HTTP/2. HTTP/2 requires the client to select HTTP/2 in the TLS Application-Layer Protocol Negotiation (ALPN) handshake; otherwise, the connection defaults to HTTP/1.1.

The default `ListenOptions.Protocols` value for any endpoint is `HttpProtocols.Http1AndHttp2`.

TLS restrictions for HTTP/2:

- TLS version 1.2 or later
- Renegotiation disabled
- Compression disabled
- Minimum ephemeral key exchange sizes:
  - Elliptic curve Diffie-Hellman (ECDHE) [RFC4492]: 224 bits minimum
  - Finite field Diffie-Hellman (DHE) [`TLS12`]: 2048 bits minimum
- Cipher suite not prohibited.

`TLS_ECDHE_RSA_WITH_AES_128_GCM_SHA256` [`TLS-ECDHE`] with the P-256 elliptic curve [`FIPS186`] is supported by default.

The following example permits HTTP/1.1 and HTTP/2 connections on port 8000. Connections are secured by TLS with a supplied certificate:

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Listen(IPAddress.Any, 8000, listenOptions =>
    {
        listenOptions.UseHttps("testCert.pfx", "testPassword");
    });
});
```

Use Connection Middleware to filter TLS handshakes on a per-connection basis for specific ciphers if required.

The following example throws NotSupportedException for any cipher algorithm that the app doesn't support. Alternatively, define and compare ITlsHandshakeFeature.CipherAlgorithm to a list of acceptable cipher suites.

No encryption is used with a CipherAlgorithmType.Null cipher algorithm.

```
// using System.Net;
// using Microsoft.AspNetCore.Connections;

webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Listen(IPAddress.Any, 8000, listenOptions =>
    {
        listenOptions.UseHttps("testCert.pfx", "testPassword");
        listenOptions.UseTlsFilter();
    });
});
```

```
using System;
using System.Security.Authentication;
using Microsoft.AspNetCore.Connections.Features;

namespace Microsoft.AspNetCore.Connections
{
    public static class TlsFilterConnectionMiddlewareExtensions
    {
        public static IConnectionBuilder UseTlsFilter(
            this IConnectionBuilder builder)
        {
            return builder.Use((connection, next) =>
            {
                var tlsFeature = connection.Features.Get<ITlsHandshakeFeature>();

                if (tlsFeature.CipherAlgorithm == CipherAlgorithmType.Null)
                {
                    throw new NotSupportedException("Prohibited cipher: " +
                        tlsFeature.CipherAlgorithm);
                }

                return next();
            });
        }
    }
}
```

Connection filtering can also be configured via an IConnectionBuilder lambda:

```
// using System;
// using System.Net;
// using System.Security.Authentication;
// using Microsoft.AspNetCore.Connections;
// using Microsoft.AspNetCore.Connections.Features;

webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Listen(IPAddress.Any, 8000, listenOptions =>
    {
        listenOptions.UseHttps("testCert.pfx", "testPassword");
        listenOptions.Use((context, next) =>
        {
            var tlsFeature = context.Features.Get<ITlsHandshakeFeature>();

            if (tlsFeature.CipherAlgorithm == CipherAlgorithmType.Null)
            {
                throw new NotSupportedException(
                    $"Prohibited cipher: {tlsFeature.CipherAlgorithm}");
            }

            return next();
        });
    });
});
```

On Linux, CipherSuitesPolicy can be used to filter TLS handshakes on a per-connection basis:

```
// using System.Net.Security;
// using Microsoft.AspNetCore.Hosting;
// using Microsoft.AspNetCore.Server.Kestrel.Core;
// using Microsoft.Extensions.DependencyInjection;
// using Microsoft.Extensions.Hosting;

webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.ConfigureHttpsDefaults(listenOptions =>
    {
        listenOptions.OnAuthenticate = (context, sslOptions) =>
        {
            sslOptions.CipherSuitesPolicy = new CipherSuitesPolicy(
                new[]
                {
                    TlsCipherSuite.TLS_ECDHE_ECDSA_WITH_AES_128_GCM_SHA256,
                    TlsCipherSuite.TLS_ECDHE_ECDSA_WITH_AES_256_GCM_SHA384,
                    // ...
                });
        };
    });
});
```

Set the protocol from configuration

`CreateDefaultBuilder` calls `serverOptions.Configure(context.Configuration.GetSection("Kestrel"))` by default to load Kestrel configuration.

The following *appsettings.json* example establishes HTTP/1.1 as the default connection protocol for all endpoints:

```
{
  "Kestrel": {
    "EndpointDefaults": {
      "Protocols": "Http1"
    }
  }
}
```

The following *appsettings.json* example establishes the HTTP/1.1 connection protocol for a specific endpoint:

```
{
  "Kestrel": {
    "Endpoints": {
      "HttpsDefaultCert": {
        "Url": "https://localhost:5001",
        "Protocols": "Http1"
      }
    }
  }
}
```

Protocols specified in code override values set by configuration.

Transport configuration

For projects that require the use of Libuv (UseLibuv):

- Add a dependency for the Microsoft.AspNetCore.Server.Kestrel.Transport.Libuv package to the app's project file:

  ```
  <PackageReference Include="Microsoft.AspNetCore.Server.Kestrel.Transport.Libuv"
                    Version="{VERSION}" />
  ```

- Call UseLibuv on the `IWebHostBuilder`:

  ```
  public class Program
  {
       public static void Main(string[] args)
       {
           CreateHostBuilder(args).Build().Run();
       }

       public static IHostBuilder CreateHostBuilder(string[] args) =>
           Host.CreateDefaultBuilder(args)
               .ConfigureWebHostDefaults(webBuilder =>
               {
                   webBuilder.UseLibuv();
                   webBuilder.UseStartup<Startup>();
               });
  }
  ```

URL prefixes

When using `UseUrls`, `--urls` command-line argument, `urls` host configuration key, or `ASPNETCORE_URLS` environment variable, the URL prefixes can be in any of the following formats.

Only HTTP URL prefixes are valid. Kestrel doesn't support HTTPS when configuring URL bindings using `UseUrls`.

- IPv4 address with port number

  ```
  http://65.55.39.10:80/
  ```

  `0.0.0.0` is a special case that binds to all IPv4 addresses.

- IPv6 address with port number

  ```
  http://[0:0:0:0:0:ffff:4137:270a]:80/
  ```

  `[::]` is the IPv6 equivalent of IPv4 `0.0.0.0`.

- Host name with port number

  ```
  http://contoso.com:80/
  http://*:80/
  ```

  Host names, `*`, and `+`, aren't special. Anything not recognized as a valid IP address or `localhost` binds to all IPv4 and IPv6 IPs. To bind different host names to different ASP.NET Core apps on the same port, use HTTP.sys or a reverse proxy server, such as IIS, Nginx, or Apache.

  > **WARNING**
  > Hosting in a reverse proxy configuration requires host filtering.

- Host `localhost` name with port number or loopback IP with port number

  ```
  http://localhost:5000/
  http://127.0.0.1:5000/
  http://[::1]:5000/
  ```

  When `localhost` is specified, Kestrel attempts to bind to both IPv4 and IPv6 loopback interfaces. If the requested port is in use by another service on either loopback interface, Kestrel fails to start. If either loopback interface is unavailable for any other reason (most commonly because IPv6 isn't supported), Kestrel logs a warning.

Host filtering

While Kestrel supports configuration based on prefixes such as `http://example.com:5000`, Kestrel largely ignores the host name. Host `localhost` is a special case used for binding to loopback addresses. Any host other than an explicit IP address binds to all public IP addresses. `Host` headers aren't validated.

As a workaround, use Host Filtering Middleware. Host Filtering Middleware is provided by the Microsoft.AspNetCore.HostFiltering package, which is implicitly provided for ASP.NET Core apps. The middleware is added by CreateDefaultBuilder, which calls AddHostFiltering:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

Host Filtering Middleware is disabled by default. To enable the middleware, define an `AllowedHosts` key in *appsettings.json*/*appsettings.<EnvironmentName>.json*. The value is a semicolon-delimited list of host names without port numbers:

appsettings.json:

```
{
  "AllowedHosts": "example.com;localhost"
}
```

> **NOTE**
>
> Forwarded Headers Middleware also has an AllowedHosts option. Forwarded Headers Middleware and Host Filtering Middleware have similar functionality for different scenarios. Setting `AllowedHosts` with Forwarded Headers Middleware is appropriate when the `Host` header isn't preserved while forwarding requests with a reverse proxy server or load balancer. Setting `AllowedHosts` with Host Filtering Middleware is appropriate when Kestrel is used as a public-facing edge server or when the `Host` header is directly forwarded.
>
> For more information on Forwarded Headers Middleware, see Configure ASP.NET Core to work with proxy servers and load balancers.

Kestrel is a cross-platform web server for ASP.NET Core. Kestrel is the web server that's included by default in ASP.NET Core project templates.

Kestrel supports the following scenarios:

- HTTPS
- Opaque upgrade used to enable WebSockets
- Unix sockets for high performance behind Nginx
- HTTP/2 (except on macOS†)

†HTTP/2 will be supported on macOS in a future release.

Kestrel is supported on all platforms and versions that .NET Core supports.

View or download sample code (how to download)

HTTP/2 support

HTTP/2 is available for ASP.NET Core apps if the following base requirements are met:

- Operating system†
  - Windows Server 2016/Windows 10 or later‡

    - Linux with OpenSSL 1.0.2 or later (for example, Ubuntu 16.04 or later)
- Target framework: .NET Core 2.2 or later
- Application-Layer Protocol Negotiation (ALPN) connection
- TLS 1.2 or later connection

†HTTP/2 will be supported on macOS in a future release. ‡Kestrel has limited support for HTTP/2 on Windows Server 2012 R2 and Windows 8.1. Support is limited because the list of supported TLS cipher suites available on these operating systems is limited. A certificate generated using an Elliptic Curve Digital Signature Algorithm (ECDSA) may be required to secure TLS connections.

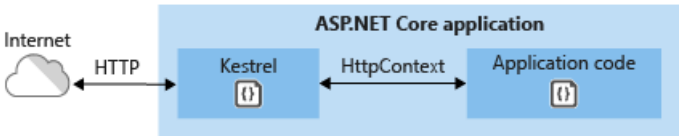
If an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/2`.

HTTP/2 is disabled by default. For more information on configuration, see the Kestrel options and ListenOptions.Protocols sections.

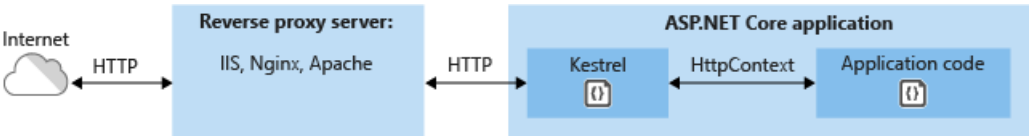
When to use Kestrel with a reverse proxy

Kestrel can be used by itself or with a *reverse proxy server*, such as Internet Information Services (IIS), Nginx, or Apache. A reverse proxy server receives HTTP requests from the network and forwards them to Kestrel.

Kestrel used as an edge (Internet-facing) web server:



Kestrel used in a reverse proxy configuration:



Either configuration, with or without a reverse proxy server, is a supported hosting configuration.

Kestrel used as an edge server without a reverse proxy server doesn't support sharing the same IP and port among multiple processes. When Kestrel is configured to listen on a port, Kestrel handles all of the traffic for that port regardless of requests' `Host` headers. A reverse proxy that can share ports has the ability to forward requests to Kestrel on a unique IP and port.

Even if a reverse proxy server isn't required, using a reverse proxy server might be a good choice.

A reverse proxy:

- Can limit the exposed public surface area of the apps that it hosts.
- Provide an additional layer of configuration and defense.
- Might integrate better with existing infrastructure.
- Simplify load balancing and secure communication (HTTPS) configuration. Only the reverse proxy server requires an X.509 certificate, and that server can communicate with the app's servers on the internal network using plain HTTP.

> **WARNING**
>
> Hosting in a reverse proxy configuration requires host filtering.

How to use Kestrel in ASP.NET Core apps

The Microsoft.AspNetCore.Server.Kestrel package is included in the Microsoft.AspNetCore.App metapackage.

ASP.NET Core project templates use Kestrel by default. In *Program.cs*, the template code calls CreateDefaultBuilder, which calls UseKestrel behind the scenes.

```
public static void Main(string[] args)
{
    CreateWebHostBuilder(args).Build().Run();
}

public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>();
```

For more information on `CreateDefaultBuilder` and building the host, see the *Set up a host* section of ASP.NET Core Web Host.

To provide additional configuration after calling `CreateDefaultBuilder`, use `ConfigureKestrel`:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, serverOptions) =>
        {
            // Set properties and call methods on serverOptions
        });
```

If the app doesn't call `CreateDefaultBuilder` to set up the host, call UseKestrel **before** calling `ConfigureKestrel`:

```
public static void Main(string[] args)
{
    var host = new WebHostBuilder()
        .UseContentRoot(Directory.GetCurrentDirectory())
        .UseKestrel()
        .UseIISIntegration()
        .UseStartup<Startup>()
        .ConfigureKestrel((context, serverOptions) =>
        {
            // Set properties and call methods on serverOptions
        })
        .Build();

    host.Run();
}
```

Kestrel options

The Kestrel web server has constraint configuration options that are especially useful in Internet-facing deployments.

Set constraints on the Limits property of the KestrelServerOptions class. The `Limits` property holds an instance of the KestrelServerLimits class.

The following examples use the Microsoft.AspNetCore.Server.Kestrel.Core namespace:

```
using Microsoft.AspNetCore.Server.Kestrel.Core;
```

Kestrel options, which are configured in C# code in the following examples, can also be set using a configuration provider. For example, the File Configuration Provider can load Kestrel configuration from an *appsettings.json* or *appsettings.{Environment}.json* file:

```
{
  "Kestrel": {
    "Limits": {
      "MaxConcurrentConnections": 100,
      "MaxConcurrentUpgradedConnections": 100
    }
  }
}
```

Use **one** of the following approaches:

- Configure Kestrel in `Startup.ConfigureServices`:

  1. Inject an instance of `IConfiguration` into the `Startup` class. The following example assumes that the injected configuration is assigned to the `Configuration` property.

  2. In `Startup.ConfigureServices`, load the `Kestrel` section of configuration into Kestrel's configuration:

     ```
     using Microsoft.Extensions.Configuration

     public class Startup
     {
         public Startup(IConfiguration configuration)
         {
             Configuration = configuration;
         }

         public IConfiguration Configuration { get; }

         public void ConfigureServices(IServiceCollection services)
         {
             services.Configure<KestrelServerOptions>(
                 Configuration.GetSection("Kestrel"));
         }

         public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
         {
             ...
         }
     }
     ```

- Configure Kestrel when building the host:

  In *Program.cs*, load the `Kestrel` section of configuration into Kestrel's configuration:

```
// using Microsoft.Extensions.DependencyInjection;

public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .ConfigureServices((context, services) =>
        {
            services.Configure<KestrelServerOptions>(
                context.Configuration.GetSection("Kestrel"));
        })
        .UseStartup<Startup>();
```

Both of the preceding approaches work with any configuration provider.

Keep-alive timeout

KeepAliveTimeout

Gets or sets the keep-alive timeout. Defaults to 2 minutes.

```
.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.Limits.MaxConcurrentConnections = 100;
    serverOptions.Limits.MaxConcurrentUpgradedConnections = 100;
    serverOptions.Limits.MaxRequestBodySize = 10 * 1024;
    serverOptions.Limits.MinRequestBodyDataRate =
        new MinDataRate(bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Limits.MinResponseDataRate =
        new MinDataRate(bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Listen(IPAddress.Loopback, 5000);
    serverOptions.Listen(IPAddress.Loopback, 5001, listenOptions =>
    {
        listenOptions.UseHttps("testCert.pfx", "testPassword");
    });
    serverOptions.Limits.KeepAliveTimeout = TimeSpan.FromMinutes(2);
    serverOptions.Limits.RequestHeadersTimeout = TimeSpan.FromMinutes(1);
});
```

Maximum client connections

MaxConcurrentConnections MaxConcurrentUpgradedConnections

The maximum number of concurrent open TCP connections can be set for the entire app with the following code:

```
.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.Limits.MaxConcurrentConnections = 100;
    serverOptions.Limits.MaxConcurrentUpgradedConnections = 100;
    serverOptions.Limits.MaxRequestBodySize = 10 * 1024;
    serverOptions.Limits.MinRequestBodyDataRate =
        new MinDataRate(bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Limits.MinResponseDataRate =
        new MinDataRate(bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Listen(IPAddress.Loopback, 5000);
    serverOptions.Listen(IPAddress.Loopback, 5001, listenOptions =>
    {
        listenOptions.UseHttps("testCert.pfx", "testPassword");
    });
    serverOptions.Limits.KeepAliveTimeout = TimeSpan.FromMinutes(2);
    serverOptions.Limits.RequestHeadersTimeout = TimeSpan.FromMinutes(1);
});
```

There's a separate limit for connections that have been upgraded from HTTP or HTTPS to

another protocol (for example, on a WebSockets request). After a connection is upgraded, it isn't counted against the `MaxConcurrentConnections` limit.

```
.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.Limits.MaxConcurrentConnections = 100;
    serverOptions.Limits.MaxConcurrentUpgradedConnections = 100;
    serverOptions.Limits.MaxRequestBodySize = 10 * 1024;
    serverOptions.Limits.MinRequestBodyDataRate =
        new MinDataRate(bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Limits.MinResponseDataRate =
        new MinDataRate(bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Listen(IPAddress.Loopback, 5000);
    serverOptions.Listen(IPAddress.Loopback, 5001, listenOptions =>
    {
        listenOptions.UseHttps("testCert.pfx", "testPassword");
    });
    serverOptions.Limits.KeepAliveTimeout = TimeSpan.FromMinutes(2);
    serverOptions.Limits.RequestHeadersTimeout = TimeSpan.FromMinutes(1);
});
```

The maximum number of connections is unlimited (null) by default.

Maximum request body size

MaxRequestBodySize

The default maximum request body size is 30,000,000 bytes, which is approximately 28.6 MB.

The recommended approach to override the limit in an ASP.NET Core MVC app is to use the RequestSizeLimitAttribute attribute on an action method:

```
[RequestSizeLimit(100000000)]
public IActionResult MyActionMethod()
```

Here's an example that shows how to configure the constraint for the app on every request:

```
.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.Limits.MaxConcurrentConnections = 100;
    serverOptions.Limits.MaxConcurrentUpgradedConnections = 100;
    serverOptions.Limits.MaxRequestBodySize = 10 * 1024;
    serverOptions.Limits.MinRequestBodyDataRate =
        new MinDataRate(bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Limits.MinResponseDataRate =
        new MinDataRate(bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Listen(IPAddress.Loopback, 5000);
    serverOptions.Listen(IPAddress.Loopback, 5001, listenOptions =>
    {
        listenOptions.UseHttps("testCert.pfx", "testPassword");
    });
    serverOptions.Limits.KeepAliveTimeout = TimeSpan.FromMinutes(2);
    serverOptions.Limits.RequestHeadersTimeout = TimeSpan.FromMinutes(1);
});
```

Override the setting on a specific request in middleware:

```
app.Run(async (context) =>
{
    context.Features.Get<IHttpMaxRequestBodySizeFeature>()
        .MaxRequestBodySize = 10 * 1024;

    var minRequestRateFeature =
        context.Features.Get<IHttpMinRequestBodyDataRateFeature>();
    var minResponseRateFeature =
        context.Features.Get<IHttpMinResponseDataRateFeature>();

    if (minRequestRateFeature != null)
    {
        minRequestRateFeature.MinDataRate = new MinDataRate(
            bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    }

    if (minResponseRateFeature != null)
    {
        minResponseRateFeature.MinDataRate = new MinDataRate(
            bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    }
```

An exception is thrown if the app configures the limit on a request after the app has started to read the request. There's an `IsReadOnly` property that indicates if the `MaxRequestBodySize` property is in read-only state, meaning it's too late to configure the limit.

When an app is run out-of-process behind the ASP.NET Core Module, Kestrel's request body size limit is disabled because IIS already sets the limit.

Minimum request body data rate

MinRequestBodyDataRate MinResponseDataRate

Kestrel checks every second if data is arriving at the specified rate in bytes/second. If the rate drops below the minimum, the connection is timed out. The grace period is the amount of time that Kestrel gives the client to increase its send rate up to the minimum; the rate isn't checked during that time. The grace period helps avoid dropping connections that are initially sending data at a slow rate due to TCP slow-start.

The default minimum rate is 240 bytes/second with a 5 second grace period.

A minimum rate also applies to the response. The code to set the request limit and the response limit is the same except for having `RequestBody` or `Response` in the property and interface names.

Here's an example that shows how to configure the minimum data rates in *Program.cs*:

```
.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.Limits.MaxConcurrentConnections = 100;
    serverOptions.Limits.MaxConcurrentUpgradedConnections = 100;
    serverOptions.Limits.MaxRequestBodySize = 10 * 1024;
    serverOptions.Limits.MinRequestBodyDataRate =
        new MinDataRate(bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Limits.MinResponseDataRate =
        new MinDataRate(bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Listen(IPAddress.Loopback, 5000);
    serverOptions.Listen(IPAddress.Loopback, 5001, listenOptions =>
    {
        listenOptions.UseHttps("testCert.pfx", "testPassword");
    });
    serverOptions.Limits.KeepAliveTimeout = TimeSpan.FromMinutes(2);
    serverOptions.Limits.RequestHeadersTimeout = TimeSpan.FromMinutes(1);
});
```

Override the minimum rate limits per request in middleware:

```
app.Run(async (context) =>
{
    context.Features.Get<IHttpMaxRequestBodySizeFeature>()
        .MaxRequestBodySize = 10 * 1024;

    var minRequestRateFeature =
        context.Features.Get<IHttpMinRequestBodyDataRateFeature>();
    var minResponseRateFeature =
        context.Features.Get<IHttpMinResponseDataRateFeature>();

    if (minRequestRateFeature != null)
    {
        minRequestRateFeature.MinDataRate = new MinDataRate(
            bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    }

    if (minResponseRateFeature != null)
    {
        minResponseRateFeature.MinDataRate = new MinDataRate(
            bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    }
```

Neither rate feature referenced in the prior sample are present in `HttpContext.Features` for HTTP/2 requests because modifying rate limits on a per-request basis isn't supported for HTTP/2 due to the protocol's support for request multiplexing. Server-wide rate limits configured via `KestrelServerOptions.Limits` still apply to both HTTP/1.x and HTTP/2 connections.

Request headers timeout

RequestHeadersTimeout

Gets or sets the maximum amount of time the server spends receiving request headers. Defaults to 30 seconds.

```
.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.Limits.MaxConcurrentConnections = 100;
    serverOptions.Limits.MaxConcurrentUpgradedConnections = 100;
    serverOptions.Limits.MaxRequestBodySize = 10 * 1024;
    serverOptions.Limits.MinRequestBodyDataRate =
        new MinDataRate(bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Limits.MinResponseDataRate =
        new MinDataRate(bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Listen(IPAddress.Loopback, 5000);
    serverOptions.Listen(IPAddress.Loopback, 5001, listenOptions =>
    {
        listenOptions.UseHttps("testCert.pfx", "testPassword");
    });
    serverOptions.Limits.KeepAliveTimeout = TimeSpan.FromMinutes(2);
    serverOptions.Limits.RequestHeadersTimeout = TimeSpan.FromMinutes(1);
});
```

Maximum streams per connection

`Http2.MaxStreamsPerConnection` limits the number of concurrent request streams per HTTP/2 connection. Excess streams are refused.

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, serverOptions) =>
        {
            serverOptions.Limits.Http2.MaxStreamsPerConnection = 100;
        });
```

The default value is 100.

Header table size

The HPACK decoder decompresses HTTP headers for HTTP/2 connections. `Http2.HeaderTableSize` limits the size of the header compression table that the HPACK decoder uses. The value is provided in octets and must be greater than zero (0).

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, serverOptions) =>
        {
            serverOptions.Limits.Http2.HeaderTableSize = 4096;
        });
```

The default value is 4096.

Maximum frame size

`Http2.MaxFrameSize` indicates the maximum size of the HTTP/2 connection frame payload to receive. The value is provided in octets and must be between 2^14 (16,384) and 2^24-1 (16,777,215).

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, serverOptions) =>
        {
            serverOptions.Limits.Http2.MaxFrameSize = 16384;
        });
```

The default value is 2^14 (16,384).

Maximum request header size

`Http2.MaxRequestHeaderFieldSize` indicates the maximum allowed size in octets of request header values. This limit applies to both name and value together in their compressed and uncompressed representations. The value must be greater than zero (0).

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, serverOptions) =>
        {
            serverOptions.Limits.Http2.MaxRequestHeaderFieldSize = 8192;
        });
```

The default value is 8,192.

Initial connection window size

`Http2.InitialConnectionWindowSize` indicates the maximum request body data in bytes the server buffers at one time aggregated across all requests (streams) per connection. Requests are also limited by `Http2.InitialStreamWindowSize`. The value must be greater than or equal to 65,535 and less than 2^31 (2,147,483,648).

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, serverOptions) =>
        {
            serverOptions.Limits.Http2.InitialConnectionWindowSize = 131072;
        });
```

The default value is 128 KB (131,072).

Initial stream window size

`Http2.InitialStreamWindowSize` indicates the maximum request body data in bytes the server buffers at one time per request (stream). Requests are also limited by `Http2.InitialStreamWindowSize`. The value must be greater than or equal to 65,535 and less than 2^31 (2,147,483,648).

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, serverOptions) =>
        {
            serverOptions.Limits.Http2.InitialStreamWindowSize = 98304;
        });
```

The default value is 96 KB (98,304).

Synchronous I/O

AllowSynchronousIO controls whether synchronous I/O is allowed for the request and response. The default value is `true`.

> **WARNING**
> A large number of blocking synchronous I/O operations can lead to thread pool starvation, which makes the app unresponsive. Only enable `AllowSynchronousIO` when using a library that doesn't support asynchronous I/O.

The following example enables synchronous I/O:

```
.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.AllowSynchronousIO = true;
});
```

For information about other Kestrel options and limits, see:

- KestrelServerOptions
- KestrelServerLimits
- ListenOptions

Endpoint configuration

By default, ASP.NET Core binds to:

- `http://localhost:5000`
- `https://localhost:5001` (when a local development certificate is present)

Specify URLs using the:

- `ASPNETCORE_URLS` environment variable.
- `--urls` command-line argument.
- `urls` host configuration key.
- `UseUrls` extension method.

The value provided using these approaches can be one or more HTTP and HTTPS endpoints (HTTPS if a default cert is available). Configure the value as a semicolon-separated list (for example, `"Urls": "http://localhost:8000;http://localhost:8001"`).

For more information on these approaches, see Server URLs and Override configuration.

A development certificate is created:

- When the .NET Core SDK is installed.
- The dev-certs tool is used to create a certificate.

Some browsers require granting explicit permission to trust the local development certificate.

Project templates configure apps to run on HTTPS by default and include HTTPS redirection and HSTS support.

Call Listen or ListenUnixSocket methods on KestrelServerOptions to configure URL prefixes and ports for Kestrel.

`UseUrls`, the `--urls` command-line argument, `urls` host configuration key, and the `ASPNETCORE_URLS` environment variable also work but have the limitations noted later in this section (a default certificate must be available for HTTPS endpoint configuration).

`KestrelServerOptions` configuration:

ConfigureEndpointDefaults(Action<ListenOptions>)

Specifies a configuration `Action` to run for each specified endpoint. Calling `ConfigureEndpointDefaults` multiple times replaces prior `Action`s with the last `Action` specified.

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, serverOptions) =>
        {
            serverOptions.ConfigureEndpointDefaults(listenOptions =>
            {
                // Configure endpoint defaults
            });
        });
```

> **NOTE**
> Endpoints created by calling Listen **before** calling ConfigureEndpointDefaults won't have the defaults applied.

ConfigureHttpsDefaults(Action<HttpsConnectionAdapterOptions>)

Specifies a configuration `Action` to run for each HTTPS endpoint. Calling `ConfigureHttpsDefaults` multiple times replaces prior `Action`s with the last `Action` specified.

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, serverOptions) =>
        {
            serverOptions.ConfigureHttpsDefaults(listenOptions =>
            {
                // certificate is an X509Certificate2
                listenOptions.ServerCertificate = certificate;
            });
        });
```

> **NOTE**
> Endpoints created by calling Listen **before** calling ConfigureHttpsDefaults won't have the defaults applied.

Configure(IConfiguration)

Creates a configuration loader for setting up Kestrel that takes an IConfiguration as input. The configuration must be scoped to the configuration section for Kestrel.

ListenOptions.UseHttps

Configure Kestrel to use HTTPS.

`ListenOptions.UseHttps` extensions:

- `UseHttps`: Configure Kestrel to use HTTPS with the default certificate. Throws an exception if no default certificate is configured.
- `UseHttps(string fileName)`
- `UseHttps(string fileName, string password)`
- `UseHttps(string fileName, string password, Action<HttpsConnectionAdapterOptions> configureOptions)`
- `UseHttps(StoreName storeName, string subject)`
- `UseHttps(StoreName storeName, string subject, bool allowInvalid)`
- `UseHttps(StoreName storeName, string subject, bool allowInvalid, StoreLocation location)`
- `UseHttps(StoreName storeName, string subject, bool allowInvalid, StoreLocation location, Action<HttpsConnectionAdapterOptions> configureOptions)`
- `UseHttps(X509Certificate2 serverCertificate)`
- `UseHttps(X509Certificate2 serverCertificate, Action<HttpsConnectionAdapterOptions> configureOptions)`
- `UseHttps(Action<HttpsConnectionAdapterOptions> configureOptions)`

`ListenOptions.UseHttps` parameters:

- `filename` is the path and file name of a certificate file, relative to the directory that contains the app's content files.
- `password` is the password required to access the X.509 certificate data.
- `configureOptions` is an `Action` to configure the `HttpsConnectionAdapterOptions`. Returns the `ListenOptions`.
- `storeName` is the certificate store from which to load the certificate.
- `subject` is the subject name for the certificate.
- `allowInvalid` indicates if invalid certificates should be considered, such as self-signed certificates.
- `location` is the store location to load the certificate from.
- `serverCertificate` is the X.509 certificate.

In production, HTTPS must be explicitly configured. At a minimum, a default certificate must be provided.

Supported configurations described next:

- No configuration
- Replace the default certificate from configuration
- Change the defaults in code

No configuration

Kestrel listens on `http://localhost:5000` and `https://localhost:5001` (if a default cert is available).

Replace the default certificate from configuration

`CreateDefaultBuilder` calls `Configure(context.Configuration.GetSection("Kestrel"))` by default to load Kestrel configuration. A default HTTPS app settings configuration schema is available for Kestrel. Configure multiple endpoints, including the URLs and the certificates to use, either from a file on disk or from a certificate store.

In the following *appsettings.json* example:

- Set **AllowInvalid** to `true` to permit the use of invalid certificates (for example, self-signed certificates).
- Any HTTPS endpoint that doesn't specify a certificate (**HttpsDefaultCert** in the example that follows) falls back to the cert defined under **Certificates** > **Default** or the development certificate.

```
{
  "Kestrel": {
    "Endpoints": {
      "Http": {
        "Url": "http://localhost:5000"
      },

      "HttpsInlineCertFile": {
        "Url": "https://localhost:5001",
        "Certificate": {
          "Path": "<path to .pfx file>",
          "Password": "<certificate password>"
        }
      },

      "HttpsInlineCertStore": {
        "Url": "https://localhost:5002",
        "Certificate": {
          "Subject": "<subject; required>",
          "Store": "<certificate store; required>",
          "Location": "<location; defaults to CurrentUser>",
          "AllowInvalid": "<true or false; defaults to false>"
        }
      },

      "HttpsDefaultCert": {
        "Url": "https://localhost:5003"
      },

      "Https": {
        "Url": "https://*:5004",
        "Certificate": {
          "Path": "<path to .pfx file>",
          "Password": "<certificate password>"
        }
      }
    },
    "Certificates": {
      "Default": {
        "Path": "<path to .pfx file>",
        "Password": "<certificate password>"
      }
    }
  }
}
```

An alternative to using **Path** and **Password** for any certificate node is to specify the certificate using certificate store fields. For example, the **Certificates** > **Default** certificate can be specified as:

```
"Default": {
  "Subject": "<subject; required>",
  "Store": "<cert store; required>",
  "Location": "<location; defaults to CurrentUser>",
  "AllowInvalid": "<true or false; defaults to false>"
}
```

Schema notes:

- Endpoints names are case-insensitive. For example, `HTTPS` and `Https` are valid.
- The `Url` parameter is required for each endpoint. The format for this parameter is the same as the top-level `Urls` configuration parameter except that it's limited to a single value.
- These endpoints replace those defined in the top-level `Urls` configuration rather than adding to them. Endpoints defined in code via `Listen` are cumulative with the endpoints defined in the configuration section.
- The `Certificate` section is optional. If the `Certificate` section isn't specified, the defaults defined in earlier scenarios are used. If no defaults are available, the server throws an exception and fails to start.
- The `Certificate` section supports both **Path–Password** and **Subject–Store** certificates.
- Any number of endpoints may be defined in this way so long as they don't cause port conflicts.
- `options.Configure(context.Configuration.GetSection("{SECTION}"))` returns a `KestrelConfigurationLoader` with an `.Endpoint(string name, listenOptions => { })` method that can be used to supplement a configured endpoint's settings:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel((context, serverOptions) =>
        {
            serverOptions.Configure(context.Configuration.GetSection("Kestrel"))
                .Endpoint("HTTPS", listenOptions =>
                {
                    listenOptions.HttpsOptions.SslProtocols = SslProtocols.Tls12;
                });
        });
```

`KestrelServerOptions.ConfigurationLoader` can be directly accessed to continue iterating on the existing loader, such as the one provided by CreateDefaultBuilder.

- The configuration section for each endpoint is available on the options in the `Endpoint` method so that custom settings may be read.
- Multiple configurations may be loaded by calling `options.Configure(context.Configuration.GetSection("{SECTION}"))` again with another section. Only the last configuration is used, unless `Load` is explicitly called on prior instances. The metapackage doesn't call `Load` so that its default configuration section may be replaced.
- `KestrelConfigurationLoader` mirrors the `Listen` family of APIs from `KestrelServerOptions` as `Endpoint` overloads, so code and config endpoints may be configured in the same place. These overloads don't use names and only consume default settings from configuration.

Change the defaults in code

`ConfigureEndpointDefaults` and `ConfigureHttpsDefaults` can be used to change default settings for `ListenOptions` and `HttpsConnectionAdapterOptions`, including overriding the default certificate specified in the prior scenario. `ConfigureEndpointDefaults` and `ConfigureHttpsDefaults` should be called before any endpoints are configured.

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel((context, serverOptions) =>
        {
            serverOptions.ConfigureEndpointDefaults(listenOptions =>
            {
                // Configure endpoint defaults
            });

            serverOptions.ConfigureHttpsDefaults(listenOptions =>
            {
                listenOptions.SslProtocols = SslProtocols.Tls12;
            });
        });
```

Kestrel support for SNI

Server Name Indication (SNI) can be used to host multiple domains on the same IP address and port. For SNI to function, the client sends the host name for the secure session to the server during the TLS handshake so that the server can provide the correct certificate. The client uses the furnished certificate for encrypted communication with the server during the secure session that follows the TLS handshake.

Kestrel supports SNI via the `ServerCertificateSelector` callback. The callback is invoked once per connection to allow the app to inspect the host name and select the appropriate certificate.

SNI support requires:

- Running on target framework `netcoreapp2.1` or later. On `net461` or later, the callback is invoked but the `name` is always `null`. The `name` is also `null` if the client doesn't provide the host name parameter in the TLS handshake.
- All websites run on the same Kestrel instance. Kestrel doesn't support sharing an IP address and port across multiple instances without a reverse proxy.

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, serverOptions) =>
        {
            serverOptions.ListenAnyIP(5005, listenOptions =>
            {
                listenOptions.UseHttps(httpsOptions =>
                {
                    var localhostCert = CertificateLoader.LoadFromStoreCert(
                        "localhost", "My", StoreLocation.CurrentUser,
                        allowInvalid: true);
                    var exampleCert = CertificateLoader.LoadFromStoreCert(
                        "example.com", "My", StoreLocation.CurrentUser,
                        allowInvalid: true);
                    var subExampleCert = CertificateLoader.LoadFromStoreCert(
                        "sub.example.com", "My", StoreLocation.CurrentUser,
                        allowInvalid: true);
                    var certs = new Dictionary<string, X509Certificate2>(
                        StringComparer.OrdinalIgnoreCase);
                    certs["localhost"] = localhostCert;
                    certs["example.com"] = exampleCert;
                    certs["sub.example.com"] = subExampleCert;

                    httpsOptions.ServerCertificateSelector = (connectionContext, name) =>
                    {
                        if (name != null && certs.TryGetValue(name, out var cert))
                        {
                            return cert;
                        }

                        return exampleCert;
                    };
                });
            });
        });
```

Connection logging

Call UseConnectionLogging to emit Debug level logs for byte-level communication on a connection. Connection logging is helpful for troubleshooting problems in low-level communication, such as during TLS encryption and behind proxies. If `UseConnectionLogging` is placed before `UseHttps`, encrypted traffic is logged. If `UseConnectionLogging` is placed after `UseHttps`, decrypted traffic is logged.

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Listen(IPAddress.Any, 8000, listenOptions =>
    {
        listenOptions.UseConnectionLogging();
    });
});
```

Bind to a TCP socket

The Listen method binds to a TCP socket, and an options lambda permits X.509 certificate configuration:

```
public static void Main(string[] args)
{
    CreateWebHostBuilder(args).Build().Run();
}

public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, serverOptions) =>
        {
            serverOptions.Listen(IPAddress.Loopback, 5000);
            serverOptions.Listen(IPAddress.Loopback, 5001, listenOptions =>
            {
                listenOptions.UseHttps("testCert.pfx", "testPassword");
            });
        });
```

The example configures HTTPS for an endpoint with ListenOptions. Use the same API to configure other Kestrel settings for specific endpoints.

On Windows, self-signed certificates can be created using the New-SelfSignedCertificate PowerShell cmdlet. For an unsupported example, see UpdateIISExpressSSLForChrome.ps1.

On macOS, Linux, and Windows, certificates can be created using OpenSSL.

Bind to a Unix socket

Listen on a Unix socket with ListenUnixSocket for improved performance with Nginx, as shown in this example:

```
.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.ListenUnixSocket("/tmp/kestrel-test.sock");
    serverOptions.ListenUnixSocket("/tmp/kestrel-test.sock", listenOptions =>
    {
        listenOptions.UseHttps("testCert.pfx", "testpassword");
    });
});
```

- In the Nginx confiuguration file, set the `server` > `location` > `proxy_pass` entry to `http://unix:/tmp/{KESTREL SOCKET}:/;`. `{KESTREL SOCKET}` is the name of the socket provided to ListenUnixSocket (for example, `kestrel-test.sock` in the preceding example).
- Ensure that the socket is writeable by Nginx (for example, `chmod go+w /tmp/kestrel-test.sock`).

Port 0

When the port number `0` is specified, Kestrel dynamically binds to an available port. The following example shows how to determine which port Kestrel actually bound at runtime:

```
public void Configure(IApplicationBuilder app)
{
    var serverAddressesFeature =
        app.ServerFeatures.Get<IServerAddressesFeature>();

    app.UseStaticFiles();

    app.Run(async (context) =>
    {
        context.Response.ContentType = "text/html";
        await context.Response
            .WriteAsync("<!DOCTYPE html><html lang=\"en\"><head>" +
                "<title></title></head><body><p>Hosted by Kestrel</p>");

        if (serverAddressesFeature != null)
        {
            await context.Response
                .WriteAsync("<p>Listening on the following addresses: " +
                    string.Join(", ", serverAddressesFeature.Addresses) +
                    "</p>");
        }

        await context.Response.WriteAsync("<p>Request URL: " +
            $"{context.Request.GetDisplayUrl()}<p>");
    });
}
```

When the app is run, the console window output indicates the dynamic port where the app can be reached:

```
Listening on the following addresses: http://127.0.0.1:48508
```

Limitations

Configure endpoints with the following approaches:

- UseUrls
- `--urls` command-line argument
- `urls` host configuration key
- `ASPNETCORE_URLS` environment variable

These methods are useful for making code work with servers other than Kestrel. However, be aware of the following limitations:

- HTTPS can't be used with these approaches unless a default certificate is provided in the HTTPS endpoint configuration (for example, using `KestrelServerOptions` configuration or a configuration file as shown earlier in this topic).
- When both the `Listen` and `UseUrls` approaches are used simultaneously, the `Listen` endpoints override the `UseUrls` endpoints.

IIS endpoint configuration

When using IIS, the URL bindings for IIS override bindings are set by either `Listen` or `UseUrls`. For more information, see the ASP.NET Core Module topic.

ListenOptions.Protocols

The `Protocols` property establishes the HTTP protocols (`HttpProtocols`) enabled on a connection endpoint or for the server. Assign a value to the `Protocols` property from the `HttpProtocols` enum.

`HttpProtocols` enum value	Connection protocol permitted
`Http1`	HTTP/1.1 only. Can be used with or without TLS.
`Http2`	HTTP/2 only. May be used without TLS only if the client supports a Prior Knowledge mode.
`Http1AndHttp2`	HTTP/1.1 and HTTP/2. HTTP/2 requires a TLS and Application-Layer Protocol Negotiation (ALPN) connection; otherwise, the connection defaults to HTTP/1.1.

The default protocol is HTTP/1.1.

TLS restrictions for HTTP/2:

- TLS version 1.2 or later
- Renegotiation disabled
- Compression disabled
- Minimum ephemeral key exchange sizes:
  - Elliptic curve Diffie-Hellman (ECDHE) [RFC4492]: 224 bits minimum
  - Finite field Diffie-Hellman (DHE) [`TLS12`]: 2048 bits minimum
- Cipher suite not blocked

`TLS_ECDHE_RSA_WITH_AES_128_GCM_SHA256` [`TLS-ECDHE`] with the P-256 elliptic curve [`FIPS186`] is supported by default.

The following example permits HTTP/1.1 and HTTP/2 connections on port 8000. Connections are secured by TLS with a supplied certificate:

```
.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.Listen(IPAddress.Any, 8000, listenOptions =>
    {
        listenOptions.Protocols = HttpProtocols.Http1AndHttp2;
        listenOptions.UseHttps("testCert.pfx", "testPassword");
    });
});
```

Optionally create an `IConnectionAdapter` implementation to filter TLS handshakes on a per-connection basis for specific ciphers:

```
.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.Listen(IPAddress.Any, 8000, listenOptions =>
    {
        listenOptions.Protocols = HttpProtocols.Http1AndHttp2;
        listenOptions.UseHttps("testCert.pfx", "testPassword");
        listenOptions.ConnectionAdapters.Add(new TlsFilterAdapter());
    });
});
```

```
private class TlsFilterAdapter : IConnectionAdapter
{
    public bool IsHttps => false;

    public Task<IAdaptedConnection> OnConnectionAsync(ConnectionAdapterContext context)
    {
        var tlsFeature = context.Features.Get<ITlsHandshakeFeature>();

        // Throw NotSupportedException for any cipher algorithm that the app doesn't
        // wish to support. Alternatively, define and compare
        // ITlsHandshakeFeature.CipherAlgorithm to a list of acceptable cipher
        // suites.
        //
        // No encryption is used with a CipherAlgorithmType.Null cipher algorithm.
        if (tlsFeature.CipherAlgorithm == CipherAlgorithmType.Null)
        {
            throw new NotSupportedException("Prohibited cipher: " +
tlsFeature.CipherAlgorithm);
        }

        return Task.FromResult<IAdaptedConnection>(new
AdaptedConnection(context.ConnectionStream));
    }

    private class AdaptedConnection : IAdaptedConnection
    {
        public AdaptedConnection(Stream adaptedStream)
        {
            ConnectionStream = adaptedStream;
        }

        public Stream ConnectionStream { get; }

        public void Dispose()
        {
        }
    }
}
```

Set the protocol from configuration

CreateDefaultBuilder calls `serverOptions.Configure(context.Configuration.GetSection("Kestrel"))` by default to load Kestrel configuration.

In the following *appsettings.json* example, a default connection protocol (HTTP/1.1 and HTTP/2) is established for all of Kestrel's endpoints:

```
{
  "Kestrel": {
    "EndpointDefaults": {
      "Protocols": "Http1AndHttp2"
    }
  }
}
```

The following configuration file example establishes a connection protocol for a specific endpoint:

```
{
  "Kestrel": {
    "Endpoints": {
      "HttpsDefaultCert": {
        "Url": "https://localhost:5001",
        "Protocols": "Http1AndHttp2"
      }
    }
  }
}
```

Protocols specified in code override values set by configuration.

Transport configuration

With the release of ASP.NET Core 2.1, Kestrel's default transport is no longer based on Libuv but instead based on managed sockets. This is a breaking change for ASP.NET Core 2.0 apps upgrading to 2.1 that call UseLibuv and depend on either of the following packages:

- Microsoft.AspNetCore.Server.Kestrel (direct package reference)
- Microsoft.AspNetCore.App

For projects that require the use of Libuv:

- Add a dependency for the Microsoft.AspNetCore.Server.Kestrel.Transport.Libuv package to the app's project file:

  ```
  <PackageReference Include="Microsoft.AspNetCore.Server.Kestrel.Transport.Libuv"
                    Version="{VERSION}" />
  ```

- Call UseLibuv:

  ```
  public class Program
  {
      public static void Main(string[] args)
      {
          CreateWebHostBuilder(args).Build().Run();
      }

      public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
          WebHost.CreateDefaultBuilder(args)
              .UseLibuv()
              .UseStartup<Startup>();
  }
  ```

URL prefixes

When using `UseUrls`, `--urls` command-line argument, `urls` host configuration key, or `ASPNETCORE_URLS` environment variable, the URL prefixes can be in any of the following formats.

Only HTTP URL prefixes are valid. Kestrel doesn't support HTTPS when configuring URL bindings using `UseUrls`.

- IPv4 address with port number

  ```
  http://65.55.39.10:80/
  ```

  `0.0.0.0` is a special case that binds to all IPv4 addresses.

- IPv6 address with port number

  ```
  http://[0:0:0:0:0:ffff:4137:270a]:80/
  ```

  `[::]` is the IPv6 equivalent of IPv4 `0.0.0.0`.

- Host name with port number

  ```
  http://contoso.com:80/
  http://*:80/
  ```

  Host names, `*`, and `+`, aren't special. Anything not recognized as a valid IP address or `localhost` binds to all IPv4 and IPv6 IPs. To bind different host names to different ASP.NET Core apps on the same port, use HTTP.sys or a reverse proxy server, such as IIS, Nginx, or Apache.

  > **WARNING**
  > Hosting in a reverse proxy configuration requires host filtering.

- Host `localhost` name with port number or loopback IP with port number

  ```
  http://localhost:5000/
  http://127.0.0.1:5000/
  http://[::1]:5000/
  ```

  When `localhost` is specified, Kestrel attempts to bind to both IPv4 and IPv6 loopback interfaces. If the requested port is in use by another service on either loopback interface, Kestrel fails to start. If either loopback interface is unavailable for any other reason (most commonly because IPv6 isn't supported), Kestrel logs a warning.

Host filtering

While Kestrel supports configuration based on prefixes such as `http://example.com:5000`, Kestrel largely ignores the host name. Host `localhost` is a special case used for binding to loopback addresses. Any host other than an explicit IP address binds to all public IP addresses. `Host` headers aren't validated.

As a workaround, use Host Filtering Middleware. Host Filtering Middleware is provided by the Microsoft.AspNetCore.HostFiltering package, which is included in the Microsoft.AspNetCore.App metapackage (ASP.NET Core 2.1 or 2.2). The middleware is added by CreateDefaultBuilder, which calls AddHostFiltering:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

Host Filtering Middleware is disabled by default. To enable the middleware, define an `AllowedHosts` key in *appsettings.json*/*appsettings.<EnvironmentName>.json*. The value is a semicolon-delimited list of host names without port numbers:

appsettings.json:

```
{
  "AllowedHosts": "example.com;localhost"
}
```

NOTE

Forwarded Headers Middleware also has an AllowedHosts option. Forwarded Headers Middleware and Host Filtering Middleware have similar functionality for different scenarios. Setting `AllowedHosts` with Forwarded Headers Middleware is appropriate when the `Host` header isn't preserved while forwarding requests with a reverse proxy server or load balancer. Setting `AllowedHosts` with Host Filtering Middleware is appropriate when Kestrel is used as a public-facing edge server or when the `Host` header is directly forwarded.

For more information on Forwarded Headers Middleware, see Configure ASP.NET Core to work with proxy servers and load balancers.

Kestrel is a cross-platform web server for ASP.NET Core. Kestrel is the web server that's included by default in ASP.NET Core project templates.

Kestrel supports the following scenarios:

- HTTPS
- Opaque upgrade used to enable WebSockets
- Unix sockets for high performance behind Nginx

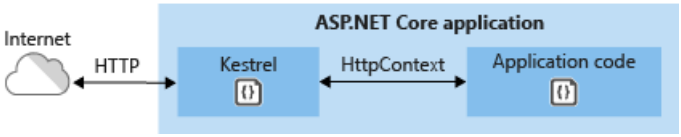
Kestrel is supported on all platforms and versions that .NET Core supports.

View or download sample code (how to download)

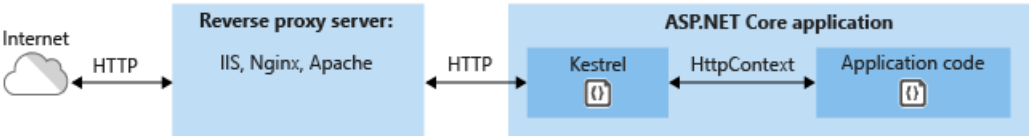
When to use Kestrel with a reverse proxy

Kestrel can be used by itself or with a *reverse proxy server*, such as Internet Information Services (IIS), Nginx, or Apache. A reverse proxy server receives HTTP requests from the network and forwards them to Kestrel.

Kestrel used as an edge (Internet-facing) web server:



Kestrel used in a reverse proxy configuration:



Either configuration, with or without a reverse proxy server, is a supported hosting configuration.

Kestrel used as an edge server without a reverse proxy server doesn't support sharing the same IP and port among multiple processes. When Kestrel is configured to listen on a port, Kestrel handles all of the traffic for that port regardless of requests' `Host` headers. A reverse proxy that can share ports has the ability to forward requests to Kestrel on a unique IP and port.

Even if a reverse proxy server isn't required, using a reverse proxy server might be a good choice.

A reverse proxy:

- Can limit the exposed public surface area of the apps that it hosts.
- Provide an additional layer of configuration and defense.
- Might integrate better with existing infrastructure.
- Simplify load balancing and secure communication (HTTPS) configuration. Only the reverse proxy server requires an X.509 certificate, and that server can communicate with the app's servers on the internal network using plain HTTP.

> **WARNING**
>
> Hosting in a reverse proxy configuration requires host filtering.

How to use Kestrel in ASP.NET Core apps

The Microsoft.AspNetCore.Server.Kestrel package is included in the Microsoft.AspNetCore.App metapackage.

ASP.NET Core project templates use Kestrel by default. In *Program.cs*, the template code calls CreateDefaultBuilder, which calls UseKestrel behind the scenes.

To provide additional configuration after calling `CreateDefaultBuilder`, call UseKestrel:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel(serverOptions =>
        {
            // Set properties and call methods on serverOptions
        });
```

For more information on `CreateDefaultBuilder` and building the host, see the *Set up a host* section of ASP.NET Core Web Host.

Kestrel options

The Kestrel web server has constraint configuration options that are especially useful in Internet-facing deployments.

Set constraints on the Limits property of the KestrelServerOptions class. The `Limits` property holds an instance of the KestrelServerLimits class.

The following examples use the Microsoft.AspNetCore.Server.Kestrel.Core namespace:

```
using Microsoft.AspNetCore.Server.Kestrel.Core;
```

Kestrel options, which are configured in C# code in the following examples, can also be set using a configuration provider. For example, the File Configuration Provider can load Kestrel configuration from an *appsettings.json* or *appsettings.{Environment}.json* file:

```
{
  "Kestrel": {
    "Limits": {
      "MaxConcurrentConnections": 100,
      "MaxConcurrentUpgradedConnections": 100
    }
  }
}
```

Use **one** of the following approaches:

- Configure Kestrel in `Startup.ConfigureServices`:

  1. Inject an instance of `IConfiguration` into the `Startup` class. The following example assumes that the injected configuration is assigned to the `Configuration` property.

  2. In `Startup.ConfigureServices`, load the `Kestrel` section of configuration into Kestrel's configuration:

     ```
     using Microsoft.Extensions.Configuration

     public class Startup
     {
         public Startup(IConfiguration configuration)
         {
             Configuration = configuration;
         }

         public IConfiguration Configuration { get; }

         public void ConfigureServices(IServiceCollection services)
         {
             services.Configure<KestrelServerOptions>(
                 Configuration.GetSection("Kestrel"));
         }

         public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
         {
             ...
         }
     }
     ```

- Configure Kestrel when building the host:

In *Program.cs*, load the `Kestrel` section of configuration into Kestrel's configuration:

```
// using Microsoft.Extensions.DependencyInjection;

public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .ConfigureServices((context, services) =>
        {
            services.Configure<KestrelServerOptions>(
                context.Configuration.GetSection("Kestrel"));
        })
        .UseStartup<Startup>();
```

Both of the preceding approaches work with any configuration provider.

Keep-alive timeout

KeepAliveTimeout

Gets or sets the keep-alive timeout. Defaults to 2 minutes.

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel(serverOptions =>
        {
            serverOptions.Limits.KeepAliveTimeout = TimeSpan.FromMinutes(2);
        });
```

Maximum client connections

MaxConcurrentConnections MaxConcurrentUpgradedConnections

The maximum number of concurrent open TCP connections can be set for the entire app with the following code:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel(serverOptions =>
        {
            serverOptions.Limits.MaxConcurrentConnections = 100;
        });
```

There's a separate limit for connections that have been upgraded from HTTP or HTTPS to another protocol (for example, on a WebSockets request). After a connection is upgraded, it isn't counted against the `MaxConcurrentConnections` limit.

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel(serverOptions =>
        {
            serverOptions.Limits.MaxConcurrentUpgradedConnections = 100;
        });
```

The maximum number of connections is unlimited (null) by default.

Maximum request body size

MaxRequestBodySize

The default maximum request body size is 30,000,000 bytes, which is approximately 28.6 MB.

The recommended approach to override the limit in an ASP.NET Core MVC app is to use the RequestSizeLimitAttribute attribute on an action method:

```
[RequestSizeLimit(100000000)]
public IActionResult MyActionMethod()
```

Here's an example that shows how to configure the constraint for the app on every request:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel(serverOptions =>
        {
            serverOptions.Limits.MaxRequestBodySize = 10 * 1024;
        });
```

Override the setting on a specific request in middleware:

```
app.Run(async (context) =>
{
    context.Features.Get<IHttpMaxRequestBodySizeFeature>()
        .MaxRequestBodySize = 10 * 1024;

    var minRequestRateFeature =
        context.Features.Get<IHttpMinRequestBodyDataRateFeature>();
    var minResponseRateFeature =
        context.Features.Get<IHttpMinResponseDataRateFeature>();

    if (minRequestRateFeature != null)
    {
        minRequestRateFeature.MinDataRate = new MinDataRate(
            bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    }

    if (minResponseRateFeature != null)
    {
        minResponseRateFeature.MinDataRate = new MinDataRate(
            bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    }
```

An exception is thrown if the app configures the limit on a request after the app has started to read the request. There's an `IsReadOnly` property that indicates if the `MaxRequestBodySize` property is in read-only state, meaning it's too late to configure the limit.

When an app is run out-of-process behind the ASP.NET Core Module, Kestrel's request body size limit is disabled because IIS already sets the limit.

Minimum request body data rate

MinRequestBodyDataRate MinResponseDataRate

Kestrel checks every second if data is arriving at the specified rate in bytes/second. If the rate drops below the minimum, the connection is timed out. The grace period is the amount of time that Kestrel gives the client to increase its send rate up to the minimum; the rate isn't checked during that time. The grace period helps avoid dropping connections that are initially sending data at a slow rate due to TCP slow-start.

The default minimum rate is 240 bytes/second with a 5 second grace period.

A minimum rate also applies to the response. The code to set the request limit and the response limit is the same except for having `RequestBody` or `Response` in the property and interface names.

Here's an example that shows how to configure the minimum data rates in *Program.cs*:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel(serverOptions =>
        {
            serverOptions.Limits.MinRequestBodyDataRate =
                new MinDataRate(bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
            serverOptions.Limits.MinResponseDataRate =
                new MinDataRate(bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
        });
```

Request headers timeout

RequestHeadersTimeout

Gets or sets the maximum amount of time the server spends receiving request headers. Defaults to 30 seconds.

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel(serverOptions =>
        {
            serverOptions.Limits.RequestHeadersTimeout = TimeSpan.FromMinutes(1);
        });
```

Synchronous I/O

AllowSynchronousIO controls whether synchronous I/O is allowed for the request and response. The default value is `true`.

> **WARNING**
> A large number of blocking synchronous I/O operations can lead to thread pool starvation, which makes the app unresponsive. Only enable `AllowSynchronousIO` when using a library that doesn't support asynchronous I/O.

The following example disables synchronous I/O:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel(serverOptions =>
        {
            serverOptions.AllowSynchronousIO = false;
        });
```

For information about other Kestrel options and limits, see:

- KestrelServerOptions
- KestrelServerLimits
- ListenOptions

Endpoint configuration

By default, ASP.NET Core binds to:

- `http://localhost:5000`
- `https://localhost:5001` (when a local development certificate is present)

Specify URLs using the:

- `ASPNETCORE_URLS` environment variable.
- `--urls` command-line argument.
- `urls` host configuration key.
- `UseUrls` extension method.

The value provided using these approaches can be one or more HTTP and HTTPS endpoints (HTTPS if a default cert is available). Configure the value as a semicolon-separated list (for example, `"Urls": "http://localhost:8000;http://localhost:8001"`).

For more information on these approaches, see Server URLs and Override configuration.

A development certificate is created:

- When the .NET Core SDK is installed.
- The dev-certs tool is used to create a certificate.

Some browsers require granting explicit permission to trust the local development certificate.

Project templates configure apps to run on HTTPS by default and include HTTPS redirection and HSTS support.

Call Listen or ListenUnixSocket methods on KestrelServerOptions to configure URL prefixes and ports for Kestrel.

`UseUrls`, the `--urls` command-line argument, `urls` host configuration key, and the `ASPNETCORE_URLS` environment variable also work but have the limitations noted later in this section (a default certificate must be available for HTTPS endpoint configuration).

`KestrelServerOptions` configuration:

ConfigureEndpointDefaults(Action<ListenOptions>)

Specifies a configuration `Action` to run for each specified endpoint. Calling `ConfigureEndpointDefaults` multiple times replaces prior `Action`s with the last `Action` specified.

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, serverOptions) =>
        {
            serverOptions.ConfigureEndpointDefaults(listenOptions =>
            {
                // Configure endpoint defaults
            });
        });
```

> **NOTE**
> Endpoints created by calling Listen **before** calling ConfigureEndpointDefaults won't have the defaults applied.

ConfigureHttpsDefaults(Action<HttpsConnectionAdapterOptions>)

Specifies a configuration `Action` to run for each HTTPS endpoint. Calling `ConfigureHttpsDefaults` multiple times replaces prior `Action`s with the last `Action` specified.

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, serverOptions) =>
        {
            serverOptions.ConfigureHttpsDefaults(listenOptions =>
            {
                // certificate is an X509Certificate2
                listenOptions.ServerCertificate = certificate;
            });
        });
```

> **NOTE**
> Endpoints created by calling Listen **before** calling ConfigureHttpsDefaults won't have the defaults applied.

Configure(IConfiguration)

Creates a configuration loader for setting up Kestrel that takes an IConfiguration as input. The configuration must be scoped to the configuration section for Kestrel.

ListenOptions.UseHttps

Configure Kestrel to use HTTPS.

`ListenOptions.UseHttps` extensions:

- `UseHttps`: Configure Kestrel to use HTTPS with the default certificate. Throws an exception if no default certificate is configured.
- `UseHttps(string fileName)`
- `UseHttps(string fileName, string password)`
- `UseHttps(string fileName, string password, Action<HttpsConnectionAdapterOptions> configureOptions)`
- `UseHttps(StoreName storeName, string subject)`
- `UseHttps(StoreName storeName, string subject, bool allowInvalid)`
- `UseHttps(StoreName storeName, string subject, bool allowInvalid, StoreLocation location)`
- `UseHttps(StoreName storeName, string subject, bool allowInvalid, StoreLocation location, Action<HttpsConnectionAdapterOptions> configureOptions)`
- `UseHttps(X509Certificate2 serverCertificate)`
- `UseHttps(X509Certificate2 serverCertificate, Action<HttpsConnectionAdapterOptions> configureOptions)`
- `UseHttps(Action<HttpsConnectionAdapterOptions> configureOptions)`

`ListenOptions.UseHttps` parameters:

- `filename` is the path and file name of a certificate file, relative to the directory that contains

the app's content files.

- `password` is the password required to access the X.509 certificate data.
- `configureOptions` is an `Action` to configure the `HttpsConnectionAdapterOptions`. Returns the `ListenOptions`.
- `storeName` is the certificate store from which to load the certificate.
- `subject` is the subject name for the certificate.
- `allowInvalid` indicates if invalid certificates should be considered, such as self-signed certificates.
- `location` is the store location to load the certificate from.
- `serverCertificate` is the X.509 certificate.

In production, HTTPS must be explicitly configured. At a minimum, a default certificate must be provided.

Supported configurations described next:

- No configuration
- Replace the default certificate from configuration
- Change the defaults in code

No configuration

Kestrel listens on `http://localhost:5000` and `https://localhost:5001` (if a default cert is available).

Replace the default certificate from configuration

`CreateDefaultBuilder` calls `Configure(context.Configuration.GetSection("Kestrel"))` by default to load Kestrel configuration. A default HTTPS app settings configuration schema is available for Kestrel. Configure multiple endpoints, including the URLs and the certificates to use, either from a file on disk or from a certificate store.

In the following *appsettings.json* example:

- Set **AllowInvalid** to `true` to permit the use of invalid certificates (for example, self-signed certificates).
- Any HTTPS endpoint that doesn't specify a certificate (**HttpsDefaultCert** in the example that follows) falls back to the cert defined under **Certificates** > **Default** or the development certificate.

```
{
  "Kestrel": {
    "Endpoints": {
      "Http": {
        "Url": "http://localhost:5000"
      },

      "HttpsInlineCertFile": {
        "Url": "https://localhost:5001",
        "Certificate": {
          "Path": "<path to .pfx file>",
          "Password": "<certificate password>"
        }
      },

      "HttpsInlineCertStore": {
        "Url": "https://localhost:5002",
        "Certificate": {
          "Subject": "<subject; required>",
          "Store": "<certificate store; required>",
          "Location": "<location; defaults to CurrentUser>",
          "AllowInvalid": "<true or false; defaults to false>"
        }
      },

      "HttpsDefaultCert": {
        "Url": "https://localhost:5003"
      },

      "Https": {
        "Url": "https://*:5004",
        "Certificate": {
          "Path": "<path to .pfx file>",
          "Password": "<certificate password>"
        }
      }
    },
    "Certificates": {
      "Default": {
        "Path": "<path to .pfx file>",
        "Password": "<certificate password>"
      }
    }
  }
}
```

An alternative to using **Path** and **Password** for any certificate node is to specify the certificate using certificate store fields. For example, the **Certificates** > **Default** certificate can be specified as:

```
"Default": {
  "Subject": "<subject; required>",
  "Store": "<cert store; required>",
  "Location": "<location; defaults to CurrentUser>",
  "AllowInvalid": "<true or false; defaults to false>"
}
```

Schema notes:

- Endpoints names are case-insensitive. For example, `HTTPS` and `Https` are valid.
- The `Url` parameter is required for each endpoint. The format for this parameter is the same as the top-level `Urls` configuration parameter except that it's limited to a single value.

- These endpoints replace those defined in the top-level `Urls` configuration rather than adding to them. Endpoints defined in code via `Listen` are cumulative with the endpoints defined in the configuration section.
- The `Certificate` section is optional. If the `Certificate` section isn't specified, the defaults defined in earlier scenarios are used. If no defaults are available, the server throws an exception and fails to start.
- The `Certificate` section supports both **Path–Password** and **Subject–Store** certificates.
- Any number of endpoints may be defined in this way so long as they don't cause port conflicts.
- `options.Configure(context.Configuration.GetSection("{SECTION}"))` returns a `KestrelConfigurationLoader` with an `.Endpoint(string name, listenOptions => { })` method that can be used to supplement a configured endpoint's settings:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel((context, serverOptions) =>
        {
            serverOptions.Configure(context.Configuration.GetSection("Kestrel"))
                .Endpoint("HTTPS", listenOptions =>
                {
                    listenOptions.HttpsOptions.SslProtocols = SslProtocols.Tls12;
                });
        });
```

`KestrelServerOptions.ConfigurationLoader` can be directly accessed to continue iterating on the existing loader, such as the one provided by CreateDefaultBuilder.

- The configuration section for each endpoint is available on the options in the `Endpoint` method so that custom settings may be read.
- Multiple configurations may be loaded by calling `options.Configure(context.Configuration.GetSection("{SECTION}"))` again with another section. Only the last configuration is used, unless `Load` is explicitly called on prior instances. The metapackage doesn't call `Load` so that its default configuration section may be replaced.
- `KestrelConfigurationLoader` mirrors the `Listen` family of APIs from `KestrelServerOptions` as `Endpoint` overloads, so code and config endpoints may be configured in the same place. These overloads don't use names and only consume default settings from configuration.

Change the defaults in code

`ConfigureEndpointDefaults` and `ConfigureHttpsDefaults` can be used to change default settings for `ListenOptions` and `HttpsConnectionAdapterOptions`, including overriding the default certificate specified in the prior scenario. `ConfigureEndpointDefaults` and `ConfigureHttpsDefaults` should be called before any endpoints are configured.

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel((context, serverOptions) =>
        {
            serverOptions.ConfigureEndpointDefaults(listenOptions =>
            {
                // Configure endpoint defaults
            });

            serverOptions.ConfigureHttpsDefaults(listenOptions =>
            {
                listenOptions.SslProtocols = SslProtocols.Tls12;
            });
        });
```

Kestrel support for SNI

Server Name Indication (SNI) can be used to host multiple domains on the same IP address and port. For SNI to function, the client sends the host name for the secure session to the server during the TLS handshake so that the server can provide the correct certificate. The client uses the furnished certificate for encrypted communication with the server during the secure session that follows the TLS handshake.

Kestrel supports SNI via the `ServerCertificateSelector` callback. The callback is invoked once per connection to allow the app to inspect the host name and select the appropriate certificate.

SNI support requires:

- Running on target framework `netcoreapp2.1` or later. On `net461` or later, the callback is invoked but the `name` is always `null`. The `name` is also `null` if the client doesn't provide the host name parameter in the TLS handshake.
- All websites run on the same Kestrel instance. Kestrel doesn't support sharing an IP address and port across multiple instances without a reverse proxy.

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel((context, serverOptions) =>
        {
            serverOptions.ListenAnyIP(5005, listenOptions =>
            {
                listenOptions.UseHttps(httpsOptions =>
                {
                    var localhostCert = CertificateLoader.LoadFromStoreCert(
                        "localhost", "My", StoreLocation.CurrentUser,
                        allowInvalid: true);
                    var exampleCert = CertificateLoader.LoadFromStoreCert(
                        "example.com", "My", StoreLocation.CurrentUser,
                        allowInvalid: true);
                    var subExampleCert = CertificateLoader.LoadFromStoreCert(
                        "sub.example.com", "My", StoreLocation.CurrentUser,
                        allowInvalid: true);
                    var certs = new Dictionary<string, X509Certificate2>(
                        StringComparer.OrdinalIgnoreCase);
                    certs["localhost"] = localhostCert;
                    certs["example.com"] = exampleCert;
                    certs["sub.example.com"] = subExampleCert;

                    httpsOptions.ServerCertificateSelector = (connectionContext, name) =>
                    {
                        if (name != null && certs.TryGetValue(name, out var cert))
                        {
                            return cert;
                        }

                        return exampleCert;
                    };
                });
            });
        })
        .Build();
```

Connection logging

Call UseConnectionLogging to emit Debug level logs for byte-level communication on a connection. Connection logging is helpful for troubleshooting problems in low-level communication, such as during TLS encryption and behind proxies. If `UseConnectionLogging` is placed before `UseHttps`, encrypted traffic is logged. If `UseConnectionLogging` is placed after `UseHttps`, decrypted traffic is logged.

```
webBuilder.ConfigureKestrel(serverOptions =>
{
    serverOptions.Listen(IPAddress.Any, 8000, listenOptions =>
    {
        listenOptions.UseConnectionLogging();
    });
});
```

Bind to a TCP socket

The Listen method binds to a TCP socket, and an options lambda permits X.509 certificate configuration:

```
public static void Main(string[] args)
{
    CreateWebHostBuilder(args).Build().Run();
}

public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel(serverOptions =>
        {
            serverOptions.Listen(IPAddress.Loopback, 5000);
            serverOptions.Listen(IPAddress.Loopback, 5001, listenOptions =>
            {
                listenOptions.UseHttps("testCert.pfx", "testPassword");
            });
        });
```

```
public static void Main(string[] args)
{
    CreateWebHostBuilder(args).Build().Run();
}

public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel(serverOptions =>
        {
            serverOptions.Listen(IPAddress.Loopback, 5000);
            serverOptions.Listen(IPAddress.Loopback, 5001, listenOptions =>
            {
                listenOptions.UseHttps("testCert.pfx", "testPassword");
            });
        });
```

The example configures HTTPS for an endpoint with ListenOptions. Use the same API to configure other Kestrel settings for specific endpoints.

On Windows, self-signed certificates can be created using the New-SelfSignedCertificate PowerShell cmdlet. For an unsupported example, see UpdateIISExpressSSLForChrome.ps1.

On macOS, Linux, and Windows, certificates can be created using OpenSSL.

Bind to a Unix socket

Listen on a Unix socket with ListenUnixSocket for improved performance with Nginx, as shown in this example:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseKestrel(serverOptions =>
        {
            serverOptions.ListenUnixSocket("/tmp/kestrel-test.sock");
            serverOptions.ListenUnixSocket("/tmp/kestrel-test.sock", listenOptions =>
            {
                listenOptions.UseHttps("testCert.pfx", "testpassword");
            });
        });
```

- In the Nginx confiuguration file, set the `server` > `location` > `proxy_pass` entry to `http://unix:/tmp/{KESTREL SOCKET}:/;`. `{KESTREL SOCKET}` is the name of the socket provided

to ListenUnixSocket (for example, `kestrel-test.sock` in the preceding example).

- Ensure that the socket is writeable by Nginx (for example, `chmod go+w /tmp/kestrel-test.sock`).

Port 0

When the port number `0` is specified, Kestrel dynamically binds to an available port. The following example shows how to determine which port Kestrel actually bound at runtime:

```
public void Configure(IApplicationBuilder app)
{
    var serverAddressesFeature =
        app.ServerFeatures.Get<IServerAddressesFeature>();

    app.UseStaticFiles();

    app.Run(async (context) =>
    {
        context.Response.ContentType = "text/html";
        await context.Response
            .WriteAsync("<!DOCTYPE html><html lang=\"en\"><head>" +
                "<title></title></head><body><p>Hosted by Kestrel</p>");

        if (serverAddressesFeature != null)
        {
            await context.Response
                .WriteAsync("<p>Listening on the following addresses: " +
                    string.Join(", ", serverAddressesFeature.Addresses) +
                    "</p>");
        }

        await context.Response.WriteAsync("<p>Request URL: " +
            $"{context.Request.GetDisplayUrl()}<p>");
    });
}
```

When the app is run, the console window output indicates the dynamic port where the app can be reached:

```
Listening on the following addresses: http://127.0.0.1:48508
```

Limitations

Configure endpoints with the following approaches:

- UseUrls
- `--urls` command-line argument
- `urls` host configuration key
- `ASPNETCORE_URLS` environment variable

These methods are useful for making code work with servers other than Kestrel. However, be aware of the following limitations:

- HTTPS can't be used with these approaches unless a default certificate is provided in the HTTPS endpoint configuration (for example, using `KestrelServerOptions` configuration or a configuration file as shown earlier in this topic).
- When both the `Listen` and `UseUrls` approaches are used simultaneously, the `Listen` endpoints override the `UseUrls` endpoints.

IIS endpoint configuration

When using IIS, the URL bindings for IIS override bindings are set by either `Listen` or `UseUrls`. For more information, see the ASP.NET Core Module topic.

Transport configuration

With the release of ASP.NET Core 2.1, Kestrel's default transport is no longer based on Libuv but instead based on managed sockets. This is a breaking change for ASP.NET Core 2.0 apps upgrading to 2.1 that call UseLibuv and depend on either of the following packages:

- Microsoft.AspNetCore.Server.Kestrel (direct package reference)
- Microsoft.AspNetCore.App

For projects that require the use of Libuv:

- Add a dependency for the Microsoft.AspNetCore.Server.Kestrel.Transport.Libuv package to the app's project file:

```
<PackageReference Include="Microsoft.AspNetCore.Server.Kestrel.Transport.Libuv"
                  Version="{VERSION}" />
```

- Call UseLibuv:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseLibuv()
            .UseStartup<Startup>();
}
```

URL prefixes

When using `UseUrls`, `--urls` command-line argument, `urls` host configuration key, or `ASPNETCORE_URLS` environment variable, the URL prefixes can be in any of the following formats.

Only HTTP URL prefixes are valid. Kestrel doesn't support HTTPS when configuring URL bindings using `UseUrls`.

- IPv4 address with port number

```
http://65.55.39.10:80/
```

  `0.0.0.0` is a special case that binds to all IPv4 addresses.

- IPv6 address with port number

```
http://[0:0:0:0:0:ffff:4137:270a]:80/
```

  `[::]` is the IPv6 equivalent of IPv4 `0.0.0.0`.

- Host name with port number

```
http://contoso.com:80/
http://*:80/
```

Host names, `*`, and `+`, aren't special. Anything not recognized as a valid IP address or `localhost` binds to all IPv4 and IPv6 IPs. To bind different host names to different ASP.NET Core apps on the same port, use HTTP.sys or a reverse proxy server, such as IIS, Nginx, or Apache.

> **WARNING**
> Hosting in a reverse proxy configuration requires host filtering.

- Host `localhost` name with port number or loopback IP with port number

```
http://localhost:5000/
http://127.0.0.1:5000/
http://[::1]:5000/
```

When `localhost` is specified, Kestrel attempts to bind to both IPv4 and IPv6 loopback interfaces. If the requested port is in use by another service on either loopback interface, Kestrel fails to start. If either loopback interface is unavailable for any other reason (most commonly because IPv6 isn't supported), Kestrel logs a warning.

Host filtering

While Kestrel supports configuration based on prefixes such as `http://example.com:5000`, Kestrel largely ignores the host name. Host `localhost` is a special case used for binding to loopback addresses. Any host other than an explicit IP address binds to all public IP addresses. `Host` headers aren't validated.

As a workaround, use Host Filtering Middleware. Host Filtering Middleware is provided by the Microsoft.AspNetCore.HostFiltering package, which is included in the Microsoft.AspNetCore.App metapackage (ASP.NET Core 2.1 or 2.2). The middleware is added by CreateDefaultBuilder, which calls AddHostFiltering:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

Host Filtering Middleware is disabled by default. To enable the middleware, define an `AllowedHosts` key in *appsettings.json*/*appsettings.<EnvironmentName>.json*. The value is a semicolon-delimited list of host names without port numbers:

appsettings.json:

```
{
  "AllowedHosts": "example.com;localhost"
}
```

NOTE

Forwarded Headers Middleware also has an AllowedHosts option. Forwarded Headers Middleware and Host Filtering Middleware have similar functionality for different scenarios. Setting `AllowedHosts` with Forwarded Headers Middleware is appropriate when the `Host` header isn't preserved while forwarding requests with a reverse proxy server or load balancer. Setting `AllowedHosts` with Host Filtering Middleware is appropriate when Kestrel is used as a public-facing edge server or when the `Host` header is directly forwarded.

For more information on Forwarded Headers Middleware, see Configure ASP.NET Core to work with proxy servers and load balancers.

HTTP/1.1 request draining

Opening HTTP connections is time consuming. For HTTPS, it's also resource intensive. Therefore, Kestrel tries to reuse connections per the HTTP/1.1 protocol. A request body must be fully consumed to allow the connection to be reused. The app doesn't always consume the request body, such as a `POST` requests where the server returns a redirect or 404 response. In the `POST` -redirect case:

- The client may already have sent part of the `POST` data.
- The server writes the 301 response.
- The connection can't be used for a new request until the `POST` data from the previous request body has been fully read.
- Kestrel tries to drain the request body. Draining the request body means reading and discarding the data without processing it.

The draining process makes a tradoff between allowing the connection to be reused and the time it takes to drain any remaining data:

- Draining has a timeout of five seconds, which isn't configurable.
- If all of the data specified by the `Content-Length` or `Transfer-Encoding` header hasn't been read before the timeout, the connection is closed.

Sometimes you may want to terminate the request immediately, before or after writing the response. For example, clients may have restrictive data caps, so limiting uploaded data might be a priority. In such cases to terminate a request, call HttpContext.Abort from a controller, Razor Page, or middleware.

There are caveats to calling `Abort`:

- Creating new connections can be slow and expensive.
- There's no guarantee that the client has read the response before the connection closes.
- Calling `Abort` should be rare and reserved for severe error cases, not common errors.
  - Only call `Abort` when a specific problem needs to be solved. For example, call `Abort` if malicious clients are trying to `POST` data or when there's a bug in client code that causes large or numerous requests.
  - Don't call `Abort` for common error situations, such as HTTP 404 (Not Found).

Calling HttpResponse.CompleteAsync before calling `Abort` ensures that the server has completed writing the response. However, client behavior isn't predictable and they may not read the response before the connection is aborted.

This process is different for HTTP/2 because the protocol supports aborting individual request streams without closing the connection. The five second drain timeout doesn't apply. If there's any unread request body data after completing a response, then the server sends an HTTP/2 RST frame. Additional request body data frames are ignored.

If possible, it's better for clients to utilize the Expect: 100-continue request header and wait for the server to respond before starting to send the request body. That gives the client an opportunity to examine the response and abort before sending unneeded data.

HTTP.sys web server implementation in ASP.NET Core

9/22/2020 • 37 minutes to read • Edit Online

By Tom Dykstra and Chris Ross

HTTP.sys is a web server for ASP.NET Core that only runs on Windows. HTTP.sys is an alternative to Kestrel server and offers some features that Kestrel doesn't provide.

> **IMPORTANT**
> HTTP.sys isn't compatible with the ASP.NET Core Module and can't be used with IIS or IIS Express.

HTTP.sys supports the following features:

- Windows Authentication
- Port sharing
- HTTPS with SNI
- HTTP/2 over TLS (Windows 10 or later)
- Direct file transmission
- Response caching
- WebSockets (Windows 8 or later)

Supported Windows versions:

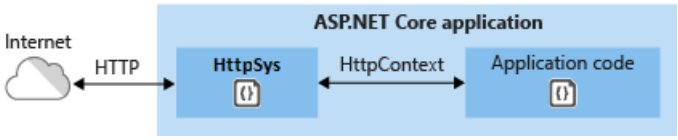
- Windows 7 or later
- Windows Server 2008 R2 or later

View or download sample code (how to download)

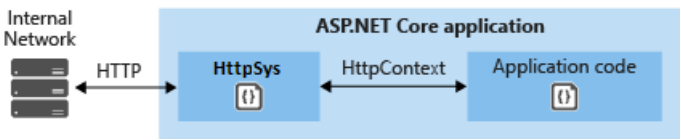
When to use HTTP.sys

HTTP.sys is useful for deployments where:

- There's a need to expose the server directly to the Internet without using IIS.



- An internal deployment requires a feature not available in Kestrel, such as Windows Authentication.



HTTP.sys is mature technology that protects against many types of attacks and provides the robustness, security, and scalability of a full-featured web server. IIS itself runs as an HTTP listener on top of HTTP.sys.

HTTP/2 support

HTTP/2 is enabled for ASP.NET Core apps if the following base requirements are met:

- Windows Server 2016/Windows 10 or later
- Application-Layer Protocol Negotiation (ALPN) connection
- TLS 1.2 or later connection

If an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/2`.

HTTP/2 is enabled by default. If an HTTP/2 connection isn't established, the connection falls back to HTTP/1.1. In a future release of Windows, HTTP/2 configuration flags will be available, including the ability to disable HTTP/2 with HTTP.sys.

Kernel mode authentication with Kerberos

HTTP.sys delegates to kernel mode authentication with the Kerberos authentication protocol. User mode authentication isn't supported with Kerberos and HTTP.sys. The machine account must be used to decrypt the Kerberos token/ticket that's obtained from Active Directory and forwarded by the client to the server to authenticate the user. Register the Service Principal Name (SPN) for the host, not the user of the app.

How to use HTTP.sys

Configure the ASP.NET Core app to use HTTP.sys

Call the UseHttpSys extension method when building the host, specifying any required HttpSysOptions. The following example sets options to their default values:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseHttpSys(options =>
            {
                options.AllowSynchronousIO = false;
                options.Authentication.Schemes = AuthenticationSchemes.None;
                options.Authentication.AllowAnonymous = true;
                options.MaxConnections = null;
                options.MaxRequestBodySize = 30000000;
                options.UrlPrefixes.Add("http://localhost:5005");
            });
            webBuilder.UseStartup<Startup>();
        });
```

Additional HTTP.sys configuration is handled through registry settings.

HTTP.sys options

PROPERTY	DESCRIPTION	DEFAULT
AllowSynchronousIO	Control whether synchronous input/output is allowed for the `HttpContext.Request.Body` and `HttpContext.Response.Body`.	`false`
Authentication.AllowAnonymous	Allow anonymous requests.	`true`

PROPERTY	DESCRIPTION	DEFAULT
Authentication.Schemes	Specify the allowed authentication schemes. May be modified at any time prior to disposing the listener. Values are provided by the AuthenticationSchemes enum: `Basic`, `Kerberos`, `Negotiate`, `None`, and `NTLM`.	`None`
EnableResponseCaching	Attempt kernel-mode caching for responses with eligible headers. The response may not include `Set-Cookie`, `Vary`, or `Pragma` headers. It must include a `Cache-Control` header that's `public` and either a `shared-max-age` or `max-age` value, or an `Expires` header.	`true`
MaxAccepts	The maximum number of concurrent accepts.	5 × Environment.ProcessorCount
MaxConnections	The maximum number of concurrent connections to accept. Use `-1` for infinite. Use `null` to use the registry's machine-wide setting.	`null` (machine-wide setting)
MaxRequestBodySize	See the MaxRequestBodySize section.	30000000 bytes (~28.6 MB)
RequestQueueLimit	The maximum number of requests that can be queued.	1000
`RequestQueueMode`	This indicates whether the server is responsible for creating and configuring the request queue, or if it should attach to an existing queue. Most existing configuration options do not apply when attaching to an existing queue.	`RequestQueueMode.Create`
`RequestQueueName`	The name of the HTTP.sys request queue.	`null` (Anonymous queue)
ThrowWriteExceptions	Indicate if response body writes that fail due to client disconnects should throw exceptions or complete normally.	`false` (complete normally)

PROPERTY	DESCRIPTION	DEFAULT
Timeouts	Expose the HTTP.sys TimeoutManager configuration, which may also be configured in the registry. Follow the API links to learn more about each setting, including default values: • TimeoutManager.DrainEntityBody: Time allowed for the HTTP Server API to drain the entity body on a Keep-Alive connection. • TimeoutManager.EntityBody: Time allowed for the request entity body to arrive. • TimeoutManager.HeaderWait: Time allowed for the HTTP Server API to parse the request header. • TimeoutManager.IdleConnection: Time allowed for an idle connection. • TimeoutManager.MinSendBytesPerSecond: The minimum send rate for the response. • TimeoutManager.RequestQueue: Time allowed for the request to remain in the request queue before the app picks it up.	
UrlPrefixes	Specify the UrlPrefixCollection to register with HTTP.sys. The most useful is UrlPrefixCollection.Add, which is used to add a prefix to the collection. These may be modified at any time prior to disposing the listener.	

MaxRequestBodySize

The maximum allowed size of any request body in bytes. When set to `null`, the maximum request body size is unlimited. This limit has no effect on upgraded connections, which are always unlimited.

The recommended method to override the limit in an ASP.NET Core MVC app for a single `IActionResult` is to use the RequestSizeLimitAttribute attribute on an action method:

```
[RequestSizeLimit(100000000)]
public IActionResult MyActionMethod()
```

An exception is thrown if the app attempts to configure the limit on a request after the app has started reading the request. An `IsReadOnly` property can be used to indicate if the `MaxRequestBodySize` property is in a read-only state, meaning it's too late to configure the limit.

If the app should override MaxRequestBodySize per-request, use the IHttpMaxRequestBodySizeFeature:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env,
    ILogger<Startup> logger, IServer server)
{
    app.Use(async (context, next) =>
    {
        context.Features.Get<IHttpMaxRequestBodySizeFeature>()
            .MaxRequestBodySize = 10 * 1024;

        var serverAddressesFeature =
            app.ServerFeatures.Get<IServerAddressesFeature>();
        var addresses = string.Join(", ", serverAddressesFeature?.Addresses);

        logger.LogInformation("Addresses: {Addresses}", addresses);

        await next.Invoke();
    });

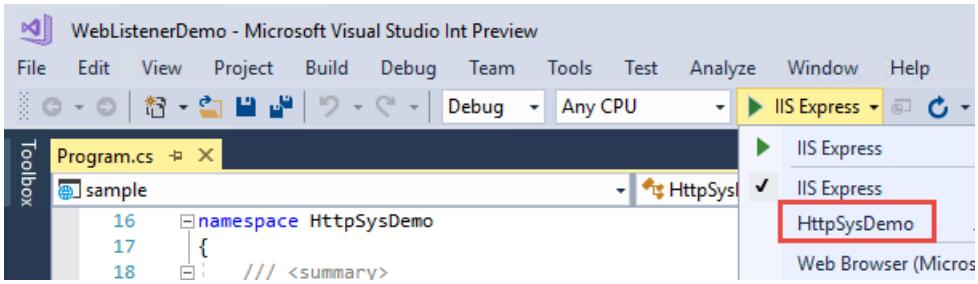
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
    }

    app.UseStaticFiles();
    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

If using Visual Studio, make sure the app isn't configured to run IIS or IIS Express.

In Visual Studio, the default launch profile is for IIS Express. To run the project as a console app, manually change the selected profile, as shown in the following screen shot:



Configure Windows Server

1. Determine the ports to open for the app and use Windows Firewall or the New-NetFirewallRule PowerShell cmdlet to open firewall ports to allow traffic to reach HTTP.sys. In the following commands and app configuration, port 443 is used.

2. When deploying to an Azure VM, open the ports in the Network Security Group. In the following commands and app configuration, port 443 is used.

3. Obtain and install X.509 certificates, if required.

   On Windows, create self-signed certificates using the New-SelfSignedCertificate PowerShell cmdlet. For an unsupported example, see UpdateIISExpressSSLForChrome.ps1.

   Install either self-signed or CA-signed certificates in the server's **Local Machine** > **Personal** store.

4. If the app is a framework-dependent deployment, install .NET Core, .NET Framework, or both (if the app is a .NET Core app targeting the .NET Framework).

   - **.NET Core**: If the app requires .NET Core, obtain and run the **.NET Core Runtime** installer from .NET Core Downloads. Don't install the full SDK on the server.
   - **.NET Framework**: If the app requires .NET Framework, see the .NET Framework installation guide. Install the required .NET Framework. The installer for the latest .NET Framework is available from the .NET Core Downloads page.

   If the app is a self-contained deployment, the app includes the runtime in its deployment. No framework installation is required on the server.

5. Configure URLs and ports in the app.

   By default, ASP.NET Core binds to `http://localhost:5000`. To configure URL prefixes and ports, options include:

   - UseUrls
   - `urls` command-line argument
   - `ASPNETCORE_URLS` environment variable
   - UrlPrefixes

   The following code example shows how to use UrlPrefixes with the server's local IP address `10.0.0.4` on port 443:

   ```
   public static IHostBuilder CreateHostBuilder(string[] args) =>
       Host.CreateDefaultBuilder(args)
           .ConfigureWebHostDefaults(webBuilder =>
           {
               webBuilder.UseHttpSys(options =>
               {
                   options.UrlPrefixes.Add("https://10.0.0.4:443");
               });
               webBuilder.UseStartup<Startup>();
           });
   ```

   An advantage of `UrlPrefixes` is that an error message is generated immediately for improperly formatted prefixes.

   The settings in `UrlPrefixes` override `UseUrls` / `urls` / `ASPNETCORE_URLS` settings. Therefore, an advantage of `UseUrls`, `urls`, and the `ASPNETCORE_URLS` environment variable is that it's easier to switch between Kestrel and HTTP.sys.

   HTTP.sys uses the HTTP Server API UrlPrefix string formats.

   > **WARNING**
   > Top-level wildcard bindings (`http://*:80/` and `http://+:80`) should **not** be used. Top-level wildcard bindings create app security vulnerabilities. This applies to both strong and weak wildcards. Use explicit host names or IP addresses rather than wildcards. Subdomain wildcard binding (for example, `*.mysub.com`) isn't a security risk if you control the entire parent domain (as opposed to `*.com`, which is vulnerable). For more information, see RFC 7230: Section 5.4: Host.

6. Preregister URL prefixes on the server.

   The built-in tool for configuring HTTP.sys is *netsh.exe*. *netsh.exe* is used to reserve URL prefixes and assign X.509 certificates. The tool requires administrator privileges.

Use the *netsh.exe* tool to register URLs for the app:

```
netsh http add urlacl url=<URL> user=<USER>
```

- `<URL>`: The fully qualified Uniform Resource Locator (URL). Don't use a wildcard binding. Use a valid hostname or local IP address. *The URL must include a trailing slash.*
- `<USER>`: Specifies the user or user-group name.

In the following example, the local IP address of the server is `10.0.0.4`:

```
netsh http add urlacl url=https://10.0.0.4:443/ user=Users
```

When a URL is registered, the tool responds with `URL reservation successfully added`.

To delete a registered URL, use the `delete urlacl` command:

```
netsh http delete urlacl url=<URL>
```

7. Register X.509 certificates on the server.

   Use the *netsh.exe* tool to register certificates for the app:

   ```
   netsh http add sslcert ipport=<IP>:<PORT> certhash=<THUMBPRINT> appid="{<GUID>}"
   ```

   - `<IP>`: Specifies the local IP address for the binding. Don't use a wildcard binding. Use a valid IP address.
   - `<PORT>`: Specifies the port for the binding.
   - `<THUMBPRINT>`: The X.509 certificate thumbprint.
   - `<GUID>`: A developer-generated GUID to represent the app for informational purposes.

   For reference purposes, store the GUID in the app as a package tag:

   - In Visual Studio:
     - Open the app's project properties by right-clicking on the app in **Solution Explorer** and selecting **Properties**.
     - Select the **Package** tab.
     - Enter the GUID that you created in the **Tags** field.
   - When not using Visual Studio:
     - Open the app's project file.
     - Add a `<PackageTags>` property to a new or existing `<PropertyGroup>` with the GUID that you created:

       ```
       <PropertyGroup>
         <PackageTags>9412ee86-c21b-4eb8-bd89-f650fbf44931</PackageTags>
       </PropertyGroup>
       ```

   In the following example:

   - The local IP address of the server is `10.0.0.4`.
   - An online random GUID generator provides the `appid` value.

```
netsh http add sslcert
    ipport=10.0.0.4:443
    certhash=b66ee04419d4ee37464ab8785ff02449980eae10
    appid="{9412ee86-c21b-4eb8-bd89-f650fbf44931}"
```

When a certificate is registered, the tool responds with `SSL Certificate successfully added`.

To delete a certificate registration, use the `delete sslcert` command:

```
netsh http delete sslcert ipport=<IP>:<PORT>
```

Reference documentation for *netsh.exe*:

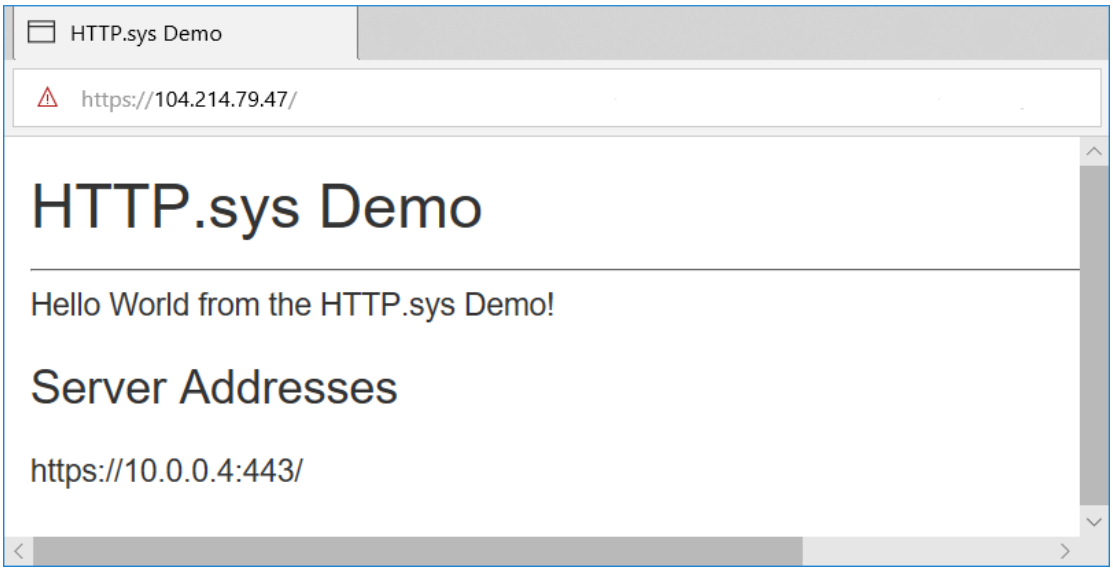
- Netsh Commands for Hypertext Transfer Protocol (HTTP)
- UrlPrefix Strings

8. Run the app.

   Administrator privileges aren't required to run the app when binding to localhost using HTTP (not HTTPS) with a port number greater than 1024. For other configurations (for example, using a local IP address or binding to port 443), run the app with administrator privileges.

   The app responds at the server's public IP address. In this example, the server is reached from the Internet at its public IP address of `104.214.79.47`.

   A development certificate is used in this example. The page loads securely after bypassing the browser's untrusted certificate warning.



Proxy server and load balancer scenarios

For apps hosted by HTTP.sys that interact with requests from the Internet or a corporate network, additional configuration might be required when hosting behind proxy servers and load balancers. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Additional resources

- Enable Windows Authentication with HTTP.sys
- HTTP Server API
- aspnet/HttpSysServer GitHub repository (source code)

- The host
- Troubleshoot and debug ASP.NET Core projects

HTTP.sys is a web server for ASP.NET Core that only runs on Windows. HTTP.sys is an alternative to Kestrel server and offers some features that Kestrel doesn't provide.

> **IMPORTANT**
> HTTP.sys isn't compatible with the ASP.NET Core Module and can't be used with IIS or IIS Express.

HTTP.sys supports the following features:

- Windows Authentication
- Port sharing
- HTTPS with SNI
- HTTP/2 over TLS (Windows 10 or later)
- Direct file transmission
- Response caching
- WebSockets (Windows 8 or later)

Supported Windows versions:

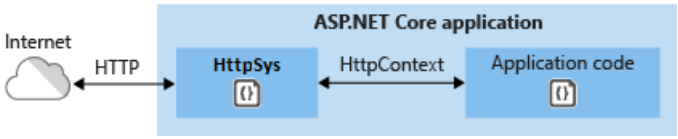
- Windows 7 or later
- Windows Server 2008 R2 or later

View or download sample code (how to download)

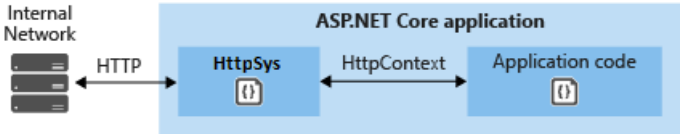
When to use HTTP.sys

HTTP.sys is useful for deployments where:

- There's a need to expose the server directly to the Internet without using IIS.



- An internal deployment requires a feature not available in Kestrel, such as Windows Authentication.



HTTP.sys is mature technology that protects against many types of attacks and provides the robustness, security, and scalability of a full-featured web server. IIS itself runs as an HTTP listener on top of HTTP.sys.

HTTP/2 support

HTTP/2 is enabled for ASP.NET Core apps if the following base requirements are met:

- Windows Server 2016/Windows 10 or later
- Application-Layer Protocol Negotiation (ALPN) connection
- TLS 1.2 or later connection

If an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/2`.

HTTP/2 is enabled by default. If an HTTP/2 connection isn't established, the connection falls back to HTTP/1.1. In a future release of Windows, HTTP/2 configuration flags will be available, including the ability to disable HTTP/2 with HTTP.sys.

Kernel mode authentication with Kerberos

HTTP.sys delegates to kernel mode authentication with the Kerberos authentication protocol. User mode authentication isn't supported with Kerberos and HTTP.sys. The machine account must be used to decrypt the Kerberos token/ticket that's obtained from Active Directory and forwarded by the client to the server to authenticate the user. Register the Service Principal Name (SPN) for the host, not the user of the app.

How to use HTTP.sys

Configure the ASP.NET Core app to use HTTP.sys

Call the UseHttpSys extension method when building the host, specifying any required HttpSysOptions. The following example sets options to their default values:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseHttpSys(options =>
            {
                options.AllowSynchronousIO = false;
                options.Authentication.Schemes = AuthenticationSchemes.None;
                options.Authentication.AllowAnonymous = true;
                options.MaxConnections = null;
                options.MaxRequestBodySize = 30000000;
                options.UrlPrefixes.Add("http://localhost:5005");
            });
            webBuilder.UseStartup<Startup>();
        });
```

Additional HTTP.sys configuration is handled through registry settings.

HTTP.sys options

PROPERTY	DESCRIPTION	DEFAULT
AllowSynchronousIO	Control whether synchronous input/output is allowed for the `HttpContext.Request.Body` and `HttpContext.Response.Body`.	`false`
Authentication.AllowAnonymous	Allow anonymous requests.	`true`
Authentication.Schemes	Specify the allowed authentication schemes. May be modified at any time prior to disposing the listener. Values are provided by the AuthenticationSchemes enum: `Basic`, `Kerberos`, `Negotiate`, `None`, and `NTLM`.	`None`

PROPERTY	DESCRIPTION	DEFAULT
EnableResponseCaching	Attempt kernel-mode caching for responses with eligible headers. The response may not include `Set-Cookie`, `Vary`, or `Pragma` headers. It must include a `Cache-Control` header that's `public` and either a `shared-max-age` or `max-age` value, or an `Expires` header.	`true`
MaxAccepts	The maximum number of concurrent accepts.	5 × Environment.ProcessorCount
MaxConnections	The maximum number of concurrent connections to accept. Use `-1` for infinite. Use `null` to use the registry's machine-wide setting.	`null` (machine-wide setting)
MaxRequestBodySize	See the MaxRequestBodySize section.	30000000 bytes (~28.6 MB)
RequestQueueLimit	The maximum number of requests that can be queued.	1000
ThrowWriteExceptions	Indicate if response body writes that fail due to client disconnects should throw exceptions or complete normally.	`false` (complete normally)

PROPERTY	DESCRIPTION	DEFAULT
Timeouts	Expose the HTTP.sys TimeoutManager configuration, which may also be configured in the registry. Follow the API links to learn more about each setting, including default values: • TimeoutManager.DrainEntityBody: Time allowed for the HTTP Server API to drain the entity body on a Keep-Alive connection. • TimeoutManager.EntityBody: Time allowed for the request entity body to arrive. • TimeoutManager.HeaderWait: Time allowed for the HTTP Server API to parse the request header. • TimeoutManager.IdleConnection: Time allowed for an idle connection. • TimeoutManager.MinSendBytesPerSecond: The minimum send rate for the response. • TimeoutManager.RequestQueue: Time allowed for the request to remain in the request queue before the app picks it up.	
UrlPrefixes	Specify the UrlPrefixCollection to register with HTTP.sys. The most useful is UrlPrefixCollection.Add, which is used to add a prefix to the collection. These may be modified at any time prior to disposing the listener.	

MaxRequestBodySize

The maximum allowed size of any request body in bytes. When set to `null`, the maximum request body size is unlimited. This limit has no effect on upgraded connections, which are always unlimited.

The recommended method to override the limit in an ASP.NET Core MVC app for a single `IActionResult` is to use the RequestSizeLimitAttribute attribute on an action method:

```
[RequestSizeLimit(100000000)]
public IActionResult MyActionMethod()
```

An exception is thrown if the app attempts to configure the limit on a request after the app has started reading the request. An `IsReadOnly` property can be used to indicate if the `MaxRequestBodySize` property is in a read-only state, meaning it's too late to configure the limit.

If the app should override MaxRequestBodySize per-request, use the IHttpMaxRequestBodySizeFeature:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env,
    ILogger<Startup> logger, IServer server)
{
    app.Use(async (context, next) =>
    {
        context.Features.Get<IHttpMaxRequestBodySizeFeature>()
            .MaxRequestBodySize = 10 * 1024;

        var serverAddressesFeature =
            app.ServerFeatures.Get<IServerAddressesFeature>();
        var addresses = string.Join(", ", serverAddressesFeature?.Addresses);

        logger.LogInformation("Addresses: {Addresses}", addresses);

        await next.Invoke();
    });

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
    }

    app.UseStaticFiles();
    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

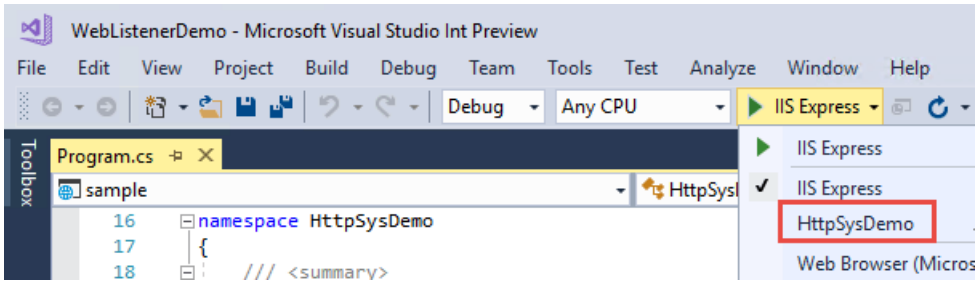
If using Visual Studio, make sure the app isn't configured to run IIS or IIS Express.

In Visual Studio, the default launch profile is for IIS Express. To run the project as a console app, manually change the selected profile, as shown in the following screen shot:



Configure Windows Server

1. Determine the ports to open for the app and use Windows Firewall or the New-NetFirewallRule PowerShell cmdlet to open firewall ports to allow traffic to reach HTTP.sys. In the following commands and app configuration, port 443 is used.

2. When deploying to an Azure VM, open the ports in the Network Security Group. In the following commands and app configuration, port 443 is used.

3. Obtain and install X.509 certificates, if required.

   On Windows, create self-signed certificates using the New-SelfSignedCertificate PowerShell cmdlet. For an unsupported example, see UpdateIISExpressSSLForChrome.ps1.

   Install either self-signed or CA-signed certificates in the server's **Local Machine** > **Personal** store.

4. If the app is a framework-dependent deployment, install .NET Core, .NET Framework, or both (if the app is a .NET Core app targeting the .NET Framework).

   - **.NET Core**: If the app requires .NET Core, obtain and run the **.NET Core Runtime** installer from .NET Core Downloads. Don't install the full SDK on the server.
   - **.NET Framework**: If the app requires .NET Framework, see the .NET Framework installation guide. Install the required .NET Framework. The installer for the latest .NET Framework is available from the .NET Core Downloads page.

   If the app is a self-contained deployment, the app includes the runtime in its deployment. No framework installation is required on the server.

5. Configure URLs and ports in the app.

   By default, ASP.NET Core binds to `http://localhost:5000`. To configure URL prefixes and ports, options include:

   - UseUrls
   - `urls` command-line argument
   - `ASPNETCORE_URLS` environment variable
   - UrlPrefixes

   The following code example shows how to use UrlPrefixes with the server's local IP address `10.0.0.4` on port 443:

   ```
   public static IHostBuilder CreateHostBuilder(string[] args) =>
       Host.CreateDefaultBuilder(args)
           .ConfigureWebHostDefaults(webBuilder =>
           {
               webBuilder.UseHttpSys(options =>
               {
                   options.UrlPrefixes.Add("https://10.0.0.4:443");
               });
               webBuilder.UseStartup<Startup>();
           });
   ```

   An advantage of `UrlPrefixes` is that an error message is generated immediately for improperly formatted prefixes.

   The settings in `UrlPrefixes` override `UseUrls` / `urls` / `ASPNETCORE_URLS` settings. Therefore, an advantage of `UseUrls`, `urls`, and the `ASPNETCORE_URLS` environment variable is that it's easier to switch between Kestrel and HTTP.sys.

   HTTP.sys uses the HTTP Server API UrlPrefix string formats.

   > **WARNING**
   > Top-level wildcard bindings (`http://*:80/` and `http://+:80`) should **not** be used. Top-level wildcard bindings create app security vulnerabilities. This applies to both strong and weak wildcards. Use explicit host names or IP addresses rather than wildcards. Subdomain wildcard binding (for example, `*.mysub.com`) isn't a security risk if you control the entire parent domain (as opposed to `*.com`, which is vulnerable). For more information, see RFC 7230: Section 5.4: Host.

6. Preregister URL prefixes on the server.

   The built-in tool for configuring HTTP.sys is *netsh.exe*. *netsh.exe* is used to reserve URL prefixes and assign X.509 certificates. The tool requires administrator privileges.

Use the *netsh.exe* tool to register URLs for the app:

```
netsh http add urlacl url=<URL> user=<USER>
```

- `<URL>`: The fully qualified Uniform Resource Locator (URL). Don't use a wildcard binding. Use a valid hostname or local IP address. *The URL must include a trailing slash.*
- `<USER>`: Specifies the user or user-group name.

In the following example, the local IP address of the server is `10.0.0.4`:

```
netsh http add urlacl url=https://10.0.0.4:443/ user=Users
```

When a URL is registered, the tool responds with `URL reservation successfully added`.

To delete a registered URL, use the `delete urlacl` command:

```
netsh http delete urlacl url=<URL>
```

7. Register X.509 certificates on the server.

   Use the *netsh.exe* tool to register certificates for the app:

   ```
   netsh http add sslcert ipport=<IP>:<PORT> certhash=<THUMBPRINT> appid="{<GUID>}"
   ```

   - `<IP>`: Specifies the local IP address for the binding. Don't use a wildcard binding. Use a valid IP address.
   - `<PORT>`: Specifies the port for the binding.
   - `<THUMBPRINT>`: The X.509 certificate thumbprint.
   - `<GUID>`: A developer-generated GUID to represent the app for informational purposes.

   For reference purposes, store the GUID in the app as a package tag:

   - In Visual Studio:
     - Open the app's project properties by right-clicking on the app in **Solution Explorer** and selecting **Properties**.
     - Select the **Package** tab.
     - Enter the GUID that you created in the **Tags** field.
   - When not using Visual Studio:
     - Open the app's project file.
     - Add a `<PackageTags>` property to a new or existing `<PropertyGroup>` with the GUID that you created:

       ```
       <PropertyGroup>
         <PackageTags>9412ee86-c21b-4eb8-bd89-f650fbf44931</PackageTags>
       </PropertyGroup>
       ```

   In the following example:

   - The local IP address of the server is `10.0.0.4`.
   - An online random GUID generator provides the `appid` value.

```
netsh http add sslcert
    ipport=10.0.0.4:443
    certhash=b66ee04419d4ee37464ab8785ff02449980eae10
    appid="{9412ee86-c21b-4eb8-bd89-f650fbf44931}"
```

When a certificate is registered, the tool responds with `SSL Certificate successfully added`.

To delete a certificate registration, use the `delete sslcert` command:

```
netsh http delete sslcert ipport=<IP>:<PORT>
```

Reference documentation for *netsh.exe*:

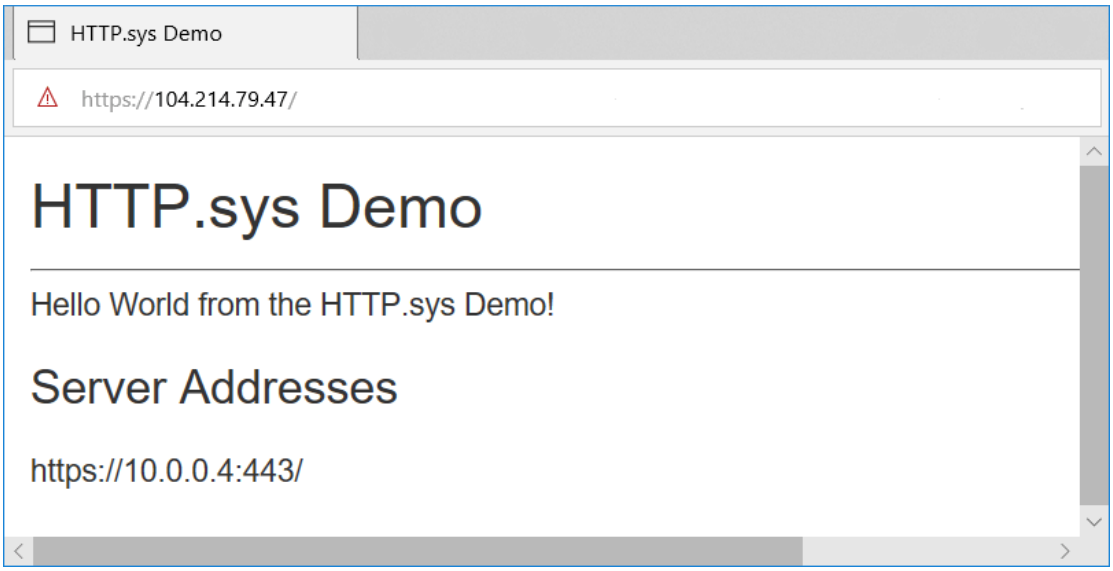
- Netsh Commands for Hypertext Transfer Protocol (HTTP)
- UrlPrefix Strings

8. Run the app.

   Administrator privileges aren't required to run the app when binding to localhost using HTTP (not HTTPS) with a port number greater than 1024. For other configurations (for example, using a local IP address or binding to port 443), run the app with administrator privileges.

   The app responds at the server's public IP address. In this example, the server is reached from the Internet at its public IP address of `104.214.79.47`.

   A development certificate is used in this example. The page loads securely after bypassing the browser's untrusted certificate warning.



Proxy server and load balancer scenarios

For apps hosted by HTTP.sys that interact with requests from the Internet or a corporate network, additional configuration might be required when hosting behind proxy servers and load balancers. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Additional resources

- Enable Windows Authentication with HTTP.sys
- HTTP Server API
- aspnet/HttpSysServer GitHub repository (source code)

- The host
- Troubleshoot and debug ASP.NET Core projects

HTTP.sys is a web server for ASP.NET Core that only runs on Windows. HTTP.sys is an alternative to Kestrel server and offers some features that Kestrel doesn't provide.

> **IMPORTANT**
> HTTP.sys isn't compatible with the ASP.NET Core Module and can't be used with IIS or IIS Express.

HTTP.sys supports the following features:

- Windows Authentication
- Port sharing
- HTTPS with SNI
- HTTP/2 over TLS (Windows 10 or later)
- Direct file transmission
- Response caching
- WebSockets (Windows 8 or later)

Supported Windows versions:

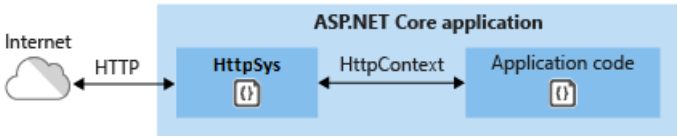
- Windows 7 or later
- Windows Server 2008 R2 or later

View or download sample code (how to download)

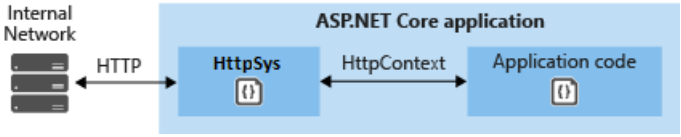
When to use HTTP.sys

HTTP.sys is useful for deployments where:

- There's a need to expose the server directly to the Internet without using IIS.



- An internal deployment requires a feature not available in Kestrel, such as Windows Authentication.



HTTP.sys is mature technology that protects against many types of attacks and provides the robustness, security, and scalability of a full-featured web server. IIS itself runs as an HTTP listener on top of HTTP.sys.

HTTP/2 support

HTTP/2 is enabled for ASP.NET Core apps if the following base requirements are met:

- Windows Server 2016/Windows 10 or later
- Application-Layer Protocol Negotiation (ALPN) connection
- TLS 1.2 or later connection

If an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/2`.

HTTP/2 is enabled by default. If an HTTP/2 connection isn't established, the connection falls back to HTTP/1.1. In a future release of Windows, HTTP/2 configuration flags will be available, including the ability to disable HTTP/2 with HTTP.sys.

Kernel mode authentication with Kerberos

HTTP.sys delegates to kernel mode authentication with the Kerberos authentication protocol. User mode authentication isn't supported with Kerberos and HTTP.sys. The machine account must be used to decrypt the Kerberos token/ticket that's obtained from Active Directory and forwarded by the client to the server to authenticate the user. Register the Service Principal Name (SPN) for the host, not the user of the app.

How to use HTTP.sys

Configure the ASP.NET Core app to use HTTP.sys

A package reference in the project file isn't required when using the Microsoft.AspNetCore.App metapackage (nuget.org). When not using the `Microsoft.AspNetCore.App` metapackage, add a package reference to Microsoft.AspNetCore.Server.HttpSys.

Call the UseHttpSys extension method when building the host, specifying any required HttpSysOptions. The following example sets options to their default values:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .UseHttpSys(options =>
        {
            options.AllowSynchronousIO = true;
            options.Authentication.Schemes = AuthenticationSchemes.None;
            options.Authentication.AllowAnonymous = true;
            options.MaxConnections = null;
            options.MaxRequestBodySize = 30000000;
            options.UrlPrefixes.Add("http://localhost:5000");
        });
```

Additional HTTP.sys configuration is handled through registry settings.

HTTP.sys options

PROPERTY	DESCRIPTION	DEFAULT
AllowSynchronousIO	Control whether synchronous input/output is allowed for the `HttpContext.Request.Body` and `HttpContext.Response.Body`.	`true`
Authentication.AllowAnonymous	Allow anonymous requests.	`true`
Authentication.Schemes	Specify the allowed authentication schemes. May be modified at any time prior to disposing the listener. Values are provided by the AuthenticationSchemes enum: `Basic`, `Kerberos`, `Negotiate`, `None`, and `NTLM`.	`None`

PROPERTY	DESCRIPTION	DEFAULT
EnableResponseCaching	Attempt kernel-mode caching for responses with eligible headers. The response may not include `Set-Cookie`, `Vary`, or `Pragma` headers. It must include a `Cache-Control` header that's `public` and either a `shared-max-age` or `max-age` value, or an `Expires` header.	`true`
MaxAccepts	The maximum number of concurrent accepts.	5 × Environment.ProcessorCount
MaxConnections	The maximum number of concurrent connections to accept. Use `-1` for infinite. Use `null` to use the registry's machine-wide setting.	`null` (machine-wide setting)
MaxRequestBodySize	See the MaxRequestBodySize section.	30000000 bytes (~28.6 MB)
RequestQueueLimit	The maximum number of requests that can be queued.	1000
ThrowWriteExceptions	Indicate if response body writes that fail due to client disconnects should throw exceptions or complete normally.	`false` (complete normally)

PROPERTY	DESCRIPTION	DEFAULT
Timeouts	Expose the HTTP.sys TimeoutManager configuration, which may also be configured in the registry. Follow the API links to learn more about each setting, including default values: • TimeoutManager.DrainEntityBody: Time allowed for the HTTP Server API to drain the entity body on a Keep-Alive connection. • TimeoutManager.EntityBody: Time allowed for the request entity body to arrive. • TimeoutManager.HeaderWait: Time allowed for the HTTP Server API to parse the request header. • TimeoutManager.IdleConnection: Time allowed for an idle connection. • TimeoutManager.MinSendBytesPerSecond: The minimum send rate for the response. • TimeoutManager.RequestQueue: Time allowed for the request to remain in the request queue before the app picks it up.	
UrlPrefixes	Specify the UrlPrefixCollection to register with HTTP.sys. The most useful is UrlPrefixCollection.Add, which is used to add a prefix to the collection. These may be modified at any time prior to disposing the listener.	

MaxRequestBodySize

The maximum allowed size of any request body in bytes. When set to `null`, the maximum request body size is unlimited. This limit has no effect on upgraded connections, which are always unlimited.

The recommended method to override the limit in an ASP.NET Core MVC app for a single `IActionResult` is to use the RequestSizeLimitAttribute attribute on an action method:

```
[RequestSizeLimit(100000000)]
public IActionResult MyActionMethod()
```

An exception is thrown if the app attempts to configure the limit on a request after the app has started reading the request. An `IsReadOnly` property can be used to indicate if the `MaxRequestBodySize` property is in a read-only state, meaning it's too late to configure the limit.

If the app should override MaxRequestBodySize per-request, use the IHttpMaxRequestBodySizeFeature:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env,
    ILogger<Startup> logger, IServer server)
{
    app.Use(async (context, next) =>
    {
        context.Features.Get<IHttpMaxRequestBodySizeFeature>()
            .MaxRequestBodySize = 10 * 1024;

        var serverAddressesFeature =
            app.ServerFeatures.Get<IServerAddressesFeature>();
        var addresses = string.Join(", ", serverAddressesFeature?.Addresses);

        logger.LogInformation("Addresses: {Addresses}", addresses);

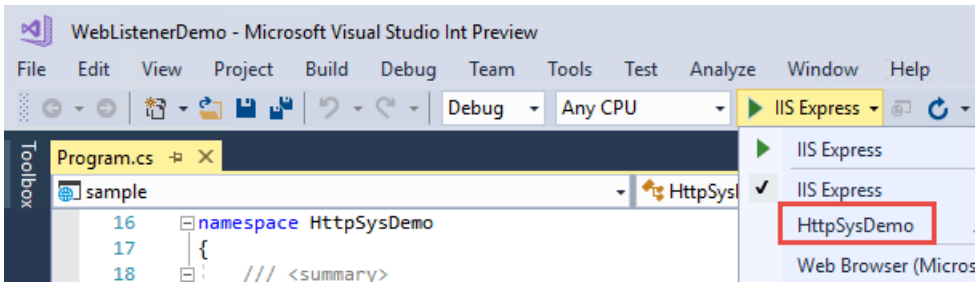
        await next.Invoke();
    });

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    // Enable HTTPS Redirection Middleware when hosting the app securely.
    //app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseCookiePolicy();
    app.UseMvc();
}
```

If using Visual Studio, make sure the app isn't configured to run IIS or IIS Express.

In Visual Studio, the default launch profile is for IIS Express. To run the project as a console app, manually change the selected profile, as shown in the following screen shot:



Configure Windows Server

1. Determine the ports to open for the app and use Windows Firewall or the New-NetFirewallRule PowerShell cmdlet to open firewall ports to allow traffic to reach HTTP.sys. In the following commands and app configuration, port 443 is used.

2. When deploying to an Azure VM, open the ports in the Network Security Group. In the following commands and app configuration, port 443 is used.

3. Obtain and install X.509 certificates, if required.

   On Windows, create self-signed certificates using the New-SelfSignedCertificate PowerShell cmdlet. For an unsupported example, see UpdateIISExpressSSLForChrome.ps1.

   Install either self-signed or CA-signed certificates in the server's **Local Machine** > **Personal** store.

4. If the app is a framework-dependent deployment, install .NET Core, .NET Framework, or both (if the app is a .NET Core app targeting the .NET Framework).

   - **.NET Core**: If the app requires .NET Core, obtain and run the **.NET Core Runtime** installer from .NET Core Downloads. Don't install the full SDK on the server.
   - **.NET Framework**: If the app requires .NET Framework, see the .NET Framework installation guide. Install the required .NET Framework. The installer for the latest .NET Framework is available from the .NET Core Downloads page.

   If the app is a self-contained deployment, the app includes the runtime in its deployment. No framework installation is required on the server.

5. Configure URLs and ports in the app.

   By default, ASP.NET Core binds to `http://localhost:5000`. To configure URL prefixes and ports, options include:

   - UseUrls
   - `urls` command-line argument
   - `ASPNETCORE_URLS` environment variable
   - UrlPrefixes

   The following code example shows how to use UrlPrefixes with the server's local IP address `10.0.0.4` on port 443:

   ```
   public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
       WebHost.CreateDefaultBuilder(args)
           .UseStartup<Startup>()
           .UseHttpSys(options =>
           {
               options.UrlPrefixes.Add("https://10.0.0.4:443");
           });
   ```

   An advantage of `UrlPrefixes` is that an error message is generated immediately for improperly formatted prefixes.

   The settings in `UrlPrefixes` override `UseUrls` / `urls` / `ASPNETCORE_URLS` settings. Therefore, an advantage of `UseUrls`, `urls`, and the `ASPNETCORE_URLS` environment variable is that it's easier to switch between Kestrel and HTTP.sys.

   HTTP.sys uses the HTTP Server API UrlPrefix string formats.

   > **WARNING**
   > Top-level wildcard bindings (`http://*:80/` and `http://+:80`) should **not** be used. Top-level wildcard bindings create app security vulnerabilities. This applies to both strong and weak wildcards. Use explicit host names or IP addresses rather than wildcards. Subdomain wildcard binding (for example, `*.mysub.com`) isn't a security risk if you control the entire parent domain (as opposed to `*.com`, which is vulnerable). For more information, see RFC 7230: Section 5.4: Host.

6. Preregister URL prefixes on the server.

   The built-in tool for configuring HTTP.sys is *netsh.exe*. *netsh.exe* is used to reserve URL prefixes and assign X.509 certificates. The tool requires administrator privileges.

   Use the *netsh.exe* tool to register URLs for the app:

```
netsh http add urlacl url=<URL> user=<USER>
```

- `<URL>`: The fully qualified Uniform Resource Locator (URL). Don't use a wildcard binding. Use a valid hostname or local IP address. *The URL must include a trailing slash.*
- `<USER>`: Specifies the user or user-group name.

In the following example, the local IP address of the server is `10.0.0.4`:

```
netsh http add urlacl url=https://10.0.0.4:443/ user=Users
```

When a URL is registered, the tool responds with `URL reservation successfully added`.

To delete a registered URL, use the `delete urlacl` command:

```
netsh http delete urlacl url=<URL>
```

7. Register X.509 certificates on the server.

   Use the *netsh.exe* tool to register certificates for the app:

   ```
   netsh http add sslcert ipport=<IP>:<PORT> certhash=<THUMBPRINT> appid="{<GUID>}"
   ```

   - `<IP>`: Specifies the local IP address for the binding. Don't use a wildcard binding. Use a valid IP address.
   - `<PORT>`: Specifies the port for the binding.
   - `<THUMBPRINT>`: The X.509 certificate thumbprint.
   - `<GUID>`: A developer-generated GUID to represent the app for informational purposes.

   For reference purposes, store the GUID in the app as a package tag:

   - In Visual Studio:
     - Open the app's project properties by right-clicking on the app in **Solution Explorer** and selecting **Properties**.
     - Select the **Package** tab.
     - Enter the GUID that you created in the **Tags** field.
   - When not using Visual Studio:
     - Open the app's project file.
     - Add a `<PackageTags>` property to a new or existing `<PropertyGroup>` with the GUID that you created:

       ```
       <PropertyGroup>
         <PackageTags>9412ee86-c21b-4eb8-bd89-f650fbf44931</PackageTags>
       </PropertyGroup>
       ```

   In the following example:

   - The local IP address of the server is `10.0.0.4`.
   - An online random GUID generator provides the `appid` value.

```
netsh http add sslcert
    ipport=10.0.0.4:443
    certhash=b66ee04419d4ee37464ab8785ff02449980eae10
    appid="{9412ee86-c21b-4eb8-bd89-f650fbf44931}"
```

When a certificate is registered, the tool responds with `SSL Certificate successfully added`.

To delete a certificate registration, use the `delete sslcert` command:

```
netsh http delete sslcert ipport=<IP>:<PORT>
```

Reference documentation for *netsh.exe*:

- Netsh Commands for Hypertext Transfer Protocol (HTTP)
- UrlPrefix Strings

8. Run the app.
