The tokens that the IP emits for the user typically are valid for short periods of time, about one hour normally, so the client app must regularly fetch new tokens. Otherwise, the user would be logged-out after the granted tokens expire. In most cases, OIDC clients are able to provision new tokens without requiring the user to authenticate again thanks to the authentication state or "session" that is kept within the IP.

There are some cases in which the client can't get a token without user interaction, for example, when for some reason the user explicitly logs out from the IP. This scenario occurs if a user visits `https://login.microsoftonline.com` and logs out. In these scenarios, the app doesn't know immediately that the user has logged out. Any token that the client holds might no longer be valid. Also, the client isn't able to provision a new token without user interaction after the current token expires.

These scenarios aren't specific to token-based authentication. They are part of the nature of SPAs. An SPA using cookies also fails to call a server API if the authentication cookie is removed.

When an app performs API calls to protected resources, you must be aware of the following:

- To provision a new access token to call the API, the user might be required to authenticate again.
- Even if the client has a token that seems to be valid, the call to the server might fail because the token was revoked by the user.

When the app requests a token, there are two possible outcomes:

- The request succeeds, and the app has a valid token.
- The request fails, and the app must authenticate the user again to obtain a new token.

When a token request fails, you need to decide whether you want to save any current state before you perform a redirection. Several approaches exist with increasing levels of complexity:

- Store the current page state in session storage. During the `OnInitializedAsync` lifecycle event (OnInitializedAsync), check if state can be restored before continuing.
- Add a query string parameter and use that as a way to signal the app that it needs to re-hydrate the previously saved state.
- Add a query string parameter with a unique identifier to store data in session storage without risking collisions with other items.

The following example shows how to:

- Preserve state before redirecting to the login page.
- Recover the previous state afterward authentication using the query string parameter.

```
<EditForm Model="User" @onsubmit="OnSaveAsync">
    <label>User
        <InputText @bind-Value="User.Name" />
    </label>
    <label>Last name
        <InputText @bind-Value="User.LastName" />
    </label>
</EditForm>

@code {
    public class Profile
    {
        public string Name { get; set; }
        public string LastName { get; set; }
    }

    public Profile User { get; set; } = new Profile();

    protected async override Task OnInitializedAsync()
    {
        var currentQuery = new Uri(Navigation.Uri).Query;

        if (currentQuery.Contains("state=resumeSavingProfile"))
        {
            User = await JS.InvokeAsync<Profile>("sessionStorage.getState",
                "resumeSavingProfile");
        }
    }

    public async Task OnSaveAsync()
    {
        var httpClient = new HttpClient();
        httpClient.BaseAddress = new Uri(Navigation.BaseUri);

        var resumeUri = Navigation.Uri + $"?state=resumeSavingProfile";

        var tokenResult = await AuthenticationService.RequestAccessToken(
            new AccessTokenRequestOptions
            {
                ReturnUrl = resumeUri
            });

        if (tokenResult.TryGetToken(out var token))
        {
            httpClient.DefaultRequestHeaders.Add("Authorization",
                $"Bearer {token.Value}");
            await httpClient.PostAsJsonAsync("Save", User);
        }
        else
        {
            await JS.InvokeVoidAsync("sessionStorage.setState",
                "resumeSavingProfile", User);
            Navigation.NavigateTo(tokenResult.RedirectUrl);
        }
    }
}
```

Save app state before an authentication operation

During an authentication operation, there are cases where you want to save the app state before the browser is redirected to the IP. This can be the case when you're using a state container and want to restore the state after the authentication succeeds. You can use a custom authentication state object to preserve app-specific state or a reference to it and restore that state after the authentication operation successfully completes. The following example demonstrates the approach.

A state container class is created in the app with properties to hold the app's state values. In the following example, the container is used to maintain the counter value of the default project template's `Counter` component (`Pages/Counter.razor`). Methods for serializing and deserializing the container are based on System.Text.Json.

```
using System.Text.Json;

public class StateContainer
{
    public int CounterValue { get; set; }

    public string GetStateForLocalStorage()
    {
        return JsonSerializer.Serialize(this);
    }

    public void SetStateFromLocalStorage(string locallyStoredState)
    {
        var deserializedState =
            JsonSerializer.Deserialize<StateContainer>(locallyStoredState);

        CounterValue = deserializedState.CounterValue;
    }
}
```

The `Counter` component uses the state container to maintain the `currentCount` value outside of the component:

```
@page "/counter"
@inject StateContainer State

<h1>Counter</h1>

<p>Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    protected override void OnInitialized()
    {
        if (State.CounterValue > 0)
        {
            currentCount = State.CounterValue;
        }
    }

    private void IncrementCount()
    {
        currentCount++;
        State.CounterValue = currentCount;
    }
}
```

Create an `ApplicationAuthenticationState` from RemoteAuthenticationState. Provide an `Id` property, which serves as an identifier for the locally-stored state.

`ApplicationAuthenticationState.cs`:

```
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

public class ApplicationAuthenticationState : RemoteAuthenticationState
{
    public string Id { get; set; }
}
```

The `Authentication` component (`Pages/Authentication.razor`) saves and restores the app's state using local session storage with the `StateContainer` serialization and deserialization methods, `GetStateForLocalStorage` and `SetStateFromLocalStorage`:

```
@page "/authentication/{action}"
@inject IJSRuntime JS
@inject StateContainer State
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorViewCore Action="@Action"
                             TAuthenticationState="ApplicationAuthenticationState"
                             AuthenticationState="AuthenticationState"
                             OnLogInSucceeded="RestoreState"
                             OnLogOutSucceeded="RestoreState" />

@code {
    [Parameter]
    public string Action { get; set; }

    public ApplicationAuthenticationState AuthenticationState { get; set; } =
        new ApplicationAuthenticationState();

    protected async override Task OnInitializedAsync()
    {
        if (RemoteAuthenticationActions.IsAction(RemoteAuthenticationActions.LogIn,
            Action) ||
            RemoteAuthenticationActions.IsAction(RemoteAuthenticationActions.LogOut,
            Action))
        {
            AuthenticationState.Id = Guid.NewGuid().ToString();

            await JS.InvokeVoidAsync("sessionStorage.setItem",
                AuthenticationState.Id, State.GetStateForLocalStorage());
        }
    }

    private async Task RestoreState(ApplicationAuthenticationState state)
    {
        if (state.Id != null)
        {
            var locallyStoredState = await JS.InvokeAsync<string>(
                "sessionStorage.getItem", state.Id);

            if (locallyStoredState != null)
            {
                State.SetStateFromLocalStorage(locallyStoredState);
                await JS.InvokeVoidAsync("sessionStorage.removeItem", state.Id);
            }
        }
    }
}
```

This example uses Azure Active Directory (AAD) for authentication. In `Program.Main` (`Program.cs`):

- The `ApplicationAuthenticationState` is configured as the Microsoft Autentication Library (MSAL) `RemoteAuthenticationState` type.

- The state container is registered in the service container.

```
builder.Services.AddMsalAuthentication<ApplicationAuthenticationState>(options =>
{
    builder.Configuration.Bind("AzureAd", options.ProviderOptions.Authentication);
});

builder.Services.AddSingleton<StateContainer>();
```

Customize app routes

By default, the `Microsoft.AspNetCore.Components.WebAssembly.Authentication` library uses the routes shown in the following table for representing different authentication states.

ROUTE	PURPOSE
`authentication/login`	Triggers a sign-in operation.
`authentication/login-callback`	Handles the result of any sign-in operation.
`authentication/login-failed`	Displays error messages when the sign-in operation fails for some reason.
`authentication/logout`	Triggers a sign-out operation.
`authentication/logout-callback`	Handles the result of a sign-out operation.
`authentication/logout-failed`	Displays error messages when the sign-out operation fails for some reason.
`authentication/logged-out`	Indicates that the user has successfully logout.
`authentication/profile`	Triggers an operation to edit the user profile.
`authentication/register`	Triggers an operation to register a new user.

The routes shown in the preceding table are configurable via RemoteAuthenticationOptions<TRemoteAuthenticationProviderOptions>.AuthenticationPaths. When setting options to provide custom routes, confirm that the app has a route that handles each path.

In the following example, all the paths are prefixed with `/security`.

`Authentication` component (`Pages/Authentication.razor`):

```
@page "/security/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action" />

@code{
    [Parameter]
    public string Action { get; set; }
}
```

`Program.Main` (`Program.cs`):

```
builder.Services.AddApiAuthorization(options => {
    options.AuthenticationPaths.LogInPath = "security/login";
    options.AuthenticationPaths.LogInCallbackPath = "security/login-callback";
    options.AuthenticationPaths.LogInFailedPath = "security/login-failed";
    options.AuthenticationPaths.LogOutPath = "security/logout";
    options.AuthenticationPaths.LogOutCallbackPath = "security/logout-callback";
    options.AuthenticationPaths.LogOutFailedPath = "security/logout-failed";
    options.AuthenticationPaths.LogOutSucceededPath = "security/logged-out";
    options.AuthenticationPaths.ProfilePath = "security/profile";
    options.AuthenticationPaths.RegisterPath = "security/register";
});
```

If the requirement calls for completely different paths, set the routes as described previously and render the RemoteAuthenticatorView with an explicit action parameter:

```
@page "/register"

<RemoteAuthenticatorView Action="@RemoteAuthenticationActions.Register" />
```

You're allowed to break the UI into different pages if you choose to do so.

Customize the authentication user interface

RemoteAuthenticatorView includes a default set of UI pieces for each authentication state. Each state can be customized by passing in a custom RenderFragment. To customize the displayed text during the initial login process, can change the RemoteAuthenticatorView as follows.

`Authentication` component (`Pages/Authentication.razor`):

```
@page "/security/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action">
    <LoggingIn>
        You are about to be redirected to https://login.microsoftonline.com.
    </LoggingIn>
</RemoteAuthenticatorView>

@code{
    [Parameter]
    public string Action { get; set; }
}
```

The RemoteAuthenticatorView has one fragment that can be used per authentication route shown in the following table.

ROUTE	FRAGMENT
`authentication/login`	`<LoggingIn>`
`authentication/login-callback`	`<CompletingLoggingIn>`
`authentication/login-failed`	`<LogInFailed>`
`authentication/logout`	`<LogOut>`

ROUTE	FRAGMENT
`authentication/logout-callback`	`<CompletingLogOut>`
`authentication/logout-failed`	`<LogOutFailed>`
`authentication/logged-out`	`<LogOutSucceeded>`
`authentication/profile`	`<UserProfile>`
`authentication/register`	`<Registering>`

Customize the user

Users bound to the app can be customized.

Customize the user with a payload claim

In the following example, the app's authenticated users receive an `amr` claim for each of the user's authentication methods. The `amr` claim identifies how the subject of the token was authenticated in Microsoft Identity Platform v1.0 payload claims. The example uses a custom user account class based on RemoteUserAccount.

Create a class that extends the RemoteUserAccount class. The following example sets the `AuthenticationMethod` property to the user's array of `amr` JSON property values. `AuthenticationMethod` is populated automatically by the framework when the user is authenticated.

```
using System.Text.Json.Serialization;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

public class CustomUserAccount : RemoteUserAccount
{
    [JsonPropertyName("amr")]
    public string[] AuthenticationMethod { get; set; }
}
```

Create a factory that extends AccountClaimsPrincipalFactory<TAccount> to create claims from the user's authentication methods stored in `CustomUserAccount.AuthenticationMethod`:

```
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication.Internal;

public class CustomAccountFactory
    : AccountClaimsPrincipalFactory<CustomUserAccount>
{
    public CustomAccountFactory(NavigationManager navigationManager,
        IAccessTokenProviderAccessor accessor) : base(accessor)
    {
    }

    public async override ValueTask<ClaimsPrincipal> CreateUserAsync(
        CustomUserAccount account, RemoteAuthenticationUserOptions options)
    {
        var initialUser = await base.CreateUserAsync(account, options);

        if (initialUser.Identity.IsAuthenticated)
        {
            foreach (var value in account.AuthenticationMethod)
            {
                ((ClaimsIdentity)initialUser.Identity)
                    .AddClaim(new Claim("amr", value));
            }
        }

        return initialUser;
    }
}
```

Register the `CustomAccountFactory` for the authentication provider in use. Any of the following registrations are valid:

- AddOidcAuthentication:

  ```
  using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

  ...

  builder.Services.AddOidcAuthentication<RemoteAuthenticationState,
      CustomUserAccount>(options =>
      {
          ...
      })
      .AddAccountClaimsPrincipalFactory<RemoteAuthenticationState,
          CustomUserAccount, CustomAccountFactory>();
  ```

- AddMsalAuthentication:

  ```
  using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

  ...

  builder.Services.AddMsalAuthentication<RemoteAuthenticationState,
      CustomUserAccount>(options =>
      {
          ...
      })
      .AddAccountClaimsPrincipalFactory<RemoteAuthenticationState,
          CustomUserAccount, CustomAccountFactory>();
  ```

- AddApiAuthorization:

```
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

...

builder.Services.AddApiAuthorization<RemoteAuthenticationState,
    CustomUserAccount>(options =>
    {
        ...
    })
    .AddAccountClaimsPrincipalFactory<RemoteAuthenticationState,
        CustomUserAccount, CustomAccountFactory>();
```

Customize the user with Graph API claims

In the following example, the app creates a mobile phone number claim for the user from Graph API using the RemoteUserAccount. The app must have the `User.Read` Graph API permission (scope) configured in AAD.

`GraphAuthorizationMessageHandler.cs`:

```
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

public class GraphAPIAuthorizationMessageHandler : AuthorizationMessageHandler
{
    public GraphAPIAuthorizationMessageHandler(IAccessTokenProvider provider,
        NavigationManager navigationManager)
        : base(provider, navigationManager)
    {
        ConfigureHandler(
            authorizedUrls: new[] { "https://graph.microsoft.com" },
            scopes: new[] { "https://graph.microsoft.com/User.Read" });
    }
}
```

A named HttpClient for Graph API is created in `Program.Main` (`Program.cs`) using the `GraphAPIAuthorizationMessageHandler`:

```
using System;

...

builder.Services.AddScoped<GraphAPIAuthorizationMessageHandler>();

builder.Services.AddHttpClient("GraphAPI",
        client => client.BaseAddress = new Uri("https://graph.microsoft.com"))
    .AddHttpMessageHandler<GraphAPIAuthorizationMessageHandler>();
```

`Models/UserInfo.cs`:

```
using System.Text.Json.Serialization;

public class UserInfo
{
    [JsonPropertyName("mobilePhone")]
    public string MobilePhone { get; set; }
}
```

In the following `CustomAccountFactory` (`CustomAccountFactory.cs`), the framework's RemoteUserAccount

represents the user's account. If the app requires a custom user account class that extends RemoteUserAccount, swap the custom user account class for RemoteUserAccount in the following code:

```
using System.Net.Http;
using System.Net.Http.Json;
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication.Internal;
using Microsoft.Extensions.Logging;

public class CustomAccountFactory
    : AccountClaimsPrincipalFactory<RemoteUserAccount>
{
    private readonly ILogger<CustomAccountFactory> logger;
    private readonly IHttpClientFactory clientFactory;

    public CustomAccountFactory(IAccessTokenProviderAccessor accessor,
        IHttpClientFactory clientFactory,
        ILogger<CustomAccountFactory> logger)
        : base(accessor)
    {
        this.clientFactory = clientFactory;
        this.logger = logger;
    }

    public async override ValueTask<ClaimsPrincipal> CreateUserAsync(
        RemoteUserAccount account,
        RemoteAuthenticationUserOptions options)
    {
        var initialUser = await base.CreateUserAsync(account, options);

        if (initialUser.Identity.IsAuthenticated)
        {
            var userIdentity = (ClaimsIdentity)initialUser.Identity;

            try
            {
                var client = clientFactory.CreateClient("GraphAPI");

                var userInfo = await client.GetFromJsonAsync<UserInfo>("v1.0/me");

                if (userInfo != null)
                {
                    userIdentity.AddClaim(new Claim("mobilephone", userInfo.MobilePhone));
                }
            }
            catch (AccessTokenNotAvailableException exception)
            {
                logger.LogError("Graph API access token failure: {MESSAGE}",
                    exception.Message);
            }
        }

        return initialUser;
    }
}
```

In `Program.Main` (`Program.cs`), configure the app to use the custom factory. If the app uses a custom user account class that extends RemoteUserAccount, swap the custom user account class for RemoteUserAccount in the following code:

```
using Microsoft.Extensions.Configuration;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

...

builder.Services.AddMsalAuthentication<RemoteAuthenticationState,
    RemoteUserAccount>(options =>
    {
        builder.Configuration.Bind("AzureAd",
            options.ProviderOptions.Authentication);
    })
    .AddAccountClaimsPrincipalFactory<RemoteAuthenticationState, RemoteUserAccount,
        CustomAccountFactory>();
```

The preceding example is for an app that uses AAD authentication with MSAL. Similar patterns exist for OIDC and API authentication. For more information, see the examples at the end of the Customize the user with a payload claim section.

AAD security groups and roles with a custom user account class

For an additional example that works with AAD security groups and AAD Administrator Roles and a custom user account class, see ASP.NET Core Blazor WebAssembly with Azure Active Directory groups and roles.

Support prerendering with authentication

After following the guidance in one of the hosted Blazor WebAssembly app topics, use the following instructions to create an app that:

- Prerenders paths for which authorization isn't required.
- Doesn't prerender paths for which authorization is required.

In the Client app's `Program` class (`Program.cs`), factor common service registrations into a separate method (for example, `ConfigureCommonServices`):

```
public class Program
{
    public static async Task Main(string[] args)
    {
        var builder = WebAssemblyHostBuilder.CreateDefault(args);
        builder.RootComponents.Add<App>("app");

        builder.Services.AddScoped(sp =>
            new HttpClient
            {
                BaseAddress = new Uri(builder.HostEnvironment.BaseAddress)
            });

        services.Add...;

        ConfigureCommonServices(builder.Services);

        await builder.Build().RunAsync();
    }

    public static void ConfigureCommonServices(IServiceCollection services)
    {
        // Common service registrations
    }
}
```

In the server app's `Startup.ConfigureServices` , register the following additional services:

```
using Microsoft.AspNetCore.Components.Authorization;
using Microsoft.AspNetCore.Components.Server;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

public void ConfigureServices(IServiceCollection services)
{
    ...

    services.AddRazorPages();
    services.AddScoped<AuthenticationStateProvider,
        ServerAuthenticationStateProvider>();
    services.AddScoped<SignOutSessionStateManager>();

    Client.Program.ConfigureCommonServices(services);
}
```

In the server app's `Startup.Configure` method, replace `endpoints.MapFallbackToFile("index.html")` with `endpoints.MapFallbackToPage("/_Host")`:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllers();
    endpoints.MapFallbackToPage("/_Host");
});
```

In the server app, create a `Pages` folder if it doesn't exist. Create a `_Host.cshtml` page inside the server app's `Pages` folder. Paste the contents from the Client app's `wwwroot/index.html` file into the `Pages/_Host.cshtml` file. Update the file's contents:

- Add `@page "_Host"` to the top of the file.
- Replace the `<app>Loading...</app>` tag with the following:

```
<app>
    @if (!HttpContext.Request.Path.StartsWithSegments("/authentication"))
    {
        <component type="typeof(Wasm.Authentication.Client.App)"
            render-mode="Static" />
    }
    else
    {
        <text>Loading...</text>
    }
</app>
```

Options for hosted apps and third-party login providers

When authenticating and authorizing a hosted Blazor WebAssembly app with a third-party provider, there are several options available for authenticating the user. Which one you choose depends on your scenario.

For more information, see Persist additional claims and tokens from external providers in ASP.NET Core.

Authenticate users to only call protected third party APIs

Authenticate the user with a client-side OAuth flow against the third-party API provider:

```
builder.services.AddOidcAuthentication(options => { ... });
```

In this scenario:

- The server hosting the app doesn't play a role.
- APIs on the server can't be protected.
- The app can only call protected third-party APIs.

Authenticate users with a third-party provider and call protected APIs on the host server and the third party

Configure Identity with a third-party login provider. Obtain the tokens required for third-party API access and store them.

When a user logs in, Identity collects access and refresh tokens as part of the authentication process. At that point, there are a couple of approaches available for making API calls to third-party APIs.

Use a server access token to retrieve the third-party access token

Use the access token generated on the server to retrieve the third-party access token from a server API endpoint. From there, use the third-party access token to call third-party API resources directly from Identity on the client.

We don't recommend this approach. This approach requires treating the third-party access token as if it were generated for a public client. In OAuth terms, the public app doesn't have a client secret because it can't be trusted to store secrets safely, and the access token is produced for a confidential client. A confidential client is a client that has a client secret and is assumed to be able to safely store secrets.

- The third-party access token might be granted additional scopes to perform sensitive operations based on the fact that the third-party emitted the token for a more trusted client.
- Similarly, refresh tokens shouldn't be issued to a client that isn't trusted, as doing so gives the client unlimited access unless other restrictions are put into place.

Make API calls from the client to the server API in order to call third-party APIs

Make an API call from the client to the server API. From the server, retrieve the access token for the third-party API resource and issue whatever call is necessary.

While this approach requires an extra network hop through the server to call a third-party API, it ultimately results in a safer experience:

- The server can store refresh tokens and ensure that the app doesn't lose access to third-party resources.
- The app can't leak access tokens from the server that might contain more sensitive permissions.

Use OpenID Connect (OIDC) v2.0 endpoints

The authentication library and Blazor project templates use OpenID Connect (OIDC) v1.0 endpoints. To use a v2.0 endpoint, configure the JWT Bearer JwtBearerOptions.Authority option. In the following example, AAD is configured for v2.0 by appending a `v2.0` segment to the Authority property:

```
builder.Services.Configure<JwtBearerOptions>(
    AzureADDefaults.JwtBearerAuthenticationScheme,
    options =>
    {
        options.Authority += "/v2.0";
    });
```

Alternatively, the setting can be made in the app settings (`appsettings.json`) file:

```
{
  "Local": {
    "Authority": "https://login.microsoftonline.com/common/oauth2/v2.0/",
    ...
  }
}
```

If tacking on a segment to the authority isn't appropriate for the app's OIDC provider, such as with non-AAD providers, set the Authority property directly. Either set the property in JwtBearerOptions or in the app settings file (`appsettings.json`) with the `Authority` key.

The list of claims in the ID token changes for v2.0 endpoints. For more information, see Why update to Microsoft identity platform (v2.0)?.

Configure and use gRPC in components

To configure a Blazor WebAssembly app to use the ASP.NET Core gRPC framework:

- Enable gRPC-Web on the server. For more information, see Use gRPC in browser apps.
- Register gRPC services for the app's message handler. The following example configures the app's authorization message handler to use the `GreeterClient` service from the gRPC tutorial (`Program.Main`):

```
using System.Net.Http;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
using Grpc.Net.Client;
using Grpc.Net.Client.Web;
using {APP ASSEMBLY}.Shared;

...

builder.Services.AddScoped(sp =>
{
    var baseAddressMessageHandler =
        sp.GetRequiredService<BaseAddressAuthorizationMessageHandler>();
    baseAddressMessageHandler.InnerHandler = new HttpClientHandler();
    var grpcWebHandler =
        new GrpcWebHandler(GrpcWebMode.GrpcWeb, baseAddressMessageHandler);
    var channel = GrpcChannel.ForAddress(builder.HostEnvironment.BaseAddress,
        new GrpcChannelOptions { HttpHandler = grpcWebHandler });

    return new Greeter.GreeterClient(channel);
});
```

The placeholder `{APP ASSEMBLY}` is the app's assembly name (for example, `BlazorSample`). Place the `.proto` file in the `Shared` project of the hosted Blazor solution.

A component in the client app can make gRPC calls using the gRPC client (`Pages/Grpc.razor`):

```
@page "/grpc"
@attribute [Authorize]
@using Microsoft.AspNetCore.Authorization
@using {APP ASSEMBLY}.Shared
@inject Greeter.GreeterClient GreeterClient

<h1>Invoke gRPC service</h1>

<p>
    <input @bind="name" placeholder="Type your name" />
    <button @onclick="GetGreeting" class="btn btn-primary">Call gRPC service</button>
</p>

Server response: <strong>@serverResponse</strong>

@code {
    private string name = "Bert";
    private string serverResponse;

    private async Task GetGreeting()
    {
        try
        {
            var request = new HelloRequest { Name = name };
            var reply = await GreeterClient.SayHelloAsync(request);
            serverResponse = reply.Message;
        }
        catch (Grpc.Core.RpcException ex)
            when (ex.Status.DebugException is
                AccessTokenNotAvailableException tokenEx)
        {
            tokenEx.Redirect();
        }
    }
}
```

The placeholder `{APP ASSEMBLY}` is the app's assembly name (for example, `BlazorSample`). To use the `Status.DebugException` property, use Grpc.Net.Client version 2.30.0 or later.

For more information, see Use gRPC in browser apps.

Azure AD Groups, Administrative Roles, and user-defined roles

9/22/2020 • 8 minutes to read • Edit Online

By Luke Latham and Javier Calvarro Nelson

Azure Active Directory (AAD) provides several authorization approaches that can be combined with ASP.NET Core Identity:

- User-defined groups
  - Security
  - Microsoft 365
  - Distribution
- Roles
  - Built-in Administrative Roles
  - User-defined roles

The guidance in this article applies to the Blazor WebAssembly AAD deployment scenarios described in the following topics:

- Standalone with Microsoft Accounts
- Standalone with AAD
- Hosted with AAD

Microsoft Graph API permission

A Microsoft Graph API call is required for any app user with more than five built-in AAD Administrator role and security group memberships.

To permit Graph API calls, give the standalone or client app of a hosted Blazor solution any of the following Graph API permissions in the Azure portal:

- `Directory.Read.All`
- `Directory.ReadWrite.All`
- `Directory.AccessAsUser.All`

`Directory.Read.All` is the least-privileged permission and is the permission used for the example described in this article.

User-defined groups and built-in Administrative Roles

To configure the app in the Azure portal to provide a `groups` membership claim, see the following Azure articles. Assign users to user-defined AAD groups and built-in Administrative Roles.

- Roles using Azure AD security groups
- `groupMembershipClaims` attribute

The following examples assume that a user is assigned to the AAD built-in *Billing Administrator* role.

The single `groups` claim sent by AAD presents the user's groups and roles as Object IDs (GUIDs) in a JSON array.

The app must convert the JSON array of groups and roles into individual `group` claims that the app can build policies against.

When the number of assigned built-in Azure Administrative Roles and user-defined groups exceeds five, AAD sends a `hasgroups` claim with a `true` value instead of sending a `groups` claim. Any app that may have more than five roles and groups assigned to its users must make a separate Graph API call to obtain a user's roles and groups. The example implementation provided in this article addresses this scenario. For more information, see the `groups` and `hasgroups` claims information in Microsoft identity platform access tokens: Payload claims article.

Extend RemoteUserAccount to include array properties for groups and roles. Assign an empty array to each property so that checking for `null` isn't required when these properties are used in `foreach` loops later.

`CustomUserAccount.cs`:

```
using System.Text.Json.Serialization;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

public class CustomUserAccount : RemoteUserAccount
{
    [JsonPropertyName("groups")]
    public string[] Groups { get; set; } = new string[] { };

    [JsonPropertyName("roles")]
    public string[] Roles { get; set; } = new string[] { };
}
```

In the standalone app or the client app of a hosted Blazor solution, create a custom AuthorizationMessageHandler class. Use the correct scope (permission) for Graph API calls that obtain role and group information.

`GraphAPIAuthorizationMessageHandler.cs`:

```
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

public class GraphAPIAuthorizationMessageHandler : AuthorizationMessageHandler
{
    public GraphAPIAuthorizationMessageHandler(IAccessTokenProvider provider,
        NavigationManager navigationManager)
        : base(provider, navigationManager)
    {
        ConfigureHandler(
            authorizedUrls: new[] { "https://graph.microsoft.com" },
            scopes: new[] { "https://graph.microsoft.com/Directory.Read.All" });
    }
}
```

In `Program.Main` (`Program.cs`), add the AuthorizationMessageHandler implementation service and add a named HttpClient for making Graph API requests. The following example names the client `GraphAPI`:

```
builder.Services.AddScoped<GraphAPIAuthorizationMessageHandler>();

builder.Services.AddHttpClient("GraphAPI",
        client => client.BaseAddress = new Uri("https://graph.microsoft.com"))
    .AddHttpMessageHandler<GraphAPIAuthorizationMessageHandler>();
```

Create AAD directory objects classes to receive the Open Data Protocol (OData) roles and groups from a Graph API call. The OData arrives in JSON format, and a call to ReadFromJsonAsync populates an instance of the `DirectoryObjects` class.

`DirectoryObjects.cs`:

```
using System.Collections.Generic;
using System.Text.Json.Serialization;

public class DirectoryObjects
{
    [JsonPropertyName("@odata.context")]
    public string Context { get; set; }

    [JsonPropertyName("value")]
    public List<Value> Values { get; set; }
}

public class Value
{
    [JsonPropertyName("@odata.type")]
    public string Type { get; set; }

    [JsonPropertyName("id")]
    public string Id { get; set; }
}
```

Create a custom user factory to process roles and groups claims. The following example implementation also handles the `roles` claim array, which is covered in the User-defined roles section. If the `hasgroups` claim is present, the named HttpClient is used to make an authorized request to Graph API to obtain the user's roles and groups. This implementation uses the Microsoft Identity Platform v1.0 endpoint `https://graph.microsoft.com/v1.0/me/memberOf` (API documentation). The guidance in this topic will be updated for Identity v2.0 when the MSAL packages are upgraded for v2.0.

`CustomAccountFactory.cs`:

```
using System.Linq;
using System.Net.Http;
using System.Net.Http.Json;
using System.Security.Claims;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication.Internal;
using Microsoft.Extensions.Logging;

public class CustomUserFactory
    : AccountClaimsPrincipalFactory<CustomUserAccount>
{
    private readonly ILogger<CustomUserFactory> logger;
    private readonly IHttpClientFactory clientFactory;

    public CustomUserFactory(IAccessTokenProviderAccessor accessor,
        IHttpClientFactory clientFactory,
        ILogger<CustomUserFactory> logger)
        : base(accessor)
    {
        this.clientFactory = clientFactory;
        this.logger = logger;
    }

    public async override ValueTask<ClaimsPrincipal> CreateUserAsync(
        CustomUserAccount account,
        RemoteAuthenticationUserOptions options)
    {
        var initialUser = await base.CreateUserAsync(account, options);

        if (initialUser.Identity.IsAuthenticated)
        {
```

```
            var userIdentity = (ClaimsIdentity)initialUser.Identity;

            foreach (var role in account.Roles)
            {
                userIdentity.AddClaim(new Claim("role", role));
            }

            if (userIdentity.HasClaim(c => c.Type == "hasgroups"))
            {
                try
                {
                    var client = clientFactory.CreateClient("GraphAPI");

                    var response = await client.GetAsync("v1.0/me/memberOf");

                    if (response.IsSuccessStatusCode)
                    {
                        var userObjects = await response.Content
                            .ReadFromJsonAsync<DirectoryObjects>();

                        foreach (var obj in userObjects?.Values)
                        {
                            userIdentity.AddClaim(new Claim("group", obj.Id));
                        }

                        var claim = userIdentity.Claims.FirstOrDefault(
                            c => c.Type == "hasgroups");

                        userIdentity.RemoveClaim(claim);
                    }
                    else
                    {
                        logger.LogError("Graph API request failure: {REASON}",
                            response.ReasonPhrase);
                    }
                }
                catch (AccessTokenNotAvailableException exception)
                {
                    logger.LogError("Graph API access token failure: {MESSAGE}",
                        exception.Message);
                }
            }
            else
            {
                foreach (var group in account.Groups)
                {
                    userIdentity.AddClaim(new Claim("group", group));
                }
            }
        }

        return initialUser;
    }
}
```

There's no need to provide code to remove the original `groups` claim, if present, because it's automatically removed by the framework.

NOTE

The approach in this example:

- Adds a custom AuthorizationMessageHandler class to attach access tokens to outgoing requests.
- Adds a named HttpClient for making web API requests to a secure, external web API endpoint.
- Uses the named HttpClient to make authorized requests.

General coverage for this approach is found in the ASP.NET Core Blazor WebAssembly additional security scenarios article.

Register the factory in `Program.Main` (`Program.cs`) of the standalone app or client app of a hosted Blazor solution. Consent to the `Directory.Read.All` permission scope as an additional scope for the app:

```
builder.Services.AddMsalAuthentication<RemoteAuthenticationState,
    CustomUserAccount>(options =>
{
    builder.Configuration.Bind("AzureAd",
        options.ProviderOptions.Authentication);
    options.ProviderOptions.DefaultAccessTokenScopes.Add("...");

    options.ProviderOptions.AdditionalScopesToConsent.Add(
        "https://graph.microsoft.com/Directory.Read.All");
})
.AddAccountClaimsPrincipalFactory<RemoteAuthenticationState, CustomUserAccount,
    CustomUserFactory>();
```

Create a policy for each group or role in `Program.Main`. The following example creates a policy for the AAD built-in *Billing Administrator* role:

```
builder.Services.AddAuthorizationCore(options =>
{
    options.AddPolicy("BillingAdministrator", policy =>
        policy.RequireClaim("group", "69ff516a-b57d-4697-a429-9de4af7b5609"));
});
```

For the complete list of AAD role Object IDs, see the AAD Adminstrative Role Group IDs section.

In the following examples, the app uses the preceding policy to authorize the user.

The `AuthorizeView` component works with the policy:

```
<AuthorizeView Policy="BillingAdministrator">
    <Authorized>
        <p>
            The user is in the 'Billing Administrator' AAD Administrative Role
            and can see this content.
        </p>
    </Authorized>
    <NotAuthorized>
        <p>
            The user is NOT in the 'Billing Administrator' role and sees this
            content.
        </p>
    </NotAuthorized>
</AuthorizeView>
```

Access to an entire component can be based on the policy using `[Authorize]` attribute directive (AuthorizeAttribute):

```
@page "/"
@using Microsoft.AspNetCore.Authorization
@attribute [Authorize(Policy = "BillingAdministrator")]
```

If the user isn't logged in, they're redirected to the AAD sign-in page and then back to the component after they sign in.

A policy check can also be performed in code with procedural logic:

```
@page "/checkpolicy"
@using Microsoft.AspNetCore.Authorization
@inject IAuthorizationService AuthorizationService

<h1>Check Policy</h1>

<p>This component checks a policy in code.</p>

<button @onclick="CheckPolicy">Check 'BillingAdministrator' policy</button>

<p>Policy Message: @policyMessage</p>

@code {
    private string policyMessage = "Check hasn't been made yet.";

    [CascadingParameter]
    private Task<AuthenticationState> authenticationStateTask { get; set; }

    private async void CheckPolicy()
    {
        var user = (await authenticationStateTask).User;

        if ((await AuthorizationService.AuthorizeAsync(user,
            "BillingAdministrator")).Succeeded)
        {
            policyMessage = "Yes! The 'BillingAdministrator' policy is met.";
        }
        else
        {
            policyMessage = "No! 'BillingAdministrator' policy is NOT met.";
        }
    }
}
```

User-defined roles

An AAD-registered app can also be configured to use user-defined roles.

To configure the app in the Azure portal to provide a `roles` membership claim, see How to: Add app roles in your application and receive them in the token in the Azure documentation.

The following example assumes that an app is configured with two roles:

- `admin`
- `developer`

> **NOTE**
>
> Although you can't assign roles to security groups without an Azure AD Premium account, you can assign users to roles and receive a `roles` claim for users with a standard Azure account. The guidance in this section doesn't require an Azure AD Premium account.
>
> Multiple roles are assigned in the Azure portal by ***re-adding a user*** for each additional role assignment.

The single `roles` claim sent by AAD presents the user-defined roles as the `appRoles`'s `value`s in a JSON array. The app must convert the JSON array of roles into individual `role` claims.

The `CustomUserFactory` shown in the User-defined groups and AAD built-in Administrative Roles section is set up to act on a `roles` claim with a JSON array value. Add and register the `CustomUserFactory` in the standalone app or client app of a hosted Blazor solution as shown in the User-defined groups and AAD built-in Administrative Roles section. There's no need to provide code to remove the original `roles` claim because it's automatically removed by the framework.

In `Program.Main` of the standalone app or client app of a hosted Blazor solution, specify the claim named "`role`" as the role claim:

```
builder.Services.AddMsalAuthentication(options =>
{
    ...

    options.UserOptions.RoleClaim = "role";
});
```

Component authorization approaches are functional at this point. Any of the authorization mechanisms in components can use the `admin` role to authorize the user:

- `AuthorizeView` component (Example: `<AuthorizeView Roles="admin">`)
- `[Authorize]` attribute directive (AuthorizeAttribute) (Example: `@attribute [Authorize(Roles = "admin")]`)
- Procedural logic (Example: `if (user.IsInRole("admin")) { ... }`)

  Multiple role tests are supported:

  ```
  if (user.IsInRole("admin") && user.IsInRole("developer"))
  {
      ...
  }
  ```

AAD Adminstrative Role Group IDs

The Object IDs presented in the following table are used to create policies for `group` claims. Policies permit an app to authorize users for various activities in an app. For more information, see the User-defined groups and AAD built-in Administrative Roles section.

AAD ADMINISTRATIVE ROLE	OBJECT ID
Application administrator	fa11557b-4f15-4ddd-85d5-313c7cd74047
Application developer	68adcbb8-9504-44f6-89f2-5cd48dc74a2c

AAD ADMINISTRATIVE ROLE	OBJECT ID
Authentication administrator	02d110a1-96b1-419e-af87-746461b60ed7
Azure DevOps administrator	a5311ace-ca41-44cd-b833-8d22caa0b34f
Azure Information Protection administrator	18632dce-f9b5-4f01-abb5-37051f06860e

Secure ASP.NET Core Blazor Server apps

9/22/2020 • 2 minutes to read • Edit Online

By Luke Latham

Blazor Server apps are configured for security in the same manner as ASP.NET Core apps. For more information, see the articles under Overview of ASP.NET Core Security. Topics under this overview apply specifically to Blazor Server.

Blazor Server project template

The Blazor Server project template can be configured for authentication when the project is created.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac
- .NET Core CLI

Follow the Visual Studio guidance in Tooling for ASP.NET Core Blazor to create a new Blazor Server project with an authentication mechanism.

After choosing the **Blazor Server App** template in the **Create a new ASP.NET Core Web Application** dialog, select **Change** under **Authentication**.

A dialog opens to offer the same set of authentication mechanisms available for other ASP.NET Core projects:

- **No Authentication**
- **Individual User Accounts**: User accounts can be stored:
  - Within the app using ASP.NET Core's Identity system.
  - With Azure AD B2C.
- **Work or School Accounts**
- **Windows Authentication**

Scaffold Identity

Scaffold Identity into a Blazor Server project:

- Without existing authorization.
- With authorization.

Threat mitigation guidance for ASP.NET Core Blazor Server

9/22/2020 • 22 minutes to read • Edit Online

By Javier Calvarro Nelson

Blazor Server apps adopt a *stateful* data processing model, where the server and client maintain a long-lived relationship. The persistent state is maintained by a circuit, which can span connections that are also potentially long-lived.

When a user visits a Blazor Server site, the server creates a circuit in the server's memory. The circuit indicates to the browser what content to render and responds to events, such as when the user selects a button in the UI. To perform these actions, a circuit invokes JavaScript functions in the user's browser and .NET methods on the server. This two-way JavaScript-based interaction is referred to as JavaScript interop (JS interop).

Because JS interop occurs over the Internet and the client uses a remote browser, Blazor Server apps share most web app security concerns. This topic describes common threats to Blazor Server apps and provides threat mitigation guidance focused on Internet-facing apps.

In constrained environments, such as inside corporate networks or intranets, some of the mitigation guidance either:

- Doesn't apply in the constrained environment.
- Isn't worth the cost to implement because the security risk is low in a constrained environment.

Blazor and shared state

Blazor server apps live in server memory. That means that there are multiple apps hosted within the same process. For each app session, Blazor starts a circuit with its own DI container scope. That means that scoped services are unique per Blazor session.

> **WARNING**
> We don't recommend apps on the same server share state using singleton services unless extreme care is taken, as this can introduce security vulnerabilities, such as leaking user state across circuits.

You can use stateful singleton services in Blazor apps if they are specifically designed for it. For example, it's ok to use a memory cache as a singleton because it requires a key to access a given entry, assuming users don't have control of what cache keys are used.

Additionally, again for security reasons, you must not use IHttpContextAccessor within Blazor apps. Blazor apps run outside of the context of the ASP.NET Core pipeline. The HttpContext isn't guaranteed to be available within the IHttpContextAccessor, nor is it guaranteed to be holding the context that started the Blazor app.

The recommended way to pass request state to the Blazor app is through parameters to the root component in the initial rendering of the app:

- Define a class with all the data you want to pass to the Blazor app.
- Populate that data from the Razor page using the HttpContext available at that time.
- Pass the data to the Blazor app as a parameter to the root component (App).

- Define a parameter in the root component to hold the data being passed to the app.
- Use the user-specific data within the app; or alternatively, copy that data into a scoped service within OnInitializedAsync so that it can be used across the app.

For more information and example code, see ASP.NET Core Blazor Server additional security scenarios.

Resource exhaustion

Resource exhaustion can occur when a client interacts with the server and causes the server to consume excessive resources. Excessive resource consumption primarily affects:

- CPU
- Memory
- Client connections

Denial of service (DoS) attacks usually seek to exhaust an app or server's resources. However, resource exhaustion isn't necessarily the result of an attack on the system. For example, finite resources can be exhausted due to high user demand. DoS is covered further in the Denial of service (DoS) attacks section.

Resources external to the Blazor framework, such as databases and file handles (used to read and write files), may also experience resource exhaustion. For more information, see ASP.NET Core Performance Best Practices.

CPU

CPU exhaustion can occur when one or more clients force the server to perform intensive CPU work.

For example, consider a Blazor Server app that calculates a *Fibonnacci number*. A Fibonnacci number is produced from a Fibonnacci sequence, where each number in the sequence is the sum of the two preceding numbers. The amount of work required to reach the answer depends on the length of the sequence and the size of the initial value. If the app doesn't place limits on a client's request, the CPU-intensive calculations may dominate the CPU's time and diminish the performance of other tasks. Excessive resource consumption is a security concern impacting availability.

CPU exhaustion is a concern for all public-facing apps. In regular web apps, requests and connections time out as a safeguard, but Blazor Server apps don't provide the same safeguards. Blazor Server apps must include appropriate checks and limits before performing potentially CPU-intensive work.

Memory

Memory exhaustion can occur when one or more clients force the server to consume a large amount of memory.

For example, consider a Blazor-server side app with a component that accepts and displays a list of items. If the Blazor app doesn't place limits on the number of items allowed or the number of items rendered back to the client, the memory-intensive processing and rendering may dominate the server's memory to the point where performance of the server suffers. The server may crash or slow to the point that it appears to have crashed.

Consider the following scenario for maintaining and displaying a list of items that pertain to a potential memory exhaustion scenario on the server:

- The items in a `List<MyItem>` property or field use the server's memory. If the app allows the list of items to grow unbounded, there's a risk of the server running out of memory. Running out of memory causes the current session to end (crash) and all of the concurrent sessions in that server instance receive an out-of-memory exception. To prevent this scenario from occurring, the app must use a data structure that imposes an item limit on concurrent users.
- If a paging scheme isn't used for rendering, the server uses additional memory for objects that aren't visible in the UI. Without a limit on the number of items, memory demands may exhaust the available server memory. To prevent this scenario, use one of the following approaches:
  - Use paginated lists when rendering.

- Only display the first 100 to 1,000 items and require the user to enter search criteria to find items beyond the items displayed.
- For a more advanced rendering scenario, implement lists or grids that support *virtualization*. Using virtualization, lists only render a subset of items currently visible to the user. When the user interacts with the scrollbar in the UI, the component renders only those items required for display. The items that aren't currently required for display can be held in secondary storage, which is the ideal approach. Undisplayed items can also be held in memory, which is less ideal.

Blazor Server apps offer a similar programming model to other UI frameworks for stateful apps, such as WPF, Windows Forms, or Blazor WebAssembly. The main difference is that in several of the UI frameworks the memory consumed by the app belongs to the client and only affects that individual client. For example, a Blazor WebAssembly app runs entirely on the client and only uses client memory resources. In the Blazor Server scenario, the memory consumed by the app belongs to the server and is shared among clients on the server instance.

Server-side memory demands are a consideration for all Blazor Server apps. However, most web apps are stateless, and the memory used while processing a request is released when the response is returned. As a general recommendation, don't permit clients to allocate an unbound amount of memory as in any other server-side app that persists client connections. The memory consumed by a Blazor Server app persists for a longer time than a single request.

> **NOTE**
> During development, a profiler can be used or a trace captured to assess memory demands of clients. A profiler or trace won't capture the memory allocated to a specific client. To capture the memory use of a specific client during development, capture a dump and examine the memory demand of all the objects rooted at a user's circuit.

Client connections

Connection exhaustion can occur when one or more clients open too many concurrent connections to the server, preventing other clients from establishing new connections.

Blazor clients establish a single connection per session and keep the connection open for as long as the browser window is open. The demands on the server of maintaining all of the connections isn't specific to Blazor apps. Given the persistent nature of the connections and the stateful nature of Blazor Server apps, connection exhaustion is a greater risk to availability of the app.

By default, there's no limit on the number of connections per user for a Blazor Server app. If the app requires a connection limit, take one or more of the following approaches:

- Require authentication, which naturally limits the ability of unauthorized users to connect to the app. For this scenario to be effective, users must be prevented from provisioning new users at will.
- Limit the number of connections per user. Limiting connections can be accomplished via the following approaches. Exercise care to allow legitimate users to access the app (for example, when a connection limit is established based on the client's IP address).
  - At the app level:
    - Endpoint routing extensibility.
    - Require authentication to connect to the app and keep track of the active sessions per user.
    - Reject new sessions upon reaching a limit.
    - Proxy WebSocket connections to an app through the use of a proxy, such as the Azure SignalR Service that multiplexes connections from clients to an app. This provides an app with greater connection capacity than a single client can establish, preventing a client from exhausting the connections to the server.
  - At the server level: Use a proxy/gateway in front of the app. For example, Azure Front Door enables you

to define, manage, and monitor the global routing of web traffic to an app.

Denial of service (DoS) attacks

Denial of service (DoS) attacks involve a client causing the server to exhaust one or more of its resources making the app unavailable. Blazor Server apps include some default limits and rely on other ASP.NET Core and SignalR limits to protect against DoS attacks that are set on CircuitOptions.

BLAZOR SERVER APP LIMIT	DESCRIPTION	DEFAULT
DisconnectedCircuitMaxRetained	Maximum number of disconnected circuits that a given server holds in memory at a time.	100
DisconnectedCircuitRetentionPeriod	Maximum amount of time a disconnected circuit is held in memory before being torn down.	3 minutes
JSInteropDefaultCallTimeout	Maximum amount of time the server waits before timing out an asynchronous JavaScript function invocation.	1 minute
MaxBufferedUnacknowledgedRenderBatches	Maximum number of unacknowledged render batches the server keeps in memory per circuit at a given time to support robust reconnection. After reaching the limit, the server stops producing new render batches until one or more batches have been acknowledged by the client.	10

Set the maximum message size of a single incoming hub message with HubConnectionContextOptions.

SIGNALR AND ASP.NET CORE LIMIT	DESCRIPTION	DEFAULT
HubConnectionContextOptions.MaximumReceiveMessageSize	Message size for an individual message.	32 KB

Interactions with the browser (client)

A client interacts with the server through JS interop event dispatching and render completion. JS interop communication goes both ways between JavaScript and .NET:

- Browser events are dispatched from the client to the server in an asynchronous fashion.
- The server responds asynchronously rerendering the UI as necessary.

JavaScript functions invoked from .NET

For calls from .NET methods to JavaScript:

- All invocations have a configurable timeout after which they fail, returning a OperationCanceledException to the caller.
  - There's a default timeout for the calls (CircuitOptions.JSInteropDefaultCallTimeout) of one minute. To configure this limit, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.
  - A cancellation token can be provided to control the cancellation on a per-call basis. Rely on the default call timeout where possible and time-bound any call to the client if a cancellation token is provided.

- The result of a JavaScript call can't be trusted. The Blazor app client running in the browser searches for the JavaScript function to invoke. The function is invoked, and either the result or an error is produced. A malicious client can attempt to:
  - Cause an issue in the app by returning an error from the JavaScript function.
  - Induce an unintended behavior on the server by returning an unexpected result from the JavaScript function.

Take the following precautions to guard against the preceding scenarios:

- Wrap JS interop calls within `try-catch` statements to account for errors that might occur during the invocations. For more information, see Handle errors in ASP.NET Core Blazor apps.
- Validate data returned from JS interop invocations, including error messages, before taking any action.

.NET methods invoked from the browser

Don't trust calls from JavaScript to .NET methods. When a .NET method is exposed to JavaScript, consider how the .NET method is invoked:

- Treat any .NET method exposed to JavaScript as you would a public endpoint to the app.
  - Validate input.
    - Ensure that values are within expected ranges.
    - Ensure that the user has permission to perform the action requested.
  - Don't allocate an excessive quantity of resources as part of the .NET method invocation. For example, perform checks and place limits on CPU and memory use.
  - Take into account that static and instance methods can be exposed to JavaScript clients. Avoid sharing state across sessions unless the design calls for sharing state with appropriate constraints.
    - For instance methods exposed through `DotNetReference` objects that are originally created through dependency injection (DI), the objects should be registered as scoped objects. This applies to any DI service that the Blazor Server app uses.
    - For static methods, avoid establishing state that can't be scoped to the client unless the app is explicitly sharing state by-design across all users on a server instance.
  - Avoid passing user-supplied data in parameters to JavaScript calls. If passing data in parameters is absolutely required, ensure that the JavaScript code handles passing the data without introducing Cross-site scripting (XSS) vulnerabilities. For example, don't write user-supplied data to the Document Object Model (DOM) by setting the `innerHTML` property of an element. Consider using Content Security Policy (CSP) to disable `eval` and other unsafe JavaScript primitives.
- Avoid implementing custom dispatching of .NET invocations on top of the framework's dispatching implementation. Exposing .NET methods to the browser is an advanced scenario, not recommended for general Blazor development.

Events

Events provide an entry point to a Blazor Server app. The same rules for safeguarding endpoints in web apps apply to event handling in Blazor Server apps. A malicious client can send any data it wishes to send as the payload for an event.

For example:

- A change event for a `<select>` could send a value that isn't within the options that the app presented to the client.
- An `<input>` could send any text data to the server, bypassing client-side validation.

The app must validate the data for any event that the app handles. The Blazor framework forms components perform basic validations. If the app uses custom forms components, custom code must be written to validate event data as appropriate.

Blazor Server events are asynchronous, so multiple events can be dispatched to the server before the app has time to react by producing a new render. This has some security implications to consider. Limiting client actions in the app must be performed inside event handlers and not depend on the current rendered view state.

Consider a counter component that should allow a user to increment a counter a maximum of three times. The button to increment the counter is conditionally based on the value of `count`:

```
<p>Count: @count<p>

@if (count < 3)
{
    <button @onclick="IncrementCount" value="Increment count" />
}

@code
{
    private int count = 0;

    private void IncrementCount()
    {
        count++;
    }
}
```

A client can dispatch one or more increment events before the framework produces a new render of this component. The result is that the `count` can be incremented *over three times* by the user because the button isn't removed by the UI quickly enough. The correct way to achieve the limit of three `count` increments is shown in the following example:

```
<p>Count: @count<p>

@if (count < 3)
{
    <button @onclick="IncrementCount" value="Increment count" />
}

@code
{
    private int count = 0;

    private void IncrementCount()
    {
        if (count < 3)
        {
            count++;
        }
    }
}
```

By adding the `if (count < 3) { ... }` check inside the handler, the decision to increment `count` is based on the current app state. The decision isn't based on the state of the UI as it was in the previous example, which might be temporarily stale.

Guard against multiple dispatches

If an event callback invokes a long running operation asynchronously, such as fetching data from an external service or database, consider using a guard. The guard can prevent the user from queueing up multiple operations while the operation is in progress with visual feedback. The following component code sets `isLoading` to `true` while `GetForecastAsync` obtains data from the server. While `isLoading` is `true`, the button is disabled in the UI:

```
@page "/fetchdata"
@using BlazorServerSample.Data
@inject WeatherForecastService ForecastService

<button disabled="@isLoading" @onclick="UpdateForecasts">Update</button>

@code {
    private bool isLoading;
    private WeatherForecast[] forecasts;

    private async Task UpdateForecasts()
    {
        if (!isLoading)
        {
            isLoading = true;
            forecasts = await ForecastService.GetForecastAsync(DateTime.Now);
            isLoading = false;
        }
    }
}
```

The guard pattern demonstrated in the preceding example works if the background operation is executed asynchronously with the `async` - `await` pattern.

Cancel early and avoid use-after-dispose

In addition to using a guard as described in the Guard against multiple dispatches section, consider using a CancellationToken to cancel long-running operations when the component is disposed. This approach has the added benefit of avoiding *use-after-dispose* in components:

```
@implements IDisposable

...

@code {
    private readonly CancellationTokenSource TokenSource =
        new CancellationTokenSource();

    private async Task UpdateForecasts()
    {
        ...

        forecasts = await ForecastService.GetForecastAsync(DateTime.Now,
            TokenSource.Token);

        if (TokenSource.Token.IsCancellationRequested)
        {
           return;
        }

        ...
    }

    public void Dispose()
    {
        TokenSource.Cancel();
    }
}
```

Avoid events that produce large amounts of data

Some DOM events, such as `oninput` or `onscroll`, can produce a large amount of data. Avoid using these events in Blazor server apps.

Additional security guidance

The guidance for securing ASP.NET Core apps apply to Blazor Server apps and are covered in the following sections:

- Logging and sensitive data
- Protect information in transit with HTTPS
- Cross-site scripting (XSS)
- Cross-origin protection
- Click-jacking
- Open redirects

Logging and sensitive data

JS interop interactions between the client and server are recorded in the server's logs with ILogger instances. Blazor avoids logging sensitive information, such as actual events or JS interop inputs and outputs.

When an error occurs on the server, the framework notifies the client and tears down the session. By default, the client receives a generic error message that can be seen in the browser's developer tools.

The client-side error doesn't include the callstack and doesn't provide detail on the cause of the error, but server logs do contain such information. For development purposes, sensitive error information can be made available to the client by enabling detailed errors.

Enable detailed errors in JavaScript with:

- CircuitOptions.DetailedErrors.
- The `DetailedErrors` configuration key set to `true`, which can be set in the app settings file (`appsettings.json`). The key can also be set using the `ASPNETCORE_DETAILEDERRORS` environment variable with a value of `true`.

> **WARNING**
> Exposing error information to clients on the Internet is a security risk that should always be avoided.

Protect information in transit with HTTPS

Blazor Server uses SignalR for communication between the client and the server. Blazor Server normally uses the transport that SignalR negotiates, which is typically WebSockets.

Blazor Server doesn't ensure the integrity and confidentiality of the data sent between the server and the client. Always use HTTPS.

Cross-site scripting (XSS)

Cross-site scripting (XSS) allows an unauthorized party to execute arbitrary logic in the context of the browser. A compromised app could potentially run arbitrary code on the client. The vulnerability could be used to potentially perform a number of malicious actions against the server:

- Dispatch fake/invalid events to the server.
- Dispatch fail/invalid render completions.
- Avoid dispatching render completions.
- Dispatch interop calls from JavaScript to .NET.
- Modify the response of interop calls from .NET to JavaScript.
- Avoid dispatching .NET to JS interop results.

The Blazor Server framework takes steps to protect against some of the preceding threats:

- Stops producing new UI updates if the client isn't acknowledging render batches. Configured with

CircuitOptions.MaxBufferedUnacknowledgedRenderBatches.

- Times out any .NET to JavaScript call after one minute without receiving a response from the client. Configured with CircuitOptions.JSInteropDefaultCallTimeout.
- Performs basic validation on all input coming from the browser during JS interop:
  - .NET references are valid and of the type expected by the .NET method.
  - The data isn't malformed.
  - The correct number of arguments for the method are present in the payload.
  - The arguments or result can be deserialized correctly before invoking the method.
- Performs basic validation in all input coming from the browser from dispatched events:
  - The event has a valid type.
  - The data for the event can be deserialized.
  - There's an event handler associated with the event.

In addition to the safeguards that the framework implements, the app must be coded by the developer to safeguard against threats and take appropriate actions:

- Always validate data when handling events.
- Take appropriate action upon receiving invalid data:
  - Ignore the data and return. This allows the app to continue processing requests.
  - If the app determines that the input is illegitimate and couldn't be produced by legitimate client, throw an exception. Throwing an exception tears down the circuit and ends the session.
- Don't trust the error message provided by render batch completions included in the logs. The error is provided by the client and can't generally be trusted, as the client might be compromised.
- Don't trust the input on JS interop calls in either direction between JavaScript and .NET methods.
- The app is responsible for validating that the content of arguments and results are valid, even if the arguments or results are correctly deserialized.

For a XSS vulnerability to exist, the app must incorporate user input in the rendered page. Blazor Server components execute a compile-time step where the markup in a `.razor` file is transformed into procedural C# logic. At runtime, the C# logic builds a *render tree* describing the elements, text, and child components. This is applied to the browser's DOM via a sequence of JavaScript instructions (or is serialized to HTML in the case of prerendering):

- User input rendered via normal Razor syntax (for example, `@someStringValue`) doesn't expose a XSS vulnerability because the Razor syntax is added to the DOM via commands that can only write text. Even if the value includes HTML markup, the value is displayed as static text. When prerendering, the output is HTML-encoded, which also displays the content as static text.
- Script tags aren't allowed and shouldn't be included in the app's component render tree. If a script tag is included in a component's markup, a compile-time error is generated.
- Component authors can author components in C# without using Razor. The component author is responsible for using the correct APIs when emitting output. For example, use `builder.AddContent(0, someUserSuppliedString)` and *not* `builder.AddMarkupContent(0, someUserSuppliedString)`, as the latter could create a XSS vulnerability.

As part of protecting against XSS attacks, consider implementing XSS mitigations, such as Content Security Policy (CSP).

For more information, see Prevent Cross-Site Scripting (XSS) in ASP.NET Core.

Cross-origin protection

Cross-origin attacks involve a client from a different origin performing an action against the server. The malicious action is typically a GET request or a form POST (Cross-Site Request Forgery, CSRF), but opening a malicious

WebSocket is also possible. Blazor Server apps offer the same guarantees that any other SignalR app using the hub protocol offer:

- Blazor Server apps can be accessed cross-origin unless additional measures are taken to prevent it. To disable cross-origin access, either disable CORS in the endpoint by adding the CORS middleware to the pipeline and adding the DisableCorsAttribute to the Blazor endpoint metadata or limit the set of allowed origins by configuring SignalR for cross-origin resource sharing.
- If CORS is enabled, extra steps might be required to protect the app depending on the CORS configuration. If CORS is globally enabled, CORS can be disabled for the Blazor Server hub by adding the DisableCorsAttribute metadata to the endpoint metadata after calling MapBlazorHub on the endpoint route builder.

For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

Click-jacking

Click-jacking involves rendering a site as an `<iframe>` inside a site from a different origin in order to trick the user into performing actions on the site under attack.

To protect an app from rendering inside of an `<iframe>`, use Content Security Policy (CSP) and the `X-Frame-Options` header. For more information, see MDN web docs: X-Frame-Options.

Open redirects

When a Blazor Server app session starts, the server performs basic validation of the URLs sent as part of starting the session. The framework checks that the base URL is a parent of the current URL before establishing the circuit. No additional checks are performed by the framework.

When a user selects a link on the client, the URL for the link is sent to the server, which determines what action to take. For example, the app may perform a client-side navigation or indicate to the browser to go to the new location.

Components can also trigger navigation requests programatically through the use of NavigationManager. In such scenarios, the app might perform a client-side navigation or indicate to the browser to go to the new location.

Components must:

- Avoid using user input as part of the navigation call arguments.
- Validate arguments to ensure that the target is allowed by the app.

Otherwise, a malicious user can force the browser to go to an attacker-controlled site. In this scenario, the attacker tricks the app into using some user input as part of the invocation of the NavigationManager.NavigateTo method.

This advice also applies when rendering links as part of the app:

- If possible, use relative links.
- Validate that absolute link destinations are valid before including them in a page.

For more information, see Prevent open redirect attacks in ASP.NET Core.

Security checklist

The following list of security considerations isn't comprehensive:

- Validate arguments from events.
- Validate inputs and results from JS interop calls.
- Avoid using (or validate beforehand) user input for .NET to JS interop calls.
- Prevent the client from allocating an unbound amount of memory.
  - Data within the component.

    - `DotNetObject` references returned to the client.
- Guard against multiple dispatches.
- Cancel long-running operations when the component is disposed.
- Avoid events that produce large amounts of data.
- Avoid using user input as part of calls to NavigationManager.NavigateTo and validate user input for URLs against a set of allowed origins first if unavoidable.
- Don't make authorization decisions based on the state of the UI but only from component state.
- Consider using Content Security Policy (CSP) to protect against XSS attacks.
- Consider using CSP and X-Frame-Options to protect against click-jacking.
- Ensure CORS settings are appropriate when enabling CORS or explicitly disable CORS for Blazor apps.
- Test to ensure that the server-side limits for the Blazor app provide an acceptable user experience without unacceptable levels of risk.

ASP.NET Core Blazor Server additional security scenarios

9/22/2020 • 3 minutes to read • Edit Online

By Javier Calvarro Nelson

Pass tokens to a Blazor Server app

Tokens available outside of the Razor components in a Blazor Server app can be passed to components with the approach described in this section. For sample code, including a complete `Startup.ConfigureServices` example, see the Passing tokens to a server-side Blazor application.

Authenticate the Blazor Server app as you would with a regular Razor Pages or MVC app. Provision and save the tokens to the authentication cookie. For example:

```
using Microsoft.AspNetCore.Authentication.OpenIdConnect;

...

services.Configure<OpenIdConnectOptions>(AzureADDefaults.OpenIdScheme, options =>
{
    options.ResponseType = "code";
    options.SaveTokens = true;

    options.Scope.Add("offline_access");
    options.Scope.Add("{SCOPE}");
    options.Resource = "{RESOURCE}";
});
```

Define a class to pass in the initial app state with the access and refresh tokens:

```
public class InitialApplicationState
{
    public string AccessToken { get; set; }
    public string RefreshToken { get; set; }
}
```

Define a **scoped** token provider service that can be used within the Blazor app to resolve the tokens from dependency injection (DI):

```
public class TokenProvider
{
    public string AccessToken { get; set; }
    public string RefreshToken { get; set; }
}
```

In `Startup.ConfigureServices`, add services for:

- `IHttpClientFactory`
- `TokenProvider`

```
services.AddHttpClient();
services.AddScoped<TokenProvider>();
```

In the `_Host.cshtml` file, create and instance of `InitialApplicationState` and pass it as a parameter to the app:

```
@using Microsoft.AspNetCore.Authentication

...

@{
    var tokens = new InitialApplicationState
    {
        AccessToken = await HttpContext.GetTokenAsync("access_token"),
        RefreshToken = await HttpContext.GetTokenAsync("refresh_token")
    };
}

<app>
    <component type="typeof(App)" param-InitialState="tokens"
        render-mode="ServerPrerendered" />
</app>
```

In the `App` component (`App.razor`), resolve the service and initialize it with the data from the parameter:

```
@inject TokenProvider TokenProvider

...

@code {
    [Parameter]
    public InitialApplicationState InitialState { get; set; }

    protected override Task OnInitializedAsync()
    {
        TokenProvider.AccessToken = InitialState.AccessToken;
        TokenProvider.RefreshToken = InitialState.RefreshToken;

        return base.OnInitializedAsync();
    }
}
```

Add a package reference to the app for the Microsoft.AspNet.WebApi.Client NuGet package.

In the service that makes a secure API request, inject the token provider and retrieve the token to call the API:

```
using System;
using System.Net.Http;
using System.Threading.Tasks;

public class WeatherForecastService
{
    private readonly TokenProvider store;

    public WeatherForecastService(IHttpClientFactory clientFactory,
        TokenProvider tokenProvider)
    {
        Client = clientFactory.CreateClient();
        store = tokenProvider;
    }

    public HttpClient Client { get; }

    public async Task<WeatherForecast[]> GetForecastAsync(DateTime startDate)
    {
        var token = store.AccessToken;
        var request = new HttpRequestMessage(HttpMethod.Get,
            "https://localhost:5003/WeatherForecast");
        request.Headers.Add("Authorization", $"Bearer {token}");
        var response = await Client.SendAsync(request);
        response.EnsureSuccessStatusCode();

        return await response.Content.ReadAsAsync<WeatherForecast[]>();
    }
}
```

Set the authentication scheme

For an app that uses more than one Authentication Middleware and thus has more than one authentication scheme, the scheme that Blazor uses can be explicitly set in the endpoint configuration of `Startup.Configure`. The following example sets the Azure Active Directory scheme:

```
endpoints.MapBlazorHub().RequireAuthorization(
    new AuthorizeAttribute
    {
        AuthenticationSchemes = AzureADDefaults.AuthenticationScheme
    });
```

Use OpenID Connect (OIDC) v2.0 endpoints

The authentication library and Blazor templates use OpenID Connect (OIDC) v1.0 endpoints. To use a v2.0 endpoint, configure the OpenIdConnectOptions.Authority option in the OpenIdConnectOptions:

```
services.Configure<OpenIdConnectOptions>(AzureADDefaults.OpenIdScheme,
    options =>
    {
        options.Authority += "/v2.0";
    }
```

Alternatively, the setting can be made in the app settings (`appsettings.json`) file:

```
{
  "AzureAd": {
    "Authority": "https://login.microsoftonline.com/common/oauth2/v2.0/",
    ...
  }
}
```

If tacking on a segment to the authority isn't appropriate for the app's OIDC provider, such as with non-AAD providers, set the Authority property directly. Either set the property in OpenIdConnectOptions or in the app settings file with the Authority key.

Code changes

- The list of claims in the ID token changes for v2.0 endpoints. For more information, see Why update to Microsoft identity platform (v2.0)? in the Azure documentation.
- Since resources are specified in scope URIs for v2.0 endpoints, remove the OpenIdConnectOptions.Resource property setting in OpenIdConnectOptions:

  ```
  services.Configure<OpenIdConnectOptions>(AzureADDefaults.OpenIdScheme, options =>
      {
          ...
          options.Resource = "...";    // REMOVE THIS LINE
          ...
      }
      ```

  For more information, see [Scopes, not resources](/azure/active-directory/azuread-dev/azure-ad-endpoint-comparison#scopes-not-resources) in the Azure documentation.

App ID URI

- When using v2.0 endpoints, APIs define an *App ID URI*, which is meant to represent a unique identifier for the API.
- All scopes include the App ID URI as a prefix, and v2.0 endpoints emit access tokens with the App ID URI as the audience.
- When using V2.0 endpoints, the client ID configured in the Server API changes from the API Application ID (Client ID) to the App ID URI.

`appsettings.json`:

```
{
  "AzureAd": {
    ...
    "ClientId": "https://{TENANT}.onmicrosoft.com/{APP NAME}"
    ...
  }
}
```

You can find the App ID URI to use in the OIDC provider app registration description.

Enforce a Content Security Policy for ASP.NET Core Blazor

9/22/2020 • 5 minutes to read • Edit Online

By Javier Calvarro Nelson and Luke Latham

Cross-Site Scripting (XSS) is a security vulnerability where an attacker places one or more malicious client-side scripts into an app's rendered content. A Content Security Policy (CSP) helps protect against XSS attacks by informing the browser of valid:

- Sources for loaded content, including scripts, stylesheets, and images.
- Actions taken by a page, specifying permitted URL targets of forms.
- Plugins that can be loaded.

To apply a CSP to an app, the developer specifies several CSP content security *directives* in one or more `Content-Security-Policy` headers or `<meta>` tags.

Policies are evaluated by the browser while a page is loading. The browser inspects the page's sources and determines if they meet the requirements of the content security directives. When policy directives aren't met for a resource, the browser doesn't load the resource. For example, consider a policy that doesn't allow third-party scripts. When a page contains a `<script>` tag with a third-party origin in the `src` attribute, the browser prevents the script from loading.

CSP is supported in most modern desktop and mobile browsers, including Chrome, Edge, Firefox, Opera, and Safari. CSP is recommended for Blazor apps.

Policy directives

Minimally, specify the following directives and sources for Blazor apps. Add additional directives and sources as needed. The following directives are used in the Apply the policy section of this article, where example security policies for Blazor WebAssembly and Blazor Server are provided:

- base-uri: Restricts the URLs for a page's `<base>` tag. Specify `self` to indicate that the app's origin, including the scheme and port number, is a valid source.
- block-all-mixed-content: Prevents loading mixed HTTP and HTTPS content.
- default-src: Indicates a fallback for source directives that aren't explicitly specified by the policy. Specify `self` to indicate that the app's origin, including the scheme and port number, is a valid source.
- img-src: Indicates valid sources for images.
  - Specify `data:` to permit loading images from `data:` URLs.
  - Specify `https:` to permit loading images from HTTPS endpoints.
- object-src: Indicates valid sources for the `<object>`, `<embed>`, and `<applet>` tags. Specify `none` to prevent all URL sources.
- script-src: Indicates valid sources for scripts.
  - Specify the `https://stackpath.bootstrapcdn.com/` host source for Bootstrap scripts.
  - Specify `self` to indicate that the app's origin, including the scheme and port number, is a valid source.
  - In a Blazor WebAssembly app:
    - Specify the following hashes to permit the required Blazor WebAssembly inline scripts to load:
      - `sha256-v8ZC9OgMhcnEQ/Me77/R9TlJfzOBqrMTW8e1KuqLaqc=`

        - `sha256-If//FtbPc03afjLezvWHnC3Nbu4fDM04IIzkPaf3pH0=`
        - `sha256-v8v3RKRPmN4odZ1CWM5gw80QKPCCWMcpNeOmimNL2AA=`
    - Specify `unsafe-eval` to use `eval()` and methods for creating code from strings.
  - In a Blazor Server app, specify the `sha256-34WLX60Tw3aG6hylk0plKbZZFXCuepeQ6Hu7OqRf8PI=` hash for the inline script that performs fallback detection for stylesheets.
- style-src: Indicates valid sources for stylesheets.
  - Specify the `https://stackpath.bootstrapcdn.com/` host source for Bootstrap stylesheets.
  - Specify `self` to indicate that the app's origin, including the scheme and port number, is a valid source.
  - Specify `unsafe-inline` to allow the use of inline styles. The inline declaration is required for the UI in Blazor Server apps for reconnecting the client and server after the initial request. In a future release, inline styling might be removed so that `unsafe-inline` is no longer required.
- upgrade-insecure-requests: Indicates that content URLs from insecure (HTTP) sources should be acquired securely over HTTPS.

The preceding directives are supported by all browsers except Microsoft Internet Explorer.

To obtain SHA hashes for additional inline scripts:

- Apply the CSP shown in the Apply the policy section.
- Access the browser's developer tools console while running the app locally. The browser calculates and displays hashes for blocked scripts when a CSP header or `meta` tag is present.
- Copy the hashes provided by the browser to the `script-src` sources. Use single quotes around each hash.

For a Content Security Policy Level 2 browser support matrix, see Can I use: Content Security Policy Level 2.

Apply the policy

Use a `<meta>` tag to apply the policy:

- Set the value of the `http-equiv` attribute to `Content-Security-Policy`.
- Place the directives in the `content` attribute value. Separate directives with a semicolon (`;`).
- Always place the `meta` tag in the `<head>` content.

The following sections show example policies for Blazor WebAssembly and Blazor Server. These examples are versioned with this article for each release of Blazor. To use a version appropriate for your release, select the document version with the **Version** drop down selector on this webpage.

Blazor WebAssembly

In the `<head>` content of the `wwwroot/index.html` host page, apply the directives described in the Policy directives section:

```
<meta http-equiv="Content-Security-Policy"
      content="base-uri 'self';
               block-all-mixed-content;
               default-src 'self';
               img-src data: https:;
               object-src 'none';
               script-src https://stackpath.bootstrapcdn.com/
                          'self'
                          'sha256-v8ZC9OgMhcnEQ/Me77/R9TlJfzOBqrMTW8e1KuqLaqc='
                          'sha256-If//FtbPc03afjLezvWHnC3Nbu4fDM04IIzkPaf3pH0='
                          'sha256-v8v3RKRPmN4odZ1CWM5gw80QKPCCWMcpNeOmimNL2AA='
                          'unsafe-eval';
               style-src https://stackpath.bootstrapcdn.com/
                         'self'
                         'unsafe-inline';
               upgrade-insecure-requests;">
```

Blazor Server

In the `<head>` content of the `Pages/_Host.cshtml` host page, apply the directives described in the Policy directives section:

```
<meta http-equiv="Content-Security-Policy"
      content="base-uri 'self';
               block-all-mixed-content;
               default-src 'self';
               img-src data: https:;
               object-src 'none';
               script-src https://stackpath.bootstrapcdn.com/
                          'self'
                          'sha256-34WLX60Tw3aG6hylk0plKbZZFXCuepeQ6Hu7OqRf8PI=';
               style-src https://stackpath.bootstrapcdn.com/
                         'self'
                         'unsafe-inline';
               upgrade-insecure-requests;">
```

Meta tag limitations

A `<meta>` tag policy doesn't support the following directives:

- frame-ancestors
- report-to
- report-uri
- sandbox

To support the preceding directives, use a header named `Content-Security-Policy`. The directive string is the header's value.

Test a policy and receive violation reports

Testing helps confirm that third-party scripts aren't inadvertently blocked when building an initial policy.

To test a policy over a period of time without enforcing the policy directives, set the `<meta>` tag's `http-equiv` attribute or header name of a header-based policy to `Content-Security-Policy-Report-Only`. Failure reports are sent as JSON documents to a specified URL. For more information, see MDN web docs: Content-Security-Policy-Report-Only.

For reporting on violations while a policy is active, see the following articles:

- report-to
- report-uri

Although `report-uri` is no longer recommended for use, both directives should be used until `report-to` is supported by all of the major browsers. Don't exclusively use `report-uri` because support for `report-uri` is subject to being dropped *at any time* from browsers. Remove support for `report-uri` in your policies when `report-to` is fully supported. To track adoption of `report-to`, see Can I use: report-to.

Test and update an app's policy every release.

Troubleshoot

- Errors appear in the browser's developer tools console. Browsers provide information about:
  - Elements that don't comply with the policy.
  - How to modify the policy to allow for a blocked item.
- A policy is only completely effective when the client's browser supports all of the included directives. For a current browser support matrix, see Can I use: Content-Security-Policy.

ASP.NET Core Blazor state management

9/22/2020 • 20 minutes to read • Edit Online

By Steve Sanderson and Luke Latham

User state created in a Blazor WebAssembly app is held in the browser's memory.

Examples of user state held in browser memory include:

- The hierarchy of component instances and their most recent render output in the rendered UI.
- The values of fields and properties in component instances.
- Data held in dependency injection (DI) service instances.
- Values set through JavaScript interop calls.

When a user closes and re-opens their browser or reloads the page, user state held in the browser's memory is lost.

Persist state across browser sessions

Generally, maintain state across browser sessions where users are actively creating data, not simply reading data that already exists.

To preserve state across browser sessions, the app must persist the data to some other storage location than the browser's memory. State persistence isn't automatic. You must take steps when developing the app to implement stateful data persistence.

Data persistence is typically only required for high-value state that users expended effort to create. In the following examples, persisting state either saves time or aids in commercial activities:

- Multi-step web forms: It's time-consuming for a user to re-enter data for several completed steps of a multi-step web form if their state is lost. A user loses state in this scenario if they navigate away from the form and return later.
- Shopping carts: Any commercially important component of an app that represents potential revenue can be maintained. A user who loses their state, and thus their shopping cart, may purchase fewer products or services when they return to the site later.

An app can only persist *app state*. UIs can't be persisted, such as component instances and their render trees. Components and render trees aren't generally serializable. To persist UI state, such as the expanded nodes of a tree view control, the app must use custom code to model the behavior of the UI state as serializable app state.

Where to persist state

Three common locations exist for persisting state:

- Server-side storage
- URL
- Browser storage

Server-side storage

For permanent data persistence that spans multiple users and devices, the app can use independent server-side storage accessed via a web API. Options include:

- Blob storage

- Key-value storage
- Relational database
- Table storage

After data is saved, the user's state is retained and available in any new browser session.

Because Blazor WebAssembly apps run entirely in the user's browser, they require additional measures to access secure external systems, such as storage services and databases. Blazor WebAssembly apps are secured in the same manner as Single Page Applications (SPAs). Typically, an app authenticates a user via OAuth/OpenID Connect (OIDC) and then interacts with storage services and databases through web API calls to a server-side app. The server-side app mediates the transfer of data between the Blazor WebAssembly app and the storage service or database. The Blazor WebAssembly app maintains an ephemeral connection to the server-side app, while the server-side app has a persistent connection to storage.

For more information, see the following resources:

- Call a web API from ASP.NET Core Blazor WebAssembly
- Secure ASP.NET Core Blazor WebAssembly
- Blazor *Security and Identity* articles

For more information on Azure data storage options, see the following:

- Azure Databases
- Azure Storage Documentation

URL

For transient data representing navigation state, model the data as a part of the URL. Examples of user state modeled in the URL include:

- The ID of a viewed entity.
- The current page number in a paged grid.

The contents of the browser's address bar are retained if the user manually reloads the page.

For information on defining URL patterns with the `@page` directive, see ASP.NET Core Blazor routing.

Browser storage

For transient data that the user is actively creating, a commonly used storage location is the browser's `localStorage` and `sessionStorage` collections:

- `localStorage` is scoped to the browser's window. If the user reloads the page or closes and re-opens the browser, the state persists. If the user opens multiple browser tabs, the state is shared across the tabs. Data persists in `localStorage` until explicitly cleared.
- `sessionStorage` is scoped to the browser tab. If the user reloads the tab, the state persists. If the user closes the tab or the browser, the state is lost. If the user opens multiple browser tabs, each tab has its own independent version of the data.

> **NOTE**
>
> `localStorage` and `sessionStorage` can be used in Blazor WebAssembly apps but only by writing custom code or using a third-party package.

Generally, `sessionStorage` is safer to use. `sessionStorage` avoids the risk that a user opens multiple tabs and encounters the following:

- Bugs in state storage across tabs.

- Confusing behavior when a tab overwrites the state of other tabs.

`localStorage` is the better choice if the app must persist state across closing and re-opening the browser.

> **WARNING**
> Users may view or tamper with the data stored in `localStorage` and `sessionStorage`.

Additional resources

- Save app state before an authentication operation
- Call a web API from ASP.NET Core Blazor WebAssembly
- Secure ASP.NET Core Blazor WebAssembly

Blazor Server is a stateful app framework. Most of the time, the app maintains a connection to the server. The user's state is held in the server's memory in a *circuit*.

Examples of user state held in a circuit include:

- The hierarchy of component instances and their most recent render output in the rendered UI.
- The values of fields and properties in component instances.
- Data held in dependency injection (DI) service instances that are scoped to the circuit.

User state might also be found in JavaScript variables in the browser's memory set via JavaScript interop calls.

If a user experiences a temporary network connection loss, Blazor attempts to reconnect the user to their original circuit with their original state. However, reconnecting a user to their original circuit in the server's memory isn't always possible:

- The server can't retain a disconnected circuit forever. The server must release a disconnected circuit after a timeout or when the server is under memory pressure.
- In multi-server, load-balanced deployment environments, individual servers may fail or be automatically removed when no longer required to handle the overall volume of requests. The original server processing requests for a user may become unavailable when the user attempts to reconnect.
- The user might close and re-open their browser or reload the page, which removes any state held in the browser's memory. For example, JavaScript variable values set through JavaScript interop calls are lost.

When a user can't be reconnected to their original circuit, the user receives a new circuit with an empty state. This is equivalent to closing and re-opening a desktop app.

Persist state across circuits

Generally, maintain state across circuits where users are actively creating data, not simply reading data that already exists.

To preserve state across circuits, the app must persist the data to some other storage location than the server's memory. State persistence isn't automatic. You must take steps when developing the app to implement stateful data persistence.

Data persistence is typically only required for high-value state that users expended effort to create. In the following examples, persisting state either saves time or aids in commercial activities:

- Multi-step web forms: It's time-consuming for a user to re-enter data for several completed steps of a multi-step web form if their state is lost. A user loses state in this scenario if they navigate away from the form and return later.

- Shopping carts: Any commercially important component of an app that represents potential revenue can be maintained. A user who loses their state, and thus their shopping cart, may purchase fewer products or services when they return to the site later.

An app can only persist *app state*. UIs can't be persisted, such as component instances and their render trees. Components and render trees aren't generally serializable. To persist UI state, such as the expanded nodes of a tree view control, the app must use custom code to model the behavior of the UI state as serializable app state.

Where to persist state

Three common locations exist for persisting state:

- Server-side storage
- URL
- Browser storage

Server-side storage

For permanent data persistence that spans multiple users and devices, the app can use server-side storage. Options include:

- Blob storage
- Key-value storage
- Relational database
- Table storage

After data is saved, the user's state is retained and available in any new circuit.

For more information on Azure data storage options, see the following:

- Azure Databases
- Azure Storage Documentation

URL

For transient data representing navigation state, model the data as a part of the URL. Examples of user state modeled in the URL include:

- The ID of a viewed entity.
- The current page number in a paged grid.

The contents of the browser's address bar are retained:

- If the user manually reloads the page.
- If the web server becomes unavailable, and the user is forced to reload the page in order to connect to a different server.

For information on defining URL patterns with the `@page` directive, see ASP.NET Core Blazor routing.

Browser storage

For transient data that the user is actively creating, a commonly used storage location is the browser's `localStorage` and `sessionStorage` collections:

- `localStorage` is scoped to the browser's window. If the user reloads the page or closes and re-opens the browser, the state persists. If the user opens multiple browser tabs, the state is shared across the tabs. Data persists in `localStorage` until explicitly cleared.
- `sessionStorage` is scoped to the browser tab. If the user reloads the tab, the state persists. If the user closes the tab or the browser, the state is lost. If the user opens multiple browser tabs, each tab has its own independent

version of the data.

Generally, `sessionStorage` is safer to use. `sessionStorage` avoids the risk that a user opens multiple tabs and encounters the following:

- Bugs in state storage across tabs.
- Confusing behavior when a tab overwrites the state of other tabs.

`localStorage` is the better choice if the app must persist state across closing and re-opening the browser.

Caveats for using browser storage:

- Similar to the use of a server-side database, loading and saving data are asynchronous.
- Unlike a server-side database, storage isn't available during prerendering because the requested page doesn't exist in the browser during the prerendering stage.
- Storage of a few kilobytes of data is reasonable to persist for Blazor Server apps. Beyond a few kilobytes, you must consider the performance implications because the data is loaded and saved across the network.
- Users may view or tamper with the data. ASP.NET Core Data Protection can mitigate the risk. For example, ASP.NET Core Protected Browser Storage uses ASP.NET Core Data Protection.

Third-party NuGet packages provide APIs for working with `localStorage` and `sessionStorage`. It's worth considering choosing a package that transparently uses ASP.NET Core Data Protection. Data Protection encrypts stored data and reduces the potential risk of tampering with stored data. If JSON-serialized data is stored in plain text, users can see the data using browser developer tools and also modify the stored data. Securing data isn't always a problem because the data might be trivial in nature. For example, reading or modifying the stored color of a UI element isn't a significant security risk to the user or the organization. Avoid allowing users to inspect or tamper with *sensitive data*.

ASP.NET Core Protected Browser Storage

ASP.NET Core Protected Browser Storage leverages ASP.NET Core Data Protection for `localStorage` and `sessionStorage`.

> **NOTE**
> Protected Browser Storage relies on ASP.NET Core Data Protection and is only supported for Blazor Server apps.

Configuration

1. Add a package reference to `Microsoft.AspNetCore.Components.Web.Extensions`.
2. In `Startup.ConfigureServices`, call `AddProtectedBrowserStorage` to add `localStorage` and `sessionStorage` services to the service collection:

   ```
   services.AddProtectedBrowserStorage();
   ```

Save and load data within a component

In any component that requires loading or saving data to browser storage, use the `@inject` directive to inject an instance of either of the following:

- `ProtectedLocalStorage`
- `ProtectedSessionStorage`

The choice depends on which browser storage location you wish to use. In the following example, `sessionStorage` is used:

```
@using Microsoft.AspNetCore.Components.Web.Extensions
@inject ProtectedSessionStorage ProtectedSessionStore
```

The `@using` directive can be placed in the app's `_Imports.razor` file instead of in the component. Use of the `_Imports.razor` file makes the namespace available to larger segments of the app or the whole app.

To persist the `currentCount` value in the `Counter` component of an app based on the Blazor Server project template, modify the `IncrementCount` method to use `ProtectedSessionStore.SetAsync`:

```
private async Task IncrementCount()
{
    currentCount++;
    await ProtectedSessionStore.SetAsync("count", currentCount);
}
```

In larger, more realistic apps, storage of individual fields is an unlikely scenario. Apps are more likely to store entire model objects that include complex state. `ProtectedSessionStore` automatically serializes and deserializes JSON data to store complex state objects.

In the preceding code example, the `currentCount` data is stored as `sessionStorage['count']` in the user's browser. The data isn't stored in plain text but rather is protected using ASP.NET Core Data Protection. The encrypted data can be inspected if `sessionStorage['count']` is evaluated in the browser's developer console.

To recover the `currentCount` data if the user returns to the `Counter` component later, including if the user is on a new circuit, use `ProtectedSessionStore.GetAsync`:

```
protected override async Task OnInitializedAsync()
{
    var result = await ProtectedSessionStore.GetAsync<int>("count");
    currentCount = result.Success ? result.Value : 0;
}
```

If the component's parameters include navigation state, call `ProtectedSessionStore.GetAsync` and assign a non-`null` result in OnParametersSetAsync, not OnInitializedAsync. OnInitializedAsync is only called once when the component is first instantiated. OnInitializedAsync isn't called again later if the user navigates to a different URL while remaining on the same page. For more information, see ASP.NET Core Blazor lifecycle.

> **WARNING**
>
> The examples in this section only work if the server doesn't have prerendering enabled. With prerendering enabled, an error is generated explaining that JavaScript interop calls cannot be issued because the component is being prerendered.
>
> Either disable prerendering or add additional code to work with prerendering. To learn more about writing code that works with prerendering, see the Handle prerendering section.

Handle the loading state

Since browser storage is accessed asynchronously over a network connection, there's always a period of time before the data is loaded and available to a component. For the best results, render a loading-state message while loading is in progress instead of displaying blank or default data.

One approach is to track whether the data is `null`, which means that the data is still loading. In the default `Counter` component, the count is held in an `int`. Make `currentCount` nullable by adding a question mark (`?`) to the type (`int`):

```
private int? currentCount;
```

Instead of unconditionally displaying the count and `Increment` button, display these elements only if the data is loaded by checking HasValue:

```
@if (currentCount.HasValue)
{
    <p>Current count: <strong>@currentCount</strong></p>
    <button @onclick="IncrementCount">Increment</button>
}
else
{
    <p>Loading...</p>
}
```

Handle prerendering

During prerendering:

- An interactive connection to the user's browser doesn't exist.
- The browser doesn't yet have a page in which it can run JavaScript code.

`localStorage` or `sessionStorage` aren't available during prerendering. If the component attempts to interact with storage, an error is generated explaining that JavaScript interop calls cannot be issued because the component is being prerendered.

One way to resolve the error is to disable prerendering. This is usually the best choice if the app makes heavy use of browser-based storage. Prerendering adds complexity and doesn't benefit the app because the app can't prerender any useful content until `localStorage` or `sessionStorage` are available.

To disable prerendering, open the `Pages/_Host.cshtml` file and change the `render-mode` attribute of the Component Tag Helper to Server:

```
<component type="typeof(App)" render-mode="Server" />
```

Prerendering might be useful for other pages that don't use `localStorage` or `sessionStorage`. To retain prerendering, defer the loading operation until the browser is connected to the circuit. The following is an example for storing a counter value:

```
@using Microsoft.AspNetCore.Components.Web.Extensions
@inject ProtectedLocalStorage ProtectedLocalStore

@if (isConnected)
{
    <p>Current count: <strong>@currentCount</strong></p>
    <button @onclick="IncrementCount">Increment</button>
}
else
{
    <p>Loading...</p>
}

@code {
    private int currentCount;
    private bool isConnected;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            isConnected = true;
            await LoadStateAsync();
            StateHasChanged();
        }
    }

    private async Task LoadStateAsync()
    {
        var result = await ProtectedLocalStore.GetAsync<int>("count");
        currentCount = result.Success ? result.Value : 0;
    }

    private async Task IncrementCount()
    {
        currentCount++;
        await ProtectedLocalStore.SetAsync("count", currentCount);
    }
}
```

Factor out the state preservation to a common location

If many components rely on browser-based storage, re-implementing state provider code many times creates code duplication. One option for avoiding code duplication is to create a *state provider parent component* that encapsulates the state provider logic. Child components can work with persisted data without regard to the state persistence mechanism.

In the following example of a `CounterStateProvider` component, counter data is persisted to `sessionStorage`:

```
@using Microsoft.AspNetCore.Components.Web.Extensions
@inject ProtectedSessionStorage ProtectedSessionStore

@if (isLoaded)
{
    <CascadingValue Value="@this">
        @ChildContent
    </CascadingValue>
}
else
{
    <p>Loading...</p>
}

@code {
    private bool isLoaded;

    [Parameter]
    public RenderFragment ChildContent { get; set; }

    public int CurrentCount { get; set; }

    protected override async Task OnInitializedAsync()
    {
        var result = await ProtectedSessionStore.GetAsync<int>("count");
        currentCount = result.Success ? result.Value : 0;
        isLoaded = true;
    }

    public async Task SaveChangesAsync()
    {
        await ProtectedSessionStore.SetAsync("count", CurrentCount);
    }
}
```

The `CounterStateProvider` component handles the loading phase by not rendering its child content until loading is complete.

To use the `CounterStateProvider` component, wrap an instance of the component around any other component that requires access to the counter state. To make the state accessible to all components in an app, wrap the `CounterStateProvider` component around the Router in the `App` component (`App.razor`):

```
<CounterStateProvider>
    <Router AppAssembly="typeof(Startup).Assembly">
        ...
    </Router>
</CounterStateProvider>
```

Wrapped components receive and can modify the persisted counter state. The following `Counter` component implements the pattern:

```
@page "/counter"

<p>Current count: <strong>@CounterStateProvider.CurrentCount</strong></p>
<button @onclick="IncrementCount">Increment</button>

@code {
    [CascadingParameter]
    private CounterStateProvider CounterStateProvider { get; set; }

    private async Task IncrementCount()
    {
        CounterStateProvider.CurrentCount++;
        await CounterStateProvider.SaveChangesAsync();
    }
}
```

The preceding component isn't required to interact with `ProtectedBrowserStorage`, nor does it deal with a "loading" phase.

To deal with prerendering as described earlier, `CounterStateProvider` can be amended so that all of the components that consume the counter data automatically work with prerendering. For more information, see the Handle prerendering section.

In general, the *state provider parent component* pattern is recommended:

- To consume state across many components.
- If there's just one top-level state object to persist.

To persist many different state objects and consume different subsets of objects in different places, it's better to avoid persisting state globally.

Protected Browser Storage experimental NuGet package

ASP.NET Core Protected Browser Storage leverages ASP.NET Core Data Protection for `localStorage` and `sessionStorage`.

> **WARNING**
>
> `Microsoft.AspNetCore.ProtectedBrowserStorage` is an unsupported, experimental package unsuitable for production use.
>
> The package is only available for use in ASP.NET Core 3.1 Blazor Server apps.

Configuration

1. Add a package reference to `Microsoft.AspNetCore.ProtectedBrowserStorage`.
2. In the `Pages/_Host.cshtml` file, add the following script inside the closing `</body>` tag:

   ```
   <script src="_content/Microsoft.AspNetCore.ProtectedBrowserStorage/protectedBrowserStorage.js"></script>
   ```

3. In `Startup.ConfigureServices`, call `AddProtectedBrowserStorage` to add `localStorage` and `sessionStorage` services to the service collection:

   ```
   services.AddProtectedBrowserStorage();
   ```

Save and load data within a component

In any component that requires loading or saving data to browser storage, use the `@inject` directive to inject an instance of either of the following:

- `ProtectedLocalStorage`
- `ProtectedSessionStorage`

The choice depends on which browser storage location you wish to use. In the following example, `sessionStorage` is used:

```
@using Microsoft.AspNetCore.ProtectedBrowserStorage
@inject ProtectedSessionStorage ProtectedSessionStore
```

The `@using` statement can be placed into an `_Imports.razor` file instead of in the component. Use of the `_Imports.razor` file makes the namespace available to larger segments of the app or the whole app.

To persist the `currentCount` value in the `Counter` component of an app based on the Blazor Server project template, modify the `IncrementCount` method to use `ProtectedSessionStore.SetAsync`:

```
private async Task IncrementCount()
{
    currentCount++;
    await ProtectedSessionStore.SetAsync("count", currentCount);
}
```

In larger, more realistic apps, storage of individual fields is an unlikely scenario. Apps are more likely to store entire model objects that include complex state. `ProtectedSessionStore` automatically serializes and deserializes JSON data.

In the preceding code example, the `currentCount` data is stored as `sessionStorage['count']` in the user's browser. The data isn't stored in plain text but rather is protected using ASP.NET Core Data Protection. The encrypted data can be inspected if `sessionStorage['count']` is evaluated in the browser's developer console.

To recover the `currentCount` data if the user returns to the `Counter` component later, including if they're on an entirely new circuit, use `ProtectedSessionStore.GetAsync`:

```
protected override async Task OnInitializedAsync()
{
    currentCount = await ProtectedSessionStore.GetAsync<int>("count");
}
```

If the component's parameters include navigation state, call `ProtectedSessionStore.GetAsync` and assign the result in OnParametersSetAsync, not OnInitializedAsync. OnInitializedAsync is only called once when the component is first instantiated. OnInitializedAsync isn't called again later if the user navigates to a different URL while remaining on the same page. For more information, see ASP.NET Core Blazor lifecycle.

> **WARNING**
>
> The examples in this section only work if the server doesn't have prerendering enabled. With prerendering enabled, an error is generated explaining that JavaScript interop calls cannot be issued because the component is being prerendered.
>
> Either disable prerendering or add additional code to work with prerendering. To learn more about writing code that works with prerendering, see the Handle prerendering section.

Handle the loading state

Since browser storage is accessed asynchronously over a network connection, there's always a period of time

before the data is loaded and available to a component. For the best results, render a loading-state message while loading is in progress instead of displaying blank or default data.

One approach is to track whether the data is `null`, which means that the data is still loading. In the default `Counter` component, the count is held in an `int`. Make `currentCount` nullable by adding a question mark (`?`) to the type (`int`):

```
private int? currentCount;
```

Instead of unconditionally displaying the count and `Increment` button, choose to display these elements only if the data is loaded:

```
@if (currentCount.HasValue)
{
    <p>Current count: <strong>@currentCount</strong></p>
    <button @onclick="IncrementCount">Increment</button>
}
else
{
    <p>Loading...</p>
}
```

Handle prerendering

During prerendering:

- An interactive connection to the user's browser doesn't exist.
- The browser doesn't yet have a page in which it can run JavaScript code.

`localStorage` or `sessionStorage` aren't available during prerendering. If the component attempts to interact with storage, an error is generated explaining that JavaScript interop calls cannot be issued because the component is being prerendered.

One way to resolve the error is to disable prerendering. This is usually the best choice if the app makes heavy use of browser-based storage. Prerendering adds complexity and doesn't benefit the app because the app can't prerender any useful content until `localStorage` or `sessionStorage` are available.

To disable prerendering, open the `Pages/_Host.cshtml` file and change the `render-mode` attribute of the Component Tag Helper to Server:

```
<component type="typeof(App)" render-mode="Server" />
```

Prerendering might be useful for other pages that don't use `localStorage` or `sessionStorage`. To retain prerendering, defer the loading operation until the browser is connected to the circuit. The following is an example for storing a counter value:

```
@using Microsoft.AspNetCore.ProtectedBrowserStorage
@inject ProtectedLocalStorage ProtectedLocalStore

@if (isConnected)
{
    <p>Current count: <strong>@currentCount</strong></p>
    <button @onclick="IncrementCount">Increment</button>
}
else
{
    <p>Loading...</p>
}

@code {
    private int? currentCount;
    private bool isConnected = false;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            isConnected = true;
            await LoadStateAsync();
            StateHasChanged();
        }
    }

    private async Task LoadStateAsync()
    {
        currentCount = await ProtectedLocalStore.GetAsync<int>("count");
    }

    private async Task IncrementCount()
    {
        currentCount++;
        await ProtectedLocalStore.SetAsync("count", currentCount);
    }
}
```

Factor out the state preservation to a common location

If many components rely on browser-based storage, re-implementing state provider code many times creates code duplication. One option for avoiding code duplication is to create a *state provider parent component* that encapsulates the state provider logic. Child components can work with persisted data without regard to the state persistence mechanism.

In the following example of a `CounterStateProvider` component, counter data is persisted to `sessionStorage`:

```
@using Microsoft.AspNetCore.ProtectedBrowserStorage
@inject ProtectedSessionStorage ProtectedSessionStore

@if (isLoaded)
{
    <CascadingValue Value="@this">
        @ChildContent
    </CascadingValue>
}
else
{
    <p>Loading...</p>
}

@code {
    private bool isLoaded;

    [Parameter]
    public RenderFragment ChildContent { get; set; }

    public int CurrentCount { get; set; }

    protected override async Task OnInitializedAsync()
    {
        CurrentCount = await ProtectedSessionStore.GetAsync<int>("count");
        isLoaded = true;
    }

    public async Task SaveChangesAsync()
    {
        await ProtectedSessionStore.SetAsync("count", CurrentCount);
    }
}
```

The `CounterStateProvider` component handles the loading phase by not rendering its child content until loading is complete.

To use the `CounterStateProvider` component, wrap an instance of the component around any other component that requires access to the counter state. To make the state accessible to all components in an app, wrap the `CounterStateProvider` component around the Router in the `App` component (`App.razor`):

```
<CounterStateProvider>
    <Router AppAssembly="typeof(Startup).Assembly">
        ...
    </Router>
</CounterStateProvider>
```

Wrapped components receive and can modify the persisted counter state. The following `Counter` component implements the pattern:

```
@page "/counter"

<p>Current count: <strong>@CounterStateProvider.CurrentCount</strong></p>
<button @onclick="IncrementCount">Increment</button>

@code {
    [CascadingParameter]
    private CounterStateProvider CounterStateProvider { get; set; }

    private async Task IncrementCount()
    {
        CounterStateProvider.CurrentCount++;
        await CounterStateProvider.SaveChangesAsync();
    }
}
```

The preceding component isn't required to interact with `ProtectedBrowserStorage`, nor does it deal with a "loading" phase.

To deal with prerendering as described earlier, `CounterStateProvider` can be amended so that all of the components that consume the counter data automatically work with prerendering. For more information, see the Handle prerendering section.

In general, *state provider parent component* pattern is recommended:

- To consume state across many components.
- If there's just one top-level state object to persist.

To persist many different state objects and consume different subsets of objects in different places, it's better to avoid persisting state globally.

Debug ASP.NET Core Blazor WebAssembly

9/22/2020 • 10 minutes to read • Edit Online

Daniel Roth

Blazor WebAssembly apps can be debugged using the browser dev tools in Chromium-based browsers (Edge/Chrome). You can also debug your app using the following integrated development environments (IDEs):

- Visual Studio
- Visual Studio for Mac
- Visual Studio Code

Available scenarios include:

- Set and remove breakpoints.
- Run the app with debugging support in IDEs.
- Single-step through the code.
- Resume code execution with a keyboard shortcut in IDEs.
- In the *Locals* window, observe the values of local variables.
- See the call stack, including call chains between JavaScript and .NET.

For now, you *can't*:

- Break on unhandled exceptions.
- Hit breakpoints during app startup before the debug proxy is running. This includes breakpoints in `Program.Main` (`Program.cs`) and breakpoints in the `OnInitialized{Async}` methods of components that are loaded by the first page requested from the app.

Prerequisites

Debugging requires either of the following browsers:

- Google Chrome (version 70 or later) (default)
- Microsoft Edge (version 80 or later)

Visual Studio for Mac requires version 8.8 (build 1532) or later:

1. Install the latest release of Visual Studio for Mac by selecting the **Download Visual Studio for Mac** button at Microsoft: Visual Studio for Mac.
2. Select the *Preview* channel from within Visual Studio. For more information, see Install a preview version of Visual Studio for Mac.

> **NOTE**
> Apple Safari on macOS isn't currently supported.

Enable debugging

To enable debugging for an existing Blazor WebAssembly app, update the `launchSettings.json` file in the startup project to include the following `inspectUri` property in each launch profile:

```
"inspectUri": "{wsProtocol}://{url.hostname}:{url.port}/_framework/debug/ws-proxy?browser={browserInspectUri}"
```

Once updated, the `launchSettings.json` file should look similar to the following example:

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iisExpress": {
      "applicationUrl": "http://localhost:50454",
      "sslPort": 44399
    }
  },
  "profiles": {
    "IIS Express": {
      "commandName": "IISExpress",
      "launchBrowser": true,
      "inspectUri": "{wsProtocol}://{url.hostname}:{url.port}/_framework/debug/ws-proxy?browser=
{browserInspectUri}",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    },
    "BlazorApp1.Server": {
      "commandName": "Project",
      "launchBrowser": true,
      "inspectUri": "{wsProtocol}://{url.hostname}:{url.port}/_framework/debug/ws-proxy?browser=
{browserInspectUri}",
      "applicationUrl": "https://localhost:5001;http://localhost:5000",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    }
  }
}
```

The `inspectUri` property:

- Enables the IDE to detect that the app is a Blazor WebAssembly app.
- Instructs the script debugging infrastructure to connect to the browser through Blazor's debugging proxy.

The placeholder values for the WebSockets protocol (`wsProtocol`), host (`url.hostname`), port (`url.port`), and inspector URI on the launched browser (`browserInspectUri`) are provided by the framework.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

To debug a Blazor WebAssembly app in Visual Studio:

1. Create a new ASP.NET Core hosted Blazor WebAssembly app.
2. Press F5 to run the app in the debugger.

   > **NOTE**
   >
   > **Start Without Debugging** (`Ctrl+F5`) isn't supported. When the app is run in Debug configuration, debugging overhead always results in a small performance reduction.

3. In the *Client* app, set a breakpoint on the `currentCount++;` line in `Pages/Counter.razor`.

4. In the browser, navigate to `Counter` page and select the **Click me** button to hit the breakpoint.
5. In Visual Studio, inspect the value of the `currentCount` field in the **Locals** window.
6. Press F5 to continue execution.

While debugging a Blazor WebAssembly app, you can also debug server code:

1. Set a breakpoint in the `Pages/FetchData.razor` page in OnInitializedAsync.
2. Set a breakpoint in the `WeatherForecastController` in the `Get` action method.
3. Browse to the `Fetch Data` page to hit the first breakpoint in the `FetchData` component just before it issues an HTTP request to the server.
4. Press F5 to continue execution and then hit the breakpoint on the server in the `WeatherForecastController`.
5. Press F5 again to let execution continue and see the weather forecast table rendered in the browser.

> **NOTE**
>
> Breakpoints are **not** hit during app startup before the debug proxy is running. This includes breakpoints in `Program.Main` (`Program.cs`) and breakpoints in the `OnInitialized{Async}` methods of components that are loaded by the first page requested from the app.

Debug in the browser

The guidance in this section applies to Google Chrome and Microsoft Edge running on Windows.

1. Run a Debug build of the app in the Development environment.
2. Launch a browser and navigate to the app's URL (for example, `https://localhost:5001`).
3. In the browser, attempt to commence remote debugging by pressing `Shift+Alt+d`.

   The browser must be running with remote debugging enabled, which isn't the default. If remote debugging is disabled, an **Unable to find debuggable browser tab** error page is rendered with instructions for launching the browser with the debugging port open. Follow the instructions for your browser, which opens a new browser window. Close the previous browser window.

1. Once the browser is running with remote debugging enabled, the debugging keyboard shortcut in the previous step opens a new debugger tab.
2. After a moment, the **Sources** tab shows a list of the app's .NET assemblies within the `file://` node.
3. In component code (`.razor` files) and C# code files (`.cs`), breakpoints that you set are hit when code executes. After a breakpoint is hit, single-step (`F10`) through the code or resume (`F8`) code execution normally.

Blazor provides a debugging proxy that implements the Chrome DevTools Protocol and augments the protocol with .NET-specific information. When debugging keyboard shortcut is pressed, Blazor points the Chrome DevTools at the proxy. The proxy connects to the browser window you're seeking to debug (hence the need to enable remote debugging).

Browser source maps

Browser source maps allow the browser to map compiled files back to their original source files and are commonly used for client-side debugging. However, Blazor doesn't currently map C# directly to JavaScript/WASM. Instead, Blazor does IL interpretation within the browser, so source maps aren't relevant.

Troubleshoot

If you're running into errors, the following tips may help:

- In the **Debugger** tab, open the developer tools in your browser. In the console, execute `localStorage.clear()` to remove any breakpoints.
- Confirm that you've installed and trusted the ASP.NET Core HTTPS development certificate. For more information, see Enforce HTTPS in ASP.NET Core.
- Visual Studio requires the **Enable JavaScript debugging for ASP.NET (Chrome, Edge and IE)** option in **Tools** > **Options** > **Debugging** > **General**. This is the default setting for Visual Studio. If debugging isn't working, confirm that the option is selected.

Breakpoints in `OnInitialized{Async}` not hit

The Blazor framework's debugging proxy takes a short time to launch, so breakpoints in the `OnInitialized{Async}` lifecycle method might not be hit. We recommend adding a delay at the start of the method body to give the debug proxy some time to launch before the breakpoint is hit. You can include the delay based on an `if` compiler directive to ensure that the delay isn't present for a release build of the app.

OnInitialized:

```
protected override void OnInitialized()
{
#if DEBUG
    Thread.Sleep(10000)
#endif

    ...
}
```

OnInitializedAsync:

```
protected override async Task OnInitializedAsync()
{
#if DEBUG
    await Task.Delay(10000)
#endif

    ...
}
```

Visual Studio (Windows) timeout

If Visual Studio throws an exception that the debug adapter failed to launch mentioning that the timeout was reached, you can adjust the timeout with a Registry setting:

```
VsRegEdit.exe set "<VSInstallFolder>" HKCU JSDebugger\Options\Debugging "BlazorTimeoutInMilliseconds" dword
{TIMEOUT}
```

The `{TIMEOUT}` placeholder in the preceding command is in milliseconds. For example, one minute is assigned as `60000`.

Lazy load assemblies in ASP.NET Core Blazor WebAssembly

9/22/2020 • 5 minutes to read • Edit Online

By Safia Abdalla and Luke Latham

Blazor WebAssembly app startup performance can be improved by deferring the loading of some application assemblies until they are required, which is called *lazy loading*. For example, assemblies that are only used to render a single component can be set up to load only if the user navigates to that component. After loading, the assemblies are cached client-side and are available for all future navigations.

Blazor's lazy loading feature allows you to mark app assemblies for lazy loading, which loads the assemblies during runtime when the user navigates to a particular route. The feature consists of changes to the project file and changes to the application's router.

> **NOTE**
> Assembly lazy loading doesn't benefit Blazor Server apps because assemblies aren't downloaded to the client in a Blazor Server app.

Project file

Mark assemblies for lazy loading in the app's project file (`.csproj`) using the `BlazorWebAssemblyLazyLoad` item. Use the assembly name without the `.dll` extension. The Blazor framework prevents the assemblies specified by this item group from loading at app launch. The following example marks a large custom assembly (`GrantImaharaRobotControls.dll`) for lazy loading. If an assembly that's marked for lazy loading has dependencies, they must also be marked for lazy loading in the project file.

```
<ItemGroup>
  <BlazorWebAssemblyLazyLoad Include="GrantImaharaRobotControls.dll" />
</ItemGroup>
```

`Router` component

Blazor's `Router` component designates which assemblies Blazor searches for routable components. The `Router` component is also responsible for rendering the component for the route where the user navigates. The `Router` component supports an `OnNavigateAsync` feature that can be used in conjunction with lazy loading.

In the app's `Router` component (`App.razor`):

- Add an `OnNavigateAsync` callback. The `OnNavigateAsync` handler is invoked when the user:
  - Visits a route for the first time by navigating to it directly from their browser.
  - Navigates to a new route using a link or a NavigationManager.NavigateTo invocation.
- If lazy-loaded assemblies contain routable components, add a List<Assembly> (for example, named `lazyLoadedAssemblies`) to the component. The assemblies are passed back to the AdditionalAssemblies collection in case the assemblies contain routable components. The framework searches the assemblies for routes and updates the route collection if any new routes are found.

```
@using System.Reflection

<Router AppAssembly="@typeof(Program).Assembly"
    AdditionalAssemblies="@lazyLoadedAssemblies" OnNavigateAsync="@OnNavigateAsync">
    ...
</Router>

@code {
    private List<Assembly> lazyLoadedAssemblies = new List<Assembly>();

    private async Task OnNavigateAsync(NavigationContext args)
    {
    }
}
```

If the `OnNavigateAsync` callback throws an unhandled exception, the Blazor error UI is invoked.

Assembly load logic in `OnNavigateAsync`

`OnNavigateAsync` has a `NavigationContext` parameter that provides information about the current asynchronous navigation event, including the target path (`Path`) and the cancellation token (`CancellationToken`):

- The `Path` property is the user's destination path relative to the app's base path, such as `/robot`.
- The `CancellationToken` can be used to observe the cancellation of the asynchronous task. `OnNavigateAsync` automatically cancels the currently running navigation task when the user navigates to a different page.

Inside `OnNavigateAsync`, implement logic to determine the assemblies to load. Options include:

- Conditional checks inside the `OnNavigateAsync` method.
- A lookup table that maps routes to assembly names, either injected into the component or implemented within the `@code` block.

`LazyAssemblyLoader` is a framework-provided singleton service for loading assemblies. Inject `LazyAssemblyLoader` into the `Router` component:

```
...
@using Microsoft.AspNetCore.Components.WebAssembly.Services
@inject LazyAssemblyLoader assemblyLoader

...
```

The `LazyAssemblyLoader` provides the `LoadAssembliesAsync` method that:

- Uses JS interop to fetch assemblies via a network call.
- Loads assemblies into the runtime executing on WebAssembly in the browser.

The framework's lazy loading implementation supports lazy loading with prerendering in a hosted Blazor solution. During prerendering, all assemblies, including those marked for lazy loading, are assumed to be loaded. Manually register `LazyAssemblyLoader` in the *Server* project's `Startup.ConfigureServices` method (`Startup.cs`):

```
services.AddSingleton<LazyAssemblyLoader>();
```

User interaction with `<Navigating>` content

While loading assemblies, which can take several seconds, the `Router` component can indicate to the user that a page transition is occurring:

- Add an `@using` directive for the Microsoft.AspNetCore.Components.Routing namespace.

- Add a `<Navigating>` tag to the component with markup to display during page transition events.

```
...
@using Microsoft.AspNetCore.Components.Routing
...

<Router ...>
    <Navigating>
        <div style="...">
            <p>Loading the requested page&hellip;</p>
        </div>
    </Navigating>
</Router>

...
```

Handle cancellations in `OnNavigateAsync`

The `NavigationContext` object passed to the `OnNavigateAsync` callback contains a `CancellationToken` that's set when a new navigation event occurs. The `OnNavigateAsync` callback must throw when this cancellation token is set to avoid continuing to run the `OnNavigateAsync` callback on a outdated navigation.

If a user navigates to Route A and then immediately to Route B, the app shouldn't continue running the `OnNavigateAsync` callback for Route A:

```
@inject HttpClient Http
@inject ProductCatalog Products

<Router AppAssembly="@typeof(Program).Assembly"
    OnNavigateAsync="@OnNavigateAsync">
    ...
</Router>

@code {
    private async Task OnNavigateAsync(NavigationContext context)
    {
        if (context.Path == "/about")
        {
            var stats = new Stats = { Page = "/about" };
            await Http.PostAsJsonAsync("api/visited", stats, context.CancellationToken);
        }
        else if (context.Path == "/store")
        {
            var productIds = [345, 789, 135, 689];

            foreach (var productId in productIds)
            {
                context.CancellationToken.ThrowIfCancellationRequested();
                Products.Prefetch(productId);
            }
        }
    }
}
```

> **NOTE**
>
> Not throwing if the cancellation token in `NavigationContext` is canceled can result in unintended behavior, such as rendering a component from a previous navigation.

`OnNavigateAsync` events and renamed assembly files

The resource loader relies on the assembly names that are defined in the `blazor.boot.json` file. If assemblies are renamed, the assembly names used in `OnNavigateAsync` methods and the assembly names in the `blazor.boot.json` file are out of sync.

To rectify this:

- Check to see if the app is running in the Production environment when determining which assembly names to use.
- Store the renamed assembly names in a separate file and read from that file to determine what assembly name to use in the `LazyLoadAssemblyService` and `OnNavigateAsync` methods.

Complete example

The following complete `Router` component demonstrates loading the `GrantImaharaRobotControls.dll` assembly when the user navigates to `/robot`. During page transitions, a styled message is displayed to the user.

```
@using System.Reflection
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.WebAssembly.Services
@inject LazyAssemblyLoader assemblyLoader

<Router AppAssembly="@typeof(Program).Assembly"
    AdditionalAssemblies="@lazyLoadedAssemblies" OnNavigateAsync="@OnNavigateAsync">
    <Navigating>
        <div style="padding:20px;background-color:blue;color:white">
            <p>Loading the requested page&hellip;</p>
        </div>
    </Navigating>
    <Found Context="routeData">
        <RouteView RouteData="@routeData" DefaultLayout="@typeof(MainLayout)" />
    </Found>
    <NotFound>
        <LayoutView Layout="@typeof(MainLayout)">
            <p>Sorry, there's nothing at this address.</p>
        </LayoutView>
    </NotFound>
</Router>

@code {
    private List<Assembly> lazyLoadedAssemblies = new List<Assembly>();

    private async Task OnNavigateAsync(NavigationContext args)
    {
        try
        {
            if (args.Path.EndsWith("/robot"))
            {
                var assemblies = await assemblyLoader.LoadAssembliesAsync(
                    new List<string>() { "GrantImaharaRobotControls.dll" });
                lazyLoadedAssemblies.AddRange(assemblies);
            }
        }
        catch (Exception ex)
        {
            ...
        }
    }
}
```

Troubleshoot

- If unexpected rendering occurs (for example, a component from a previous navigation is rendered), confirm that the code throws if the cancellation token is set.

- If assemblies are still loaded at application start, check that the assembly is marked as lazy loaded in the project file.

ASP.NET Core Blazor WebAssembly performance best practices

9/22/2020 • 5 minutes to read • Edit Online

By Pranav Krishnamoorthy

This article provides guidelines for ASP.NET Core Blazor WebAssembly performance best practices.

Avoid unnecessary component renders

Blazor's diffing algorithm avoids rerendering a component when the algorithm perceives that the component hasn't changed. Override ComponentBase.ShouldRender for fine-grained control over component rendering.

If authoring a UI-only component that never changes after the initial render, configure ShouldRender to return `false`:

```
@code {
    protected override bool ShouldRender() => false;
}
```

Most apps don't require fine-grained control, but ShouldRender can be used to selectively render a component responding to a UI event. Using ShouldRender might also be important in scenarios where a large number of components are rendered. Consider a grid, where use of EventCallback in one component in one cell of the grid calls StateHasChanged on the grid. Calling StateHasChanged causes a re-render of every child component. If only a small number of cells require rerendering, use ShouldRender to avoid the performance penalty of unnecessary renders.

In the following example:

- ShouldRender is overridden and set to the value of the ShouldRender field, which is initially `false` when the component loads.
- When the button is selected, ShouldRender is set to `true`, which forces the component to rerender with the updated `currentCount`.
- Immediately after rerendering, OnAfterRender sets the value of ShouldRender back to `false` to prevent further rerendering until the next time the button is selected.

```
<p>Current count: @currentCount</p>

<button @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;
    private bool shouldRender;

    protected override bool ShouldRender() => shouldRender;

    protected override void OnAfterRender(bool first)
    {
        shouldRender = false;
    }

    private void IncrementCount()
    {
        currentCount++;
        shouldRender = true;
    }
}
```

For more information, see ASP.NET Core Blazor lifecycle.

Virtualize re-usable fragments

Components offer a convenient approach to produce re-usable fragments of code and markup. In general, we recommend authoring individual components that best align with the app's requirements. One caveat is that each additional child component contributes to the total time it takes to render a parent component. For most apps, the additional overhead is negligible. Apps that produce a large number of components should consider using strategies to reduce processing overhead, such as limiting the number of rendered components.

For more information, see ASP.NET Core Blazor component virtualization.

Avoid JavaScript interop to marshal data

In Blazor WebAssembly, a JavaScript (JS) interop call must traverse the WebAssembly-JS boundary. Serializing and deserializing content across the two contexts creates processing overhead for the app. Frequent JS interop calls often adversely affects performance. To reduce the marshalling of data across the boundary, determine if the app can consolidate many small payloads into a single large payload to avoid the high volume of context switching between WebAssembly and JS.

Use System.Text.Json

Blazor's JS interop implementation relies on System.Text.Json, which is a high-performance JSON serialization library with low memory allocation. Using System.Text.Json doesn't result in additional app payload size over adding one or more alternate JSON libraries.

For migration guidance, see How to migrate from `Newtonsoft.Json` to `System.Text.Json`.

Use synchronous and unmarshalled JS interop APIs where appropriate

Blazor WebAssembly offers two additional versions of IJSRuntime over the single version available to Blazor Server apps:

- IJSInProcessRuntime allows invoking JS interop calls synchronously, which has less overhead than the asynchronous versions:

```
@inject IJSRuntime JS

@code {
    protected override void OnInitialized()
    {
        var jsInProcess = (IJSInProcessRuntime)JS;

        var value = jsInProcess.Invoke<string>("jsInteropCall");
    }
}
```

- WebAssemblyJSRuntime permits unmarshalled JS interop calls:

```
function jsInteropCall() {
  return BINDING.js_to_mono_obj("Hello world");
}
```

```
@inject IJSRuntime JS

@code {
    protected override void OnInitialized()
    {
        var jsInProcess = (WebAssemblyJSRuntime)JS;

        var value = jsInProcess.InvokeUnmarshalled<string>("jsInteropCall");
    }
}
```

> **WARNING**
> While using WebAssemblyJSRuntime has the least overhead of the JS interop approaches, the JavaScript APIs required to interact with these APIs are currently undocumented and subject to breaking changes in future releases.

Reduce app size

Intermediate Language (IL) trimming

Trimming unused assemblies from a Blazor WebAssembly app reduces the app's size by removing unused code in the app's binaries. By default, the Trimmer is executed when publishing an application. To benefit from trimming, publish the app for deployment using the `dotnet publish` command with the -c|--configuration option set to `Release`:

Intermediate Language (IL) linking

Linking a Blazor WebAssembly app reduces the app's size by trimming unused code in the app's binaries. By default, the Intermediate Language (IL) Linker is only enabled when building in `Release` configuration. To benefit from this, publish the app for deployment using the `dotnet publish` command with the -c|--configuration option set to `Release`:

```
dotnet publish -c Release
```

Lazy load assemblies

Load assemblies at runtime when the assemblies are required by a route. For more information, see Lazy load assemblies in ASP.NET Core Blazor WebAssembly.

Compression

When a Blazor WebAssembly app is published, the output is statically compressed during publish to reduce the app's size and remove the overhead for runtime compression. Blazor relies on the server to perform content negotation and serve statically-compressed files.

After an app is deployed, verify that the app serves compressed files. Inspect the Network tab in a browser's Developer Tools and verify that the files are served with `Content-Encoding: br` or `Content-Encoding: gz`. If the host isn't serving compressed files, follow the instructions in Host and deploy ASP.NET Core Blazor WebAssembly.

Disable unused features

Blazor WebAssembly's runtime includes the following .NET features that can be disabled if the app doesn't require them for a smaller payload size:

- A data file is included to make timezone information correct. If the app doesn't require this feature, consider disabling it by setting the `BlazorEnableTimeZoneSupport` MSBuild property in the app's project file to `false`:

  ```
  <PropertyGroup>
    <BlazorEnableTimeZoneSupport>false</BlazorEnableTimeZoneSupport>
  </PropertyGroup>
  ```

- By default, Blazor WebAssembly carries globalization resources required to display values, such as dates and currency, in the user's culture. If the app doesn't require localization, you may configure the app to support the invariant culture, which is based on the `en-US` culture:

  ```
  <PropertyGroup>
    <InvariantGlobalization>true</InvariantGlobalization>
  </PropertyGroup>
  ```

- Collation information is included to make APIs such as StringComparison.InvariantCultureIgnoreCase work correctly. If you're certain that the app doesn't require the collation data, consider disabling it by setting the `BlazorWebAssemblyPreserveCollationData` MSBuild property in the app's project file to `false`:

  ```
  <PropertyGroup>
    <BlazorWebAssemblyPreserveCollationData>false</BlazorWebAssemblyPreserveCollationData>
  </PropertyGroup>
  ```

Test components in ASP.NET Core Blazor

9/22/2020 • 5 minutes to read • Edit Online

Egil Hansen

Testing is an important aspect of building stable and maintainable software.

To test a Blazor component, the *Component Under Test* (CUT) is:

- Rendered with relevant input for the test.
- Depending on the type of test performed, possibly subject to interaction or modification. For example, event handlers can be triggered, such as an `onclick` event for a button.
- Inspected for expected values.

Test approaches

Two common approaches for testing Blazor components are end-to-end (E2E) testing and unit testing:

- **Unit testing**: Unit tests are written with a unit testing library that provides:
  - Component rendering.
  - Inspection of component output and state.
  - Triggering of event handlers and life cycle methods.
  - Assertions that component behavior is correct.

  bUnit is an example of a library that enables Razor component unit testing.
- **E2E testing**: A test runner runs a Blazor app containing the CUT and automates a browser instance. The testing tool inspects and interacts with the CUT through the browser. Selenium is an example of an E2E testing framework that can be used with Blazor apps.

In unit testing, only the Blazor component (Razor/C#) is involved. External dependencies, such as services and JS interop, must be mocked. In E2E testing, the Blazor component and all of it's auxiliary infrastructure are part of the test, including CSS, JS, and the DOM and browser APIs.

Test scope describes how extensive the tests are. Test scope typically has an influence on the speed of the tests. Unit tests run on a subset of the app's subsystems and usually execute in milliseconds. E2E tests, which test a broad group of the app's subsystems, can take several seconds to complete.

Unit testing also provides access to the instance of the CUT, allowing for inspection and verification of the component's internal state. This normally isn't possible in E2E testing.

With regard to the component's environment, E2E tests must make sure that the expected environmental state has been reached before verification starts. Otherwise, the result is unpredictable. In unit testing, the rendering of the CUT and the life cycle of the test are more integrated, which improves test stability.

E2E testing involves launching multiple processes, network and disk I/O, and other subsystem activity that often lead to poor test reliability. Unit tests are typically insulated from these sorts of issues.

The following table summarizes the difference between the two testing approaches.

CAPABILITY	UNIT TESTING	E2E TESTING

CAPABILITY	UNIT TESTING	E2E TESTING
Test scope	Blazor component (Razor/C#) only	Blazor component (Razor/C#) with CSS/JS
Test execution time	Milliseconds	Seconds
Access to the component instance	Yes	No
Sensitive to the environment	No	Yes
Reliability	More reliable	Less reliable

Choose the most appropriate test approach

Consider the scenario when choosing the type of testing to perform. Some considerations are described in the following table.

SCENARIO	SUGGESTED APPROACH	REMARKS
Component without JS interop logic	Unit testing	When there's no dependency on JS interop in a Blazor component, the component can be tested without access to JS or the DOM API. In this scenario, there are no disadvantages to choosing unit testing.
Component with simple JS interop logic	Unit testing	It's common for components to query the DOM or trigger animations through JS interop. Unit testing is usually preferred in this scenario, since it's straightforward to mock the JS interaction through the IJSRuntime interface.
Component that depends on complex JS code	Unit testing and separate JS testing	If a component uses JS interop to call a large or complex JS library but the interaction between the Blazor component and JS library is simple, then the best approach is likely to treat the component and JS library or code as two separate parts and test each individually. Test the Blazor component with a unit testing library, and test the JS with a JS testing library.
Component with logic that depends on JS manipulation of the browser DOM	E2E testing	When a component's functionality is dependent on JS and its manipulation of the DOM, verify both the JS and Blazor code together in an E2E test. This is the approach that the Blazor framework developers have taken with Blazor's browser rendering logic, which has tightly-coupled C# and JS code. The C# and JS code must work together to correctly render Blazor components in a browser.

SCENARIO	SUGGESTED APPROACH	REMARKS
Component that depends on 3rd party component library with hard-to-mock dependencies	E2E testing	When a component's functionality is dependent on a 3rd party component library that has hard-to-mock dependencies, such as JS interop, E2E testing might be the only option to test the component.

Test components with bUnit

There's no official Microsoft testing framework for Blazor, but the community-driven project bUnit provides a convenient way to unit test Blazor components.

> **NOTE**
> bUnit is a third-party testing library and isn't supported or maintained by Microsoft.

bUnit works with general-purpose testing frameworks, such as MSTest, NUnit, and xUnit. These testing frameworks make bUnit tests look and feel like regular unit tests. bUnit tests integrated with a general-purpose testing framework are ordinarily executed with:

- Visual Studio's Test Explorer.
- `dotnet test` CLI command in a command shell.
- An automated DevOps testing pipeline.

> **NOTE**
> Test concepts and test implementations across different test frameworks are similar but not identical. Refer to the test framework's documentation for guidance.

The following demonstrates the structure of a bUnit test on the `Counter` component in an app based on a Blazor project template. The `Counter` component displays and increments a counter based on the user selecting a button in the page:

```
@page "/counter"

<h1>Counter</h1>

<p>Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    private void IncrementCount()
    {
        currentCount++;
    }
}
```

The following bUnit test verifies that the CUT's counter is incremented correctly when the button is selected:

```
[Fact]
public void CounterShouldIncrementWhenSelected()
{
    // Arrange
    using var ctx = new TestContext();
    var cut = ctx.RenderComponent<Counter>();
    var paraElm = cut.Find("p");

    // Act
    cut.Find("button").Click();
    var paraElmText = paraElm.TextContent;

    // Assert
    paraElmText.MarkupMatches("Current count: 1");
}
```

The following actions take place at each step of the test:

- *Arrange*: The `Counter` component is rendered using bUnit's `TestContext`. The CUT's paragraph element (`<p>`) is found and assigned to `paraElm`.
- *Act*: The button's element (`<button>`) is located and then selected by calling `Click`, which should increment the counter and update the content of the paragraph tag (`<p>`). The paragraph element text content is obtained by calling `TextContent`.
- *Assert*: `MarkupMatches` is called on the text content to verify that it matches the expected string, which is `Current count: 1`.

> **NOTE**
>
> The `MarkupMatches` assert method differs from a regular string comparison assertion (for example, `Assert.Equal("Current count: 1", paraElmText);`) `MarkupMatches` performs a semantic comparison of the input and expected HTML markup. A semantic comparison is aware of HTML semantics, meaning things like insignificant whitespace is ignored. This results in more stable tests. For more information, see Customizing the Semantic HTML Comparison.

Build Progressive Web Applications with ASP.NET Core Blazor WebAssembly

9/22/2020 • 16 minutes to read • Edit Online

By Steve Sanderson

A Progressive Web Application (PWA) is usually a Single Page Application (SPA) that uses modern browser APIs and capabilities to behave like a desktop app. Blazor WebAssembly is a standards-based client-side web app platform, so it can use any browser API, including PWA APIs required for the following capabilities:

- Working offline and loading instantly, independent of network speed.
- Running in its own app window, not just a browser window.
- Being launched from the host's operating system start menu, dock, or home screen.
- Receiving push notifications from a backend server, even while the user isn't using the app.
- Automatically updating in the background.

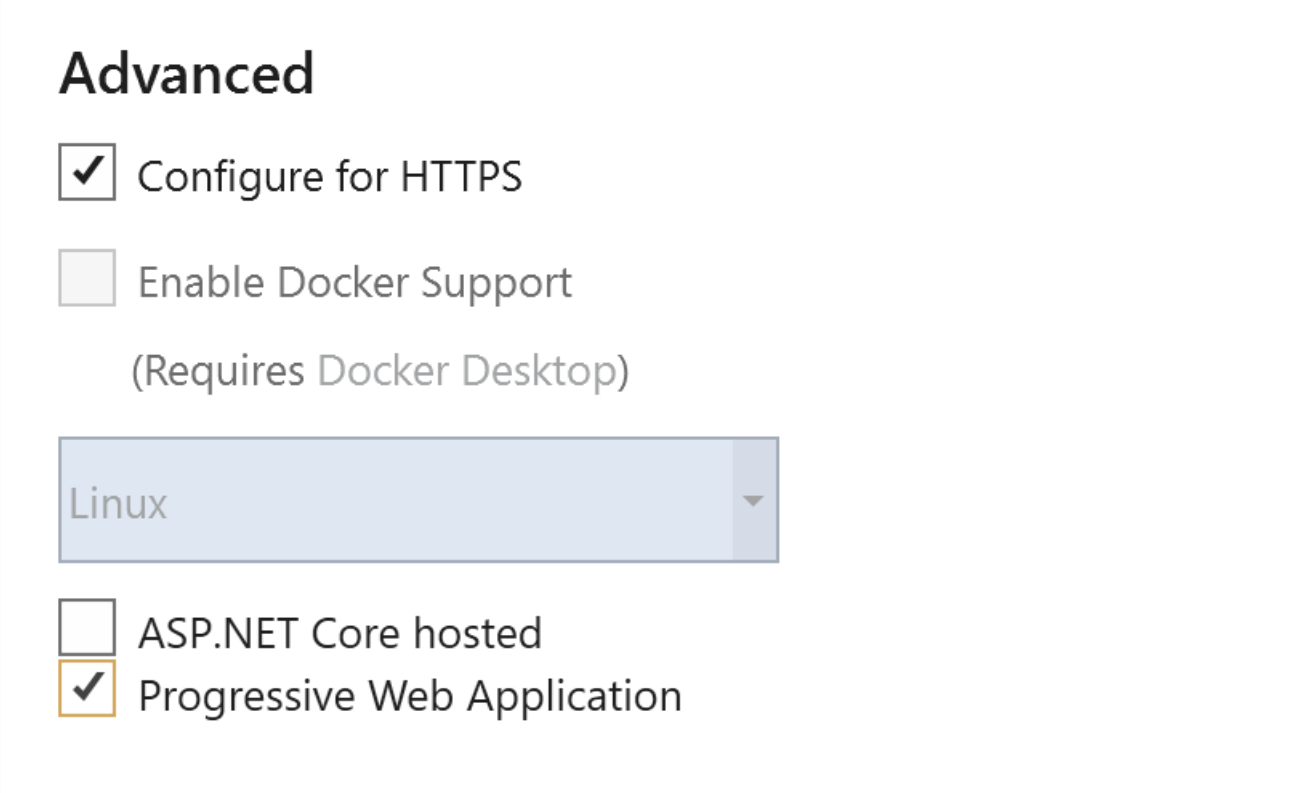
The word *progressive* is used to describe such apps because:

- A user might first discover and use the app within their web browser like any other SPA.
- Later, the user progresses to installing it in their OS and enabling push notifications.

Create a project from the PWA template

- Visual Studio
- Visual Studio Code / .NET Core CLI

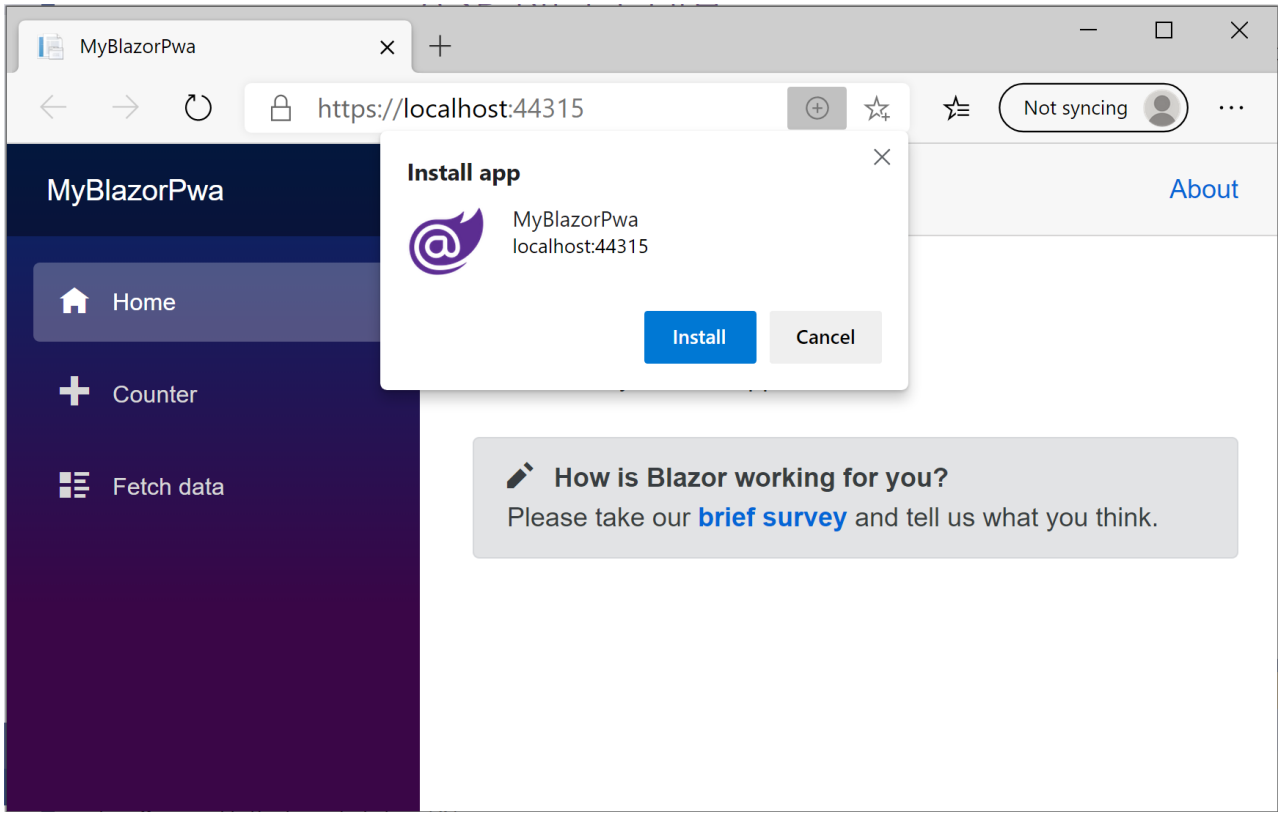
When creating a new **Blazor WebAssembly App** in the **Create a New Project** dialog, select the **Progressive Web Application** check box:



Optionally, PWA can be configured for an app created from the ASP.NET Core Hosted template. The PWA scenario is independent of the hosting model.

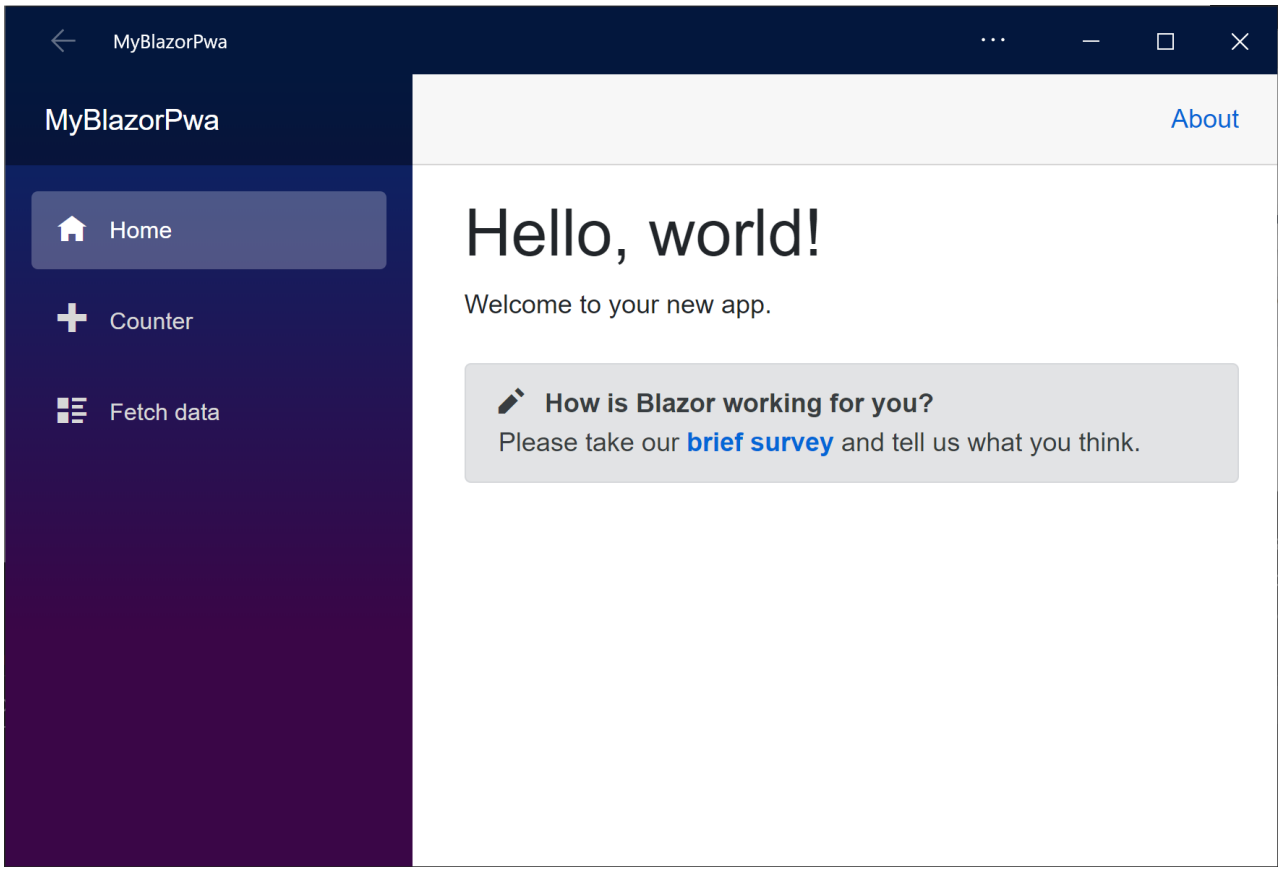
Installation and app manifest

When visiting an app created using the PWA template, users have the option of installing the app into their OS's start menu, dock, or home screen. The way this option is presented depends on the user's browser. When using desktop Chromium-based browsers, such as Edge or Chrome, an **Add** button appears within the URL bar. After the user selects the **Add** button, they receive a confirmation dialog:



On iOS, visitors can install the PWA using Safari's **Share** button and its **Add to Homescreen** option. On Chrome for Android, users should select the **Menu** button in the upper-right corner, followed by **Add to Home screen**.

Once installed, the app appears in its own window without an address bar:



To customize the window's title, color scheme, icon, or other details, see the `manifest.json` file in the project's `wwwroot` directory. The schema of this file is defined by web standards. For more information, see MDN web docs: Web App Manifest.

Offline support

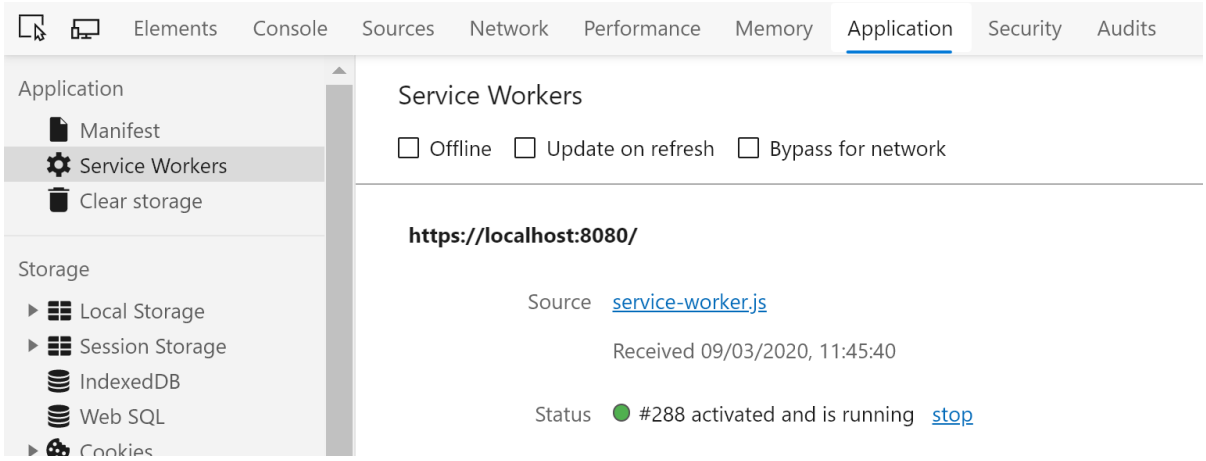
By default, apps created using the PWA template option have support for running offline. A user must first visit the app while they're online. The browser automatically downloads and caches all of the resources required to operate offline.

> **IMPORTANT**
> Development support would interfere with the usual development cycle of making changes and testing them. Therefore, offline support is only enabled for *published* apps.

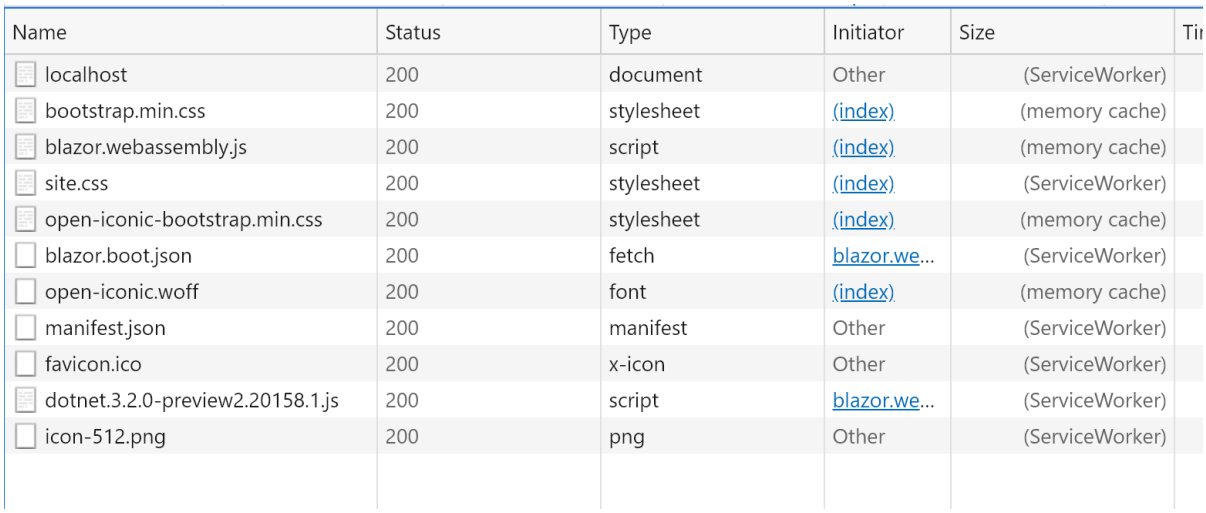
> **WARNING**
> If you intend to distribute an offline-enabled PWA, there are several important warnings and caveats. These scenarios are inherent to offline PWAs and not specific to Blazor. Be sure to read and understand these caveats before making assumptions about how your offline-enabled app will work.

To see how offline support works:

1. Publish the app. For more information, see Host and deploy ASP.NET Core Blazor.
2. Deploy the app to a server that supports HTTPS, and access the app in a browser at its secure HTTPS address.
3. Open the browser's dev tools and verify that a *Service Worker* is registered for the host on the **Application** tab:



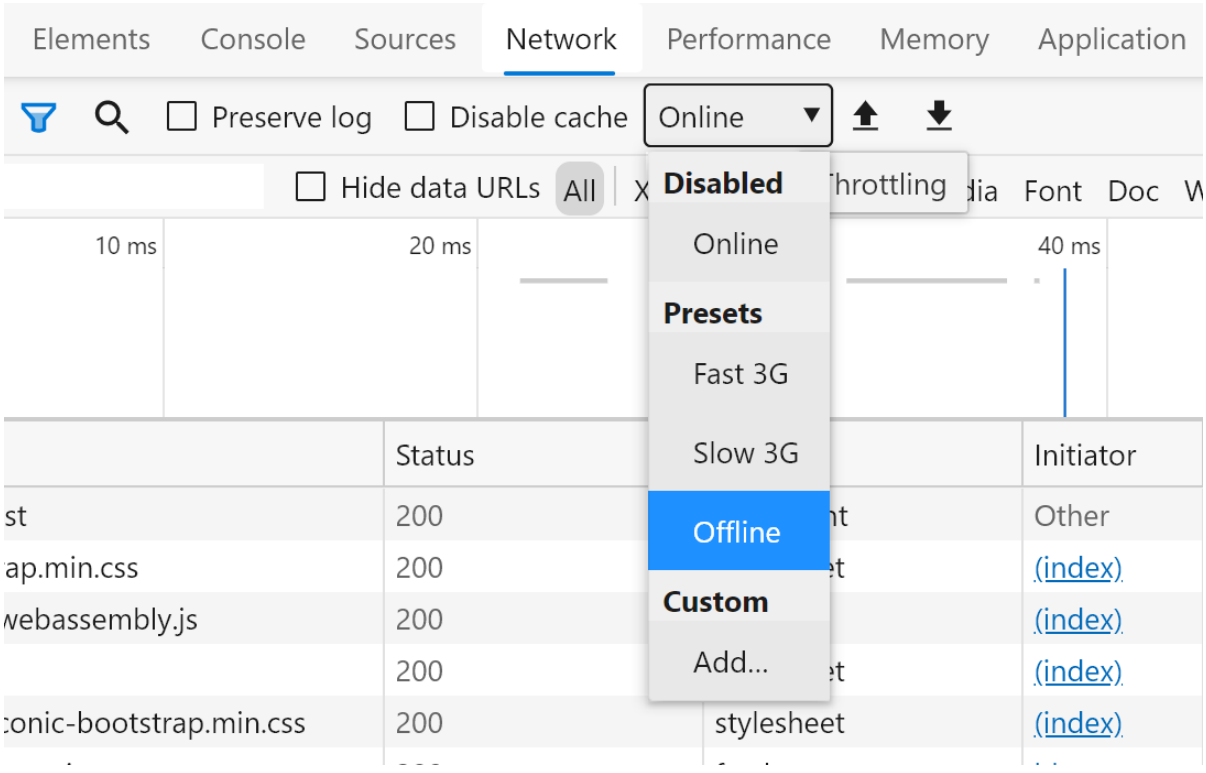
4. Reload the page and examine the **Network** tab. **Service Worker** or **memory cache** are listed as the sources for all of the page's assets:



Name	Status	Type	Initiator	Size	Ti
localhost	200	document	Other	(ServiceWorker)	
bootstrap.min.css	200	stylesheet	(index)	(memory cache)	
blazor.webassembly.js	200	script	(index)	(memory cache)	
site.css	200	stylesheet	(index)	(ServiceWorker)	
open-iconic-bootstrap.min.css	200	stylesheet	(index)	(memory cache)	
blazor.boot.json	200	fetch	blazor.we...	(ServiceWorker)	
open-iconic.woff	200	font	(index)	(memory cache)	
manifest.json	200	manifest	Other	(ServiceWorker)	
favicon.ico	200	x-icon	Other	(ServiceWorker)	
dotnet.3.2.0-preview2.20158.1.js	200	script	blazor.we...	(ServiceWorker)	
icon-512.png	200	png	Other	(ServiceWorker)	

5. To verify that the browser isn't dependent on network access to load the app, either:

   - Shut down the web server and see how the app continues to function normally, which includes page reloads. Likewise, the app continues to function normally when there's a slow network connection.
   - Instruct the browser to simulate offline mode in the **Network** tab:



Offline support using a service worker is a web standard, not specific to Blazor. For more information on service workers, see MDN web docs: Service Worker API. To learn more about common usage patterns for service workers, see Google Web: The Service Worker Lifecycle.

Blazor's PWA template produces two service worker files:

- `wwwroot/service-worker.js`, which is used during development.
- `wwwroot/service-worker.published.js`, which is used after the app is published.

To share logic between the two service worker files, consider the following approach:

- Add a third JavaScript file to hold the common logic.
- Use `self.importScripts` to load the common logic into both service worker files.

Cache-first fetch strategy

The built-in `service-worker.published.js` service worker resolves requests using a *cache-first* strategy. This means that the service worker prefers to return cached content, regardless of whether the user has network access or newer content is available on the server.

The cache-first strategy is valuable because:

- **It ensures reliability.** Network access isn't a boolean state. A user isn't simply online or offline:
  - The user's device may assume it's online, but the network might be so slow as to be impractical to wait for.
  - The network might return invalid results for certain URLs, such as when there's a captive WIFI portal that's currently blocking or redirecting certain requests.

  This is why the browser's `navigator.onLine` API isn't reliable and shouldn't be depended upon.
- **It ensures correctness.** When building a cache of offline resources, the service worker uses content hashing to guarantee it has fetched a complete and self-consistent snapshot of resources at a single instant in time. This cache is then used as an atomic unit. There's no point asking the network for newer resources, since the only versions required are the ones already cached. Anything else risks inconsistency and incompatibility (for example, trying to use versions of .NET assemblies that weren't compiled together).

Background updates

As a mental model, you can think of an offline-first PWA as behaving like a mobile app that can be installed. The app starts up immediately regardless of network connectivity, but the installed app logic comes from a point-in-time snapshot that might not be the latest version.

The Blazor PWA template produces apps that automatically try to update themselves in the background whenever the user visits and has a working network connection. The way this works is as follows:

- During compilation, the project generates a *service worker assets manifest*. By default, this is called `service-worker-assets.js`. The manifest lists all the static resources that the app requires to function offline, such as .NET assemblies, JavaScript files, and CSS, including their content hashes. The resource list is loaded by the service worker so that it knows which resources to cache.
- Each time the user visits the app, the browser re-requests `service-worker.js` and `service-worker-assets.js` in the background. The files are compared byte-for-byte with the existing installed service worker. If the server returns changed content for either of these files, the service worker attempts to install a new version of itself.
- When installing a new version of itself, the service worker creates a new, separate cache for offline resources and starts populating the cache with resources listed in `service-worker-assets.js`. This logic is implemented in the `onInstall` function inside `service-worker.published.js`.
- The process completes successfully when all of the resources are loaded without error and all content hashes match. If successful, the new service worker enters a *waiting for activation* state. As soon as the user closes the

app (no remaining app tabs or windows), the new service worker becomes *active* and is used for subsequent app visits. The old service worker and its cache are deleted.

- If the process doesn't complete successfully, the new service worker instance is discarded. The update process is attempted again on the user's next visit, when hopefully the client has a better network connection that can complete the requests.

Customize this process by editing the service worker logic. None of the preceding behavior is specific to Blazor but is merely the default experience provided by the PWA template option. For more information, see MDN web docs: Service Worker API.

How requests are resolved

As described in the Cache-first fetch strategy section, the default service worker uses a *cache-first* strategy, meaning that it tries to serve cached content when available. If there is no content cached for a certain URL, for example when requesting data from a backend API, the service worker falls back on a regular network request. The network request succeeds if the server is reachable. This logic is implemented inside `onFetch` function within `service-worker.published.js`.

If the app's Razor components rely on requesting data from backend APIs and you want to provide a friendly user experience for failed requests due to network unavailability, implement logic within the app's components. For example, use `try/catch` around HttpClient requests.

Support server-rendered pages

Consider what happens when the user first navigates to a URL such as `/counter` or any other deep link in the app. In these cases, you don't want to return content cached as `/counter`, but instead need the browser to load the content cached as `/index.html` to start up your Blazor WebAssembly app. These initial requests are known as *navigation* requests, as opposed to:

- `subresource` requests for images, stylesheets, or other files.
- `fetch/XHR` requests for API data.

The default service worker contains special-case logic for navigation requests. The service worker resolves the requests by returning the cached content for `/index.html`, regardless of the requested URL. This logic is implemented in the `onFetch` function inside `service-worker.published.js`.

If your app has certain URLs that must return server-rendered HTML, and not serve `/index.html` from the cache, then you need to edit the logic in your service worker. If all URLs containing `/Identity/` need to be handled as regular online-only requests to the server, then modify `service-worker.published.js` `onFetch` logic. Locate the following code:

```
const shouldServeIndexHtml = event.request.mode === 'navigate';
```

Change the code to the following:

```
const shouldServeIndexHtml = event.request.mode === 'navigate'
    && !event.request.url.includes('/Identity/');
```

If you don't do this, then regardless of network connectivity, the service worker intercepts requests for such URLs and resolves them using `/index.html`.

Control asset caching

If your project defines the `ServiceWorkerAssetsManifest` MSBuild property, Blazor's build tooling generates a service worker assets manifest with the specified name. The default PWA template produces a project file containing the following property:

```
<ServiceWorkerAssetsManifest>service-worker-assets.js</ServiceWorkerAssetsManifest>
```

The file is placed in the `wwwroot` output directory, so the browser can retrieve this file by requesting `/service-worker-assets.js`. To see the contents of this file, open `/bin/Debug/{TARGET FRAMEWORK}/wwwroot/service-worker-assets.js` in a text editor. However, don't edit the file, as it's regenerated on each build.

By default, this manifest lists:

- Any Blazor-managed resources, such as .NET assemblies and the .NET WebAssembly runtime files required to function offline.
- All resources for publishing to the app's `wwwroot` directory, such as images, stylesheets, and JavaScript files, including static web assets supplied by external projects and NuGet packages.

You can control which of these resources are fetched and cached by the service worker by editing the logic in `onInstall` in `service-worker.published.js`. By default, the service worker fetches and caches files matching typical web filename extensions such as `.html`, `.css`, `.js`, and `.wasm`, plus file types specific to Blazor WebAssembly (`.dll`, `.pdb`).

To include additional resources that aren't present in the app's `wwwroot` directory, define extra MSBuild `ItemGroup` entries, as shown in the following example:

```
<ItemGroup>
  <ServiceWorkerAssetsManifestItem Include="MyDirectory\AnotherFile.json"
    RelativePath="MyDirectory\AnotherFile.json" AssetUrl="files/AnotherFile.json" />
</ItemGroup>
```

The `AssetUrl` metadata specifies the base-relative URL that the browser should use when fetching the resource to cache. This can be independent of its original source file name on disk.

> **IMPORTANT**
> Adding a `ServiceWorkerAssetsManifestItem` doesn't cause the file to be published in the app's `wwwroot` directory. The publish output must be controlled separately. The `ServiceWorkerAssetsManifestItem` only causes an additional entry to appear in the service worker assets manifest.

Push notifications

Like any other PWA, a Blazor WebAssembly PWA can receive push notifications from a backend server. The server can send push notifications at any time, even when the user isn't actively using the app. For example, push notifications can be sent when a different user performs a relevant action.

The mechanism for sending a push notification is entirely independent of Blazor WebAssembly, since it's implemented by the backend server which can use any technology. If you want to send push notifications from an ASP.NET Core server, consider using a technique similar to the approach taken in the Blazing Pizza workshop.

The mechanism for receiving and displaying a push notification on the client is also independent of Blazor WebAssembly, since it's implemented in the service worker JavaScript file. For an example, see the approach used in the Blazing Pizza workshop.

Caveats for offline PWAs

Not all apps should attempt to support offline use. Offline support adds significant complexity, while not always

being relevant for the use cases required.

Offline support is usually relevant only:

- If the primary data store is local to the browser. For example, the approach is relevant in an app with a UI for an IoT device that stores data in `localStorage` or IndexedDB.
- If the app performs a significant amount of work to fetch and cache the backend API data relevant to each user so that they can navigate through the data offline. If the app must support editing, a system for tracking changes and synchronizing data with the backend must be built.
- If the goal is to guarantee that the app loads immediately regardless of network conditions. Implement a suitable user experience around backend API requests to show the progress of requests and behave gracefully when requests fail due to network unavailability.

Additionally, offline-capable PWAs must deal with a range of additional complications. Developers should carefully familiarize themselves with the caveats in the following sections.

Offline support only when published

During development you typically want to see each change reflected immediately in the browser without going through a background update process. Therefore, Blazor's PWA template enables offline support only when published.

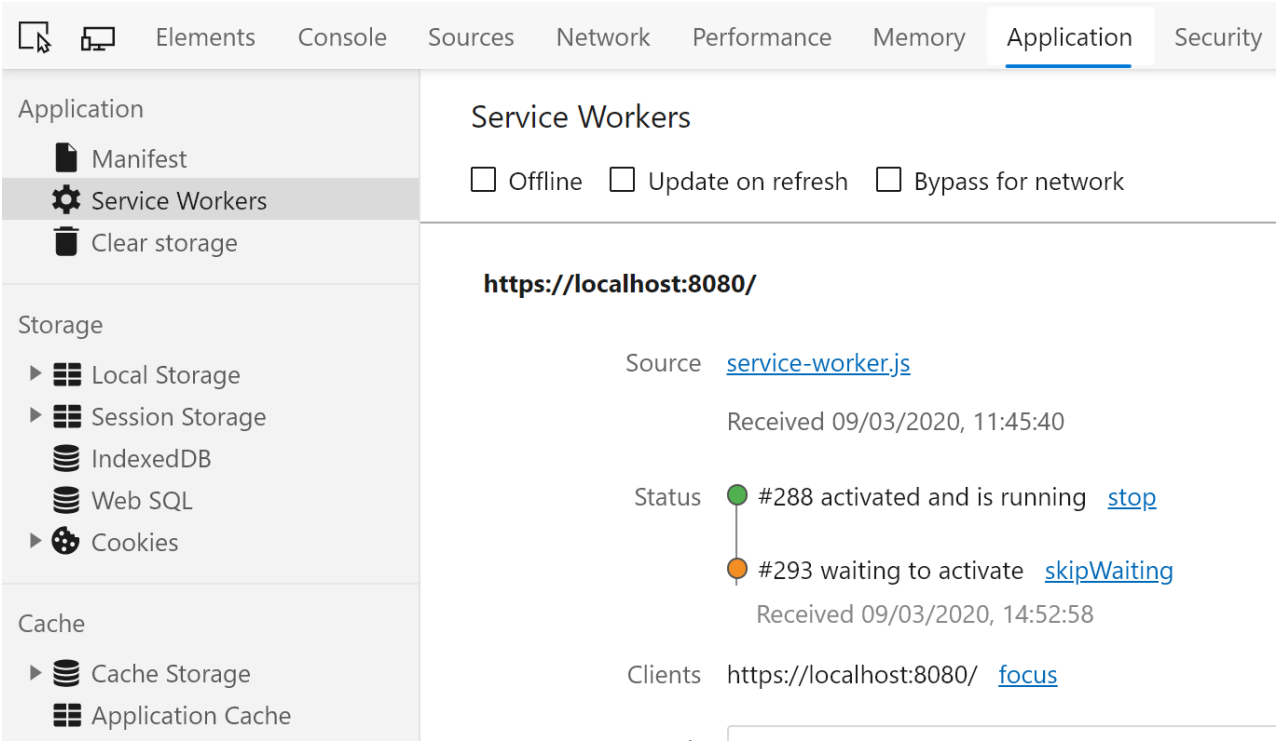
When building an offline-capable app, it's not enough to test the app in the Development environment. You must test the app in its published state to understand how it responds to different network conditions.

Update completion after user navigation away from app

Updates don't complete until the user has navigated away from the app in all tabs. As explained in the Background updates section, after you deploy an update to the app, the browser fetches the updated service worker files to begin the update process.

What surprises many developers is that, even when this update completes, it does **not** take effect until the user has navigated away in all tabs. It is **not** sufficient to refresh the tab displaying the app, even if it's the only tab displaying the app. Until your app is completely closed, the new service worker remains in the *waiting to activate* status. **This is not specific to Blazor, but rather is a standard web platform behavior.**

This commonly troubles developers who are trying to test updates to their service worker or offline cached resources. If you check in the browser's developer tools, you may see something like the following:



For as long as the list of "clients," which are tabs or windows displaying your app, is nonempty, the worker continues waiting. The reason service workers do this is to guarantee consistency. Consistency means that all resources are fetched from the same atomic cache.

When testing changes, you may find it convenient to click the "skipWaiting" link as shown in the preceding screenshot, then reload the page. You can automate this for all users by coding your service worker to skip the "waiting" phase and immediately activate on update. If you skip the waiting phase, you're giving up the guarantee that resources are always fetched consistently from the same cache instance.

Users may run any historical version of the app

Web developers habitually expect that users only run the latest deployed version of their web app, since that's normal within the traditional web distribution model. However, an offline-first PWA is more akin to a native mobile app, where users aren't necessarily running the latest version.

As explained in the Background updates section, after you deploy an update to your app, **each existing user continues to use a previous version for at least one further visit** because the update occurs in the background and isn't activated until the user thereafter navigates away. Plus, the previous version being used isn't necessarily the previous one you deployed. The previous version can be *any* historical version, depending on when the user last completed an update.

This can be an issue if the frontend and backend parts of your app require agreement about the schema for API requests. You must not deploy backward-incompatible API schema changes until you can be sure that all users have upgraded. Alternatively, block users from using incompatible older versions of the app. This scenario requirement is the same as for native mobile apps. If you deploy a breaking change in server APIs, the client app is broken for users who haven't yet updated.

If possible, don't deploy breaking changes to your backend APIs. If you must do so, consider using standard Service Worker APIs such as ServiceWorkerRegistration to determine whether the app is up-to-date, and if not, to prevent usage.

Interference with server-rendered pages

As described in the Support server-rendered pages section, if you want to bypass the service worker's behavior of returning `/index.html` contents for all navigation requests, edit the logic in your service worker.

All service worker asset manifest contents are cached by default

As described in the Control asset caching section, the file `service-worker-assets.js` is generated during build and lists all assets the service worker should fetch and cache.

Since this list by default includes everything emitted to `wwwroot`, including content supplied by external packages and projects, you must be careful not to put too much content there. If the `wwwroot` directory contains millions of images, the service worker tries to fetch and cache them all, consuming excessive bandwidth and most likely not completing successfully.

Implement arbitrary logic to control which subset of the manifest's contents should be fetched and cached by editing the `onInstall` function in `service-worker.published.js`.

Interaction with authentication

The PWA template can be used in conjunction with authentication. An offline-capable PWA can also support authentication when the user has initial network connectivity.

When a user doesn't have network connectivity, they can't authenticate or obtain access tokens. By default, attempting to visit the login page without network access results in a "network error" message. You must design a UI flow that allows the user perform useful tasks while offline without attempting to authenticate the user or obtain access tokens. Alternatively, you can design the app to gracefully fail when the network isn't available. If the app can't be designed to handle these scenarios, you might not want to enable offline support.

When an app that's designed for online and offline use is online again:

- The app might need to provision a new access token.
- The app must detect if a different user is signed into the service so that it can apply operations to the user's account that were made while they were offline.

To create an offline PWA app that interacts with authentication:

- Replace the AccountClaimsPrincipalFactory<TAccount> with a factory that stores the last signed-in user and uses the stored user when the app is offline.
- Queue operations while the app is offline and apply them when the app returns online.
- During sign out, clear the stored user.

The `CarChecker` sample app demonstrates the preceding approaches. See the following parts of the app:

- `OfflineAccountClaimsPrincipalFactory` (`Client/Data/OfflineAccountClaimsPrincipalFactory.cs`)
- `LocalVehiclesStore` (`Client/Data/LocalVehiclesStore.cs`)
- `LoginStatus` component (`Client/Shared/LoginStatus.razor`)

Host and deploy ASP.NET Core Blazor

9/22/2020 • 4 minutes to read • Edit Online

By Luke Latham, Rainer Stropek, and Daniel Roth

Publish the app

Apps are published for deployment in Release configuration.

- Visual Studio
- Visual Studio for Mac
- .NET Core CLI

1. Select **Build** > **Publish {APPLICATION}** from the navigation bar.
2. Select the *publish target*. To publish locally, select **Folder**.
3. Accept the default location in the **Choose a folder** field or specify a different location. Select the `Publish` button.

Publishing the app triggers a restore of the project's dependencies and builds the project before creating the assets for deployment. As part of the build process, unused methods and assemblies are removed to reduce app download size and load times.

Publish locations:

- Blazor WebAssembly
  - Standalone: The app is published into the `/bin/Release/{TARGET FRAMEWORK}/publish/wwwroot` folder. To deploy the app as a static site, copy the contents of the `wwwroot` folder to the static site host.
  - Hosted: The client Blazor WebAssembly app is published into the `/bin/Release/{TARGET FRAMEWORK}/publish/wwwroot` folder of the server app, along with any other static web assets of the server app. Deploy the contents of the `publish` folder to the host.
- Blazor Server: The app is published into the `/bin/Release/{TARGET FRAMEWORK}/publish` folder. Deploy the contents of the `publish` folder to the host.

The assets in the folder are deployed to the web server. Deployment might be a manual or automated process depending on the development tools in use.

App base path

The *app base path* is the app's root URL path. Consider the following ASP.NET Core app and Blazor sub-app:

- The ASP.NET Core app is named `MyApp`:
  - The app physically resides at `d:/MyApp`.
  - Requests are received at `https://www.contoso.com/{MYAPP RESOURCE}`.
- A Blazor app named `CoolApp` is a sub-app of `MyApp`:
  - The sub-app physically resides at `d:/MyApp/CoolApp`.
  - Requests are received at `https://www.contoso.com/CoolApp/{COOLAPP RESOURCE}`.

Without specifying additional configuration for `CoolApp`, the sub-app in this scenario has no knowledge of where it resides on the server. For example, the app can't construct correct relative URLs to its resources without knowing that it resides at the relative URL path `/CoolApp/`.

To provide configuration for the Blazor app's base path of `https://www.contoso.com/CoolApp/`, the `<base>` tag's `href` attribute is set to the relative root path in the `Pages/_Host.cshtml` file (Blazor Server) or `wwwroot/index.html` file (Blazor WebAssembly):

```
<base href="/CoolApp/">
```

Blazor Server apps additionally set the server-side base path by calling UsePathBase in the app's request pipeline of `Startup.Configure`:

```
app.UsePathBase("/CoolApp");
```

By providing the relative URL path, a component that isn't in the root directory can construct URLs relative to the app's root path. Components at different levels of the directory structure can build links to other resources at locations throughout the app. The app base path is also used to intercept selected hyperlinks where the `href` target of the link is within the app base path URI space. The Blazor router handles the internal navigation.

In many hosting scenarios, the relative URL path to the app is the root of the app. In these cases, the app's relative URL base path is a forward slash (`<base href="/" />`), which is the default configuration for a Blazor app. In other hosting scenarios, such as GitHub Pages and IIS sub-apps, the app base path must be set to the server's relative URL path of the app.

To set the app's base path, update the `<base>` tag within the `<head>` tag elements of the `Pages/_Host.cshtml` file (Blazor Server) or `wwwroot/index.html` file (Blazor WebAssembly). Set the `href` attribute value to `/{RELATIVE URL PATH}/` (the trailing slash is required), where `{RELATIVE URL PATH}` is the app's full relative URL path.

For an Blazor WebAssembly app with a non-root relative URL path (for example, `<base href="/CoolApp/">`), the app fails to find its resources *when run locally*. To overcome this problem during local development and testing, you can supply a *path base* argument that matches the `href` value of the `<base>` tag at runtime. Don't include a trailing slash. To pass the path base argument when running the app locally, execute the `dotnet run` command from the app's directory with the `--pathbase` option:

```
dotnet run --pathbase=/{RELATIVE URL PATH (no trailing slash)}
```

For a Blazor WebAssembly app with a relative URL path of `/CoolApp/` (`<base href="/CoolApp/">`), the command is:

```
dotnet run --pathbase=/CoolApp
```

The Blazor WebAssembly app responds locally at `http://localhost:port/CoolApp`.

Blazor Server `MapFallbackToPage` configuration

Pass the following path to MapFallbackToPage in `Startup.Configure`:

```
endpoints.MapFallbackToPage("/{RELATIVE PATH}/{**path:nonfile}");
```

The placeholder `{RELATIVE PATH}` is the non-root path on the server. For example, `CoolApp` is the placeholder segment if the non-root URL to the app is `https://{HOST}:{PORT}/CoolApp/`):

```
endpoints.MapFallbackToPage("/CoolApp/{**path:nonfile}");
```

Host multiple Blazor WebAssembly apps

For more information on hosting multiple Blazor WebAssembly apps in a hosted Blazor solution, see Host and deploy ASP.NET Core Blazor WebAssembly.

Deployment

For deployment guidance, see the following topics:

- Host and deploy ASP.NET Core Blazor WebAssembly
- Host and deploy ASP.NET Core Blazor Server

Host and deploy ASP.NET Core Blazor WebAssembly

9/22/2020 • 21 minutes to read • Edit Online

By Luke Latham, Rainer Stropek, Daniel Roth, Ben Adams, and Safia Abdalla

With the Blazor WebAssembly hosting model:

- The Blazor app, its dependencies, and the .NET runtime are downloaded to the browser in parallel.
- The app is executed directly on the browser UI thread.

The following deployment strategies are supported:

- The Blazor app is served by an ASP.NET Core app. This strategy is covered in the Hosted deployment with ASP.NET Core section.
- The Blazor app is placed on a static hosting web server or service, where .NET isn't used to serve the Blazor app. This strategy is covered in the Standalone deployment section, which includes information on hosting a Blazor WebAssembly app as an IIS sub-app.

Compression

When a Blazor WebAssembly app is published, the output is statically compressed during publish to reduce the app's size and remove the overhead for runtime compression. The following compression algorithms are used:

- Brotli (highest level)
- Gzip

Blazor relies on the host to the serve the appropriate compressed files. When using an ASP.NET Core hosted project, the host project is capable of performing content negotiation and serving the statically-compressed files. When hosting a Blazor WebAssembly standalone app, additional work might be required to ensure that statically-compressed files are served:

- For IIS `web.config` compression configuration, see the IIS: Brotli and Gzip compression section.
- When hosting on static hosting solutions that don't support statically-compressed file content negotiation, such as GitHub Pages, consider configuring the app to fetch and decode Brotli compressed files:
  - Obtain the JavaScript Brotli decoder from the google/brotli GitHub repository. As of July 2020, the decoder file is named `decode.min.js` and found in the repository's `js` folder.
  - Update the app to use the decoder. Change the markup inside the closing `<body>` tag in `wwwroot/index.html` to the following:

```
<script src="decode.min.js"></script>
<script src="_framework/blazor.webassembly.js" autostart="false"></script>
<script>
  Blazor.start({
    loadBootResource: function (type, name, defaultUri, integrity) {
      if (type !== 'dotnetjs' && location.hostname !== 'localhost') {
        return (async function () {
          const response = await fetch(defaultUri + '.br', { cache: 'no-cache' });
          if (!response.ok) {
            throw new Error(response.statusText);
          }
          const originalResponseBuffer = await response.arrayBuffer();
          const originalResponseArray = new Int8Array(originalResponseBuffer);
          const decompressedResponseArray = BrotliDecode(originalResponseArray);
          const contentType = type ===
            'dotnetwasm' ? 'application/wasm' : 'application/octet-stream';
          return new Response(decompressedResponseArray,
            { headers: { 'content-type': contentType } });
        })();
      }
    }
  });
</script>
```

To disable compression, add the `BlazorEnableCompression` MSBuild property to the app's project file and set the value to `false`:

```
<PropertyGroup>
  <BlazorEnableCompression>false</BlazorEnableCompression>
</PropertyGroup>
```

The `BlazorEnableCompression` property can be passed to the `dotnet publish` command with the following syntax in a command shell:

```
dotnet publish -p:BlazorEnableCompression=false
```

Rewrite URLs for correct routing

Routing requests for page components in a Blazor WebAssembly app isn't as straightforward as routing requests in a Blazor Server, hosted app. Consider a Blazor WebAssembly app with two components:

- `Main.razor`: Loads at the root of the app and contains a link to the `About` component (`href="About"`).
- `About.razor`: `About` component.

When the app's default document is requested using the browser's address bar (for example, `https://www.contoso.com/`):

1. The browser makes a request.
2. The default page is returned, which is usually `index.html`.
3. `index.html` bootstraps the app.
4. Blazor's router loads, and the Razor `Main` component is rendered.

In the Main page, selecting the link to the `About` component works on the client because the Blazor router stops the browser from making a request on the Internet to `www.contoso.com` for `About` and serves the rendered `About` component itself. All of the requests for internal endpoints *within the Blazor WebAssembly app* work the same way: Requests don't trigger browser-based requests to server-hosted resources on the Internet. The router handles the

requests internally.

If a request is made using the browser's address bar for `www.contoso.com/About`, the request fails. No such resource exists on the app's Internet host, so a *404 - Not Found* response is returned.

Because browsers make requests to Internet-based hosts for client-side pages, web servers and hosting services must rewrite all requests for resources not physically on the server to the `index.html` page. When `index.html` is returned, the app's Blazor router takes over and responds with the correct resource.

When deploying to an IIS server, you can use the URL Rewrite Module with the app's published `web.config` file. For more information, see the IIS section.

Hosted deployment with ASP.NET Core

A *hosted deployment* serves the Blazor WebAssembly app to browsers from an ASP.NET Core app that runs on a web server.

The client Blazor WebAssembly app is published into the `/bin/Release/{TARGET FRAMEWORK}/publish/wwwroot` folder of the server app, along with any other static web assets of the server app. The two apps are deployed together. A web server that is capable of hosting an ASP.NET Core app is required. For a hosted deployment, Visual Studio includes the **Blazor WebAssembly App** project template (`blazorwasm` template when using the `dotnet new` command) with the `Hosted` option selected (`-ho|--hosted` when using the `dotnet new` command).

For more information on ASP.NET Core app hosting and deployment, see Host and deploy ASP.NET Core.

For information on deploying to Azure App Service, see Publish an ASP.NET Core app to Azure with Visual Studio.

Hosted deployment with multiple Blazor WebAssembly apps

App configuration

To configure a hosted Blazor solution to serve multiple Blazor WebAssembly apps:

- Use an existing hosted Blazor solution or create a new solution from the Blazor Hosted project template.
- In the client app's project file, add a `<StaticWebAssetBasePath>` property to the `<PropertyGroup>` with a value of `FirstApp` to set the base path for the project's static assets:

  ```
  <PropertyGroup>
    ...
    <StaticWebAssetBasePath>FirstApp</StaticWebAssetBasePath>
  </PropertyGroup>
  ```

- Add a second client app to the solution:
  - Add a folder named `SecondClient` to the solution's folder.
  - Create a Blazor WebAssembly app named `SecondBlazorApp.Client` in the `SecondClient` folder from the Blazor WebAssembly project template.
  - In the app's project file:
    - Add a `<StaticWebAssetBasePath>` property to the `<PropertyGroup>` with a value of `SecondApp`:

      ```
      <PropertyGroup>
        ...
        <StaticWebAssetBasePath>SecondApp</StaticWebAssetBasePath>
      </PropertyGroup>
      ```

- Add a project reference to the `Shared` project:

  ```
  <ItemGroup>
    <ProjectReference Include="..\Shared\{SOLUTION NAME}.Shared.csproj" />
  </ItemGroup>
  ```

  The placeholder `{SOLUTION NAME}` is the solution's name.

- In the server app's project file, create a project reference for the added client app:

  ```
  <ItemGroup>
    ...
    <ProjectReference Include="..\SecondClient\SecondBlazorApp.Client.csproj" />
  </ItemGroup>
  ```

- In the server app's `Properties/launchSettings.json` file, configure the `applicationUrl` of the Kestrel profile (`{SOLUTION NAME}.Server`) to access the client apps at ports 5001 and 5002:

  ```
  "applicationUrl": "https://localhost:5001;https://localhost:5002",
  ```

- In the server app's `Startup.Configure` method (`Startup.cs`), remove the following lines, which appear after the call to UseHttpsRedirection:

  ```
  app.UseBlazorFrameworkFiles();
  app.UseStaticFiles();

  app.UseRouting();

  app.UseEndpoints(endpoints =>
  {
      endpoints.MapRazorPages();
      endpoints.MapControllers();
      endpoints.MapFallbackToFile("index.html");
  });
  ```

  Add middleware that maps requests to the client apps. The following example configures the middleware to run when:

  - The request port is either 5001 for the original client app or 5002 for the added client app.
  - The request host is either `firstapp.com` for the original client app or `secondapp.com` for the added client app.

  > **NOTE**
  >
  > The example shown in this section requires additional configuration for:
  >
  > - Accessing the apps at the example host domains, `firstapp.com` and `secondapp.com`.
  > - Certificates for the client apps to enable TLS security (HTTPS).
  >
  > The required configuration is beyond the scope of this article and depends on how the solution is hosted. For more information see the Host and deploy articles.

  Place the following code where the lines were removed earlier:

```
app.MapWhen(ctx => ctx.Request.Host.Port == 5001 ||
    ctx.Request.Host.Equals("firstapp.com"), first =>
{
    first.Use((ctx, nxt) =>
    {
        ctx.Request.Path = "/FirstApp" + ctx.Request.Path;
        return nxt();
    });

    first.UseBlazorFrameworkFiles("/FirstApp");
    first.UseStaticFiles();
    first.UseStaticFiles("/FirstApp");
    first.UseRouting();

    first.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
        endpoints.MapFallbackToFile("/FirstApp/{*path:nonfile}",
            "FirstApp/index.html");
    });
});

app.MapWhen(ctx => ctx.Request.Host.Port == 5002 ||
    ctx.Request.Host.Equals("secondapp.com"), second =>
{
    second.Use((ctx, nxt) =>
    {
        ctx.Request.Path = "/SecondApp" + ctx.Request.Path;
        return nxt();
    });

    second.UseBlazorFrameworkFiles("/SecondApp");
    second.UseStaticFiles();
    second.UseStaticFiles("/SecondApp");
    second.UseRouting();

    second.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
        endpoints.MapFallbackToFile("/SecondApp/{*path:nonfile}",
            "SecondApp/index.html");
    });
});
```

- In the server app's weather forecast controller (`Controllers/WeatherForecastController.cs`), replace the existing route (`[Route("[controller]")]`) to `WeatherForecastController` with the following routes:

  ```
  [Route("FirstApp/[controller]")]
  [Route("SecondApp/[controller]")]
  ```

  The middleware added to the server app's `Startup.Configure` method earlier modifies incoming requests to `/WeatherForecast` to either `/FirstApp/WeatherForecast` or `/SecondApp/WeatherForecast` depending on the port (5001/5002) or domain (`firstapp.com` / `secondapp.com`). The preceding controller routes are required in order to return weather data from the server app to the client apps.

Static assets and class libraries

Use the following approaches for static assets:

- When the asset is in the client app's `wwwroot` folder, provide their paths normally:

```
<img alt="..." src="/{ASSET FILE NAME}" />
```

- When the asset is in the `wwwroot` folder of a Razor Class Library (RCL), reference the static asset in the client app per the guidance in the RCL article:

  ```
  <img alt="..." src="_content/{LIBRARY NAME}/{ASSET FILE NAME}" />
  ```

Components provided to a client app by a class library are referenced normally. If any components require stylesheets or JavaScript files, use either of the following approaches to obtain the static assets:

- The client app's `wwwroot/index.html` file can link (`<link>`) to the static assets.
- The component can use the framework's `Link` component to obtain the static assets.

The preceding approaches are demonstrated in the following examples.

Components provided to a client app by a class library are referenced normally. If any components require stylesheets or JavaScript files, the client app's `wwwroot/index.html` file must include the correct static asset links. These approaches are demonstrated in the following examples.

Add the following `Jeep` component to one of the client apps. The `Jeep` component uses:

- An image from the client app's `wwwroot` folder (`jeep-cj.png`).
- An image from an added Razor component library (`JeepImage`) `wwwroot` folder (`jeep-yj.png`).
- The example component (`Component1`) is created automatically by the RCL project template when the `JeepImage` library is added to the solution.

```
@page "/Jeep"

<h1>1979 Jeep CJ-5&trade;</h1>

<p>
    <img alt="1979 Jeep CJ-5&trade;" src="/jeep-cj.png" />
</p>

<h1>1991 Jeep YJ&trade;</h1>

<p>
    <img alt="1991 Jeep YJ&trade;" src="_content/JeepImage/jeep-yj.png" />
</p>

<p>
    <em>Jeep CJ-5</em> and <em>Jeep YJ</em> are a trademarks of
    <a href="https://www.fcagroup.com">Fiat Chrysler Automobiles</a>.
</p>

<JeepImage.Component1 />
```

WARNING

Do **not** publish images of vehicles publicly unless you own the images. Otherwise, you risk copyright infringement.

The library's `jeep-yj.png` image can also be added to the library's `Component1` component (`Component1.razor`). To provide the `my-component` CSS class to the client app's page, link to the library's stylesheet using the framework's `Link` component:

```
<div class="my-component">
    <Link href="_content/JeepImage/styles.css" rel="stylesheet" />

    <h1>JeepImage.Component1</h1>

    <p>
        This Blazor component is defined in the <strong>JeepImage</strong> package.
    </p>

    <p>
        <img alt="1991 Jeep YJ&trade;" src="_content/JeepImage/jeep-yj.png" />
    </p>
</div>
```

An alternative to using the `Link` component is to load the stylesheet from the client app's `wwwroot/index.html` file. This approach makes the stylesheet available to all of the components in the client app:

```
<head>
    ...
    <link href="_content/JeepImage/styles.css" rel="stylesheet" />
</head>
```

The library's `jeep-yj.png` image can also be added to the library's `Component1` component (`Component1.razor`):

```
<div class="my-component">
    <h1>JeepImage.Component1</h1>

    <p>
        This Blazor component is defined in the <strong>JeepImage</strong> package.
    </p>

    <p>
        <img alt="1991 Jeep YJ&trade;" src="_content/JeepImage/jeep-yj.png" />
    </p>
</div>
```

The client app's `wwwroot/index.html` file requests the library's stylesheet with the following added `<link>` tag:

```
<head>
    ...
    <link href="_content/JeepImage/styles.css" rel="stylesheet" />
</head>
```

Add navigation to the `Jeep` component in the client app's `NavMenu` component (`Shared/NavMenu.razor`):

```
<li class="nav-item px-3">
    <NavLink class="nav-link" href="Jeep">
        <span class="oi oi-list-rich" aria-hidden="true"></span> Jeep
    </NavLink>
</li>
```

For more information on RCLs, see:

- ASP.NET Core Razor components class libraries
- Reusable Razor UI in class libraries with ASP.NET Core

Standalone deployment

A *standalone deployment* serves the Blazor WebAssembly app as a set of static files that are requested directly by clients. Any static file server is able to serve the Blazor app.

Standalone deployment assets are published into the `/bin/Release/{TARGET FRAMEWORK}/publish/wwwroot` folder.

Azure App Service

Blazor WebAssembly apps can be deployed to Azure App Services on Windows, which hosts the app on IIS.

Deploying a standalone Blazor WebAssembly app to Azure App Service for Linux isn't currently supported. A Linux server image to host the app isn't available at this time. Work is in progress to enable this scenario.

IIS

IIS is a capable static file server for Blazor apps. To configure IIS to host Blazor, see Build a Static Website on IIS.

Published assets are created in the `/bin/Release/{TARGET FRAMEWORK}/publish` folder. Host the contents of the `publish` folder on the web server or hosting service.

web.config

When a Blazor project is published, a `web.config` file is created with the following IIS configuration:

- MIME types are set for the following file extensions:
  - `.dll` : `application/octet-stream`
  - `.json` : `application/json`
  - `.wasm` : `application/wasm`
  - `.woff` : `application/font-woff`
  - `.woff2` : `application/font-woff`
- HTTP compression is enabled for the following MIME types:
  - `application/octet-stream`
  - `application/wasm`
- URL Rewrite Module rules are established:
  - Serve the sub-directory where the app's static assets reside (`wwwroot/{PATH REQUESTED}`).
  - Create SPA fallback routing so that requests for non-file assets are redirected to the app's default document in its static assets folder (`wwwroot/index.html`).

Use a custom web.config

To use a custom `web.config` file, place the custom `web.config` file at the root of the project folder and publish the project.

Install the URL Rewrite Module

The URL Rewrite Module is required to rewrite URLs. The module isn't installed by default, and it isn't available for install as a Web Server (IIS) role service feature. The module must be downloaded from the IIS website. Use the Web Platform Installer to install the module:

1. Locally, navigate to the URL Rewrite Module downloads page. For the English version, select **WebPI** to download the WebPI installer. For other languages, select the appropriate architecture for the server (x86/x64) to download the installer.
2. Copy the installer to the server. Run the installer. Select the **Install** button and accept the license terms. A server restart isn't required after the install completes.

Configure the website

Set the website's **Physical path** to the app's folder. The folder contains:

- The `web.config` file that IIS uses to configure the website, including the required redirect rules and file content types.
- The app's static asset folder.

Host as an IIS sub-app

If a standalone app is hosted as an IIS sub-app, perform either of the following:

- Disable the inherited ASP.NET Core Module handler.

  Remove the handler in the Blazor app's published `web.config` file by adding a `<handlers>` section to the file:

  ```
  <handlers>
    <remove name="aspNetCore" />
  </handlers>
  ```

- Disable inheritance of the root (parent) app's `<system.webServer>` section using a `<location>` element with `inheritInChildApplications` set to `false`:

  ```
  <?xml version="1.0" encoding="utf-8"?>
  <configuration>
    <location path="." inheritInChildApplications="false">
      <system.webServer>
        <handlers>
          <add name="aspNetCore" ... />
        </handlers>
        <aspNetCore ... />
      </system.webServer>
    </location>
  </configuration>
  ```

Removing the handler or disabling inheritance is performed in addition to configuring the app's base path. Set the app base path in the app's `index.html` file to the IIS alias used when configuring the sub-app in IIS.

Brotli and Gzip compression

IIS can be configured via `web.config` to serve Brotli or Gzip compressed Blazor assets. For an example configuration, see `web.config`.

Troubleshooting

If a *500 - Internal Server Error* is received and IIS Manager throws errors when attempting to access the website's configuration, confirm that the URL Rewrite Module is installed. When the module isn't installed, the `web.config` file can't be parsed by IIS. This prevents the IIS Manager from loading the website's configuration and the website from serving Blazor's static files.

For more information on troubleshooting deployments to IIS, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

Azure Storage

Azure Storage static file hosting allows serverless Blazor app hosting. Custom domain names, the Azure Content Delivery Network (CDN), and HTTPS are supported.

When the blob service is enabled for static website hosting on a storage account:

- Set the **Index document name** to `index.html`.
- Set the **Error document path** to `index.html`. Razor components and other non-file endpoints don't reside at physical paths in the static content stored by the blob service. When a request for one of these resources is received that the Blazor router should handle, the *404 - Not Found* error generated by the blob service routes the request to the **Error document path**. The `index.html` blob is returned, and the Blazor router loads and processes the path.

If files aren't loaded at runtime due to inappropriate MIME types in the files' `Content-Type` headers, take either of the following actions:

- Configure your tooling to set the correct MIME types (`Content-Type` headers) when the files are deployed.
- Change the MIME types (`Content-Type` headers) for the files after the app is deployed.

  In Storage Explorer (Azure portal) for each file:

  1. Right-click the file and select **Properties**.
  2. Set the **ContentType** and select the **Save** button.

For more information, see Static website hosting in Azure Storage.

Nginx

The following `nginx.conf` file is simplified to show how to configure Nginx to send the `index.html` file whenever it can't find a corresponding file on disk.

```
events { }
http {
    server {
        listen 80;

        location / {
            root      /usr/share/nginx/html;
            try_files $uri $uri/ /index.html =404;
        }
    }
}
```

When setting the NGINX burst rate limit with `limit_req`, Blazor WebAssembly apps may require a large `burst` parameter value to accommodate the relatively large number of requests made by an app. Initially, set the value to at least 60:

```
http {
    server {
        ...

        location / {
            ...

            limit_req zone=one burst=60 nodelay;
        }
    }
}
```

Increase the value if browser developer tools or a network traffic tool indicates that requests are receiving a *503 - Service Unavailable* status code.

For more information on production Nginx web server configuration, see Creating NGINX Plus and NGINX Configuration Files.

Nginx in Docker

To host Blazor in Docker using Nginx, setup the Dockerfile to use the Alpine-based Nginx image. Update the Dockerfile to copy the `nginx.config` file into the container.

Add one line to the Dockerfile, as shown in the following example:

```
FROM nginx:alpine
COPY ./bin/Release/netstandard2.0/publish /usr/share/nginx/html/
COPY nginx.conf /etc/nginx/nginx.conf
```

Apache

To deploy a Blazor WebAssembly app to CentOS 7 or later:

1. Create the Apache configuration file. The following example is a simplified configuration file (`blazorapp.config`):

```
<VirtualHost *:80>
    ServerName www.example.com
    ServerAlias *.example.com

    DocumentRoot "/var/www/blazorapp"
    ErrorDocument 404 /index.html

    AddType application/wasm .wasm
    AddType application/octet-stream .dll

    <Directory "/var/www/blazorapp">
        Options -Indexes
        AllowOverride None
    </Directory>

    <IfModule mod_deflate.c>
        AddOutputFilterByType DEFLATE text/css
        AddOutputFilterByType DEFLATE application/javascript
        AddOutputFilterByType DEFLATE text/html
        AddOutputFilterByType DEFLATE application/octet-stream
        AddOutputFilterByType DEFLATE application/wasm
        <IfModule mod_setenvif.c>
        BrowserMatch ^Mozilla/4 gzip-only-text/html
        BrowserMatch ^Mozilla/4.0[678] no-gzip
        BrowserMatch bMSIE !no-gzip !gzip-only-text/html
    </IfModule>
    </IfModule>

    ErrorLog /var/log/httpd/blazorapp-error.log
    CustomLog /var/log/httpd/blazorapp-access.log common
</VirtualHost>
```

2. Place the Apache configuration file into the `/etc/httpd/conf.d/` directory, which is the default Apache configuration directory in CentOS 7.
3. Place the app's files into the `/var/www/blazorapp` directory (the location specified to `DocumentRoot` in the configuration file).
4. Restart the Apache service.

For more information, see `mod_mime` and `mod_deflate` .

GitHub Pages

To handle URL rewrites, add a `wwwroot/404.html` file with a script that handles redirecting the request to the `index.html` page. For an example, see the SteveSandersonMS/BlazorOnGitHubPages GitHub repository:

- `wwwroot/404.html`
- Live site)

When using a project site instead of an organization site, update the `<base>` tag in `wwwroot/index.html` . Set the `href` attribute value to the GitHub repository name with a trailing slash (for example, `/my-repository/`). In the SteveSandersonMS/BlazorOnGitHubPages GitHub repository, the base `href` is updated at publish by the `.github/workflows/main.yml` configuration file.

> **NOTE**
> The SteveSandersonMS/BlazorOnGitHubPages GitHub repository isn't owned, maintained, or supported by the .NET Foundation or Microsoft.

Host configuration values

Blazor WebAssembly apps can accept the following host configuration values as command-line arguments at runtime in the development environment.

Content root

The `--contentroot` argument sets the absolute path to the directory that contains the app's content files (content root). In the following examples, `/content-root-path` is the app's content root path.

- Pass the argument when running the app locally at a command prompt. From the app's directory, execute:

```
dotnet run --contentroot=/content-root-path
```

- Add an entry to the app's `launchSettings.json` file in the **IIS Express** profile. This setting is used when the app is run with the Visual Studio Debugger and from a command prompt with `dotnet run`.

```
"commandLineArgs": "--contentroot=/content-root-path"
```

- In Visual Studio, specify the argument in **Properties** > **Debug** > **Application arguments**. Setting the argument in the Visual Studio property page adds the argument to the `launchSettings.json` file.

```
--contentroot=/content-root-path
```

Path base

The `--pathbase` argument sets the app base path for an app run locally with a non-root relative URL path (the `<base>` tag `href` is set to a path other than `/` for staging and production). In the following examples, `/relative-URL-path` is the app's path base. For more information, see App base path.

> **IMPORTANT**
> Unlike the path provided to `href` of the `<base>` tag, don't include a trailing slash (`/`) when passing the `--pathbase` argument value. If the app base path is provided in the `<base>` tag as `<base href="/CoolApp/">` (includes a trailing slash), pass the command-line argument value as `--pathbase=/CoolApp` (no trailing slash).

- Pass the argument when running the app locally at a command prompt. From the app's directory, execute:

```
dotnet run --pathbase=/relative-URL-path
```

- Add an entry to the app's `launchSettings.json` file in the **IIS Express** profile. This setting is used when running the app with the Visual Studio Debugger and from a command prompt with `dotnet run`.

```
"commandLineArgs": "--pathbase=/relative-URL-path"
```

- In Visual Studio, specify the argument in **Properties** > **Debug** > **Application arguments**. Setting the

argument in the Visual Studio property page adds the argument to the `launchSettings.json` file.

```
--pathbase=/relative-URL-path
```

URLs

The `--urls` argument sets the IP addresses or host addresses with ports and protocols to listen on for requests.

- Pass the argument when running the app locally at a command prompt. From the app's directory, execute:

  ```
  dotnet run --urls=http://127.0.0.1:0
  ```

- Add an entry to the app's `launchSettings.json` file in the **IIS Express** profile. This setting is used when running the app with the Visual Studio Debugger and from a command prompt with `dotnet run`.

  ```
  "commandLineArgs": "--urls=http://127.0.0.1:0"
  ```

- In Visual Studio, specify the argument in **Properties** > **Debug** > **Application arguments**. Setting the argument in the Visual Studio property page adds the argument to the `launchSettings.json` file.

  ```
  --urls=http://127.0.0.1:0
  ```

Configure the Trimmer

Blazor performs Intermediate Language (IL) trimming on each Release build to remove unnecessary IL from the output assemblies. For more information, see Configure the Trimmer for ASP.NET Core Blazor.

Configure the Linker

Blazor performs Intermediate Language (IL) linking on each Release build to remove unnecessary IL from the output assemblies. For more information, see Configure the Linker for ASP.NET Core Blazor.

Custom boot resource loading

A Blazor WebAssembly app can be initialized with the `loadBootResource` function to override the built-in boot resource loading mechanism. Use `loadBootResource` for the following scenarios:

- Allow users to load static resources, such as timezone data or `dotnet.wasm` from a CDN.
- Load compressed assemblies using an HTTP request and decompress them on the client for hosts that don't support fetching compressed contents from the server.
- Alias resources to a different name by redirecting each `fetch` request to a new name.

`loadBootResource` parameters appear in the following table.

PARAMETER	DESCRIPTION
`type`	The type of the resource. Permissable types: `assembly`, `pdb`, `dotnetjs`, `dotnetwasm`, `timezonedata`
`name`	The name of the resource.

PARAMETER	DESCRIPTION
`defaultUri`	The relative or absolute URI of the resource.
`integrity`	The integrity string representing the expected content in the response.

`loadBootResource` returns any of the following to override the loading process:

- URI string. In the following example (`wwwroot/index.html`), the following files are served from a CDN at `https://my-awesome-cdn.com/`:
  - `dotnet.*.js`
  - `dotnet.wasm`
  - Timezone data

  ```
  ...

  <script src="_framework/blazor.webassembly.js" autostart="false"></script>
  <script>
    Blazor.start({
      loadBootResource: function (type, name, defaultUri, integrity) {
        console.log(`Loading: '${type}', '${name}', '${defaultUri}', '${integrity}'`);
        switch (type) {
          case 'dotnetjs':
          case 'dotnetwasm':
          case 'timezonedata':
            return `https://my-awesome-cdn.com/blazorwebassembly/3.2.0/${name}`;
        }
      }
    });
  </script>
  ```

- `Promise<Response>`. Pass the `integrity` parameter in a header to retain the default integrity-checking behavior.

  The following example (`wwwroot/index.html`) adds a custom HTTP header to the outbound requests and passes the `integrity` parameter through to the `fetch` call:

  ```
  <script src="_framework/blazor.webassembly.js" autostart="false"></script>
  <script>
    Blazor.start({
      loadBootResource: function (type, name, defaultUri, integrity) {
        return fetch(defaultUri, {
          cache: 'no-cache',
          integrity: integrity,
          headers: { 'MyCustomHeader': 'My custom value' }
        });
      }
    });
  </script>
  ```

- `null` / `undefined`, which results in the default loading behavior.

External sources must return the required CORS headers for browsers to allow the cross-origin resource loading. CDNs usually provide the required headers by default.

You only need to specify types for custom behaviors. Types not specified to `loadBootResource` are loaded by the framework per their default loading behaviors.

Change the filename extension of DLL files

In case you have a need to change the filename extensions of the app's published `.dll` files, follow the guidance in this section.

After publishing the app, use a shell script or DevOps build pipeline to rename `.dll` files to use a different file extension. Target the `.dll` files in the `wwwroot` directory of the app's published output (for example, `{CONTENT ROOT}/bin/Release/netstandard2.1/publish/wwwroot`).

In the following examples, `.dll` files are renamed to use the `.bin` file extension.

On Windows:

```
dir .\_framework\_bin | rename-item -NewName { $_.name -replace ".dll\b",".bin" }
((Get-Content .\_framework\blazor.boot.json -Raw) -replace '.dll"','.bin"') | Set-Content
.\_framework\blazor.boot.json
```

If service worker assets are also in use, add the following command:

```
((Get-Content .\service-worker-assets.js -Raw) -replace '.dll"','.bin"') | Set-Content .\service-worker-
assets.js
```

On Linux or macOS:

```
for f in _framework/_bin/*; do mv "$f" "`echo $f | sed -e 's/\.dll\b/.bin/g'`"; done
sed -i 's/\.dll"/.bin"/g' _framework/blazor.boot.json
```

If service worker assets are also in use, add the following command:

```
sed -i 's/\.dll"/.bin"/g' service-worker-assets.js
```

To use a different file extension than `.bin`, replace `.bin` in the preceding commands.

To address the compressed `blazor.boot.json.gz` and `blazor.boot.json.br` files, adopt either of the following approaches:

- Remove the compressed `blazor.boot.json.gz` and `blazor.boot.json.br` files. Compression is disabled with this approach.
- Recompress the updated `blazor.boot.json` file.

The preceding guidance also applies when service worker assets are in use. Remove or recompress `wwwroot/service-worker-assets.js.br` and `wwwroot/service-worker-assets.js.gz`. Otherwise, file integrity checks fail in the browser.

The following Windows example uses a PowerShell script placed at the root of the project.

`ChangeDLLExtensions.ps1:`:

```
param([string]$filepath,[string]$tfm)
dir $filepath\bin\Release\$tfm\wwwroot\_framework\_bin | rename-item -NewName { $_.name -replace
".dll\b",".bin" }
((Get-Content $filepath\bin\Release\$tfm\wwwroot\_framework\blazor.boot.json -Raw) -replace '.dll"','.bin"') |
Set-Content $filepath\bin\Release\$tfm\wwwroot\_framework\blazor.boot.json
Remove-Item $filepath\bin\Release\$tfm\wwwroot\_framework\blazor.boot.json.gz
```

If service worker assets are also in use, add the following command:

```
((Get-Content $filepath\bin\Release\$tfm\wwwroot\service-worker-assets.js -Raw) -replace '.dll"','.bin"') |
Set-Content $filepath\bin\Release\$tfm\wwwroot\service-worker-assets.js
```

In the project file, the script is run after publishing the app:

```
<Target Name="ChangeDLLFileExtensions" AfterTargets="Publish" Condition="'$(Configuration)'=='Release'">
  <Exec Command="powershell.exe -command &amp;quot;&amp;amp; { .\ChangeDLLExtensions.ps1 '$(SolutionDir)'
'$(TargetFramework)'}&amp;quot;" />
</Target>
```

> **NOTE**
>
> When renaming and lazy loading the same assemblies, see the guidance in Lazy load assemblies in ASP.NET Core Blazor WebAssembly.

Host and deploy Blazor Server

9/22/2020 • 5 minutes to read • Edit Online

By Luke Latham, Rainer Stropek, and Daniel Roth

Host configuration values

Blazor Server apps can accept Generic Host configuration values.

Deployment

Using the Blazor Server hosting model, Blazor is executed on the server from within an ASP.NET Core app. UI updates, event handling, and JavaScript calls are handled over a SignalR connection.

A web server capable of hosting an ASP.NET Core app is required. Visual Studio includes the **Blazor Server App** project template (`blazorserverside` template when using the `dotnet new` command).

Scalability

Plan a deployment to make the best use of the available infrastructure for a Blazor Server app. See the following resources to address Blazor Server app scalability:

- Fundamentals of Blazor Server apps
- Threat mitigation guidance for ASP.NET Core Blazor Server

Deployment server

When considering the scalability of a single server (scale up), the memory available to an app is likely the first resource that the app will exhaust as user demands increase. The available memory on the server affects the:

- Number of active circuits that a server can support.
- UI latency on the client.

For guidance on building secure and scalable Blazor server apps, see Threat mitigation guidance for ASP.NET Core Blazor Server.

Each circuit uses approximately 250 KB of memory for a minimal *Hello World*-style app. The size of a circuit depends on the app's code and the state maintenance requirements associated with each component. We recommend that you measure resource demands during development for your app and infrastructure, but the following baseline can be a starting point in planning your deployment target: If you expect your app to support 5,000 concurrent users, consider budgeting at least 1.3 GB of server memory to the app (or ~273 KB per user).

SignalR configuration

Blazor Server apps use ASP.NET Core SignalR to communicate with the browser. SignalR's hosting and scaling conditions apply to Blazor Server apps.

Blazor works best when using WebSockets as the SignalR transport due to lower latency, reliability, and security. Long Polling is used by SignalR when WebSockets isn't available or when the app is explicitly configured to use Long Polling. When deploying to Azure App Service, configure the app to use WebSockets in the Azure portal settings for the service. For details on configuring the app for Azure App Service, see the SignalR publishing guidelines.

Azure SignalR Service

We recommend using the Azure SignalR Service for Blazor Server apps. The service allows for scaling up a Blazor Server app to a large number of concurrent SignalR connections. In addition, the SignalR service's global reach and high-performance data centers significantly aid in reducing latency due to geography.

> **IMPORTANT**
>
> When WebSockets are disabled, Azure App Service simulates a real-time connection using HTTP long-polling. HTTP long-polling is noticeably slower than running with WebSockets enabled, which doesn't use polling to simulate a client-server connection.
>
> We recommend using WebSockets for Blazor Server apps deployed to Azure App Service. The Azure SignalR Service uses WebSockets by default. If the app doesn't use the Azure SignalR Service, see Publish an ASP.NET Core SignalR app to Azure App Service.
>
> For more information, see:
>
> - What is Azure SignalR Service?
> - Performance guide for Azure SignalR Service

To configure an app (and optionally provision) the Azure SignalR Service:

1. Enable the service to support *sticky sessions*, where clients are redirected back to the same server when prerendering. Set the `ServerStickyMode` option or configuration value to `Required`. Typically, an app creates the configuration using **one** of the following approaches:

   - `Startup.ConfigureServices`:

     ```
     services.AddSignalR().AddAzureSignalR(options =>
     {
         options.ServerStickyMode =
             Microsoft.Azure.SignalR.ServerStickyMode.Required;
     });
     ```

   - Configuration (use **one** of the following approaches):

     - `appsettings.json`:

       ```
       "Azure:SignalR:ServerStickyMode": "Required"
       ```

     - The app service's **Configuration** > **Application settings** in the Azure portal (**Name**: `Azure:SignalR:ServerStickyMode`, **Value**: `Required`).

2. Create an Azure Apps publish profile in Visual Studio for the Blazor Server app.
3. Add the **Azure SignalR Service** dependency to the profile. If the Azure subscription doesn't have a pre-existing Azure SignalR Service instance to assign to the app, select **Create a new Azure SignalR Service instance** to provision a new service instance.
4. Publish the app to Azure.

IIS

When using IIS, enable:

- WebSockets on IIS.
- Sticky sessions with Application Request Routing.

Kubernetes

Create an ingress definition with the following Kubernetes annotations for sticky sessions:

```
apiVersion: extensions/v1beta1
kind: Ingress
metadata:
  name: <ingress-name>
  annotations:
    nginx.ingress.kubernetes.io/affinity: "cookie"
    nginx.ingress.kubernetes.io/session-cookie-name: "affinity"
    nginx.ingress.kubernetes.io/session-cookie-expires: "14400"
    nginx.ingress.kubernetes.io/session-cookie-max-age: "14400"
```

Linux with Nginx

For SignalR WebSockets to function properly, confirm that the proxy's `Upgrade` and `Connection` headers are set to the following values and that `$connection_upgrade` is mapped to either:

- The Upgrade header value by default.
- `close` when the Upgrade header is missing or empty.

```
http {
    map $http_upgrade $connection_upgrade {
        default Upgrade;
        ''      close;
    }

    server {
        listen      80;
        server_name example.com *.example.com
        location / {
            proxy_pass         http://localhost:5000;
            proxy_http_version 1.1;
            proxy_set_header   Upgrade $http_upgrade;
            proxy_set_header   Connection $connection_upgrade;
            proxy_set_header   Host $host;
            proxy_cache_bypass $http_upgrade;
            proxy_set_header   X-Forwarded-For $proxy_add_x_forwarded_for;
            proxy_set_header   X-Forwarded-Proto $scheme;
        }
    }
}
```

For more information, see the following articles:

- NGINX as a WebSocket Proxy
- WebSocket proxying
- Host ASP.NET Core on Linux with Nginx

Linux with Apache

To host a Blazor app behind Apache on Linux, configure `ProxyPass` for HTTP and WebSockets traffic.

In the following example:

- Kestrel server is running on the host machine.
- The app listens for traffic on port 5000.

```
ProxyRequests       On
ProxyPreserveHost   On
ProxyPassMatch      ^/_blazor/(.*) http://localhost:5000/_blazor/$1
ProxyPass           /_blazor ws://localhost:5000/_blazor
ProxyPass           / http://localhost:5000/
ProxyPassReverse    / http://localhost:5000/
```

Enable the following modules:

```
a2enmod   proxy
a2enmod   proxy_wstunnel
```

Check the browser console for WebSockets errors. Example errors:

- Firefox can't establish a connection to the server at ws://the-domain-name.tld/_blazor?id=XXX.
- Error: Failed to start the transport 'WebSockets': Error: There was an error with the transport.
- Error: Failed to start the transport 'LongPolling': TypeError: this.transport is undefined
- Error: Unable to connect to the server with any of the available transports. WebSockets failed
- Error: Cannot send data if the connection is not in the 'Connected' State.

For more information, see the Apache documentation.

Measure network latency

JS interop can be used to measure network latency, as the following example demonstrates:

```
@inject IJSRuntime JS

@if (latency is null)
{
    <span>Calculating...</span>
}
else
{
    <span>@(latency.Value.TotalMilliseconds)ms</span>
}

@code {
    private DateTime startTime;
    private TimeSpan? latency;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            startTime = DateTime.UtcNow;
            var _ = await JS.InvokeAsync<string>("toString");
            latency = DateTime.UtcNow - startTime;
            StateHasChanged();
        }
    }
}
```

For a reasonable UI experience, we recommend a sustained UI latency of 250ms or less.

Configure the Linker for ASP.NET Core Blazor

9/22/2020 • 2 minutes to read • Edit Online

By Luke Latham

Blazor WebAssembly performs Intermediate Language (IL) linking during a build to trim unnecessary IL from the app's output assemblies. The linker is disabled when building in Debug configuration. Apps must build in Release configuration to enable the linker. We recommend building in Release when deploying your Blazor WebAssembly apps.

Linking an app optimizes for size but may have detrimental effects. Apps that use reflection or related dynamic features may break when trimmed because the linker doesn't know about this dynamic behavior and can't determine in general which types are required for reflection at runtime. To trim such apps, the linker must be informed about any types required by reflection in the code and in packages or frameworks that the app depends on.

To ensure the trimmed app works correctly once deployed, it's important to test Release builds of the app frequently while developing.

Linking for Blazor apps can be configured using these MSBuild features:

- Configure linking globally with a MSBuild property.
- Control linking on a per-assembly basis with a configuration file.

Control linking with an MSBuild property

Linking is enabled when an app is built in `Release` configuration. To change this, configure the `BlazorWebAssemblyEnableLinking` MSBuild property in the project file:

```
<PropertyGroup>
  <BlazorWebAssemblyEnableLinking>false</BlazorWebAssemblyEnableLinking>
</PropertyGroup>
```

Control linking with a configuration file

Control linking on a per-assembly basis by providing an XML configuration file and specifying the file as a MSBuild item in the project file:

```
<ItemGroup>
  <BlazorLinkerDescriptor Include="LinkerConfig.xml" />
</ItemGroup>
```

`LinkerConfig.xml`:

```
<?xml version="1.0" encoding="UTF-8" ?>
<!--
  This file specifies which parts of the BCL or Blazor packages must not be
  stripped by the IL Linker even if they aren't referenced by user code.
-->
<linker>
  <assembly fullname="mscorlib">
    <!--
      Preserve the methods in WasmRuntime because its methods are called by
      JavaScript client-side code to implement timers.
      Fixes: https://github.com/dotnet/blazor/issues/239
    -->
    <type fullname="System.Threading.WasmRuntime" />
  </assembly>
  <assembly fullname="System.Core">
    <!--
      System.Linq.Expressions* is required by Json.NET and any
      expression.Compile caller. The assembly isn't stripped.
    -->
    <type fullname="System.Linq.Expressions*" />
  </assembly>
  <!--
    In this example, the app's entry point assembly is listed. The assembly
    isn't stripped by the IL Linker.
  -->
  <assembly fullname="MyCoolBlazorApp" />
</linker>
```

For more information and examples, see Data Formats (mono/linker GitHub repository).

Add an XML linker configuration file to a library

To configure the linker for a specific library, add an XML linker configuration file into the library as an embedded resource. The embedded resource must have the same name as the assembly.

In the following example, the `LinkerConfig.xml` file is specified as an embedded resource that has the same name as the library's assembly:

```
<ItemGroup>
  <EmbeddedResource Include="LinkerConfig.xml">
    <LogicalName>$(MSBuildProjectName).xml</LogicalName>
  </EmbeddedResource>
</ItemGroup>
```

Configure the linker for internationalization

By default, Blazor's linker configuration for Blazor WebAssembly apps strips out internationalization information except for locales explicitly requested. Removing these assemblies minimizes the app's size.

To control which I18N assemblies are retained, set the `<BlazorWebAssemblyI18NAssemblies>` MSBuild property in the project file:

```
<PropertyGroup>
  <BlazorWebAssemblyI18NAssemblies>{all|none|REGION1,REGION2,...}</BlazorWebAssemblyI18NAssemblies>
</PropertyGroup>
```

REGION VALUE	MONO REGION ASSEMBLY
`all`	All assemblies included

REGION VALUE	MONO REGION ASSEMBLY
`cjk`	`I18N.CJK.dll`
`mideast`	`I18N.MidEast.dll`
`none` (default)	None
`other`	`I18N.Other.dll`
`rare`	`I18N.Rare.dll`
`west`	`I18N.West.dll`

Use a comma to separate multiple values (for example, `mideast,west`).

For more information, see I18N: Pnetlib Internationalization Framework Library (mono/mono GitHub repository).

Configure the Trimmer for ASP.NET Core Blazor

9/22/2020 • 2 minutes to read • Edit Online

By Pranav Krishnamoorthy

Blazor WebAssembly performs Intermediate Language (IL) trimming to reduce the size of the published output.

Trimming an app optimizes for size but may have detrimental effects. Apps that use reflection or related dynamic features may break when trimmed because the trimmer doesn't know about dynamic behavior and can't determine in general which types are required for reflection at runtime. To trim such apps, the trimmer must be informed about any types required by reflection in the code and in packages or frameworks that the app depends on.

To ensure the trimmed app works correctly once deployed, it's important to test published output frequently while developing.

Trimming for .NET apps can be disabled by setting the `PublishTrimmed` MSBuild property to `false` in the app's project file:

```
<PropertyGroup>
  <PublishTrimmed>false</PublishTrimmed>
</PropertyGroup>
```

Additional options to configure the trimmer can be found at Trimming options.

ASP.NET Core Blazor Server with Entity Framework Core (EFCore)

9/22/2020 • 8 minutes to read • Edit Online

By: Jeremy Likness

Blazor Server is a stateful app framework. The app maintains an ongoing connection to the server, and the user's state is held in the server's memory in a *circuit*. One example of user state is data held in dependency injection (DI) service instances that are scoped to the circuit. The unique application model that Blazor Server provides requires a special approach to use Entity Framework Core.

> **NOTE**
> This article addresses EF Core in Blazor Server apps. Blazor WebAssembly apps run in a WebAssembly sandbox that prevents most direct database connections. Running EF Core in Blazor WebAssembly is beyond the scope of this article.

Sample app

The sample app was built as a reference for Blazor Server apps that use EF Core. The sample app includes a grid with sorting and filtering, delete, add, and update operations. The sample demonstrates use of EF Core to handle optimistic concurrency.

View or download sample code (how to download)

The sample uses a local SQLite database so that it can be used on any platform. The sample also configures database logging to show the SQL queries that are generated. This is configured in `appsettings.Development.json`:

```
{
  "DetailedErrors": true,
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information",
      "Microsoft.EntityFrameworkCore.Database.Command": "Information"
    }
  }
}
```

The grid, add, and view components use the "context-per-operation" pattern, where a context is created for each operation. The edit component uses the "context-per-component" pattern, where a context is created for each component.

> **NOTE**
> Some of the code examples in this topic require namespaces and services that aren't shown. To inspect the fully working code, including the required `@using` and `@inject` directives for Razor examples, see the sample app.

Database access

EF Core relies on a DbContext as the means to configure database access and act as a *unit of work*. EF Core provides the AddDbContext extension for ASP.NET Core apps that registers the context as a *scoped* service by default. In Blazor Server apps, scoped service registrations can be problematic because the instance is shared across components within the user's circuit. DbContext isn't thread safe and isn't designed for concurrent use. The existing lifetimes are inappropriate for these reasons:

- **Singleton** shares state across all users of the app and leads to inappropriate concurrent use.
- **Scoped** (the default) poses a similar issue between components for the same user.
- **Transient** results in a new instance per request; but as components can be long-lived, this results in a longer-lived context than may be intended.

The following recommendations are designed to provide a consistent approach to using EF Core in Blazor Server apps.

- By default, consider using one context per operation. The context is designed for fast, low overhead instantiation:

  ```
  var using context = new MyContext();

  return await context.MyEntities.ToListAsync();
  ```

- Use a flag to prevent multiple concurrent operations:

  ```
  if (Loading)
  {
      return;
  }

  try
  {
      Loading = true;

      ...
  }
  finally
  {
      Loading = false;
  }
  ```

  Place operations after the `Loading = true;` line in the `try` block.

- For longer-lived operations that take advantage of EF Core's change tracking or concurrency control, scope the context to the lifetime of the component.

New DbContext instances

The fastest way to create a new DbContext instance is by using `new` to create a new instance. However, there are several scenarios that may require resolving additional dependencies. For example, you may wish to use `DbContextOptions` to configure the context.

The recommended solution to create a new DbContext with dependencies is to use a factory. EF Core 5.0 or later provides a built-in factory for creating new contexts.

The following example configures SQLite and enables data logging. The code uses an extension method to configure the database factory for DI and provide default options:

```
services.AddDbContextFactory<ContactContext>(opt =>
    opt.UseSqlite($"Data Source={nameof(ContactContext.ContactsDb)}.db")
    .EnableSensitiveDataLogging());
```

The factory is injected into components and used to create new instances. For example, in `Pages/Index.razor`:

```
private async Task DeleteContactAsync()
{
    using var context = DbFactory.CreateDbContext();

    Filters.Loading = true;

    var contact = await context.Contacts.FirstAsync(
        c => c.Id == Wrapper.DeleteRequestId);

    if (contact != null)
    {
        context.Contacts.Remove(contact);
        await context.SaveChangesAsync();
    }

    Filters.Loading = false;

    await ReloadAsync();
}
```

NOTE

`Wrapper` is a component reference to the `GridWrapper` component. See the `Index` component (`Pages/Index.razor`) in the sample app.

Scope to the component lifetime

You may wish to create a DbContext that exists for the lifetime of a component. This allows you to use it as a unit of work and take advantage of built-in features, such as change tracking and concurrency resolution. You can use the factory to create a context and track it for the lifetime of the component. First, implement IDisposable and inject the factory as shown in `Pages/EditContact.razor`:

```
@implements IDisposable
@inject IDbContextFactory<ContactContext> DbFactory
```

The sample app ensures the context is disposed when the component is disposed:

```
public void Dispose()
{
    Context.Dispose();
}
```

Finally, `OnInitializedAsync` is overridden to create a new context. In the sample app, `OnInitializedAsync` loads the contact in the same method:

```
protected override async Task OnInitializedAsync()
{
    Busy = true;

    try
    {
        Context = DbFactory.CreateDbContext();
        Contact = await Context.Contacts
            .SingleOrDefaultAsync(c => c.Id == ContactId);
    }
    finally
    {
        Busy = false;
    }

    await base.OnInitializedAsync();
}
```

Blazor Server is a stateful app framework. The app maintains an ongoing connection to the server, and the user's state is held in the server's memory in a *circuit*. One example of user state is data held in dependency injection (DI) service instances that are scoped to the circuit. The unique application model that Blazor Server provides requires a special approach to use Entity Framework Core.

> **NOTE**
> This article addresses EF Core in Blazor Server apps. Blazor WebAssembly apps run in a WebAssembly sandbox that prevents most direct database connections. Running EF Core in Blazor WebAssembly is beyond the scope of this article.

Sample app

The sample app was built as a reference for Blazor Server apps that use EF Core. The sample app includes a grid with sorting and filtering, delete, add, and update operations. The sample demonstrates use of EF Core to handle optimistic concurrency.

View or download sample code (how to download)

The sample uses a local SQLite database so that it can be used on any platform. The sample also configures database logging to show the SQL queries that are generated. This is configured in `appsettings.Development.json`:

```
{
  "DetailedErrors": true,
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information",
      "Microsoft.EntityFrameworkCore.Database.Command": "Information"
    }
  }
}
```

The grid, add, and view components use the "context-per-operation" pattern, where a context is created for each operation. The edit component uses the "context-per-component" pattern, where a context is created for each component.

> **NOTE**
>
> Some of the code examples in this topic require namespaces and services that aren't shown. To inspect the fully working code, including the required `@using` and `@inject` directives for Razor examples, see the sample app.

Database access

EF Core relies on a DbContext as the means to configure database access and act as a *unit of work*. EF Core provides the AddDbContext extension for ASP.NET Core apps that registers the context as a *scoped* service by default. In Blazor Server apps, this can be problematic because the instance is shared across components within the user's circuit. DbContext isn't thread safe and isn't designed for concurrent use. The existing lifetimes are inappropriate for these reasons:

- **Singleton** shares state across all users of the app and leads to inappropriate concurrent use.
- **Scoped** (the default) poses a similar issue between components for the same user.
- **Transient** results in a new instance per request; but as components can be long-lived, this results in a longer-lived context than may be intended.

The following recommendations are designed to provide a consistent approach to using EF Core in Blazor Server apps.

- By default, consider using one context per operation. The context is designed for fast, low overhead instantiation:

  ```
  var using context = new MyContext();

  return await context.MyEntities.ToListAsync();
  ```

- Use a flag to prevent multiple concurrent operations:

  ```
  if (Loading)
  {
      return;
  }

  try
  {
      Loading = true;

      ...
  }
  finally
  {
      Loading = false;
  }
  ```

  Place operations after the `Loading = true;` line in the `try` block.

- For longer-lived operations that take advantage of EF Core's change tracking or concurrency control, scope the context to the lifetime of the component.

New DbContext instances

The fastest way to create a new DbContext instance is by using `new` to create a new instance. However, there are several scenarios that may require resolving additional dependencies. For example, you may wish to use `DbContextOptions` to configure the context.

The recommended solution to create a new DbContext with dependencies is to use a factory. The sample app implements its own factory in `Data/DbContextFactory.cs`.

```
using System;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;

namespace BlazorServerDbContextExample.Data
{
    public class DbContextFactory<TContext>
        : IDbContextFactory<TContext> where TContext : DbContext
    {
        private readonly IServiceProvider provider;

        public DbContextFactory(IServiceProvider provider)
        {
            this.provider = provider;
        }

        public TContext CreateDbContext()
        {
            if (provider == null)
            {
                throw new InvalidOperationException(
                    $"You must configure an instance of IServiceProvider");
            }

            return ActivatorUtilities.CreateInstance<TContext>(provider);
        }
    }
}
```

In the preceding factory, ActivatorUtilities.CreateInstance satisfies any dependencies via the service provider.

The following example configures SQLite and enables data logging. The code uses an extension method to configure the database factory for DI and provide default options:

```
services.AddDbContextFactory<ContactContext>(opt =>
    opt.UseSqlite($"Data Source={nameof(ContactContext.ContactsDb)}.db")
    .EnableSensitiveDataLogging());
```

The factory is injected into components and used to create new instances. For example, in `Pages/Index.razor`:

```
private async Task DeleteContactAsync()
{
    using var context = DbFactory.CreateDbContext();

    Filters.Loading = true;

    var contact = await context.Contacts.FirstAsync(
        c => c.Id == Wrapper.DeleteRequestId);

    if (contact != null)
    {
        context.Contacts.Remove(contact);
        await context.SaveChangesAsync();
    }

    Filters.Loading = false;

    await ReloadAsync();
}
```

> **NOTE**
>
> `Wrapper` is a component reference to the `GridWrapper` component. See the `Index` component (`Pages/Index.razor`) in the sample app.

Scope to the component lifetime

You may wish to create a DbContext that exists for the lifetime of a component. This allows you to use it as a unit of work and take advantage of built-in features, such as change tracking and concurrency resolution. You can use the factory to create a context and track it for the lifetime of the component. First, implement IDisposable and inject the factory as shown in `Pages/EditContact.razor`:

```
@implements IDisposable
@inject IDbContextFactory<ContactContext> DbFactory
```

The sample app ensures the context is disposed when the component is disposed:

```
public void Dispose()
{
    Context.Dispose();
}
```

Finally, `OnInitializedAsync` is overridden to create a new context. In the sample app, `OnInitializedAsync` loads the contact in the same method:

```
protected override async Task OnInitializedAsync()
{
    Busy = true;

    try
    {
        Context = DbFactory.CreateDbContext();
        Contact = await Context.Contacts
            .SingleOrDefaultAsync(c => c.Id == ContactId);
    }
    finally
    {
        Busy = false;
    }

    await base.OnInitializedAsync();
}
```

In the preceding example:

- When `Busy` is set to `true`, asynchronous operations may begin. When `Busy` is set back to `false`, asynchronous operations should be finished.
- Place additional error handling logic in a `catch` block.

ASP.NET Core Blazor advanced scenarios

9/22/2020 • 10 minutes to read • Edit Online

By Luke Latham and Daniel Roth

Blazor Server circuit handler

Blazor Server allows code to define a *circuit handler*, which allows running code on changes to the state of a user's circuit. A circuit handler is implemented by deriving from `CircuitHandler` and registering the class in the app's service container. The following example of a circuit handler tracks open SignalR connections:

```
using System.Collections.Generic;
using System.Threading;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Components.Server.Circuits;

public class TrackingCircuitHandler : CircuitHandler
{
    private HashSet<Circuit> circuits = new HashSet<Circuit>();

    public override Task OnConnectionUpAsync(Circuit circuit,
        CancellationToken cancellationToken)
    {
        circuits.Add(circuit);

        return Task.CompletedTask;
    }

    public override Task OnConnectionDownAsync(Circuit circuit,
        CancellationToken cancellationToken)
    {
        circuits.Remove(circuit);

        return Task.CompletedTask;
    }

    public int ConnectedCircuits => circuits.Count;
}
```

Circuit handlers are registered using DI. Scoped instances are created per instance of a circuit. Using the `TrackingCircuitHandler` in the preceding example, a singleton service is created because the state of all circuits must be tracked:

```
public void ConfigureServices(IServiceCollection services)
{
    ...
    services.AddSingleton<CircuitHandler, TrackingCircuitHandler>();
}
```

If a custom circuit handler's methods throw an unhandled exception, the exception is fatal to the Blazor Server circuit. To tolerate exceptions in a handler's code or called methods, wrap the code in one or more `try-catch` statements with error handling and logging.

When a circuit ends because a user has disconnected and the framework is cleaning up the circuit state, the framework disposes of the circuit's DI scope. Disposing the scope disposes any circuit-scoped DI services that

implement System.IDisposable. If any DI service throws an unhandled exception during disposal, the framework logs the exception.

Manual RenderTreeBuilder logic

RenderTreeBuilder provides methods for manipulating components and elements, including building components manually in C# code.

> **NOTE**
> Use of RenderTreeBuilder to create components is an advanced scenario. A malformed component (for example, an unclosed markup tag) can result in undefined behavior.

Consider the following `PetDetails` component, which can be manually built into another component:

```
<h2>Pet Details Component</h2>

<p>@PetDetailsQuote</p>

@code
{
    [Parameter]
    public string PetDetailsQuote { get; set; }
}
```

In the following example, the loop in the `CreateComponent` method generates three `PetDetails` components. In RenderTreeBuilder methods with a sequence number, sequence numbers are source code line numbers. The Blazor difference algorithm relies on the sequence numbers corresponding to distinct lines of code, not distinct call invocations. When creating a component with RenderTreeBuilder methods, hardcode the arguments for sequence numbers. **Using a calculation or counter to generate the sequence number can lead to poor performance.** For more information, see the Sequence numbers relate to code line numbers and not execution order section.

`BuiltContent` component:

```
@page "/BuiltContent"

<h1>Build a component</h1>

@CustomRender

<button type="button" @onclick="RenderComponent">
    Create three Pet Details components
</button>

@code {
    private RenderFragment CustomRender { get; set; }

    private RenderFragment CreateComponent() => builder =>
    {
        for (var i = 0; i < 3; i++)
        {
            builder.OpenComponent(0, typeof(PetDetails));
            builder.AddAttribute(1, "PetDetailsQuote", "Someone's best friend!");
            builder.CloseComponent();
        }
    };

    private void RenderComponent()
    {
        CustomRender = CreateComponent();
    }
}
```

WARNING

The types in Microsoft.AspNetCore.Components.RenderTree allow processing of the *results* of rendering operations. These are internal details of the Blazor framework implementation. These types should be considered *unstable* and subject to change in future releases.

Sequence numbers relate to code line numbers and not execution order

Razor component files (`.razor`) are always compiled. Compilation is a potential advantage over interpreting code because the compile step can be used to inject information that improves app performance at runtime.

A key example of these improvements involves *sequence numbers*. Sequence numbers indicate to the runtime which outputs came from which distinct and ordered lines of code. The runtime uses this information to generate efficient tree diffs in linear time, which is far faster than is normally possible for a general tree diff algorithm.

Consider the following Razor component (`.razor`) file:

```
@if (someFlag)
{
    <text>First</text>
}

Second
```

The preceding code compiles to something like the following:

```
if (someFlag)
{
    builder.AddContent(0, "First");
}

builder.AddContent(1, "Second");
```

When the code executes for the first time, if `someFlag` is `true`, the builder receives:

SEQUENCE	TYPE	DATA
0	Text node	First
1	Text node	Second

Imagine that `someFlag` becomes `false`, and the markup is rendered again. This time, the builder receives:

SEQUENCE	TYPE	DATA
1	Text node	Second

When the runtime performs a diff, it sees that the item at sequence `0` was removed, so it generates the following trivial *edit script*:

- Remove the first text node.

The problem with generating sequence numbers programmatically

Imagine instead that you wrote the following render tree builder logic:

```
var seq = 0;

if (someFlag)
{
    builder.AddContent(seq++, "First");
}

builder.AddContent(seq++, "Second");
```

Now, the first output is:

SEQUENCE	TYPE	DATA
0	Text node	First
1	Text node	Second

This outcome is identical to the prior case, so no negative issues exist. `someFlag` is `false` on the second rendering, and the output is:

SEQUENCE	TYPE	DATA
0	Text node	Second

This time, the diff algorithm sees that *two* changes have occurred, and the algorithm generates the following edit script:

- Change the value of the first text node to `Second`.
- Remove the second text node.

Generating the sequence numbers has lost all the useful information about where the `if/else` branches and loops were present in the original code. This results in a diff **twice as long** as before.

This is a trivial example. In more realistic cases with complex and deeply nested structures, and especially with loops, the performance cost is usually higher. Instead of immediately identifying which loop blocks or branches have been inserted or removed, the diff algorithm has to recurse deeply into the render trees. This usually results in having to build longer edit scripts because the diff algorithm is misinformed about how the old and new structures relate to each other.

Guidance and conclusions

- App performance suffers if sequence numbers are generated dynamically.
- The framework can't create its own sequence numbers automatically at runtime because the necessary information doesn't exist unless it's captured at compile time.
- Don't write long blocks of manually-implemented RenderTreeBuilder logic. Prefer `.razor` files and allow the compiler to deal with the sequence numbers. If you're unable to avoid manual RenderTreeBuilder logic, split long blocks of code into smaller pieces wrapped in OpenRegion/CloseRegion calls. Each region has its own separate space of sequence numbers, so you can restart from zero (or any other arbitrary number) inside each region.
- If sequence numbers are hardcoded, the diff algorithm only requires that sequence numbers increase in value. The initial value and gaps are irrelevant. One legitimate option is to use the code line number as the sequence number, or start from zero and increase by ones or hundreds (or any preferred interval).
- Blazor uses sequence numbers, while other tree-diffing UI frameworks don't use them. Diffing is far faster when sequence numbers are used, and Blazor has the advantage of a compile step that deals with sequence numbers automatically for developers authoring `.razor` files.

Perform large data transfers in Blazor Server apps

In some scenarios, large amounts of data must be transferred between JavaScript and Blazor. Typically, large data transfers occur when:

- Browser file system APIs are used to upload or download a file.
- Interop with a third party library is required.

In Blazor Server, a limitation is in place to prevent passing single large messages that may result in performance issues.

Consider the following guidance when developing code that transfers data between JavaScript and Blazor:

- Slice the data into smaller pieces, and send the data segments sequentially until all of the data is received by the server.
- Don't allocate large objects in JavaScript and C# code.
- Don't block the main UI thread for long periods when sending or receiving data.
- Free any memory consumed when the process is completed or cancelled.
- Enforce the following additional requirements for security purposes:
  - Declare the maximum file or data size that can be passed.
  - Declare the minimum upload rate from the client to the server.
- After the data is received by the server, the data can be:
  - Temporarily stored in a memory buffer until all of the segments are collected.
  - Consumed immediately. For example, the data can be stored immediately in a database or written to disk as each segment is received.

The following file uploader class handles JS interop with the client. The uploader class uses JS interop to:

- Poll the client to send a data segment.
- Abort the transaction if polling times out.

```
using System;
using System.Buffers;
using System.Collections.Generic;
using System.IO;
using System.Threading.Tasks;
using Microsoft.JSInterop;

public class FileUploader : IDisposable
{
    private readonly IJSRuntime jsRuntime;
    private readonly int segmentSize = 6144;
    private readonly int maxBase64SegmentSize = 8192;
    private readonly DotNetObjectReference<FileUploader> thisReference;
    private List<IMemoryOwner<byte>> uploadedSegments =
        new List<IMemoryOwner<byte>>();

    public FileUploader(IJSRuntime jsRuntime)
    {
        this.jsRuntime = jsRuntime;
    }

    public async Task<Stream> ReceiveFile(string selector, int maxSize)
    {
        var fileSize =
            await jsRuntime.InvokeAsync<int>("getFileSize", selector);

        if (fileSize > maxSize)
        {
            return null;
        }

        var numberOfSegments = Math.Floor(fileSize / (double)segmentSize) + 1;
        var lastSegmentBytes = 0;
        string base64EncodedSegment;

        for (var i = 0; i < numberOfSegments; i++)
        {
            try
            {
                base64EncodedSegment =
                    await jsRuntime.InvokeAsync<string>(
                        "receiveSegment", i, selector);

                if (base64EncodedSegment.Length < maxBase64SegmentSize &&
                    i < numberOfSegments - 1)
                {
                    return null;
                }
            }
            catch
            {
                return null;
            }

          var current = MemoryPool<byte>.Shared.Rent(segmentSize);

          if (!Convert.TryFromBase64String(base64EncodedSegment,
              current.Memory.Slice(0, segmentSize).Span, out lastSegmentBytes))
          {
              return null;
          }
```

```
            uploadedSegments.Add(current);
        }

        var segments = uploadedSegments;
        uploadedSegments = null;

        return new SegmentedStream(segments, segmentSize, lastSegmentBytes);
    }

    public void Dispose()
    {
        if (uploadedSegments != null)
        {
            foreach (var segment in uploadedSegments)
            {
                segment.Dispose();
            }
        }
    }
}
```

In the preceding example:

- The `maxBase64SegmentSize` is set to `8192`, which is calculated from `maxBase64SegmentSize = segmentSize * 4 / 3`.
- Low-level .NET Core memory management APIs are used to store the memory segments on the server in `uploadedSegments`.
- A `ReceiveFile` method is used to handle the upload through JS interop:
  - The file size is determined in bytes through JS interop with `jsRuntime.InvokeAsync<FileInfo>('getFileSize', selector)`.
  - The number of segments to receive are calculated and stored in `numberOfSegments`.
  - The segments are requested in a `for` loop through JS interop with `jsRuntime.InvokeAsync<string>('receiveSegment', i, selector)`. All segments but the last must be 8,192 bytes before decoding. The client is forced to send the data in an efficient manner.
  - For each segment received, checks are performed before decoding with TryFromBase64String.
  - A stream with the data is returned as a new Stream (`SegmentedStream`) after the upload is complete.

The segmented stream class exposes the list of segments as a readonly non-seekable Stream:

```
using System;
using System.Buffers;
using System.Collections.Generic;
using System.IO;

public class SegmentedStream : Stream
{
    private readonly ReadOnlySequence<byte> sequence;
    private long currentPosition = 0;

    public SegmentedStream(IList<IMemoryOwner<byte>> segments, int segmentSize,
        int lastSegmentSize)
    {
        if (segments.Count == 1)
        {
            sequence = new ReadOnlySequence<byte>(
                segments[0].Memory.Slice(0, lastSegmentSize));
            return;
        }

        var sequenceSegment = new BufferSegment<byte>(
            segments[0].Memory.Slice(0, segmentSize));
        var lastSegment = sequenceSegment;
```

```
        for (int i = 1; i < segments.Count; i++)
        {
            var isLastSegment = i + 1 == segments.Count;
            lastSegment = lastSegment.Append(segments[i].Memory.Slice(
                0, isLastSegment ? lastSegmentSize : segmentSize));
        }

        sequence = new ReadOnlySequence<byte>(
            sequenceSegment, 0, lastSegment, lastSegmentSize);
    }

    public override long Position
    {
        get => throw new NotImplementedException();
        set => throw new NotImplementedException();
    }

    public override int Read(byte[] buffer, int offset, int count)
    {
        var bytesToWrite = (int)(currentPosition + count < sequence.Length ?
            count : sequence.Length - currentPosition);
        var data = sequence.Slice(currentPosition, bytesToWrite);
        data.CopyTo(buffer.AsSpan(offset, bytesToWrite));
        currentPosition += bytesToWrite;

        return bytesToWrite;
    }

    private class BufferSegment<T> : ReadOnlySequenceSegment<T>
    {
        public BufferSegment(ReadOnlyMemory<T> memory)
        {
            Memory = memory;
        }

        public BufferSegment<T> Append(ReadOnlyMemory<T> memory)
        {
            var segment = new BufferSegment<T>(memory)
            {
                RunningIndex = RunningIndex + Memory.Length
            };

            Next = segment;

            return segment;
        }
    }

    public override bool CanRead => true;

    public override bool CanSeek => false;

    public override bool CanWrite => false;

    public override long Length => throw new NotImplementedException();

    public override void Flush() => throw new NotImplementedException();

    public override long Seek(long offset, SeekOrigin origin) =>
        throw new NotImplementedException();

    public override void SetLength(long value) =>
        throw new NotImplementedException();

    public override void Write(byte[] buffer, int offset, int count) =>
        throw new NotImplementedException();
}
```

The following code implements JavaScript functions to receive the data:

```
function getFileSize(selector) {
  const file = getFile(selector);
  return file.size;
}

async function receiveSegment(segmentNumber, selector) {
  const file = getFile(selector);
  var segments = getFileSegments(file);
  var index = segmentNumber * 6144;
  return await getNextChunk(file, index);
}

function getFile(selector) {
  const element = document.querySelector(selector);
  if (!element) {
    throw new Error('Invalid selector');
  }
  const files = element.files;
  if (!files || files.length === 0) {
    throw new Error(`Element ${elementId} doesn't contain any files.`);
  }
  const file = files[0];
  return file;
}

function getFileSegments(file) {
  const segments = Math.floor(size % 6144 === 0 ? size / 6144 : 1 + size / 6144);
  return segments;
}

async function getNextChunk(file, index) {
  const length = file.size - index <= 6144 ? file.size - index : 6144;
  const chunk = file.slice(index, index + length);
  index += length;
  const base64Chunk = await this.base64EncodeAsync(chunk);
  return { base64Chunk, index };
}

async function base64EncodeAsync(chunk) {
  const reader = new FileReader();
  const result = new Promise((resolve, reject) => {
    reader.addEventListener('load',
      () => {
        const base64Chunk = reader.result;
        const cleanChunk =
          base64Chunk.replace('data:application/octet-stream;base64,', '');
        resolve(cleanChunk);
      },
      false);
    reader.addEventListener('error', reject);
  });
  reader.readAsDataURL(chunk);
  return result;
}
```

Use the Angular project template with ASP.NET Core

9/22/2020 • 6 minutes to read • Edit Online

The updated Angular project template provides a convenient starting point for ASP.NET Core apps using Angular and the Angular CLI to implement a rich, client-side user interface (UI).

The template is equivalent to creating an ASP.NET Core project to act as an API backend and an Angular CLI project to act as a UI. The template offers the convenience of hosting both project types in a single app project. Consequently, the app project can be built and published as a single unit.

Create a new app

If you have ASP.NET Core 2.1 installed, there's no need to install the Angular project template.

Create a new project from a command prompt using the command `dotnet new angular` in an empty directory. For example, the following commands create the app in a *my-new-app* directory and switch to that directory:

```
dotnet new angular -o my-new-app
cd my-new-app
```

Run the app from either Visual Studio or the .NET Core CLI:

- Visual Studio
- .NET Core CLI

Open the generated *.csproj* file, and run the app as normal from there.

The build process restores npm dependencies on the first run, which can take several minutes. Subsequent builds are much faster.

The project template creates an ASP.NET Core app and an Angular app. The ASP.NET Core app is intended to be used for data access, authorization, and other server-side concerns. The Angular app, residing in the *ClientApp* subdirectory, is intended to be used for all UI concerns.

Add pages, images, styles, modules, etc.

The *ClientApp* directory contains a standard Angular CLI app. See the official Angular documentation for more information.

There are slight differences between the Angular app created by this template and the one created by Angular CLI itself (via `ng new`); however, the app's capabilities are unchanged. The app created by the template contains a Bootstrap-based layout and a basic routing example.

Run ng commands

In a command prompt, switch to the *ClientApp* subdirectory:

```
cd ClientApp
```

If you have the `ng` tool installed globally, you can run any of its commands. For example, you can run `ng lint`, `ng test`, or any of the other Angular CLI commands. There's no need to run `ng serve` though, because your

ASP.NET Core app deals with serving both server-side and client-side parts of your app. Internally, it uses `ng serve` in development.

If you don't have the `ng` tool installed, run `npm run ng` instead. For example, you can run `npm run ng lint` or `npm run ng test`.

Install npm packages

To install third-party npm packages, use a command prompt in the *ClientApp* subdirectory. For example:

```
cd ClientApp
npm install --save <package_name>
```

Publish and deploy

In development, the app runs in a mode optimized for developer convenience. For example, JavaScript bundles include source maps (so that when debugging, you can see your original TypeScript code). The app watches for TypeScript, HTML, and CSS file changes on disk and automatically recompiles and reloads when it sees those files change.

In production, serve a version of your app that's optimized for performance. This is configured to happen automatically. When you publish, the build configuration emits a minified, ahead-of-time (AoT) compiled build of your client-side code. Unlike the development build, the production build doesn't require Node.js to be installed on the server (unless you have enabled server-side rendering (SSR)).

You can use standard ASP.NET Core hosting and deployment methods.

Run "ng serve" independently

The project is configured to start its own instance of the Angular CLI server in the background when the ASP.NET Core app starts in development mode. This is convenient because you don't have to run a separate server manually.

There's a drawback to this default setup. Each time you modify your C# code and your ASP.NET Core app needs to restart, the Angular CLI server restarts. Around 10 seconds is required to start back up. If you're making frequent C# code edits and don't want to wait for Angular CLI to restart, run the Angular CLI server externally, independently of the ASP.NET Core process. To do so:

1. In a command prompt, switch to the *ClientApp* subdirectory, and launch the Angular CLI development server:

   ```
   cd ClientApp
   npm start
   ```

   IMPORTANT

   Use `npm start` to launch the Angular CLI development server, not `ng serve`, so that the configuration in *package.json* is respected. To pass additional parameters to the Angular CLI server, add them to the relevant `scripts` line in your *package.json* file.

2. Modify your ASP.NET Core app to use the external Angular CLI instance instead of launching one of its own. In your *Startup* class, replace the `spa.UseAngularCliServer` invocation with the following:

```
spa.UseProxyToSpaDevelopmentServer("http://localhost:4200");
```

When you start your ASP.NET Core app, it won't launch an Angular CLI server. The instance you started manually is used instead. This enables it to start and restart faster. It's no longer waiting for Angular CLI to rebuild your client app each time.

Pass data from .NET code into TypeScript code

During SSR, you might want to pass per-request data from your ASP.NET Core app into your Angular app. For example, you could pass cookie information or something read from a database. To do this, edit your *Startup* class. In the callback for `UseSpaPrerendering`, set a value for `options.SupplyData` such as the following:

```
options.SupplyData = (context, data) =>
{
    // Creates a new value called isHttpsRequest that's passed to TypeScript code
    data["isHttpsRequest"] = context.Request.IsHttps;
};
```

The `SupplyData` callback lets you pass arbitrary, per-request, JSON-serializable data (for example, strings, booleans, or numbers). Your *main.server.ts* code receives this as `params.data`. For example, the preceding code sample passes a boolean value as `params.data.isHttpsRequest` into the `createServerRenderer` callback. You can pass this to other parts of your app in any way supported by Angular. For example, see how *main.server.ts* passes the `BASE_URL` value to any component whose constructor is declared to receive it.

Drawbacks of SSR

Not all apps benefit from SSR. The primary benefit is perceived performance. Visitors reaching your app over a slow network connection or on slow mobile devices see the initial UI quickly, even if it takes a while to fetch or parse the JavaScript bundles. However, many SPAs are mainly used over fast, internal company networks on fast computers where the app appears almost instantly.

At the same time, there are significant drawbacks to enabling SSR. It adds complexity to your development process. Your code must run in two different environments: client-side and server-side (in a Node.js environment invoked from ASP.NET Core). Here are some things to bear in mind:

- SSR requires a Node.js installation on your production servers. This is automatically the case for some deployment scenarios, such as Azure App Services, but not for others, such as Azure Service Fabric.
- Enabling the `BuildServerSideRenderer` build flag causes your *node_modules* directory to publish. This folder contains 20,000+ files, which increases deployment time.
- To run your code in a Node.js environment, it can't rely on the existence of browser-specific JavaScript APIs such as `window` or `localStorage`. If your code (or some third-party library you reference) tries to use these APIs, you'll get an error during SSR. For example, don't use jQuery because it references browser-specific APIs in many places. To prevent errors, you must either avoid SSR or avoid browser-specific APIs or libraries. You can wrap any calls to such APIs in checks to ensure they aren't invoked during SSR. For example, use a check such as the following in JavaScript or TypeScript code:

  ```
  if (typeof window !== 'undefined') {
      // Call browser-specific APIs here
  }
  ```

Use the React project template with ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

The updated React project template provides a convenient starting point for ASP.NET Core apps using React and create-react-app (CRA) conventions to implement a rich, client-side user interface (UI).

The template is equivalent to creating both an ASP.NET Core project to act as an API backend, and a standard CRA React project to act as a UI, but with the convenience of hosting both in a single app project that can be built and published as a single unit.

The React project template isn't meant for server-side rendering (SSR). For SSR with React and Node.js, consider Next.js or Razzle.

Create a new app

If you have ASP.NET Core 2.1 installed, there's no need to install the React project template.

Create a new project from a command prompt using the command `dotnet new react` in an empty directory. For example, the following commands create the app in a *my-new-app* directory and switch to that directory:

```
dotnet new react -o my-new-app
cd my-new-app
```

Run the app from either Visual Studio or the .NET Core CLI:

- Visual Studio
- .NET Core CLI

Open the generated *.csproj* file, and run the app as normal from there.

The build process restores npm dependencies on the first run, which can take several minutes. Subsequent builds are much faster.

The project template creates an ASP.NET Core app and a React app. The ASP.NET Core app is intended to be used for data access, authorization, and other server-side concerns. The React app, residing in the *ClientApp* subdirectory, is intended to be used for all UI concerns.

Add pages, images, styles, modules, etc.

The *ClientApp* directory is a standard CRA React app. See the official CRA documentation for more information.

There are slight differences between the React app created by this template and the one created by CRA itself; however, the app's capabilities are unchanged. The app created by the template contains a Bootstrap-based layout and a basic routing example.

Install npm packages

To install third-party npm packages, use a command prompt in the *ClientApp* subdirectory. For example:

```
cd ClientApp
npm install --save <package_name>
```

Publish and deploy

In development, the app runs in a mode optimized for developer convenience. For example, JavaScript bundles include source maps (so that when debugging, you can see your original source code). The app watches JavaScript, HTML, and CSS file changes on disk and automatically recompiles and reloads when it sees those files change.

In production, serve a version of your app that's optimized for performance. This is configured to happen automatically. When you publish, the build configuration emits a minified, transpiled build of your client-side code. Unlike the development build, the production build doesn't require Node.js to be installed on the server.

You can use standard ASP.NET Core hosting and deployment methods.

Run the CRA server independently

The project is configured to start its own instance of the CRA development server in the background when the ASP.NET Core app starts in development mode. This is convenient because it means you don't have to run a separate server manually.

There's a drawback to this default setup. Each time you modify your C# code and your ASP.NET Core app needs to restart, the CRA server restarts. A few seconds are required to start back up. If you're making frequent C# code edits and don't want to wait for the CRA server to restart, run the CRA server externally, independently of the ASP.NET Core process. To do so:

1. Add a *.env* file to the *ClientApp* subdirectory with the following setting:

   ```
   BROWSER=none
   ```

   This will prevent your web browser from opening when starting the CRA server externally.

2. In a command prompt, switch to the *ClientApp* subdirectory, and launch the CRA development server:

   ```
   cd ClientApp
   npm start
   ```

3. Modify your ASP.NET Core app to use the external CRA server instance instead of launching one of its own. In your *Startup* class, replace the `spa.UseReactDevelopmentServer` invocation with the following:

   ```
   spa.UseProxyToSpaDevelopmentServer("http://localhost:3000");
   ```

When you start your ASP.NET Core app, it won't launch a CRA server. The instance you started manually is used instead. This enables it to start and restart faster. It's no longer waiting for your React app to rebuild each time.

> **IMPORTANT**
> "Server-side rendering" is not a supported feature of this template. Our goal with this template is to meet parity with "create-react-app". As such, scenarios and features not included in a "create-react-app" project (such as SSR) are not supported and are left as an exercise for the user.

Use the React-with-Redux project template with ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

The updated React-with-Redux project template provides a convenient starting point for ASP.NET Core apps using React, Redux, and create-react-app (CRA) conventions to implement a rich, client-side user interface (UI).

With the exception of the project creation command, all information about the React-with-Redux template is the same as the React template. To create this project type, run `dotnet new reactredux` instead of `dotnet new react`. For more information about the functionality common to both React-based templates, see React template documentation.

For information on configuring a React-with-Redux sub-application in IIS, see ReactRedux Template 2.1: Unable to use SPA on IIS (aspnet/Templating #555).

Use JavaScript Services to Create Single Page Applications in ASP.NET Core

9/22/2020 • 11 minutes to read • Edit Online

By Scott Addie and Fiyaz Hasan

A Single Page Application (SPA) is a popular type of web application due to its inherent rich user experience. Integrating client-side SPA frameworks or libraries, such as Angular or React, with server-side frameworks such as ASP.NET Core can be difficult. JavaScript Services was developed to reduce friction in the integration process. It enables seamless operation between the different client and server technology stacks.

> **WARNING**
> The features described in this article are obsolete as of ASP.NET Core 3.0. A simpler SPA frameworks integration mechanism is available in the Microsoft.AspNetCore.SpaServices.Extensions NuGet package. For more information, see [Announcement] Obsoleting Microsoft.AspNetCore.SpaServices and Microsoft.AspNetCore.NodeServices.

What is JavaScript Services

JavaScript Services is a collection of client-side technologies for ASP.NET Core. Its goal is to position ASP.NET Core as developers' preferred server-side platform for building SPAs.

JavaScript Services consists of two distinct NuGet packages:

- Microsoft.AspNetCore.NodeServices (NodeServices)
- Microsoft.AspNetCore.SpaServices (SpaServices)

These packages are useful in the following scenarios:

- Run JavaScript on the server
- Use a SPA framework or library
- Build client-side assets with Webpack

Much of the focus in this article is placed on using the SpaServices package.

What is SpaServices

SpaServices was created to position ASP.NET Core as developers' preferred server-side platform for building SPAs. SpaServices isn't required to develop SPAs with ASP.NET Core, and it doesn't lock developers into a particular client framework.

SpaServices provides useful infrastructure such as:

- Server-side prerendering
- Webpack Dev Middleware
- Hot Module Replacement
- Routing helpers

Collectively, these infrastructure components enhance both the development workflow and the runtime experience. The components can be adopted individually.

Prerequisites for using SpaServices

To work with SpaServices, install the following:

- Node.js (version 6 or later) with npm
  - To verify these components are installed and can be found, run the following from the command line:

    ```
    node -v && npm -v
    ```

  - If deploying to an Azure web site, no action is required—Node.js is installed and available in the server environments.
- .NET Core SDK 2.0 or later
  - On Windows using Visual Studio 2017, the SDK is installed by selecting the **.NET Core cross-platform development** workload.
- Microsoft.AspNetCore.SpaServices NuGet package

Server-side prerendering

A universal (also known as isomorphic) application is a JavaScript application capable of running both on the server and the client. Angular, React, and other popular frameworks provide a universal platform for this application development style. The idea is to first render the framework components on the server via Node.js, and then delegate further execution to the client.

ASP.NET Core Tag Helpers provided by SpaServices simplify the implementation of server-side prerendering by invoking the JavaScript functions on the server.

Server-side prerendering prerequisites

Install the aspnet-prerendering npm package:

```
npm i -S aspnet-prerendering
```

Server-side prerendering configuration

The Tag Helpers are made discoverable via namespace registration in the project's *_ViewImports.cshtml* file:

```
@using SpaServicesSampleApp
@addTagHelper "*, Microsoft.AspNetCore.Mvc.TagHelpers"
@addTagHelper "*, Microsoft.AspNetCore.SpaServices"
```

These Tag Helpers abstract away the intricacies of communicating directly with low-level APIs by leveraging an HTML-like syntax inside the Razor view:

```
<app asp-prerender-module="ClientApp/dist/main-server">Loading...</app>
```

asp-prerender-module Tag Helper

The `asp-prerender-module` Tag Helper, used in the preceding code example, executes *ClientApp/dist/main-server.js* on the server via Node.js. For clarity's sake, *main-server.js* file is an artifact of the TypeScript-to-JavaScript transpilation task in the Webpack build process. Webpack defines an entry point alias of `main-server`; and, traversal of the dependency graph for this alias begins at the *ClientApp/boot-server.ts* file:

```
entry: { 'main-server': './ClientApp/boot-server.ts' },
```

In the following Angular example, the *ClientApp/boot-server.ts* file utilizes the `createServerRenderer` function and `RenderResult` type of the `aspnet-prerendering` npm package to configure server rendering via Node.js. The HTML markup destined for server-side rendering is passed to a resolve function call, which is wrapped in a strongly-typed JavaScript `Promise` object. The `Promise` object's significance is that it asynchronously supplies the HTML markup to the page for injection in the DOM's placeholder element.

```
import { createServerRenderer, RenderResult } from 'aspnet-prerendering';

export default createServerRenderer(params => {
    const providers = [
        { provide: INITIAL_CONFIG, useValue: { document: '<app></app>', url: params.url } },
        { provide: 'ORIGIN_URL', useValue: params.origin }
    ];

    return platformDynamicServer(providers).bootstrapModule(AppModule).then(moduleRef => {
        const appRef = moduleRef.injector.get(ApplicationRef);
        const state = moduleRef.injector.get(PlatformState);
        const zone = moduleRef.injector.get(NgZone);

        return new Promise<RenderResult>((resolve, reject) => {
            zone.onError.subscribe(errorInfo => reject(errorInfo));
            appRef.isStable.first(isStable => isStable).subscribe(() => {
                // Because 'onStable' fires before 'onError', we have to delay slightly before
                // completing the request in case there's an error to report
                setImmediate(() => {
                    resolve({
                        html: state.renderToString()
                    });
                    moduleRef.destroy();
                });
            });
        });
    });
});
```

asp-prerender-data Tag Helper

When coupled with the `asp-prerender-module` Tag Helper, the `asp-prerender-data` Tag Helper can be used to pass contextual information from the Razor view to the server-side JavaScript. For example, the following markup passes user data to the `main-server` module:

```
<app asp-prerender-module="ClientApp/dist/main-server"
        asp-prerender-data='new {
            UserName = "John Doe"
        }'>Loading...</app>
```

The received `UserName` argument is serialized using the built-in JSON serializer and is stored in the `params.data` object. In the following Angular example, the data is used to construct a personalized greeting within an `h1` element:

```
import { createServerRenderer, RenderResult } from 'aspnet-prerendering';

export default createServerRenderer(params => {
    const providers = [
        { provide: INITIAL_CONFIG, useValue: { document: '<app></app>', url: params.url } },
        { provide: 'ORIGIN_URL', useValue: params.origin }
    ];

    return platformDynamicServer(providers).bootstrapModule(AppModule).then(moduleRef => {
        const appRef = moduleRef.injector.get(ApplicationRef);
        const state = moduleRef.injector.get(PlatformState);
        const zone = moduleRef.injector.get(NgZone);

        return new Promise<RenderResult>((resolve, reject) => {
            const result = `<h1>Hello, ${params.data.userName}</h1>`;

            zone.onError.subscribe(errorInfo => reject(errorInfo));
            appRef.isStable.first(isStable => isStable).subscribe(() => {
                // Because 'onStable' fires before 'onError', we have to delay slightly before
                // completing the request in case there's an error to report
                setImmediate(() => {
                    resolve({
                        html: result
                    });
                    moduleRef.destroy();
                });
            });
        });
    });
});
```

Property names passed in Tag Helpers are represented with **PascalCase** notation. Contrast that to JavaScript, where the same property names are represented with **camelCase**. The default JSON serialization configuration is responsible for this difference.

To expand upon the preceding code example, data can be passed from the server to the view by hydrating the `globals` property provided to the `resolve` function:

```
import { createServerRenderer, RenderResult } from 'aspnet-prerendering';

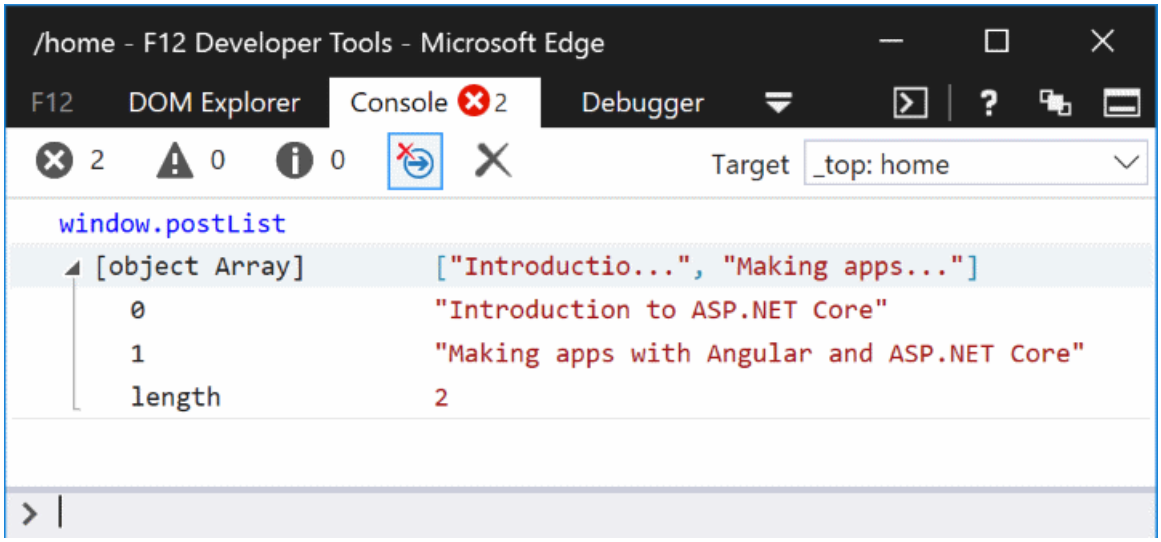
export default createServerRenderer(params => {
    const providers = [
        { provide: INITIAL_CONFIG, useValue: { document: '<app></app>', url: params.url } },
        { provide: 'ORIGIN_URL', useValue: params.origin }
    ];

    return platformDynamicServer(providers).bootstrapModule(AppModule).then(moduleRef => {
        const appRef = moduleRef.injector.get(ApplicationRef);
        const state = moduleRef.injector.get(PlatformState);
        const zone = moduleRef.injector.get(NgZone);

        return new Promise<RenderResult>((resolve, reject) => {
            const result = `<h1>Hello, ${params.data.userName}</h1>`;

            zone.onError.subscribe(errorInfo => reject(errorInfo));
            appRef.isStable.first(isStable => isStable).subscribe(() => {
                // Because 'onStable' fires before 'onError', we have to delay slightly before
                // completing the request in case there's an error to report
                setImmediate(() => {
                    resolve({
                        html: result,
                        globals: {
                            postList: [
                                'Introduction to ASP.NET Core',
                                'Making apps with Angular and ASP.NET Core'
                            ]
                        }
                    });
                    moduleRef.destroy();
                });
            });
        });
    });
});
```

The `postList` array defined inside the `globals` object is attached to the browser's global `window` object. This variable hoisting to global scope eliminates duplication of effort, particularly as it pertains to loading the same data once on the server and again on the client.



Webpack Dev Middleware

Webpack Dev Middleware introduces a streamlined development workflow whereby Webpack builds resources on demand. The middleware automatically compiles and serves client-side resources when a page is reloaded in the browser. The alternate approach is to manually invoke Webpack via the project's npm build script when a third-

party dependency or the custom code changes. An npm build script in the *package.json* file is shown in the following example:

```
"build": "npm run build:vendor && npm run build:custom",
```

Webpack Dev Middleware prerequisites

Install the aspnet-webpack npm package:

```
npm i -D aspnet-webpack
```

Webpack Dev Middleware configuration

Webpack Dev Middleware is registered into the HTTP request pipeline via the following code in the *Startup.cs* file's `Configure` method:

```
if (env.IsDevelopment())
{
    app.UseDeveloperExceptionPage();
    app.UseWebpackDevMiddleware();
}
else
{
    app.UseExceptionHandler("/Home/Error");
}

// Call UseWebpackDevMiddleware before UseStaticFiles
app.UseStaticFiles();
```

The `UseWebpackDevMiddleware` extension method must be called before registering static file hosting via the `UseStaticFiles` extension method. For security reasons, register the middleware only when the app runs in development mode.

The *webpack.config.js* file's `output.publicPath` property tells the middleware to watch the `dist` folder for changes:

```
module.exports = (env) => {
        output: {
            filename: '[name].js',
            publicPath: '/dist/' // Webpack dev middleware, if enabled, handles requests for this URL prefix
        },
```

Hot Module Replacement

Think of Webpack's Hot Module Replacement (HMR) feature as an evolution of Webpack Dev Middleware. HMR introduces all the same benefits, but it further streamlines the development workflow by automatically updating page content after compiling the changes. Don't confuse this with a refresh of the browser, which would interfere with the current in-memory state and debugging session of the SPA. There's a live link between the Webpack Dev Middleware service and the browser, which means changes are pushed to the browser.

Hot Module Replacement prerequisites

Install the webpack-hot-middleware npm package:

```
npm i -D webpack-hot-middleware
```

Hot Module Replacement configuration

The HMR component must be registered into MVC's HTTP request pipeline in the `Configure` method:

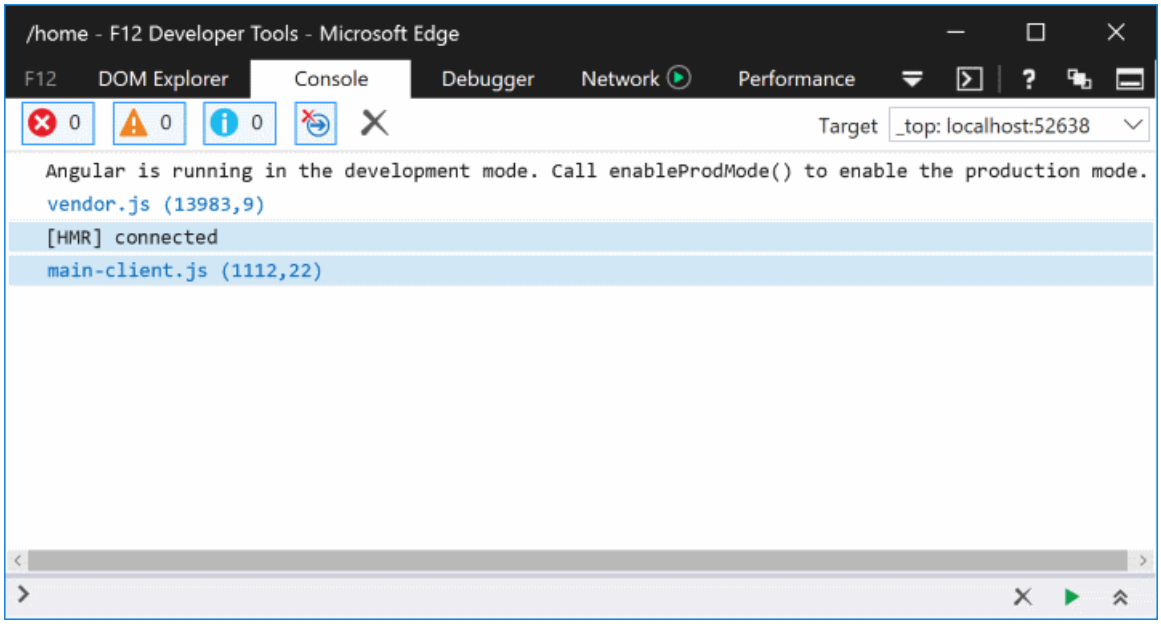
```
app.UseWebpackDevMiddleware(new WebpackDevMiddlewareOptions {
    HotModuleReplacement = true
});
```

As was true with Webpack Dev Middleware, the `UseWebpackDevMiddleware` extension method must be called before the `UseStaticFiles` extension method. For security reasons, register the middleware only when the app runs in development mode.

The *webpack.config.js* file must define a `plugins` array, even if it's left empty:

```
module.exports = (env) => {
        plugins: [new CheckerPlugin()]
```

After loading the app in the browser, the developer tools' Console tab provides confirmation of HMR activation:



Routing helpers

In most ASP.NET Core-based SPAs, client-side routing is often desired in addition to server-side routing. The SPA and MVC routing systems can work independently without interference. There's, however, one edge case posing challenges: identifying 404 HTTP responses.

Consider the scenario in which an extensionless route of `/some/page` is used. Assume the request doesn't pattern-match a server-side route, but its pattern does match a client-side route. Now consider an incoming request for `/images/user-512.png`, which generally expects to find an image file on the server. If that requested resource path doesn't match any server-side route or static file, it's unlikely that the client-side application would handle it—generally returning a 404 HTTP status code is desired.

Routing helpers prerequisites

Install the client-side routing npm package. Using Angular as an example:

```
npm i -S @angular/router
```

Routing helpers configuration

An extension method named `MapSpaFallbackRoute` is used in the `Configure` method:

```
app.UseMvc(routes =>
{
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");

    routes.MapSpaFallbackRoute(
        name: "spa-fallback",
        defaults: new { controller = "Home", action = "Index" });
});
```

Routes are evaluated in the order in which they're configured. Consequently, the `default` route in the preceding code example is used first for pattern matching.

Create a new project

JavaScript Services provide pre-configured application templates. SpaServices is used in these templates in conjunction with different frameworks and libraries such as Angular, React, and Redux.

These templates can be installed via the .NET Core CLI by running the following command:

```
dotnet new --install Microsoft.AspNetCore.SpaTemplates::*
```

A list of available SPA templates is displayed:

TEMPLATES	SHORT NAME	LANGUAGE	TAGS
MVC ASP.NET Core with Angular	angular	[C#]	Web/MVC/SPA
MVC ASP.NET Core with React.js	react	[C#]	Web/MVC/SPA
MVC ASP.NET Core with React.js and Redux	reactredux	[C#]	Web/MVC/SPA

To create a new project using one of the SPA templates, include the **Short Name** of the template in the dotnet new command. The following command creates an Angular application with ASP.NET Core MVC configured for the server side:

```
dotnet new angular
```

Set the runtime configuration mode

Two primary runtime configuration modes exist:

- **Development**:
  - Includes source maps to ease debugging.
  - Doesn't optimize the client-side code for performance.
- **Production**:
  - Excludes source maps.
  - Optimizes the client-side code via bundling and minification.

ASP.NET Core uses an environment variable named `ASPNETCORE_ENVIRONMENT` to store the configuration mode. For more information, see Set the environment.

Run with .NET Core CLI

Restore the required NuGet and npm packages by running the following command at the project root:

```
dotnet restore && npm i
```

Build and run the application:

```
dotnet run
```

The application starts on localhost according to the runtime configuration mode. Navigating to `http://localhost:5000` in the browser displays the landing page.

Run with Visual Studio 2017

Open the *.csproj* file generated by the dotnet new command. The required NuGet and npm packages are restored automatically upon project open. This restoration process may take up to a few minutes, and the application is ready to run when it completes. Click the green run button or press `Ctrl + F5`, and the browser opens to the application's landing page. The application runs on localhost according to the runtime configuration mode.

Test the app

SpaServices templates are pre-configured to run client-side tests using Karma and Jasmine. Jasmine is a popular unit testing framework for JavaScript, whereas Karma is a test runner for those tests. Karma is configured to work with the Webpack Dev Middleware such that the developer isn't required to stop and run the test every time changes are made. Whether it's the code running against the test case or the test case itself, the test runs automatically.

Using the Angular application as an example, two Jasmine test cases are already provided for the `CounterComponent` in the *counter.component.spec.ts* file:

```
it('should display a title', async(() => {
    const titleText = fixture.nativeElement.querySelector('h1').textContent;
    expect(titleText).toEqual('Counter');
}));

it('should start with count 0, then increments by 1 when clicked', async(() => {
    const countElement = fixture.nativeElement.querySelector('strong');
    expect(countElement.textContent).toEqual('0');

    const incrementButton = fixture.nativeElement.querySelector('button');
    incrementButton.click();
    fixture.detectChanges();
    expect(countElement.textContent).toEqual('1');
}));
```

Open the command prompt in the *ClientApp* directory. Run the following command:

```
npm test
```

The script launches the Karma test runner, which reads the settings defined in the *karma.conf.js* file. Among other settings, the *karma.conf.js* identifies the test files to be executed via its `files` array:

```
module.exports = function (config) {
    config.set({
        files: [
            '../../wwwroot/dist/vendor.js',
            './boot-tests.ts'
        ],
```

Publish the app

See this GitHub issue for more information on publishing to Azure.

Combining the generated client-side assets and the published ASP.NET Core artifacts into a ready-to-deploy package can be cumbersome. Thankfully, SpaServices orchestrates that entire publication process with a custom MSBuild target named `RunWebpack`:

```
<Target Name="RunWebpack" AfterTargets="ComputeFilesToPublish">
  <!-- As part of publishing, ensure the JS resources are freshly built in production mode -->
  <Exec Command="npm install" />
  <Exec Command="node node_modules/webpack/bin/webpack.js --config webpack.config.vendor.js --env.prod" />
  <Exec Command="node node_modules/webpack/bin/webpack.js --env.prod" />

  <!-- Include the newly-built files in the publish output -->
  <ItemGroup>
    <DistFiles Include="wwwroot\dist\**; ClientApp\dist\**" />
    <ResolvedFileToPublish Include="@(DistFiles->'%(FullPath)')" Exclude="@(ResolvedFileToPublish)">
      <RelativePath>%(DistFiles.Identity)</RelativePath>
      <CopyToPublishDirectory>PreserveNewest</CopyToPublishDirectory>
    </ResolvedFileToPublish>
  </ItemGroup>
</Target>
```

The MSBuild target has the following responsibilities:

1. Restore the npm packages.
2. Create a production-grade build of the third-party, client-side assets.
3. Create a production-grade build of the custom client-side assets.
4. Copy the Webpack-generated assets to the publish folder.

The MSBuild target is invoked when running:

```
dotnet publish -c Release
```

Client-side library acquisition in ASP.NET Core with LibMan

9/22/2020 • 2 minutes to read • Edit Online

By Scott Addie

Library Manager (LibMan) is a lightweight, client-side library acquisition tool. LibMan downloads popular libraries and frameworks from the file system or from a content delivery network (CDN). The supported CDNs include CDNJS, jsDelivr, and unpkg. The selected library files are fetched and placed in the appropriate location within the ASP.NET Core project.

LibMan use cases

LibMan offers the following benefits:

- Only the library files you need are downloaded.
- Additional tooling, such as Node.js, npm, and WebPack, isn't necessary to acquire a subset of files in a library.
- Files can be placed in a specific location without resorting to build tasks or manual file copying.

For more information about LibMan's benefits, watch Modern front-end web development in Visual Studio 2017: LibMan segment.

LibMan isn't a package management system. If you're already using a package manager, such as npm or yarn, continue doing so. LibMan wasn't developed to replace those tools.

Additional resources

- Use LibMan with ASP.NET Core in Visual Studio
- Use the LibMan CLI with ASP.NET Core
- LibMan GitHub repository

Use the LibMan CLI with ASP.NET Core

9/22/2020 • 8 minutes to read • Edit Online

By Scott Addie

The LibMan CLI is a cross-platform tool that's supported everywhere .NET Core is supported.

Prerequisites

- .NET Core 2.1 SDK or later

Installation

To install the LibMan CLI:

```
dotnet tool install -g Microsoft.Web.LibraryManager.Cli
```

A .NET Core Global Tool is installed from the Microsoft.Web.LibraryManager.Cli NuGet package.

To install the LibMan CLI from a specific NuGet package source:

```
dotnet tool install -g Microsoft.Web.LibraryManager.Cli --version 1.0.94-g606058a278 --add-source C:\Temp\
```

In the preceding example, a .NET Core Global Tool is installed from the local Windows machine's *C:\Temp\Microsoft.Web.LibraryManager.Cli.1.0.94-g606058a278.nupkg* file.

Usage

After successful installation of the CLI, the following command can be used:

```
libman
```

To view the installed CLI version:

```
libman --version
```

To view the available CLI commands:

```
libman --help
```

The preceding command displays output similar to the following:

```
 1.0.163+g45474d37ed

Usage: libman [options] [command]

Options:
  --help|-h  Show help information
  --version  Show version information

Commands:
  cache      List or clean libman cache contents
  clean      Deletes all library files defined in libman.json from the project
  init       Create a new libman.json
  install    Add a library definition to the libman.json file, and download the
             library to the specified location
  restore    Downloads all files from provider and saves them to specified
             destination
  uninstall  Deletes all files for the specified library from their specified
             destination, then removes the specified library definition from
             libman.json
  update     Updates the specified library

Use "libman [command] --help" for more information about a command.
```

The following sections outline the available CLI commands.

Initialize LibMan in the project

The `libman init` command creates a *libman.json* file if one doesn't exist. The file is created with the default item template content.

Synopsis

```
libman init [-d|--default-destination] [-p|--default-provider] [--verbosity]
libman init [-h|--help]
```

Options

The following options are available for the `libman init` command:

- `-d|--default-destination <PATH>`

  A path relative to the current folder. Library files are installed in this location if no `destination` property is defined for a library in *libman.json*. The `<PATH>` value is written to the `defaultDestination` property of *libman.json*.

- `-p|--default-provider <PROVIDER>`

  The provider to use if no provider is defined for a given library. The `<PROVIDER>` value is written to the `defaultProvider` property of *libman.json*. Replace `<PROVIDER>` with one of the following values:

  - `cdnjs`
  - `filesystem`
  - `jsdelivr`
  - `unpkg`

- `-h|--help`

  Show help information.

- `--verbosity <LEVEL>`

Set the verbosity of the output. Replace `<LEVEL>` with one of the following values:

- `quiet`
- `normal`
- `detailed`

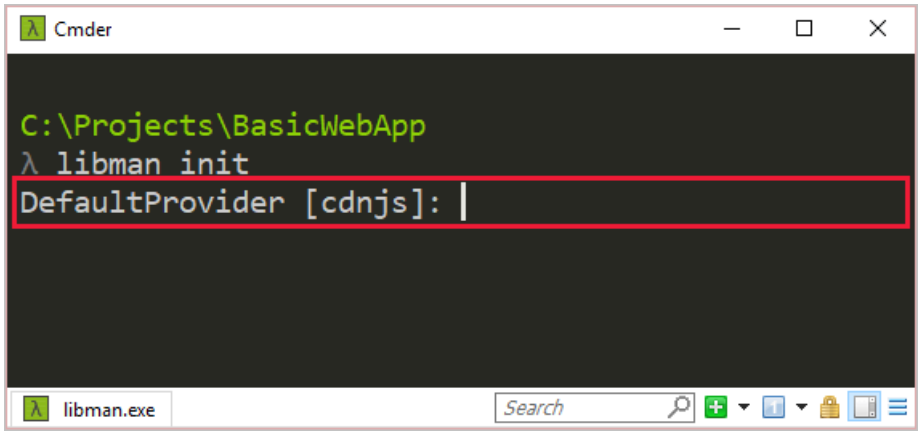
Examples

To create a *libman.json* file in an ASP.NET Core project:

- Navigate to the project root.
- Run the following command:

```
libman init
```

- Type the name of the default provider, or press `Enter` to use the default CDNJS provider. Valid values include:
  - `cdnjs`
  - `filesystem`
  - `jsdelivr`
  - `unpkg`



A *libman.json* file is added to the project root with the following content:

```
{
  "version": "1.0",
  "defaultProvider": "cdnjs",
  "libraries": []
}
```

Add library files

The `libman install` command downloads and installs library files into the project. A *libman.json* file is added if one doesn't exist. The *libman.json* file is modified to store configuration details for the library files.

Synopsis

```
libman install <LIBRARY> [-d|--destination] [--files] [-p|--provider] [--verbosity]
libman install [-h|--help]
```

Arguments

`LIBRARY`

The name of the library to install. This name may include version number notation (for example, `@1.2.0`).

Options

The following options are available for the `libman install` command:

- `-d|--destination <PATH>`

  The location to install the library. If not specified, the default location is used. If no `defaultDestination` property is specified in *libman.json*, this option is required.

- `--files <FILE>`

  Specify the name of the file to install from the library. If not specified, all files from the library are installed. Provide one `--files` option per file to be installed. Relative paths are supported too. For example: `--files dist/browser/signalr.js`.

- `-p|--provider <PROVIDER>`

  The name of the provider to use for the library acquisition. Replace `<PROVIDER>` with one of the following values:

  - `cdnjs`
  - `filesystem`
  - `jsdelivr`
  - `unpkg`

  If not specified, the `defaultProvider` property in *libman.json* is used. If no `defaultProvider` property is specified in *libman.json*, this option is required.

- `-h|--help`

  Show help information.

- `--verbosity <LEVEL>`

  Set the verbosity of the output. Replace `<LEVEL>` with one of the following values:

  - `quiet`
  - `normal`
  - `detailed`

Examples

Consider the following *libman.json* file:

```
{
  "version": "1.0",
  "defaultProvider": "cdnjs",
  "libraries": []
}
```

To install the jQuery version 3.2.1 *jquery.min.js* file to the *wwwroot/scripts/jquery* folder using the CDNJS provider:

```
libman install jquery@3.2.1 --provider cdnjs --destination wwwroot/scripts/jquery --files jquery.min.js
```

The *libman.json* file resembles the following:

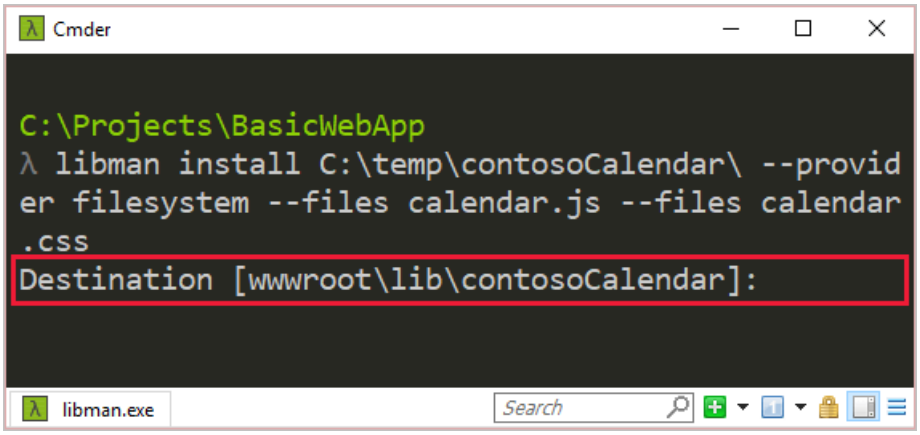
```
{
  "version": "1.0",
  "defaultProvider": "cdnjs",
  "libraries": [
    {
      "library": "jquery@3.2.1",
      "destination": "wwwroot/scripts/jquery",
      "files": [
        "jquery.min.js"
      ]
    }
  ]
}
```

To install the *calendar.js* and *calendar.css* files from *C:\temp\contosoCalendar* using the file system provider:

```
libman install C:\temp\contosoCalendar\ --provider filesystem --files calendar.js --files calendar.css
```

The following prompt appears for two reasons:

- The *libman.json* file doesn't contain a `defaultDestination` property.
- The `libman install` command doesn't contain the `-d|--destination` option.



After accepting the default destination, the *libman.json* file resembles the following:

```
{
  "version": "1.0",
  "defaultProvider": "cdnjs",
  "libraries": [
    {
      "library": "jquery@3.2.1",
      "destination": "wwwroot/scripts/jquery",
      "files": [
        "jquery.min.js"
      ]
    },
    {
      "library": "C:\\temp\\contosoCalendar\\",
      "provider": "filesystem",
      "destination": "wwwroot/lib/contosoCalendar",
      "files": [
        "calendar.js",
        "calendar.css"
      ]
    }
  ]
}
```

Restore library files

The `libman restore` command installs library files defined in *libman.json*. The following rules apply:

- If no *libman.json* file exists in the project root, an error is returned.
- If a library specifies a provider, the `defaultProvider` property in *libman.json* is ignored.
- If a library specifies a destination, the `defaultDestination` property in *libman.json* is ignored.

Synopsis

```
libman restore [--verbosity]
libman restore [-h|--help]
```

Options

The following options are available for the `libman restore` command:

- `-h|--help`

  Show help information.

- `--verbosity <LEVEL>`

  Set the verbosity of the output. Replace `<LEVEL>` with one of the following values:

  - `quiet`
  - `normal`
  - `detailed`

Examples

To restore the library files defined in *libman.json*:

```
libman restore
```

Delete library files

The `libman clean` command deletes library files previously restored via LibMan. Folders that become empty after this operation are deleted. The library files' associated configurations in the `libraries` property of *libman.json* aren't removed.

Synopsis

```
libman clean [--verbosity]
libman clean [-h|--help]
```

Options

The following options are available for the `libman clean` command:

- `-h|--help`

  Show help information.

- `--verbosity <LEVEL>`

  Set the verbosity of the output. Replace `<LEVEL>` with one of the following values:

  - `quiet`

- `normal`
- `detailed`

Examples

To delete library files installed via LibMan:

```
libman clean
```

Uninstall library files

The `libman uninstall` command:

- Deletes all files associated with the specified library from the destination in *libman.json*.
- Removes the associated library configuration from *libman.json*.

An error occurs when:

- No *libman.json* file exists in the project root.
- The specified library doesn't exist.

If more than one library with the same name is installed, you're prompted to choose one.

Synopsis

```
libman uninstall <LIBRARY> [--verbosity]
libman uninstall [-h|--help]
```

Arguments

`LIBRARY`

The name of the library to uninstall. This name may include version number notation (for example, `@1.2.0`).

Options

The following options are available for the `libman uninstall` command:

- `-h|--help`

  Show help information.

- `--verbosity <LEVEL>`

  Set the verbosity of the output. Replace `<LEVEL>` with one of the following values:

  - `quiet`
  - `normal`
  - `detailed`

Examples

Consider the following *libman.json* file:

```
{
  "version": "1.0",
  "defaultProvider": "cdnjs",
  "libraries": [
    {
      "library": "jquery@3.3.1",
      "files": [
        "jquery.min.js",
        "jquery.js",
        "jquery.min.map"
      ],
      "destination": "wwwroot/lib/jquery/"
    },
    {
      "provider": "unpkg",
      "library": "bootstrap@4.1.3",
      "destination": "wwwroot/lib/bootstrap/"
    },
    {
      "provider": "filesystem",
      "library": "C:\\temp\\lodash\\",
      "files": [
        "lodash.js",
        "lodash.min.js"
      ],
      "destination": "wwwroot/lib/lodash/"
    }
  ]
}
```

- To uninstall jQuery, either of the following commands succeed:

```
libman uninstall jquery
```

```
libman uninstall jquery@3.3.1
```

- To uninstall the Lodash files installed via the `filesystem` provider:

```
libman uninstall C:\temp\lodash\
```

Update library version

The `libman update` command updates a library installed via LibMan to the specified version.

An error occurs when:

- No *libman.json* file exists in the project root.
- The specified library doesn't exist.

If more than one library with the same name is installed, you're prompted to choose one.

Synopsis

```
libman update <LIBRARY> [-pre] [--to] [--verbosity]
libman update [-h|--help]
```

Arguments

`LIBRARY`

The name of the library to update.

Options

The following options are available for the `libman update` command:

- `-pre`

  Obtain the latest prerelease version of the library.

- `--to <VERSION>`

  Obtain a specific version of the library.

- `-h|--help`

  Show help information.

- `--verbosity <LEVEL>`

  Set the verbosity of the output. Replace `<LEVEL>` with one of the following values:

  - `quiet`
  - `normal`
  - `detailed`

Examples

- To update jQuery to the latest version:

  ```
  libman update jquery
  ```

- To update jQuery to version 3.3.1:

  ```
  libman update jquery --to 3.3.1
  ```

- To update jQuery to the latest prerelease version:

  ```
  libman update jquery -pre
  ```

Manage library cache

The `libman cache` command manages the LibMan library cache. The `filesystem` provider doesn't use the library cache.

Synopsis

```
libman cache clean [<PROVIDER>] [--verbosity]
libman cache list [--files] [--libraries] [--verbosity]
libman cache [-h|--help]
```

Arguments

`PROVIDER`

Only used with the `clean` command. Specifies the provider cache to clean. Valid values include:

- `cdnjs`
- `filesystem`
- `jsdelivr`
- `unpkg`

Options

The following options are available for the `libman cache` command:

- `--files`

  List the names of files that are cached.

- `--libraries`

  List the names of libraries that are cached.

- `-h|--help`

  Show help information.

- `--verbosity <LEVEL>`

  Set the verbosity of the output. Replace `<LEVEL>` with one of the following values:

  - `quiet`
  - `normal`
  - `detailed`

Examples

- To view the names of cached libraries per provider, use one of the following commands:

  ```
  libman cache list
  ```

  ```
  libman cache list --libraries
  ```

  Output similar to the following is displayed:

  ```
  Cache contents:
  ---------------
  unpkg:
      knockout
      react
      vue
  cdnjs:
      font-awesome
      jquery
      knockout
      lodash.js
      react
  ```

- To view the names of cached library files per provider:

  ```
  libman cache list --files
  ```

  Output similar to the following is displayed:

```
Cache contents:
---------------
unpkg:
    knockout:
        <list omitted for brevity>
    react:
        <list omitted for brevity>
    vue:
        <list omitted for brevity>
cdnjs:
    font-awesome
        metadata.json
    jquery
        metadata.json
        3.2.1\core.js
        3.2.1\jquery.js
        3.2.1\jquery.min.js
        3.2.1\jquery.min.map
        3.2.1\jquery.slim.js
        3.2.1\jquery.slim.min.js
        3.2.1\jquery.slim.min.map
        3.3.1\core.js
        3.3.1\jquery.js
        3.3.1\jquery.min.js
        3.3.1\jquery.min.map
        3.3.1\jquery.slim.js
        3.3.1\jquery.slim.min.js
        3.3.1\jquery.slim.min.map
    knockout
        metadata.json
        3.4.2\knockout-debug.js
        3.4.2\knockout-min.js
    lodash.js
        metadata.json
        4.17.10\lodash.js
        4.17.10\lodash.min.js
    react
        metadata.json
```

Notice the preceding output shows that jQuery versions 3.2.1 and 3.3.1 are cached under the CDNJS provider.

- To empty the library cache for the CDNJS provider:

```
libman cache clean cdnjs
```

After emptying the CDNJS provider cache, the `libman cache list` command displays the following:

```
Cache contents:
---------------
unpkg:
    knockout
    react
    vue
cdnjs:
    (empty)
```

- To empty the cache for all supported providers:

```
libman cache clean
```

After emptying all provider caches, the `libman cache list` command displays the following:

```
Cache contents:
---------------
unpkg:
    (empty)
cdnjs:
    (empty)
```

Use LibMan with ASP.NET Core in Visual Studio

9/22/2020 • 7 minutes to read • Edit Online

By Scott Addie

Visual Studio has built-in support for LibMan in ASP.NET Core projects, including:

- Support for configuring and running LibMan restore operations on build.
- Menu items for triggering LibMan restore and clean operations.
- Search dialog for finding libraries and adding the files to a project.
- Editing support for *libman.json*—the LibMan manifest file.

View or download sample code (how to download)

Prerequisites

- Visual Studio 2019 with the **ASP.NET and web development** workload

Add library files

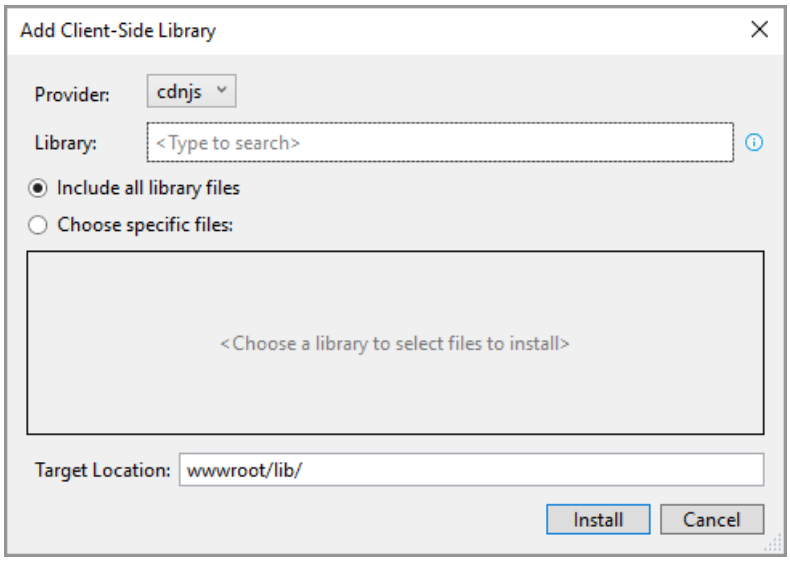
Library files can be added to an ASP.NET Core project in two different ways:

1. Use the Add Client-Side Library dialog
2. Manually configure LibMan manifest file entries

Use the Add Client-Side Library dialog

Follow these steps to install a client-side library:

- In **Solution Explorer**, right-click the project folder in which the files should be added. Choose **Add** > **Client-Side Library**. The **Add Client-Side Library** dialog appears:



- Select the library provider from the **Provider** drop down. CDNJS is the default provider.
- Type the library name to fetch in the **Library** text box. IntelliSense provides a list of libraries beginning with the provided text.
- Select the library from the IntelliSense list. Notice the library name is suffixed with the `@` symbol and the

latest stable version known to the selected provider.

- Decide which files to include:
  - Select the **Include all library files** radio button to include all of the library's files.
  - Select the **Choose specific files** radio button to include a subset of the library's files. When the radio button is selected, the file selector tree is enabled. Check the boxes to the left of the file names to download.
- Specify the project folder for storing the files in the **Target Location** text box. As a recommendation, store each library in a separate folder.

  The suggested **Target Location** folder is based on the location from which the dialog launched:

  - If launched from the project root:
    - *wwwroot/lib* is used if *wwwroot* exists.
    - *lib* is used if *wwwroot* doesn't exist.
  - If launched from a project folder, the corresponding folder name is used.

  The folder suggestion is suffixed with the library name. The following table illustrates folder suggestions when installing jQuery in a Razor Pages project.

LAUNCH LOCATION	SUGGESTED FOLDER
project root (if *wwwroot* exists)	*wwwroot/lib/jquery/*
project root (if *wwwroot* doesn't exist)	*lib/jquery/*
Pages folder in project	*Pages/jquery/*

- Click the **Install** button to download the files, per the configuration in *libman.json*.
- Review the **Library Manager** feed of the **Output** window for installation details. For example:

```
Restore operation started...
Restoring libraries for project LibManSample
Restoring library jquery@3.3.1... (LibManSample)
wwwroot/lib/jquery/jquery.min.js written to destination (LibManSample)
wwwroot/lib/jquery/jquery.js written to destination (LibManSample)
wwwroot/lib/jquery/jquery.min.map written to destination (LibManSample)
Restore operation completed
1 libraries restored in 2.32 seconds
```

Manually configure LibMan manifest file entries

All LibMan operations in Visual Studio are based on the content of the project root's LibMan manifest (*libman.json*). You can manually edit *libman.json* to configure library files for the project. Visual Studio restores all library files once *libman.json* is saved.

To open *libman.json* for editing, the following options exist:

- Double-click the *libman.json* file in **Solution Explorer**.
- Right-click the project in **Solution Explorer** and select **Manage Client-Side Libraries**. †
- Select **Manage Client-Side Libraries** from the Visual Studio **Project** menu. †

† If the *libman.json* file doesn't already exist in the project root, it will be created with the default item template content.

Visual Studio offers rich JSON editing support such as colorization, formatting, IntelliSense, and schema validation.

The LibMan manifest's JSON schema is found at https://json.schemastore.org/libman.

With the following manifest file, LibMan retrieves files per the configuration defined in the `libraries` property. An explanation of the object literals defined within `libraries` follows:

- A subset of jQuery version 3.3.1 is retrieved from the CDNJS provider. The subset is defined in the `files` property—*jquery.min.js*, *jquery.js*, and *jquery.min.map*. The files are placed in the project's *wwwroot/lib/jquery* folder.
- The entirety of Bootstrap version 4.1.3 is retrieved and placed in a *wwwroot/lib/bootstrap* folder. The object literal's `provider` property overrides the `defaultProvider` property value. LibMan retrieves the Bootstrap files from the unpkg provider.
- A subset of Lodash was approved by a governing body within the organization. The *lodash.js* and *lodash.min.js* files are retrieved from the local file system at *C:\temp\lodash*. The files are copied to the project's *wwwroot/lib/lodash* folder.

```
{
  "version": "1.0",
  "defaultProvider": "cdnjs",
  "libraries": [
    {
      "library": "jquery@3.3.1",
      "files": [
        "jquery.min.js",
        "jquery.js",
        "jquery.min.map"
      ],
      "destination": "wwwroot/lib/jquery/"
    },
    {
      "provider": "unpkg",
      "library": "bootstrap@4.1.3",
      "destination": "wwwroot/lib/bootstrap/"
    },
    {
      "provider": "filesystem",
      "library": "C:\\temp\\lodash\\",
      "files": [
        "lodash.js",
        "lodash.min.js"
      ],
      "destination": "wwwroot/lib/lodash/"
    }
  ]
}
```

> **NOTE**
> LibMan only supports one version of each library from each provider. The *libman.json* file fails schema validation if it contains two libraries with the same library name for a given provider.

Restore library files

To restore library files from within Visual Studio, there must be a valid *libman.json* file in the project root. Restored files are placed in the project at the location specified for each library.

Library files can be restored in an ASP.NET Core project in two ways:

1. Restore files during build
2. Restore files manually

Restore files during build

LibMan can restore the defined library files as part of the build process. By default, the *restore-on-build* behavior is disabled.

To enable and test the restore-on-build behavior:

- Right-click *libman.json* in **Solution Explorer** and select **Enable Restore Client-Side Libraries on Build** from the context menu.
- Click the **Yes** button when prompted to install a NuGet package. The Microsoft.Web.LibraryManager.Build NuGet package is added to the project:

  ```
  <PackageReference Include="Microsoft.Web.LibraryManager.Build" Version="1.0.113" />
  ```

- Build the project to confirm LibMan file restoration occurs. The `Microsoft.Web.LibraryManager.Build` package injects an MSBuild target that runs LibMan during the project's build operation.
- Review the **Build** feed of the **Output** window for a LibMan activity log:

  ```
  1>------ Build started: Project: LibManSample, Configuration: Debug Any CPU ------
  1>
  1>Restore operation started...
  1>Restoring library jquery@3.3.1...
  1>Restoring library bootstrap@4.1.3...
  1>
  1>2 libraries restored in 10.66 seconds
  1>LibManSample -> C:\LibManSample\bin\Debug\netcoreapp2.1\LibManSample.dll
  ========== Build: 1 succeeded, 0 failed, 0 up-to-date, 0 skipped ==========
  ```

When the restore-on-build behavior is enabled, the *libman.json* context menu displays a **Disable Restore Client-Side Libraries on Build** option. Selecting this option removes the `Microsoft.Web.LibraryManager.Build` package reference from the project file. Consequently, the client-side libraries are no longer restored on each build.

Regardless of the restore-on-build setting, you can manually restore at any time from the *libman.json* context menu. For more information, see Restore files manually.

Restore files manually

To manually restore library files:

- For all projects in the solution:
  - Right-click the solution name in **Solution Explorer**.
  - Select the **Restore Client-Side Libraries** option.
- For a specific project:
  - Right-click the *libman.json* file in **Solution Explorer**.
  - Select the **Restore Client-Side Libraries** option.

While the restore operation is running:

- The Task Status Center (TSC) icon on the Visual Studio status bar will be animated and will read *Restore operation started*. Clicking the icon opens a tooltip listing the known background tasks.
- Messages will be sent to the status bar and the **Library Manager** feed of the **Output** window. For example:

```
Restore operation started...
Restoring libraries for project LibManSample
Restoring library jquery@3.3.1... (LibManSample)
wwwroot/lib/jquery/jquery.min.js written to destination (LibManSample)
wwwroot/lib/jquery/jquery.js written to destination (LibManSample)
wwwroot/lib/jquery/jquery.min.map written to destination (LibManSample)
Restore operation completed
1 libraries restored in 2.32 seconds
```

Delete library files

To perform the *clean* operation, which deletes library files previously restored in Visual Studio:

- Right-click the *libman.json* file in **Solution Explorer**.
- Select the **Clean Client-Side Libraries** option.

To prevent unintentional removal of non-library files, the clean operation doesn't delete whole directories. It only removes files that were included in the previous restore.

While the clean operation is running:

- The TSC icon on the Visual Studio status bar will be animated and will read *Client libraries operation started*. Clicking the icon opens a tooltip listing the known background tasks.
- Messages are sent to the status bar and the **Library Manager** feed of the **Output** window. For example:

```
Clean libraries operation started...
Clean libraries operation completed
2 libraries were successfully deleted in 1.91 secs
```

The clean operation only deletes files from the project. Library files stay in the cache for faster retrieval on future restore operations. To manage library files stored in the local machine's cache, use the LibMan CLI.

Uninstall library files

To uninstall library files:

- Open *libman.json*.
- Position the caret inside the corresponding `libraries` object literal.
- Click the light bulb icon that appears in the left margin, and select **Uninstall <library_name>@<library_version>**:

Alternatively, you can manually edit and save the LibMan manifest (*libman.json*). The restore operation runs when the file is saved. Library files that are no longer defined in *libman.json* are removed from the project.

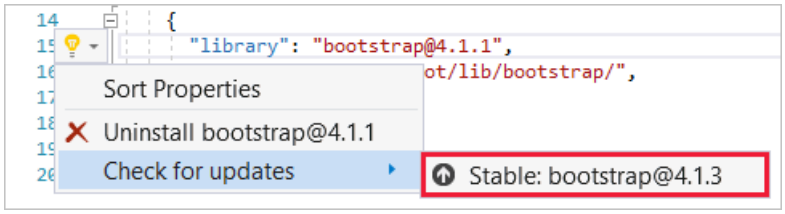
Update library version

To check for an updated library version:

- Open *libman.json*.
- Position the caret inside the corresponding `libraries` object literal.
- Click the light bulb icon that appears in the left margin. Hover over **Check for updates**.

LibMan checks for a library version newer than the version installed. The following outcomes can occur:

- A **No updates found** message is displayed if the latest version is already installed.
- The latest stable version is displayed if not already installed.



- If a pre-release newer than the installed version is available, the pre-release is displayed.

To downgrade to an older library version, manually edit the *libman.json* file. When the file is saved, the LibMan restore operation:

- Removes redundant files from the previous version.
- Adds new and updated files from the new version.

Additional resources

- Use the LibMan CLI with ASP.NET Core
- LibMan GitHub repository

Use Grunt in ASP.NET Core

9/22/2020 • 8 minutes to read • Edit Online

Grunt is a JavaScript task runner that automates script minification, TypeScript compilation, code quality "lint" tools, CSS pre-processors, and just about any repetitive chore that needs doing to support client development. Grunt is fully supported in Visual Studio.

This example uses an empty ASP.NET Core project as its starting point, to show how to automate the client build process from scratch.

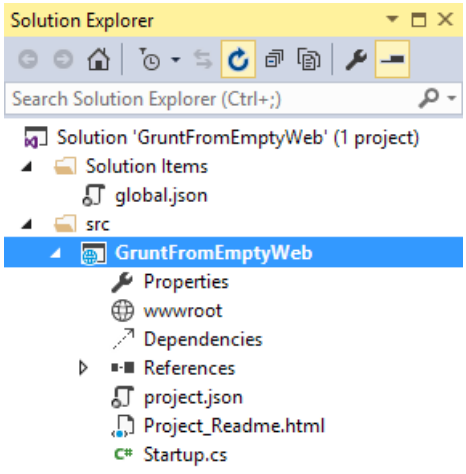
The finished example cleans the target deployment directory, combines JavaScript files, checks code quality, condenses JavaScript file content and deploys to the root of your web application. We will use the following packages:

- **grunt**: The Grunt task runner package.
- **grunt-contrib-clean**: A plugin that removes files or directories.
- **grunt-contrib-jshint**: A plugin that reviews JavaScript code quality.
- **grunt-contrib-concat**: A plugin that joins files into a single file.
- **grunt-contrib-uglify**: A plugin that minifies JavaScript to reduce size.
- **grunt-contrib-watch**: A plugin that watches file activity.

Preparing the application

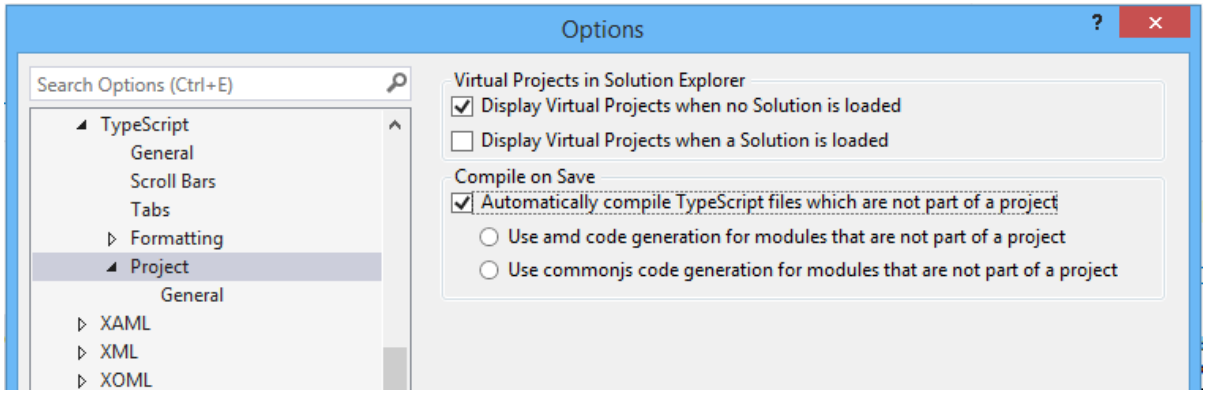
To begin, set up a new empty web application and add TypeScript example files. TypeScript files are automatically compiled into JavaScript using default Visual Studio settings and will be our raw material to process using Grunt.

1. In Visual Studio, create a new `ASP.NET Web Application`.
2. In the **New ASP.NET Project** dialog, select the ASP.NET Core **Empty** template and click the OK button.
3. In the Solution Explorer, review the project structure. The `\src` folder includes empty `wwwroot` and `Dependencies` nodes.



4. Add a new folder named `TypeScript` to your project directory.

5. Before adding any files, make sure that Visual Studio has the option 'compile on save' for TypeScript files checked. Navigate to **Tools** > **Options** > **Text Editor** > **Typescript** > **Project**:



6. Right-click the `TypeScript` directory and select **Add** > **New Item** from the context menu. Select the **JavaScript file** item and name the file *Tastes.ts* (note the *.ts extension). Copy the line of TypeScript code below into the file (when you save, a new *Tastes.js* file will appear with the JavaScript source).

```
enum Tastes { Sweet, Sour, Salty, Bitter }
```

7. Add a second file to the **TypeScript** directory and name it `Food.ts`. Copy the code below into the file.

```
class Food {
  constructor(name: string, calories: number) {
    this._name = name;
    this._calories = calories;
  }

  private _name: string;
  get Name() {
    return this._name;
  }

  private _calories: number;
  get Calories() {
    return this._calories;
  }

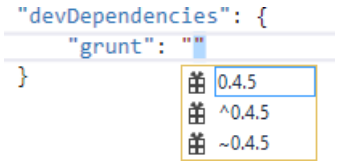
  private _taste: Tastes;
  get Taste(): Tastes { return this._taste }
  set Taste(value: Tastes) {
    this._taste = value;
  }
}
```

Configuring NPM

Next, configure NPM to download grunt and grunt-tasks.

1. In the Solution Explorer, right-click the project and select **Add** > **New Item** from the context menu. Select the **NPM configuration file** item, leave the default name, *package.json*, and click the **Add** button.

2. In the *package.json* file, inside the `devDependencies` object braces, enter "grunt". Select `grunt` from the Intellisense list and press the Enter key. Visual Studio will quote the grunt package name, and add a colon. To the right of the colon, select the latest stable version of the package from the top of the Intellisense list (press `Ctrl-Space` if Intellisense doesn't appear).



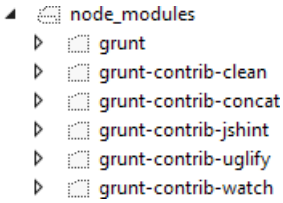
> **NOTE**
>
> NPM uses semantic versioning to organize dependencies. Semantic versioning, also known as SemVer, identifies packages with the numbering scheme <major>.<minor>.<patch>. Intellisense simplifies semantic versioning by showing only a few common choices. The top item in the Intellisense list (0.4.5 in the example above) is considered the latest stable version of the package. The caret (^) symbol matches the most recent major version and the tilde (~) matches the most recent minor version. See the NPM semver version parser reference as a guide to the full expressivity that SemVer provides.

3. Add more dependencies to load grunt-contrib-* packages for *clean*, *jshint*, *concat*, *uglify*, and *watch* as shown in the example below. The versions don't need to match the example.

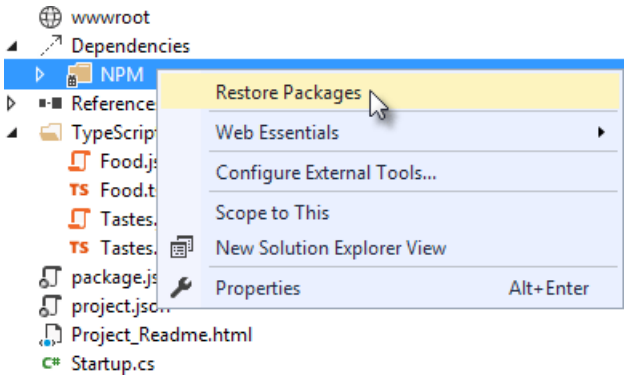
```
"devDependencies": {
  "grunt": "0.4.5",
  "grunt-contrib-clean": "0.6.0",
  "grunt-contrib-jshint": "0.11.0",
  "grunt-contrib-concat": "0.5.1",
  "grunt-contrib-uglify": "0.8.0",
  "grunt-contrib-watch": "0.6.1"
}
```

4. Save the *package.json* file.

The packages for each `devDependencies` item will download, along with any files that each package requires. You can find the package files in the *node_modules* directory by enabling the **Show All Files** button in **Solution Explorer**.



> **NOTE**
>
> If you need to, you can manually restore dependencies in **Solution Explorer** by right-clicking on `Dependencies\NPM` and selecting the **Restore Packages** menu option.



Configuring Grunt

Grunt is configured using a manifest named *Gruntfile.js* that defines, loads and registers tasks that can be run manually or configured to run automatically based on events in Visual Studio.

1. Right-click the project and select **Add** > **New Item**. Select the **JavaScript File** item template, change the name to *Gruntfile.js*, and click the **Add** button.

2. Add the following code to *Gruntfile.js*. The `initConfig` function sets options for each package, and the remainder of the module loads and register tasks.

```
module.exports = function (grunt) {
  grunt.initConfig({
  });
};
```

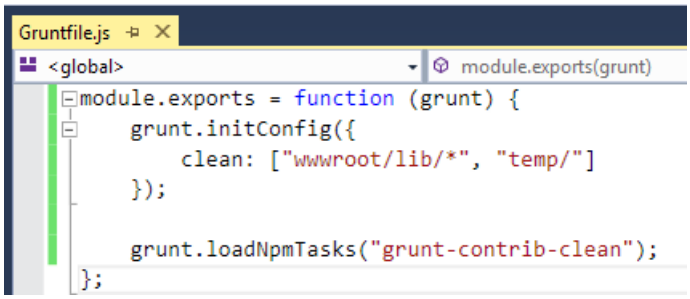
3. Inside the `initConfig` function, add options for the `clean` task as shown in the example *Gruntfile.js* below. The `clean` task accepts an array of directory strings. This task removes files from *wwwroot/lib* and removes the entire */temp* directory.

```
module.exports = function (grunt) {
  grunt.initConfig({
    clean: ["wwwroot/lib/*", "temp/"],
  });
};
```

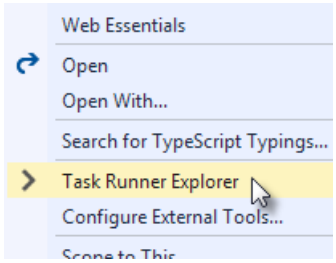
4. Below the `initConfig` function, add a call to `grunt.loadNpmTasks`. This will make the task runnable from Visual Studio.

```
grunt.loadNpmTasks("grunt-contrib-clean");
```

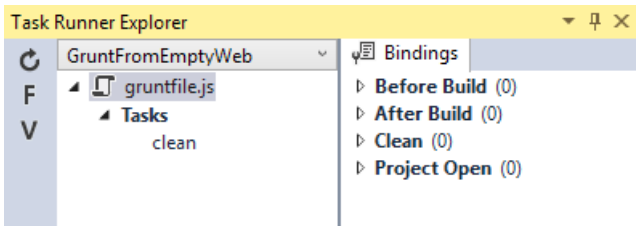
5. Save *Gruntfile.js*. The file should look something like the screenshot below.



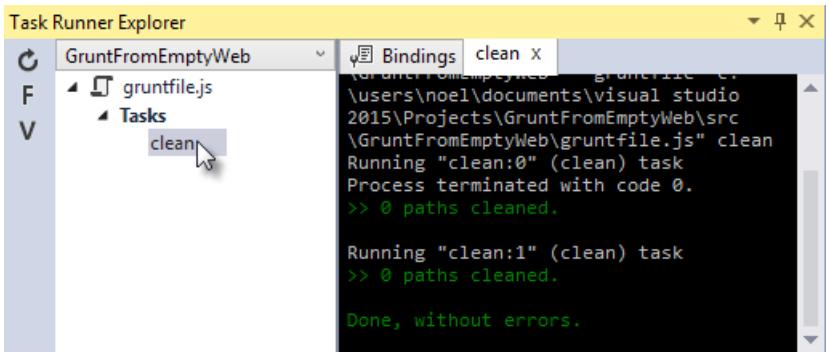
6. Right-click *Gruntfile.js* and select **Task Runner Explorer** from the context menu. The **Task Runner Explorer** window will open.



7. Verify that `clean` shows under **Tasks** in the **Task Runner Explorer**.



8. Right-click the clean task and select **Run** from the context menu. A command window displays progress of the task.



> **NOTE**
>
> There are no files or directories to clean yet. If you like, you can manually create them in the Solution Explorer and then run the clean task as a test.

9. In the `initConfig` function, add an entry for `concat` using the code below.

   The `src` property array lists files to combine, in the order that they should be combined. The `dest` property assigns the path to the combined file that's produced.

```
concat: {
  all: {
    src: ['TypeScript/Tastes.js', 'TypeScript/Food.js'],
    dest: 'temp/combined.js'
  }
},
```

> **NOTE**
>
> The `all` property in the code above is the name of a target. Targets are used in some Grunt tasks to allow multiple build environments. You can view the built-in targets using IntelliSense or assign your own.

10. Add the `jshint` task using the code below.

    The jshint `code-quality` utility is run against every JavaScript file found in the *temp* directory.

```
jshint: {
  files: ['temp/*.js'],
  options: {
    '-W069': false,
  }
},
```

> **NOTE**
>
> The option "-W069" is an error produced by jshint when JavaScript uses bracket syntax to assign a property instead of dot notation, i.e. `Tastes["Sweet"]` instead of `Tastes.Sweet`. The option turns off the warning to allow the rest of the process to continue.

11. Add the `uglify` task using the code below.

    The task minifies the *combined.js* file found in the temp directory and creates the result file in wwwroot/lib following the standard naming convention *<file name>.min.js*.

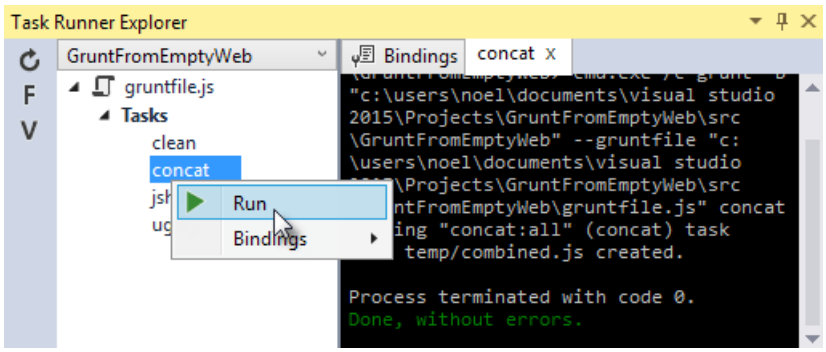
```
uglify: {
 all: {
   src: ['temp/combined.js'],
   dest: 'wwwroot/lib/combined.min.js'
 }
},
```

12. Under the call to `grunt.loadNpmTasks` that loads `grunt-contrib-clean`, include the same call for jshint, concat, and uglify using the code below.

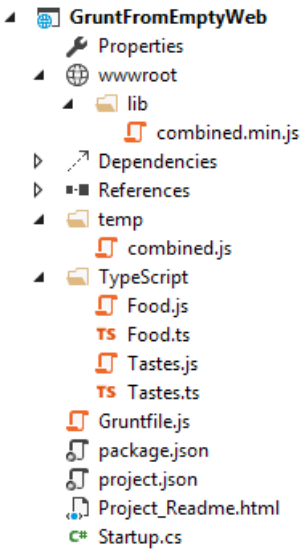
```
grunt.loadNpmTasks('grunt-contrib-jshint');
grunt.loadNpmTasks('grunt-contrib-concat');
grunt.loadNpmTasks('grunt-contrib-uglify');
```

13. Save *Gruntfile.js*. The file should look something like the example below.

14. Notice that the **Task Runner Explorer** Tasks list includes `clean`, `concat`, `jshint` and `uglify` tasks. Run each task in order and observe the results in **Solution Explorer**. Each task should run without errors.



The concat task creates a new *combined.js* file and places it into the temp directory. The `jshint` task simply runs and doesn't produce output. The `uglify` task creates a new *combined.min.js* file and places it into *wwwroot/lib*. On completion, the solution should look something like the screenshot below:



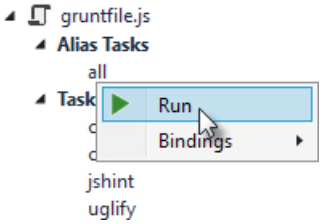
> **NOTE**
>
> For more information on the options for each package, visit https://www.npmjs.com/ and lookup the package name in the search box on the main page. For example, you can look up the grunt-contrib-clean package to get a documentation link that explains all of its parameters.

All together now

Use the Grunt `registerTask()` method to run a series of tasks in a particular sequence. For example, to run the example steps above in the order clean -> concat -> jshint -> uglify, add the code below to the module. The code should be added to the same level as the loadNpmTasks() calls, outside initConfig.

```
grunt.registerTask("all", ['clean', 'concat', 'jshint', 'uglify']);
```

The new task shows up in Task Runner Explorer under Alias Tasks. You can right-click and run it just as you would other tasks. The `all` task will run `clean`, `concat`, `jshint` and `uglify`, in order.



Watching for changes

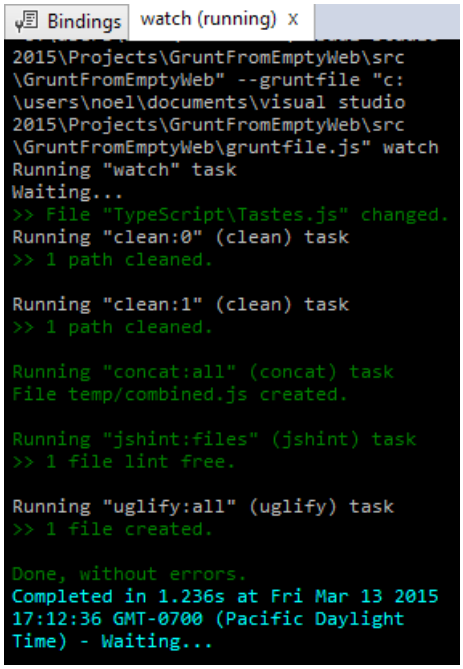
A `watch` task keeps an eye on files and directories. The watch triggers tasks automatically if it detects changes. Add the code below to initConfig to watch for changes to *.js files in the TypeScript directory. If a JavaScript file is changed, `watch` will run the `all` task.

```
watch: {
  files: ["TypeScript/*.js"],
  tasks: ["all"]
}
```

Add a call to `loadNpmTasks()` to show the `watch` task in Task Runner Explorer.

```
grunt.loadNpmTasks('grunt-contrib-watch');
```

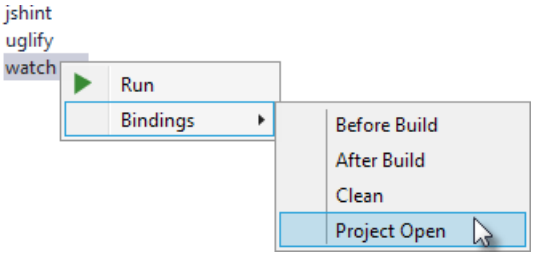
Right-click the watch task in Task Runner Explorer and select Run from the context menu. The command window that shows the watch task running will display a "Waiting..." message. Open one of the TypeScript files, add a space, and then save the file. This will trigger the watch task and trigger the other tasks to run in order. The screenshot below shows a sample run.



Binding to Visual Studio events

Unless you want to manually start your tasks every time you work in Visual Studio, bind tasks to **Before Build**, **After Build**, **Clean**, and **Project Open** events.

Bind `watch` so that it runs every time Visual Studio opens. In Task Runner Explorer, right-click the watch task and select **Bindings** > **Project Open** from the context menu.



Unload and reload the project. When the project loads again, the watch task starts running automatically.

Summary

Grunt is a powerful task runner that can be used to automate most client-build tasks. Grunt leverages NPM to deliver its packages, and features tooling integration with Visual Studio. Visual Studio's Task Runner Explorer detects changes to configuration files and provides a convenient interface to run tasks, view running tasks, and bind tasks to Visual Studio events.

Bundle and minify static assets in ASP.NET Core

9/22/2020 • 7 minutes to read • Edit Online

By Scott Addie and David Pine

This article explains the benefits of applying bundling and minification, including how these features can be used with ASP.NET Core web apps.

What is bundling and minification

Bundling and minification are two distinct performance optimizations you can apply in a web app. Used together, bundling and minification improve performance by reducing the number of server requests and reducing the size of the requested static assets.

Bundling and minification primarily improve the first page request load time. Once a web page has been requested, the browser caches the static assets (JavaScript, CSS, and images). Consequently, bundling and minification don't improve performance when requesting the same page, or pages, on the same site requesting the same assets. If the expires header isn't set correctly on the assets and if bundling and minification isn't used, the browser's freshness heuristics mark the assets stale after a few days. Additionally, the browser requires a validation request for each asset. In this case, bundling and minification provide a performance improvement even after the first page request.

Bundling

Bundling combines multiple files into a single file. Bundling reduces the number of server requests that are necessary to render a web asset, such as a web page. You can create any number of individual bundles specifically for CSS, JavaScript, etc. Fewer files means fewer HTTP requests from the browser to the server or from the service providing your application. This results in improved first page load performance.

Minification

Minification removes unnecessary characters from code without altering functionality. The result is a significant size reduction in requested assets (such as CSS, images, and JavaScript files). Common side effects of minification include shortening variable names to one character and removing comments and unnecessary whitespace.

Consider the following JavaScript function:

```
AddAltToImg = function (imageTagAndImageID, imageContext) {
    ///<signature>
    ///<summary> Adds an alt tab to the image
    // </summary>
    //<param name="imgElement" type="String">The image selector.</param>
    //<param name="ContextForImage" type="String">The image context.</param>
    ///</signature>
    var imageElement = $(imageTagAndImageID, imageContext);
    imageElement.attr('alt', imageElement.attr('id').replace(/ID/, ''));
}
```

Minification reduces the function to the following:

```
AddAltToImg=function(t,a){var r=$(t,a);r.attr("alt",r.attr("id").replace(/ID/,""))};
```

In addition to removing the comments and unnecessary whitespace, the following parameter and variable names were renamed as follows:

ORIGINAL	RENAMED
`imageTagAndImageID`	`t`
`imageContext`	`a`
`imageElement`	`r`

Impact of bundling and minification

The following table outlines differences between individually loading assets and using bundling and minification:

ACTION	WITH B/M	WITHOUT B/M	CHANGE
File Requests	7	18	157%
KB Transferred	156	264.68	70%
Load Time (ms)	885	2360	167%

Browsers are fairly verbose with regard to HTTP request headers. The total bytes sent metric saw a significant reduction when bundling. The load time shows a significant improvement, however this example ran locally. Greater performance gains are realized when using bundling and minification with assets transferred over a network.

Choose a bundling and minification strategy

The MVC and Razor Pages project templates provide a solution for bundling and minification consisting of a JSON configuration file. Third-party tools, such as the Grunt task runner, accomplish the same tasks with a bit more complexity. A third-party tool is a great fit when your development workflow requires processing beyond bundling and minification—such as linting and image optimization. By using design-time bundling and minification, the minified files are created prior to the app's deployment. Bundling and minifying before deployment provides the advantage of reduced server load. However, it's important to recognize that design-time bundling and minification increases build complexity and only works with static files.

Configure bundling and minification

> **NOTE**
> The BuildBundlerMinifier NuGet package needs to be added to your project for this to work.

In ASP.NET Core 2.0 or earlier, the MVC and Razor Pages project templates provide a *bundleconfig.json* configuration file that defines the options for each bundle:

In ASP.NET Core 2.1 or later, add a new JSON file, named *bundleconfig.json*, to the MVC or Razor Pages project root. Include the following JSON in that file as a starting point:

```
[
  {
    "outputFileName": "wwwroot/css/site.min.css",
    "inputFiles": [
      "wwwroot/css/site.css"
    ]
  },
  {
    "outputFileName": "wwwroot/js/site.min.js",
    "inputFiles": [
      "wwwroot/js/site.js"
    ],
    "minify": {
      "enabled": true,
      "renameLocals": true
    },
    "sourceMap": false
  }
]
```

The *bundleconfig.json* file defines the options for each bundle. In the preceding example, a single bundle configuration is defined for the custom JavaScript (*wwwroot/js/site.js*) and stylesheet (*wwwroot/css/site.css*) files.

Configuration options include:

- `outputFileName`: The name of the bundle file to output. Can contain a relative path from the *bundleconfig.json* file. **required**
- `inputFiles`: An array of files to bundle together. These are relative paths to the configuration file. **optional**, *an empty value results in an empty output file. globbing patterns are supported.
- `minify`: The minification options for the output type. **optional**, *default* - `minify: { enabled: true }`
  - Configuration options are available per output file type.
    - CSS Minifier
    - JavaScript Minifier
    - HTML Minifier
- `includeInProject`: Flag indicating whether to add generated files to project file. **optional**, *default - false*
- `sourceMap`: Flag indicating whether to generate a source map for the bundled file. **optional**, *default - false*
- `sourceMapRootPath`: The root path for storing the generated source map file.

Add files to workflow

Consider an example in which an additional *custom.css* file is added resembling the following:

```
.about, [role=main], [role=complementary] {
    margin-top: 60px;
}

footer {
    margin-top: 10px;
}
```

To minify *custom.css* and bundle it with *site.css* into a *site.min.css* file, add the relative path to *bundleconfig.json*:

```
[
  {
    "outputFileName": "wwwroot/css/site.min.css",
    "inputFiles": [
      "wwwroot/css/site.css",
      "wwwroot/css/custom.css"
    ]
  },
  {
    "outputFileName": "wwwroot/js/site.min.js",
    "inputFiles": [
      "wwwroot/js/site.js"
    ],
    "minify": {
      "enabled": true,
      "renameLocals": true
    },
    "sourceMap": false
  }
]
```

NOTE

Alternatively, the following globbing pattern could be used:

```
"inputFiles": ["wwwroot/**/!(*.min).css" ]
```

This globbing pattern matches all CSS files and excludes the minified file pattern.

Build the application. Open *site.min.css* and notice the content of *custom.css* is appended to the end of the file.

Environment-based bundling and minification

As a best practice, the bundled and minified files of your app should be used in a production environment. During development, the original files make for easier debugging of the app.

Specify which files to include in your pages by using the Environment Tag Helper in your views. The Environment Tag Helper only renders its contents when running in specific environments.

The following `environment` tag renders the unprocessed CSS files when running in the `Development` environment:

```
<environment include="Development">
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" />
</environment>
```

```
<environment names="Development">
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" />
</environment>
```

The following `environment` tag renders the bundled and minified CSS files when running in an environment other than `Development`. For example, running in `Production` or `Staging` triggers the rendering of these stylesheets:

```
<environment exclude="Development">
    <link rel="stylesheet" href="https://ajax.aspnetcdn.com/ajax/bootstrap/3.3.7/css/bootstrap.min.css"
          asp-fallback-href="~/lib/bootstrap/dist/css/bootstrap.min.css"
          asp-fallback-test-class="sr-only" asp-fallback-test-property="position" asp-fallback-test-
value="absolute" />
    <link rel="stylesheet" href="~/css/site.min.css" asp-append-version="true" />
</environment>
```

```
<environment names="Staging,Production">
    <link rel="stylesheet" href="https://ajax.aspnetcdn.com/ajax/bootstrap/3.3.7/css/bootstrap.min.css"
          asp-fallback-href="~/lib/bootstrap/dist/css/bootstrap.min.css"
          asp-fallback-test-class="sr-only" asp-fallback-test-property="position" asp-fallback-test-
value="absolute" />
    <link rel="stylesheet" href="~/css/site.min.css" asp-append-version="true" />
</environment>
```

Consume bundleconfig.json from Gulp

There are cases in which an app's bundling and minification workflow requires additional processing. Examples include image optimization, cache busting, and CDN asset processing. To satisfy these requirements, you can convert the bundling and minification workflow to use Gulp.

Manually convert the bundling and minification workflow to use Gulp

Add a *package.json* file, with the following `devDependencies`, to the project root:

> **WARNING**
> The `gulp-uglify` module doesn't support ECMAScript (ES) 2015 / ES6 and later. Install gulp-terser instead of `gulp-uglify` to use ES2015 / ES6 or later.

```
"devDependencies": {
  "del": "^3.0.0",
  "gulp": "^4.0.0",
  "gulp-concat": "^2.6.1",
  "gulp-cssmin": "^0.2.0",
  "gulp-htmlmin": "^3.0.0",
  "gulp-uglify": "^3.0.0",
  "merge-stream": "^1.0.1"
}
```

Install the dependencies by running the following command at the same level as *package.json*:

```
npm i
```

Install the Gulp CLI as a global dependency:

```
npm i -g gulp-cli
```

Copy the *gulpfile.js* file below to the project root:

```
'use strict';

var gulp = require('gulp'),
    concat = require('gulp-concat'),
```

```
    cssmin = require('gulp-cssmin'),
    htmlmin = require('gulp-htmlmin'),
    uglify = require('gulp-uglify'),
    merge = require('merge-stream'),
    del = require('del'),
    bundleconfig = require('./bundleconfig.json');

const regex = {
    css: /\.css$/,
    html: /\.(html|htm)$/,
    js: /\.js$/
};

gulp.task('min:js', async function () {
    merge(getBundles(regex.js).map(bundle => {
        return gulp.src(bundle.inputFiles, { base: '.' })
            .pipe(concat(bundle.outputFileName))
            .pipe(uglify())
            .pipe(gulp.dest('.'));
    }))
});

gulp.task('min:css', async function () {
    merge(getBundles(regex.css).map(bundle => {
        return gulp.src(bundle.inputFiles, { base: '.' })
            .pipe(concat(bundle.outputFileName))
            .pipe(cssmin())
            .pipe(gulp.dest('.'));
    }))
});

gulp.task('min:html', async function () {
    merge(getBundles(regex.html).map(bundle => {
        return gulp.src(bundle.inputFiles, { base: '.' })
            .pipe(concat(bundle.outputFileName))
            .pipe(htmlmin({ collapseWhitespace: true, minifyCSS: true, minifyJS: true }))
            .pipe(gulp.dest('.'));
    }))
});

gulp.task('min', gulp.series(['min:js', 'min:css', 'min:html']));

gulp.task('clean', () => {
    return del(bundleconfig.map(bundle => bundle.outputFileName));
});

gulp.task('watch', () => {
    getBundles(regex.js).forEach(
        bundle => gulp.watch(bundle.inputFiles, gulp.series(["min:js"])));

    getBundles(regex.css).forEach(
        bundle => gulp.watch(bundle.inputFiles, gulp.series(["min:css"])));

    getBundles(regex.html).forEach(
        bundle => gulp.watch(bundle.inputFiles, gulp.series(['min:html'])));
});

const getBundles = (regexPattern) => {
    return bundleconfig.filter(bundle => {
        return regexPattern.test(bundle.outputFileName);
    });
};

gulp.task('default', gulp.series("min"));
```

Run Gulp tasks

To trigger the Gulp minification task before the project builds in Visual Studio:

1. Install the BuildBundlerMinifier NuGet package.
2. Add the following MSBuild Target to the project file:

```
<Target Name="MyPreCompileTarget" BeforeTargets="Build">
  <Exec Command="gulp min" />
</Target>
```

In this example, any tasks defined within the `MyPreCompileTarget` target run before the predefined `Build` target. Output similar to the following appears in Visual Studio's Output window:

```
1>------ Build started: Project: BuildBundlerMinifierApp, Configuration: Debug Any CPU ------
1>BuildBundlerMinifierApp -> C:\BuildBundlerMinifierApp\bin\Debug\netcoreapp2.0\BuildBundlerMinifierApp.dll
1>[14:17:49] Using gulpfile C:\BuildBundlerMinifierApp\gulpfile.js
1>[14:17:49] Starting 'min:js'...
1>[14:17:49] Starting 'min:css'...
1>[14:17:49] Starting 'min:html'...
1>[14:17:49] Finished 'min:js' after 83 ms
1>[14:17:49] Finished 'min:css' after 88 ms
========== Build: 1 succeeded, 0 failed, 0 up-to-date, 0 skipped ==========
```

Browser Link in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

By Nicolò Carandini, Mike Wasson, and Tom Dykstra

Browser Link is a Visual Studio feature. It creates a communication channel between the development environment and one or more web browsers. You can use Browser Link to refresh your web app in several browsers at once, which is useful for cross-browser testing.

Browser Link setup

Add the Microsoft.VisualStudio.Web.BrowserLink package to your project. For ASP.NET Core Razor Pages or MVC projects, also enable runtime compilation of Razor (*.cshtml*) files as described in Razor file compilation in ASP.NET Core. Razor syntax changes are applied only when runtime compilation has been enabled.

When converting an ASP.NET Core 2.0 project to ASP.NET Core 2.1 and transitioning to the Microsoft.AspNetCore.App metapackage, install the Microsoft.VisualStudio.Web.BrowserLink package for Browser Link functionality. The ASP.NET Core 2.1 project templates use the `Microsoft.AspNetCore.App` metapackage by default.

The ASP.NET Core 2.0 **Web Application**, **Empty**, and **Web API** project templates use the Microsoft.AspNetCore.All metapackage, which contains a package reference for Microsoft.VisualStudio.Web.BrowserLink. Therefore, using the `Microsoft.AspNetCore.All` metapackage requires no further action to make Browser Link available for use.

The ASP.NET Core 1.x **Web Application** project template has a package reference for the Microsoft.VisualStudio.Web.BrowserLink package. Other project types require you to add a package reference to `Microsoft.VisualStudio.Web.BrowserLink`.

Configuration

Call `UseBrowserLink` in the `Startup.Configure` method:

```
app.UseBrowserLink();
```

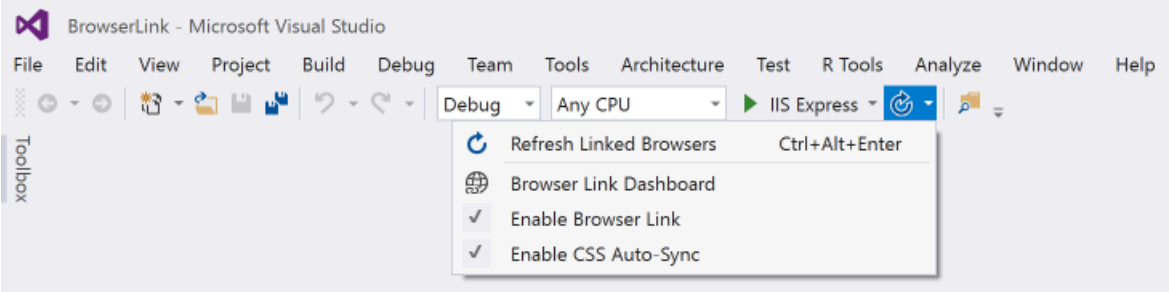
The `UseBrowserLink` call is typically placed inside an `if` block that only enables Browser Link in the Development environment. For example:

```
if (env.IsDevelopment())
{
    app.UseDeveloperExceptionPage();
    app.UseBrowserLink();
}
```

For more information, see Use multiple environments in ASP.NET Core.

How to use Browser Link

When you have an ASP.NET Core project open, Visual Studio shows the Browser Link toolbar control next to the **Debug Target** toolbar control:

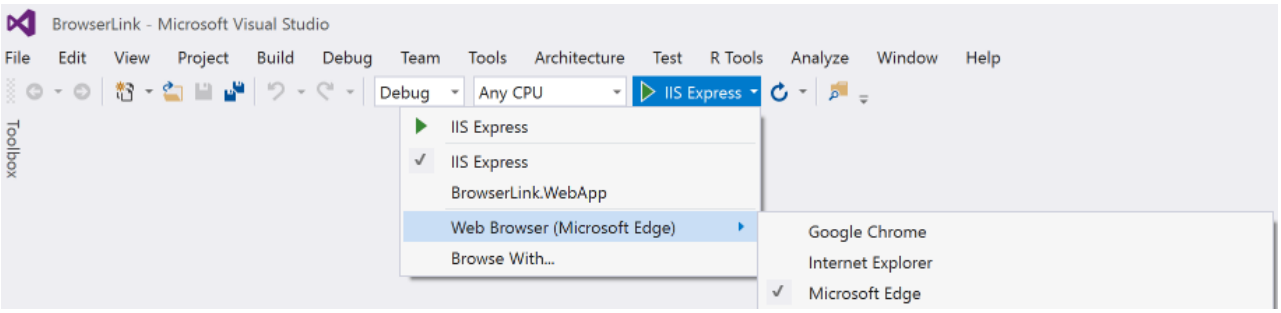


From the Browser Link toolbar control, you can:

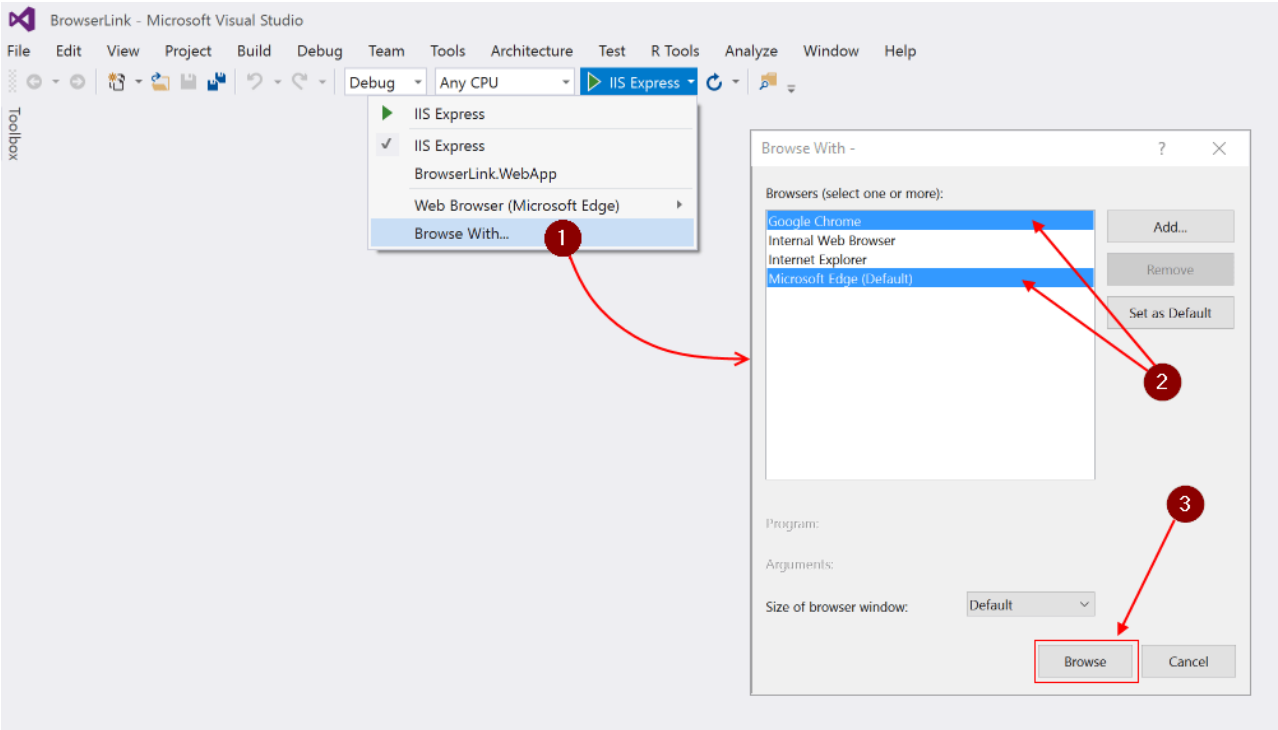
- Refresh the web app in several browsers at once.
- Open the **Browser Link Dashboard**.
- Enable or disable **Browser Link**. Note: Browser Link is disabled by default in Visual Studio.
- Enable or disable CSS Auto-Sync.

Refresh the web app in several browsers at once

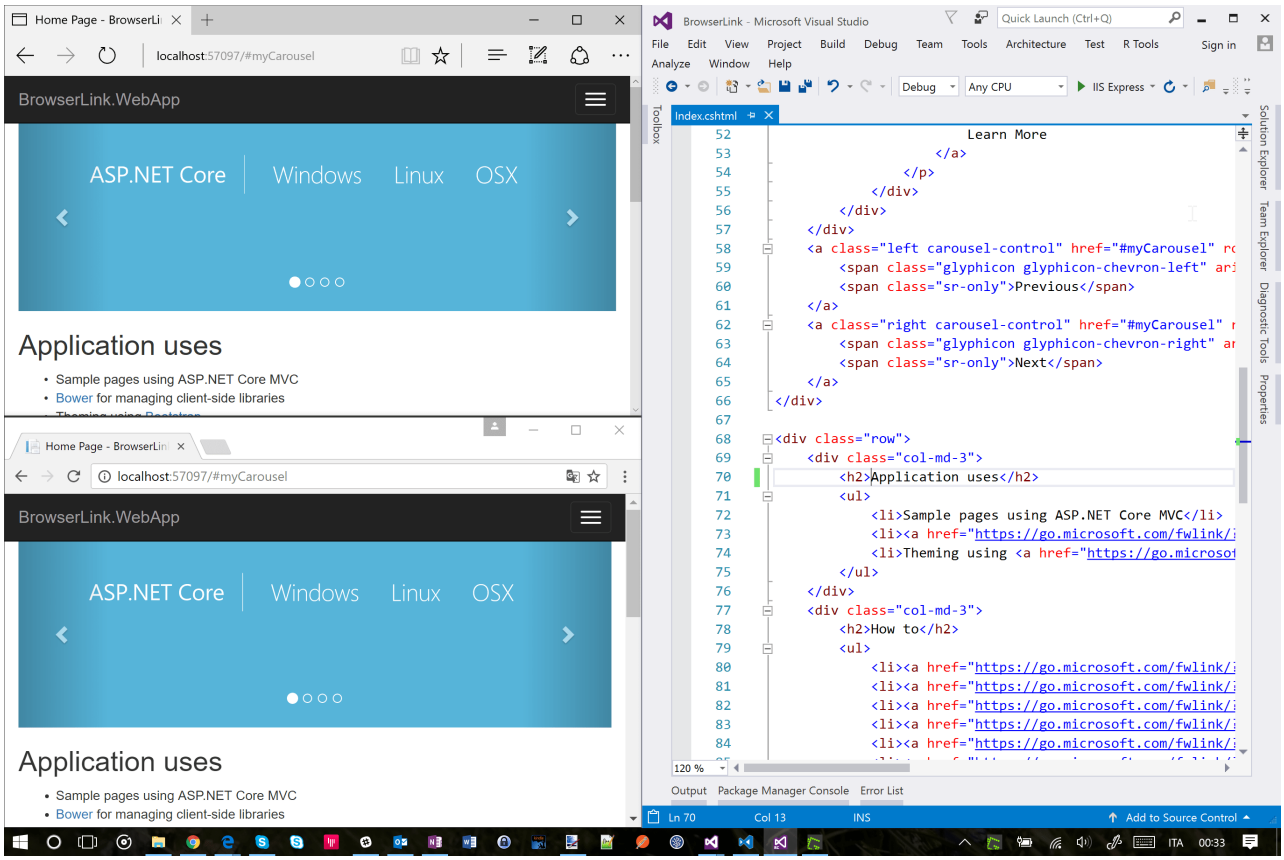
To choose a single web browser to launch when starting the project, use the drop-down menu in the **Debug Target** toolbar control:



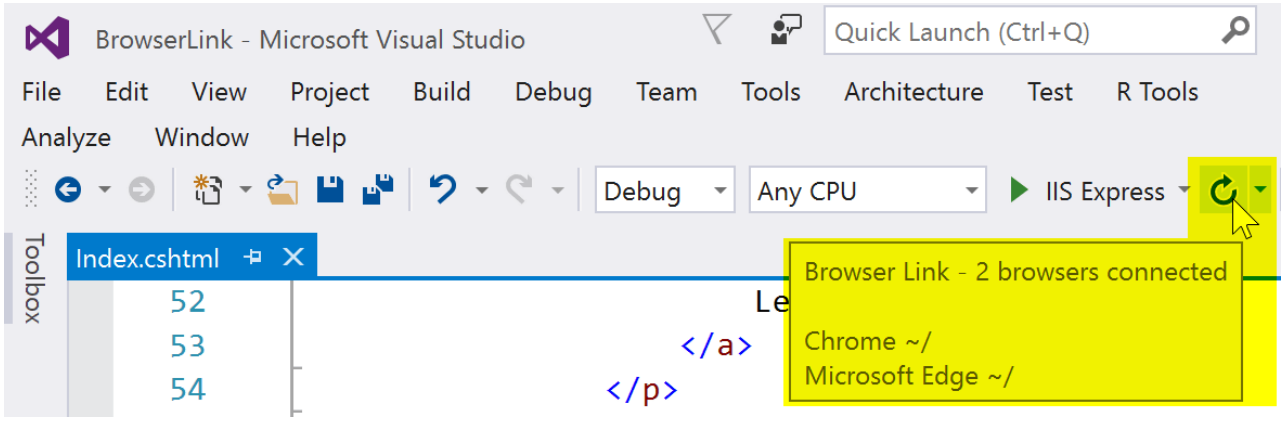
To open multiple browsers at once, choose **Browse with...** from the same drop-down. Hold down the `Ctrl` key to select the browsers you want, and then click **Browse**:



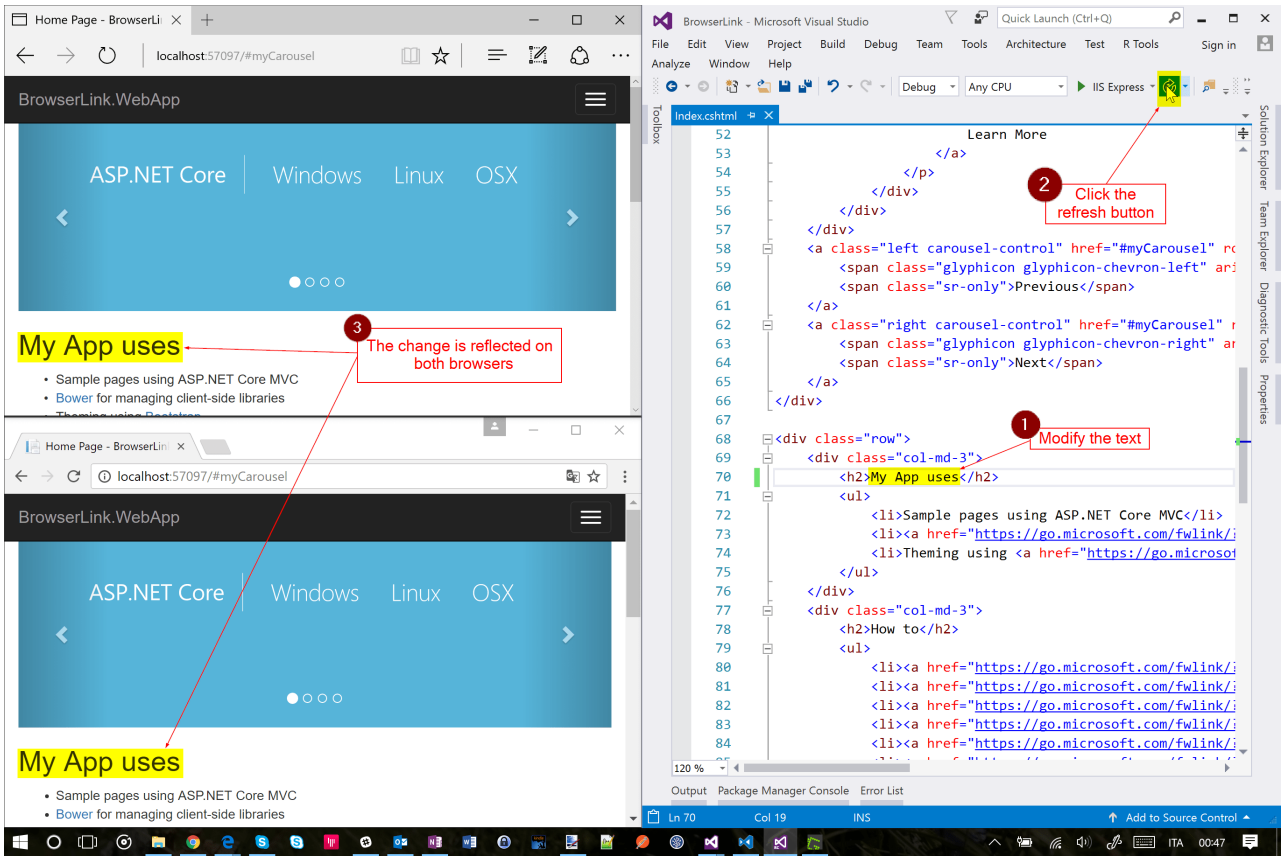
The following screenshot shows Visual Studio with the Index view open and two open browsers:



Hover over the Browser Link toolbar control to see the browsers that are connected to the project:



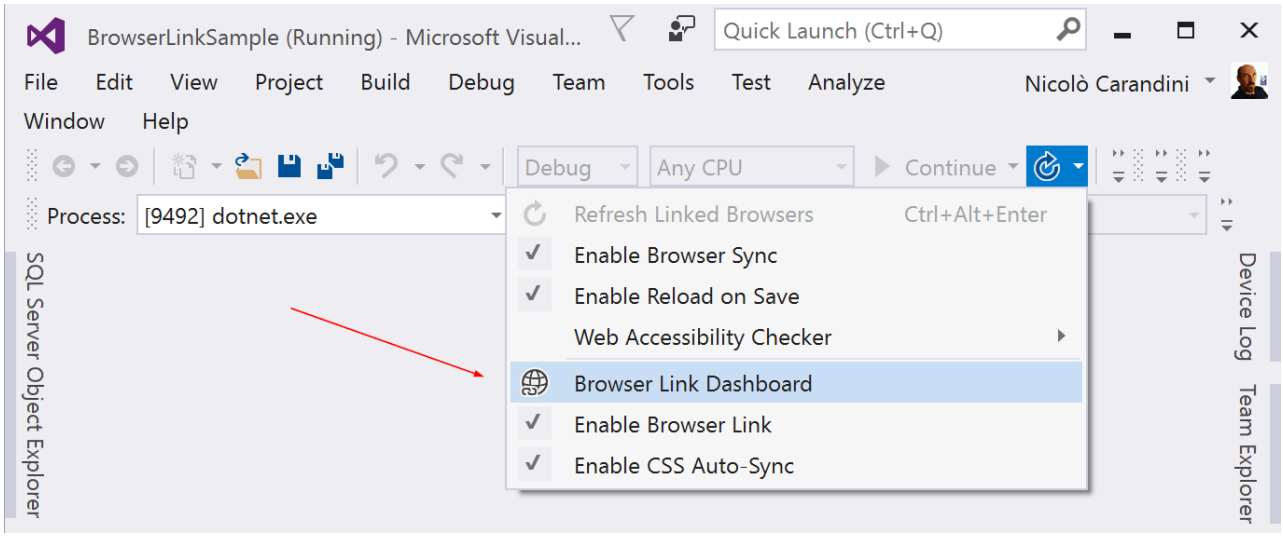
Change the Index view, and all connected browsers are updated when you click the Browser Link refresh button:



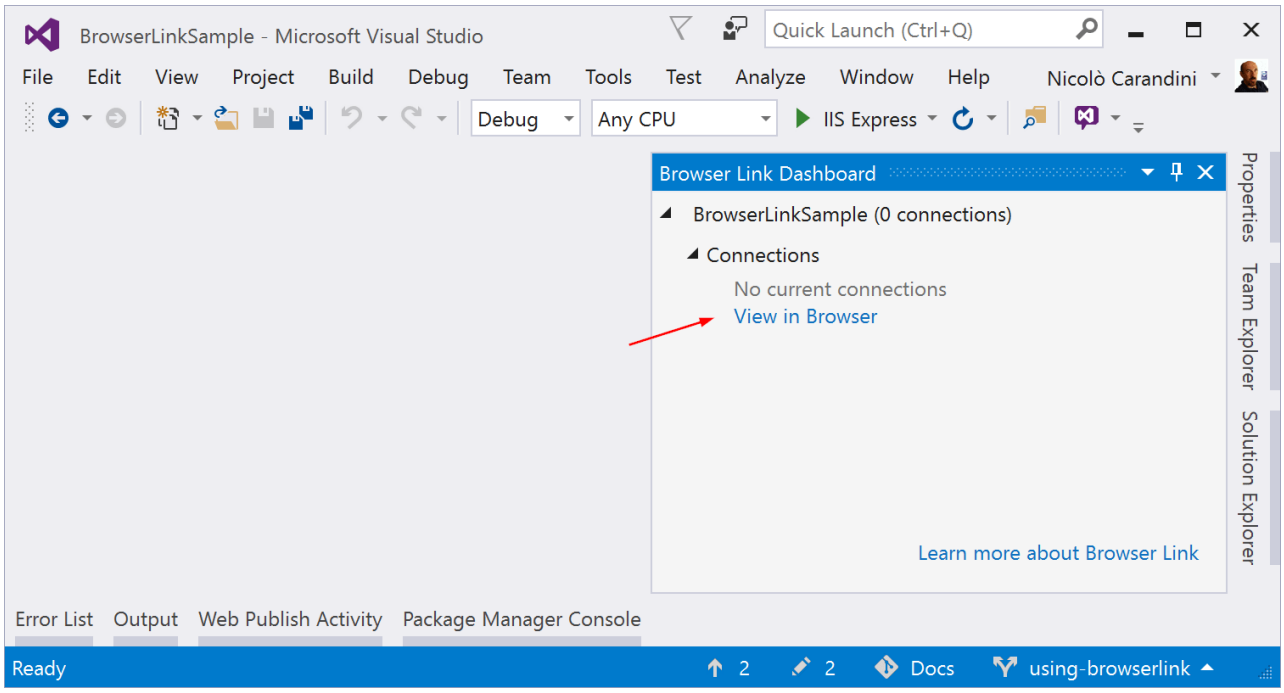
Browser Link also works with browsers that you launch from outside Visual Studio and navigate to the app URL.

The Browser Link Dashboard

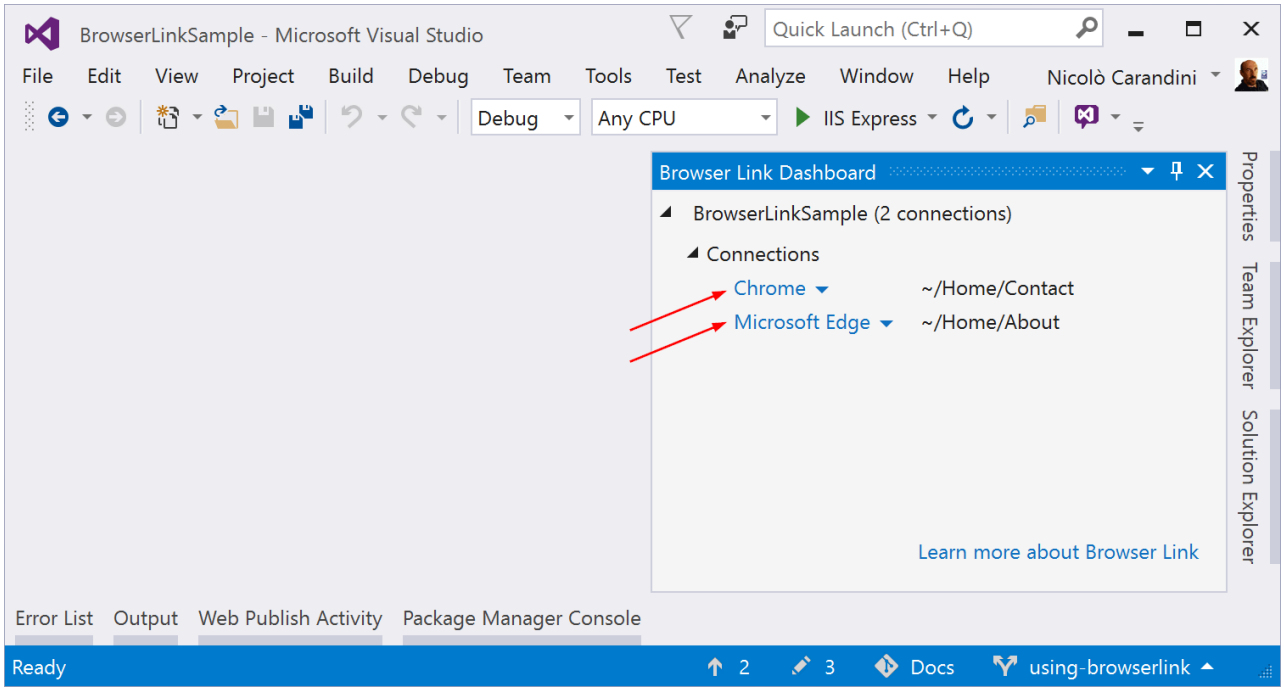
Open the **Browser Link Dashboard** window from the Browser Link drop down menu to manage the connection with open browsers:



If no browser is connected, you can start a non-debugging session by selecting the **View in Browser** link:



Otherwise, the connected browsers are shown with the path to the page that each browser is showing:



You can also click on an individual browser name to refresh only that browser.

Enable or disable Browser Link

When you re-enable Browser Link after disabling it, you must refresh the browsers to reconnect them.

Enable or disable CSS Auto-Sync

When CSS Auto-Sync is enabled, connected browsers are automatically refreshed when you make any change to CSS files.

How it works

Browser Link uses SignalR to create a communication channel between Visual Studio and the browser. When Browser Link is enabled, Visual Studio acts as a SignalR server that multiple clients (browsers) can connect to. Browser Link also registers a middleware component in the ASP.NET Core request pipeline. This component injects special `<script>` references into every page request from the server. You can see the script references by selecting

View source in the browser and scrolling to the end of the `<body>` tag content:

```
    <!-- Visual Studio Browser Link -->
    <script type="application/json" id="__browserLink_initializationData">
        {"requestId":"a717d5a07c1741949a7cefd6fa2bad08","requestMappingFromServer":false}
    </script>
    <script type="text/javascript" src="http://localhost:54139/b6e36e429d034f578ebccd6a79bf19bf/browserLink"
async="async"></script>
    <!-- End Browser Link -->
</body>
```

Your source files aren't modified. The middleware component injects the script references dynamically.

Because the browser-side code is all JavaScript, it works on all browsers that SignalR supports without requiring a browser plug-in.

Session and state management in ASP.NET Core

9/22/2020 • 31 minutes to read • Edit Online

By Rick Anderson, Kirk Larkin, and Diana LaRose

HTTP is a stateless protocol. By default, HTTP requests are independent messages that don't retain user values. This article describes several approaches to preserve user data between requests.

View or download sample code (how to download)

State management

State can be stored using several approaches. Each approach is described later in this topic.

STORAGE APPROACH	STORAGE MECHANISM
Cookies	HTTP cookies. May include data stored using server-side app code.
Session state	HTTP cookies and server-side app code
TempData	HTTP cookies or session state
Query strings	HTTP query strings
Hidden fields	HTTP form fields
HttpContext.Items	Server-side app code
Cache	Server-side app code

Cookies

Cookies store data across requests. Because cookies are sent with every request, their size should be kept to a minimum. Ideally, only an identifier should be stored in a cookie with the data stored by the app. Most browsers restrict cookie size to 4096 bytes. Only a limited number of cookies are available for each domain.

Because cookies are subject to tampering, they must be validated by the app. Cookies can be deleted by users and expire on clients. However, cookies are generally the most durable form of data persistence on the client.

Cookies are often used for personalization, where content is customized for a known user. The user is only identified and not authenticated in most cases. The cookie can store the user's name, account name, or unique user ID such as a GUID. The cookie can be used to access the user's personalized settings, such as their preferred website background color.

See the European Union General Data Protection Regulations (GDPR) when issuing cookies and dealing with privacy concerns. For more information, see General Data Protection Regulation (GDPR) support in ASP.NET Core.

Session state

Session state is an ASP.NET Core scenario for storage of user data while the user browses a web app. Session state

uses a store maintained by the app to persist data across requests from a client. The session data is backed by a cache and considered ephemeral data. The site should continue to function without the session data. Critical application data should be stored in the user database and cached in session only as a performance optimization.

Session isn't supported in SignalR apps because a SignalR Hub may execute independent of an HTTP context. For example, this can occur when a long polling request is held open by a hub beyond the lifetime of the request's HTTP context.

ASP.NET Core maintains session state by providing a cookie to the client that contains a session ID. The cookie session ID:

- Is sent to the app with each request.
- Is used by the app to fetch the session data.

Session state exhibits the following behaviors:

- The session cookie is specific to the browser. Sessions aren't shared across browsers.
- Session cookies are deleted when the browser session ends.
- If a cookie is received for an expired session, a new session is created that uses the same session cookie.
- Empty sessions aren't retained. The session must have at least one value set to persist the session across requests. When a session isn't retained, a new session ID is generated for each new request.
- The app retains a session for a limited time after the last request. The app either sets the session timeout or uses the default value of 20 minutes. Session state is ideal for storing user data:
  - That's specific to a particular session.
  - Where the data doesn't require permanent storage across sessions.
- Session data is deleted either when the ISession.Clear implementation is called or when the session expires.
- There's no default mechanism to inform app code that a client browser has been closed or when the session cookie is deleted or expired on the client.
- Session state cookies aren't marked essential by default. Session state isn't functional unless tracking is permitted by the site visitor. For more information, see General Data Protection Regulation (GDPR) support in ASP.NET Core.

> **WARNING**
> Don't store sensitive data in session state. The user might not close the browser and clear the session cookie. Some browsers maintain valid session cookies across browser windows. A session might not be restricted to a single user. The next user might continue to browse the app with the same session cookie.

The in-memory cache provider stores session data in the memory of the server where the app resides. In a server farm scenario:

- Use *sticky sessions* to tie each session to a specific app instance on an individual server. Azure App Service uses Application Request Routing (ARR) to enforce sticky sessions by default. However, sticky sessions can affect scalability and complicate web app updates. A better approach is to use a Redis or SQL Server distributed cache, which doesn't require sticky sessions. For more information, see Distributed caching in ASP.NET Core.
- The session cookie is encrypted via IDataProtector. Data Protection must be properly configured to read session cookies on each machine. For more information, see ASP.NET Core Data Protection and Key storage providers.

Configure session state

The Microsoft.AspNetCore.Session package:

- Is included implicitly by the framework.
- Provides middleware for managing session state.

To enable the session middleware, `Startup` must contain:

- Any of the IDistributedCache memory caches. The `IDistributedCache` implementation is used as a backing store for session. For more information, see Distributed caching in ASP.NET Core.
- A call to AddSession in `ConfigureServices`.
- A call to UseSession in `Configure`.

The following code shows how to set up the in-memory session provider with a default in-memory implementation of `IDistributedCache`:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddDistributedMemoryCache();

        services.AddSession(options =>
        {
            options.IdleTimeout = TimeSpan.FromSeconds(10);
            options.Cookie.HttpOnly = true;
            options.Cookie.IsEssential = true;
        });

        services.AddControllersWithViews();
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Home/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthentication();
        app.UseAuthorization();

        app.UseSession();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapDefaultControllerRoute();
            endpoints.MapRazorPages();
        });
    }
}
```

The preceding code sets a short timeout to simplify testing.

The order of middleware is important. Call `UseSession` after `UseRouting` and before `UseEndpoints`. See Middleware Ordering.

HttpContext.Session is available after session state is configured.

`HttpContext.Session` can't be accessed before `UseSession` has been called.

A new session with a new session cookie can't be created after the app has begun writing to the response stream. The exception is recorded in the web server log and not displayed in the browser.

Load session state asynchronously

The default session provider in ASP.NET Core loads session records from the underlying IDistributedCache backing store asynchronously only if the ISession.LoadAsync method is explicitly called before the TryGetValue, Set, or Remove methods. If `LoadAsync` isn't called first, the underlying session record is loaded synchronously, which can incur a performance penalty at scale.

To have apps enforce this pattern, wrap the DistributedSessionStore and DistributedSession implementations with versions that throw an exception if the `LoadAsync` method isn't called before `TryGetValue`, `Set`, or `Remove`. Register the wrapped versions in the services container.

Session options

To override session defaults, use SessionOptions.

OPTION	DESCRIPTION
Cookie	Determines the settings used to create the cookie. Name defaults to SessionDefaults.CookieName (`.AspNetCore.Session`). Path defaults to SessionDefaults.CookiePath (`/`). SameSite defaults to SameSiteMode.Lax (`1`). HttpOnly defaults to `true`. IsEssential defaults to `false`.
IdleTimeout	The `IdleTimeout` indicates how long the session can be idle before its contents are abandoned. Each session access resets the timeout. This setting only applies to the content of the session, not the cookie. The default is 20 minutes.
IOTimeout	The maximum amount of time allowed to load a session from the store or to commit it back to the store. This setting may only apply to asynchronous operations. This timeout can be disabled using InfiniteTimeSpan. The default is 1 minute.

Session uses a cookie to track and identify requests from a single browser. By default, this cookie is named `.AspNetCore.Session`, and it uses a path of `/`. Because the cookie default doesn't specify a domain, it isn't made available to the client-side script on the page (because HttpOnly defaults to `true`).

To override cookie session defaults, use SessionOptions:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDistributedMemoryCache();

    services.AddSession(options =>
    {
        options.Cookie.Name = ".AdventureWorks.Session";
        options.IdleTimeout = TimeSpan.FromSeconds(10);
        options.Cookie.IsEssential = true;
    });

    services.AddControllersWithViews();
    services.AddRazorPages();
}
```

The app uses the IdleTimeout property to determine how long a session can be idle before its contents in the server's cache are abandoned. This property is independent of the cookie expiration. Each request that passes through the Session Middleware resets the timeout.

Session state is *non-locking*. If two requests simultaneously attempt to modify the contents of a session, the last request overrides the first. `Session` is implemented as a *coherent session*, which means that all the contents are stored together. When two requests seek to modify different session values, the last request may override session changes made by the first.

Set and get Session values

Session state is accessed from a Razor Pages PageModel class or MVC Controller class with HttpContext.Session. This property is an ISession implementation.

The `ISession` implementation provides several extension methods to set and retrieve integer and string values. The extension methods are in the Microsoft.AspNetCore.Http namespace.

`ISession` extension methods:

- Get(ISession, String)
- GetInt32(ISession, String)
- GetString(ISession, String)
- SetInt32(ISession, String, Int32)
- SetString(ISession, String, String)

The following example retrieves the session value for the `IndexModel.SessionKeyName` key (`_Name` in the sample app) in a Razor Pages page:

```
@page
@using Microsoft.AspNetCore.Http
@model IndexModel

...

Name: @HttpContext.Session.GetString(IndexModel.SessionKeyName)
```

The following example shows how to set and get an integer and a string:

```
public class IndexModel : PageModel
{
    public const string SessionKeyName = "_Name";
    public const string SessionKeyAge = "_Age";
    const string SessionKeyTime = "_Time";

    public string SessionInfo_Name { get; private set; }
    public string SessionInfo_Age { get; private set; }
    public string SessionInfo_CurrentTime { get; private set; }
    public string SessionInfo_SessionTime { get; private set; }
    public string SessionInfo_MiddlewareValue { get; private set; }

    public void OnGet()
    {
        // Requires: using Microsoft.AspNetCore.Http;
        if (string.IsNullOrEmpty(HttpContext.Session.GetString(SessionKeyName)))
        {
            HttpContext.Session.SetString(SessionKeyName, "The Doctor");
            HttpContext.Session.SetInt32(SessionKeyAge, 773);
        }

        var name = HttpContext.Session.GetString(SessionKeyName);
        var age = HttpContext.Session.GetInt32(SessionKeyAge);
```

All session data must be serialized to enable a distributed cache scenario, even when using the in-memory cache. String and integer serializers are provided by the extension methods of ISession. Complex types must be serialized by the user using another mechanism, such as JSON.

Use the following sample code to serialize objects:

```
public static class SessionExtensions
{
    public static void Set<T>(this ISession session, string key, T value)
    {
        session.SetString(key, JsonSerializer.Serialize(value));
    }

    public static T Get<T>(this ISession session, string key)
    {
        var value = session.GetString(key);
        return value == null ? default : JsonSerializer.Deserialize<T>(value);
    }
}
```

The following example shows how to set and get a serializable object with the `SessionExtensions` class:

```
// Requires SessionExtensions from sample download.
if (HttpContext.Session.Get<DateTime>(SessionKeyTime) == default)
{
    HttpContext.Session.Set<DateTime>(SessionKeyTime, currentTime);
}
```

TempData

ASP.NET Core exposes the Razor Pages TempData or Controller TempData. This property stores data until it's read in another request. The Keep(String) and Peek(string) methods can be used to examine the data without deletion at the end of the request. Keep marks all items in the dictionary for retention. `TempData` is:

- Useful for redirection when data is required for more than a single request.
- Implemented by `TempData` providers using either cookies or session state.

TempData samples

Consider the following page that creates a customer:

```
public class CreateModel : PageModel
{
    private readonly RazorPagesContactsContext _context;

    public CreateModel(RazorPagesContactsContext context)
    {
        _context = context;
    }

    public IActionResult OnGet()
    {
        return Page();
    }

    [TempData]
    public string Message { get; set; }

    [BindProperty]
    public Customer Customer { get; set; }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _context.Customer.Add(Customer);
        await _context.SaveChangesAsync();
        Message = $"Customer {Customer.Name} added";

        return RedirectToPage("./IndexPeek");
    }
}
```

The following page displays `TempData["Message"]`:

```
@page
@model IndexModel

<h1>Peek Contacts</h1>

@{
    if (TempData.Peek("Message") != null)
    {
        <h3>Message: @TempData.Peek("Message")</h3>
    }
}

@*Content removed for brevity.*@
```

In the preceding markup, at the end of the request, `TempData["Message"]` is **not** deleted because `Peek` is used. Refreshing the page displays the contents of `TempData["Message"]`.

The following markup is similar to the preceding code, but uses `Keep` to preserve the data at the end of the request:

```
@page
@model IndexModel

<h1>Contacts Keep</h1>

@{
    if (TempData["Message"] != null)
    {
        <h3>Message: @TempData["Message"]</h3>
    }
    TempData.Keep("Message");
}

@*Content removed for brevity.*@
```

Navigating between the *IndexPeek* and *IndexKeep* pages won't delete `TempData["Message"]`.

The following code displays `TempData["Message"]`, but at the end of the request, `TempData["Message"]` is deleted:

```
@page
@model IndexModel

<h1>Index no Keep or Peek</h1>

@{
    if (TempData["Message"] != null)
    {
        <h3>Message: @TempData["Message"]</h3>
    }
}

@*Content removed for brevity.*@
```

TempData providers

The cookie-based TempData provider is used by default to store TempData in cookies.

The cookie data is encrypted using IDataProtector, encoded with Base64UrlTextEncoder, then chunked. The maximum cookie size is less than 4096 bytes due to encryption and chunking. The cookie data isn't compressed because compressing encrypted data can lead to security problems such as the CRIME and BREACH attacks. For more information on the cookie-based TempData provider, see CookieTempDataProvider.

Choose a TempData provider

Choosing a TempData provider involves several considerations, such as:

- Does the app already use session state? If so, using the session state TempData provider has no additional cost to the app beyond the size of the data.
- Does the app use TempData only sparingly for relatively small amounts of data, up to 500 bytes? If so, the cookie TempData provider adds a small cost to each request that carries TempData. If not, the session state TempData provider can be beneficial to avoid round-tripping a large amount of data in each request until the TempData is consumed.
- Does the app run in a server farm on multiple servers? If so, there's no additional configuration required to use the cookie TempData provider outside of Data Protection (see ASP.NET Core Data Protection and Key storage providers).

Most web clients such as web browsers enforce limits on the maximum size of each cookie and the total number of cookies. When using the cookie TempData provider, verify the app won't exceed these limits. Consider the total size of the data. Account for increases in cookie size due to encryption and chunking.

Configure the TempData provider

The cookie-based TempData provider is enabled by default.

To enable the session-based TempData provider, use the AddSessionStateTempDataProvider extension method. Only one call to `AddSessionStateTempDataProvider` is required:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews()
        .AddSessionStateTempDataProvider();
    services.AddRazorPages()
        .AddSessionStateTempDataProvider();

    services.AddSession();
}

public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }
    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseSession();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
        endpoints.MapRazorPages();
    });
}
```

Query strings

A limited amount of data can be passed from one request to another by adding it to the new request's query string. This is useful for capturing state in a persistent manner that allows links with embedded state to be shared through email or social networks. Because URL query strings are public, never use query strings for sensitive data.

In addition to unintended sharing, including data in query strings can expose the app to Cross-Site Request Forgery (CSRF) attacks. Any preserved session state must protect against CSRF attacks. For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

Hidden fields

Data can be saved in hidden form fields and posted back on the next request. This is common in multi-page forms. Because the client can potentially tamper with the data, the app must always revalidate the data stored in hidden fields.

HttpContext.Items

The HttpContext.Items collection is used to store data while processing a single request. The collection's contents are discarded after a request is processed. The `Items` collection is often used to allow components or middleware to communicate when they operate at different points in time during a request and have no direct way to pass parameters.

In the following example, middleware adds `isVerified` to the `Items` collection:

```
public void Configure(IApplicationBuilder app, ILogger<Startup> logger)
{
    app.UseRouting();

    app.Use(async (context, next) =>
    {
        logger.LogInformation($"Before setting: Verified: {context.Items["isVerified"]}");
        context.Items["isVerified"] = true;
        await next.Invoke();
    });

    app.Use(async (context, next) =>
    {
        logger.LogInformation($"Next: Verified: {context.Items["isVerified"]}");
        await next.Invoke();
    });

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapGet("/", async context =>
        {
            await context.Response.WriteAsync($"Verified: {context.Items["isVerified"]}");
        });
    });
}
```

For middleware that's only used in a single app, fixed `string` keys are acceptable. Middleware shared between apps should use unique object keys to avoid key collisions. The following example shows how to use a unique object key defined in a middleware class:

```
public class HttpContextItemsMiddleware
{
    private readonly RequestDelegate _next;
    public static readonly object HttpContextItemsMiddlewareKey = new Object();

    public HttpContextItemsMiddleware(RequestDelegate next)
    {
        _next = next;
    }

    public async Task Invoke(HttpContext httpContext)
    {
        httpContext.Items[HttpContextItemsMiddlewareKey] = "K-9";

        await _next(httpContext);
    }
}

public static class HttpContextItemsMiddlewareExtensions
{
    public static IApplicationBuilder
        UseHttpContextItemsMiddleware(this IApplicationBuilder app)
    {
        return app.UseMiddleware<HttpContextItemsMiddleware>();
    }
}
```

Other code can access the value stored in `HttpContext.Items` using the key exposed by the middleware class:

```
HttpContext.Items
    .TryGetValue(HttpContextItemsMiddleware.HttpContextItemsMiddlewareKey,
        out var middlewareSetValue);
SessionInfo_MiddlewareValue =
    middlewareSetValue?.ToString() ?? "Middleware value not set!";
```

This approach also has the advantage of eliminating the use of key strings in the code.

Cache

Caching is an efficient way to store and retrieve data. The app can control the lifetime of cached items. For more information, see Response caching in ASP.NET Core.

Cached data isn't associated with a specific request, user, or session. **Do not cache user-specific data that may be retrieved by other user requests.**

To cache application wide data, see Cache in-memory in ASP.NET Core.

Common errors

- "Unable to resolve service for type 'Microsoft.Extensions.Caching.Distributed.IDistributedCache' while attempting to activate 'Microsoft.AspNetCore.Session.DistributedSessionStore'."

  This is typically caused by failing to configure at least one `IDistributedCache` implementation. For more information, see Distributed caching in ASP.NET Core and Cache in-memory in ASP.NET Core.

If the session middleware fails to persist a session:

- The middleware logs the exception and the request continues normally.
- This leads to unpredictable behavior.

The session middleware can fail to persist a session if the backing store isn't available. For example, a user stores a shopping cart in session. The user adds an item to the cart but the commit fails. The app doesn't know about the failure so it reports to the user that the item was added to their cart, which isn't true.

The recommended approach to check for errors is to call `await feature.Session.CommitAsync` when the app is done writing to the session. CommitAsync throws an exception if the backing store is unavailable. If `CommitAsync` fails, the app can process the exception. LoadAsync throws under the same conditions when the data store is unavailable.

SignalR and session state

SignalR apps should not use session state to store information. SignalR apps can store per connection state in `Context.Items` in the hub.

Additional resources

Host ASP.NET Core in a web farm

By Rick Anderson, Steve Smith, Diana LaRose, and Luke Latham

HTTP is a stateless protocol. Without taking additional steps, HTTP requests are independent messages that don't retain user values or app state. This article describes several approaches to preserve user data and app state between requests.

View or download sample code (how to download)

State management

State can be stored using several approaches. Each approach is described later in this topic.

STORAGE APPROACH	STORAGE MECHANISM
Cookies	HTTP cookies (may include data stored using server-side app code)
Session state	HTTP cookies and server-side app code
TempData	HTTP cookies or session state
Query strings	HTTP query strings
Hidden fields	HTTP form fields
HttpContext.Items	Server-side app code
Cache	Server-side app code
Dependency Injection	Server-side app code

Cookies

Cookies store data across requests. Because cookies are sent with every request, their size should be kept to a minimum. Ideally, only an identifier should be stored in a cookie with the data stored by the app. Most browsers restrict cookie size to 4096 bytes. Only a limited number of cookies are available for each domain.

Because cookies are subject to tampering, they must be validated by the app. Cookies can be deleted by users and expire on clients. However, cookies are generally the most durable form of data persistence on the client.

Cookies are often used for personalization, where content is customized for a known user. The user is only identified and not authenticated in most cases. The cookie can store the user's name, account name, or unique user ID (such as a GUID). You can then use the cookie to access the user's personalized settings, such as their preferred website background color.

Be mindful of the European Union General Data Protection Regulations (GDPR) when issuing cookies and dealing with privacy concerns. For more information, see General Data Protection Regulation (GDPR) support in ASP.NET Core.

Session state

Session state is an ASP.NET Core scenario for storage of user data while the user browses a web app. Session state uses a store maintained by the app to persist data across requests from a client. The session data is backed by a cache and considered ephemeral data—the site should continue to function without the session data. Critical application data should be stored in the user database and cached in session only as a performance optimization.

> **NOTE**
> Session isn't supported in SignalR apps because a SignalR Hub may execute independent of an HTTP context. For example, this can occur when a long polling request is held open by a hub beyond the lifetime of the request's HTTP context.

ASP.NET Core maintains session state by providing a cookie to the client that contains a session ID, which is sent to the app with each request. The app uses the session ID to fetch the session data.

Session state exhibits the following behaviors:

- Because the session cookie is specific to the browser, sessions aren't shared across browsers.
- Session cookies are deleted when the browser session ends.
- If a cookie is received for an expired session, a new session is created that uses the same session cookie.
- Empty sessions aren't retained—the session must have at least one value set into it to persist the session across requests. When a session isn't retained, a new session ID is generated for each new request.
- The app retains a session for a limited time after the last request. The app either sets the session timeout or uses the default value of 20 minutes. Session state is ideal for storing user data that's specific to a particular session but where the data doesn't require permanent storage across sessions.
- Session data is deleted either when the ISession.Clear implementation is called or when the session expires.
- There's no default mechanism to inform app code that a client browser has been closed or when the session cookie is deleted or expired on the client.
- The ASP.NET Core MVC and Razor pages templates include support for General Data Protection Regulation (GDPR). Session state cookies aren't marked essential by default, so session state isn't functional unless tracking is permitted by the site visitor. For more information, see General Data Protection Regulation (GDPR) support in ASP.NET Core.

> **WARNING**
> Don't store sensitive data in session state. The user might not close the browser and clear the session cookie. Some browsers maintain valid session cookies across browser windows. A session might not be restricted to a single user—the next user might continue to browse the app with the same session cookie.

The in-memory cache provider stores session data in the memory of the server where the app resides. In a server farm scenario:

- Use *sticky sessions* to tie each session to a specific app instance on an individual server. Azure App Service uses Application Request Routing (ARR) to enforce sticky sessions by default. However, sticky sessions can affect scalability and complicate web app updates. A better approach is to use a Redis or SQL Server distributed cache, which doesn't require sticky sessions. For more information, see Distributed caching in ASP.NET Core.
- The session cookie is encrypted via IDataProtector. Data Protection must be properly configured to read session cookies on each machine. For more information, see ASP.NET Core Data Protection and Key storage providers.

Configure session state

The Microsoft.AspNetCore.Session package, which is included in the Microsoft.AspNetCore.App metapackage, provides middleware for managing session state. To enable the session middleware, `Startup` must contain:

- Any of the IDistributedCache memory caches. The `IDistributedCache` implementation is used as a backing store for session. For more information, see Distributed caching in ASP.NET Core.
- A call to AddSession in `ConfigureServices`.
- A call to UseSession in `Configure`.

The following code shows how to set up the in-memory session provider with a default in-memory implementation of `IDistributedCache`:

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddDistributedMemoryCache();

        services.AddSession(options =>
        {
            // Set a short timeout for easy testing.
            options.IdleTimeout = TimeSpan.FromSeconds(10);
            options.Cookie.HttpOnly = true;
            // Make the session cookie essential
            options.Cookie.IsEssential = true;
        });

        services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseSession();
        app.UseHttpContextItemsMiddleware();
        app.UseMvc();
    }
}
```

The order of middleware is important. In the preceding example, an `InvalidOperationException` exception occurs when `UseSession` is invoked after `UseMvc`. For more information, see Middleware Ordering.

HttpContext.Session is available after session state is configured.

`HttpContext.Session` can't be accessed before `UseSession` has been called.

A new session with a new session cookie can't be created after the app has begun writing to the response stream. The exception is recorded in the web server log and not displayed in the browser.

Load session state asynchronously

The default session provider in ASP.NET Core loads session records from the underlying IDistributedCache backing store asynchronously only if the ISession.LoadAsync method is explicitly called before the TryGetValue, Set, or Remove methods. If `LoadAsync` isn't called first, the underlying session record is loaded synchronously, which can incur a performance penalty at scale.

To have apps enforce this pattern, wrap the DistributedSessionStore and DistributedSession implementations with versions that throw an exception if the `LoadAsync` method isn't called before `TryGetValue`, `Set`, or `Remove`. Register the wrapped versions in the services container.

Session options

To override session defaults, use SessionOptions.

OPTION	DESCRIPTION
Cookie	Determines the settings used to create the cookie. Name defaults to SessionDefaults.CookieName (`.AspNetCore.Session`). Path defaults to SessionDefaults.CookiePath (`/`). SameSite defaults to SameSiteMode.Lax (`1`). HttpOnly defaults to `true` . IsEssential defaults to `false` .
IdleTimeout	The `IdleTimeout` indicates how long the session can be idle before its contents are abandoned. Each session access resets the timeout. This setting only applies to the content of the session, not the cookie. The default is 20 minutes.
IOTimeout	The maximum amount of time allowed to load a session from the store or to commit it back to the store. This setting may only apply to asynchronous operations. This timeout can be disabled using InfiniteTimeSpan. The default is 1 minute.

Session uses a cookie to track and identify requests from a single browser. By default, this cookie is named `.AspNetCore.Session` , and it uses a path of `/` . Because the cookie default doesn't specify a domain, it isn't made available to the client-side script on the page (because HttpOnly defaults to `true`).

To override cookie session defaults, use `SessionOptions` :

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddDistributedMemoryCache();

    services.AddMvc()
        .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    services.AddSession(options =>
    {
        options.Cookie.Name = ".AdventureWorks.Session";
        options.IdleTimeout = TimeSpan.FromSeconds(10);
        options.Cookie.IsEssential = true;
    });
}
```

The app uses the IdleTimeout property to determine how long a session can be idle before its contents in the server's cache are abandoned. This property is independent of the cookie expiration. Each request that passes through the Session Middleware resets the timeout.

Session state is *non-locking*. If two requests simultaneously attempt to modify the contents of a session, the last request overrides the first. `Session` is implemented as a *coherent session*, which means that all the contents are stored together. When two requests seek to modify different session values, the last request may override session changes made by the first.

Set and get Session values

Session state is accessed from a Razor Pages PageModel class or MVC Controller class with HttpContext.Session. This property is an ISession implementation.

The `ISession` implementation provides several extension methods to set and retrieve integer and string values. The extension methods are in the Microsoft.AspNetCore.Http namespace (add a `using Microsoft.AspNetCore.Http;` statement to gain access to the extension methods) when the Microsoft.AspNetCore.Http.Extensions package is referenced by the project. Both packages are included in the Microsoft.AspNetCore.App metapackage.

`ISession` extension methods:

- Get(ISession, String)
- GetInt32(ISession, String)
- GetString(ISession, String)
- SetInt32(ISession, String, Int32)
- SetString(ISession, String, String)

The following example retrieves the session value for the `IndexModel.SessionKeyName` key (`_Name` in the sample app) in a Razor Pages page:

```
@page
@using Microsoft.AspNetCore.Http
@model IndexModel

...

Name: @HttpContext.Session.GetString(IndexModel.SessionKeyName)
```

The following example shows how to set and get an integer and a string:

```
public class IndexModel : PageModel
{
    public const string SessionKeyName = "_Name";
    public const string SessionKeyAge = "_Age";
    const string SessionKeyTime = "_Time";

    public string SessionInfo_Name { get; private set; }
    public string SessionInfo_Age { get; private set; }
    public string SessionInfo_CurrentTime { get; private set; }
    public string SessionInfo_SessionTime { get; private set; }
    public string SessionInfo_MiddlewareValue { get; private set; }

    public void OnGet()
    {
        // Requires: using Microsoft.AspNetCore.Http;
        if (string.IsNullOrEmpty(HttpContext.Session.GetString(SessionKeyName)))
        {
            HttpContext.Session.SetString(SessionKeyName, "The Doctor");
            HttpContext.Session.SetInt32(SessionKeyAge, 773);
        }

        var name = HttpContext.Session.GetString(SessionKeyName);
        var age = HttpContext.Session.GetInt32(SessionKeyAge);
```

All session data must be serialized to enable a distributed cache scenario, even when using the in-memory cache. String and integer serializers are provided by the extension methods of ISession). Complex types must be serialized by the user using another mechanism, such as JSON.

Add the following extension methods to set and get serializable objects:

```
public static class SessionExtensions
{
    public static void Set<T>(this ISession session, string key, T value)
    {
        session.SetString(key, JsonConvert.SerializeObject(value));
    }

    public static T Get<T>(this ISession session, string key)
    {
        var value = session.GetString(key);

        return value == null ? default(T) :
            JsonConvert.DeserializeObject<T>(value);
    }
}
```

The following example shows how to set and get a serializable object with the extension methods:

```
// Requires you add the Set and Get extension method mentioned in the topic.
if (HttpContext.Session.Get<DateTime>(SessionKeyTime) == default(DateTime))
{
    HttpContext.Session.Set<DateTime>(SessionKeyTime, currentTime);
}
```

TempData

ASP.NET Core exposes the Razor Pages TempData or Controller TempData. This property stores data until it's read in another request. Keep(String) and Peek(string) methods can be used to examine the data without deletion at the

end of the request. Keep() marks all items in the dictionary for retention. `TempData` is particularly useful for redirection when data is required for more than a single request. `TempData` is implemented by `TempData` providers using either cookies or session state.

TempData samples

Consider the following page that creates a customer:

```
public class CreateModel : PageModel
{
    private readonly RazorPagesContactsContext _context;

    public CreateModel(RazorPagesContactsContext context)
    {
        _context = context;
    }

    public IActionResult OnGet()
    {
        return Page();
    }

    [TempData]
    public string Message { get; set; }

    [BindProperty]
    public Customer Customer { get; set; }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _context.Customer.Add(Customer);
        await _context.SaveChangesAsync();
        Message = $"Customer {Customer.Name} added";

        return RedirectToPage("./IndexPeek");
    }
}
```

The following page displays `TempData["Message"]`:

```
@page
@model IndexModel

<h1>Peek Contacts</h1>

@{
    if (TempData.Peek("Message") != null)
    {
        <h3>Message: @TempData.Peek("Message")</h3>
    }
}

@*Content removed for brevity.*@
```

In the preceding markup, at the end of the request, `TempData["Message"]` is **not** deleted because `Peek` is used. Refreshing the page displays `TempData["Message"]`.

The following markup is similar to the preceding code, but uses `Keep` to preserve the data at the end of the request:

```
@page
@model IndexModel

<h1>Contacts Keep</h1>

@{
    if (TempData["Message"] != null)
    {
        <h3>Message: @TempData["Message"]</h3>
    }
    TempData.Keep("Message");
}

@*Content removed for brevity.*@
```

Navigating between the *IndexPeek* and *IndexKeep* pages won't delete `TempData["Message"]`.

The following code displays `TempData["Message"]`, but at the end of the request, `TempData["Message"]` is deleted:

```
@page
@model IndexModel

<h1>Index no Keep or Peek</h1>

@{
    if (TempData["Message"] != null)
    {
        <h3>Message: @TempData["Message"]</h3>
    }
}

@*Content removed for brevity.*@
```

TempData providers

The cookie-based TempData provider is used by default to store TempData in cookies.

The cookie data is encrypted using IDataProtector, encoded with Base64UrlTextEncoder, then chunked. Because the cookie is chunked, the single cookie size limit found in ASP.NET Core 1.x doesn't apply. The cookie data isn't compressed because compressing encrypted data can lead to security problems such as the CRIME and BREACH attacks. For more information on the cookie-based TempData provider, see CookieTempDataProvider.

Choose a TempData provider

Choosing a TempData provider involves several considerations, such as:

1. Does the app already use session state? If so, using the session state TempData provider has no additional cost to the app (aside from the size of the data).
2. Does the app use TempData only sparingly for relatively small amounts of data (up to 500 bytes)? If so, the cookie TempData provider adds a small cost to each request that carries TempData. If not, the session state TempData provider can be beneficial to avoid round-tripping a large amount of data in each request until the TempData is consumed.
3. Does the app run in a server farm on multiple servers? If so, there's no additional configuration required to use the cookie TempData provider outside of Data Protection (see ASP.NET Core Data Protection and Key storage providers).

> **NOTE**
>
> Most web clients (such as web browsers) enforce limits on the maximum size of each cookie, the total number of cookies, or both. When using the cookie TempData provider, verify the app won't exceed these limits. Consider the total size of the data. Account for increases in cookie size due to encryption and chunking.

Configure the TempData provider

The cookie-based TempData provider is enabled by default.

To enable the session-based TempData provider, use the AddSessionStateTempDataProvider extension method:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddMvc()
        .SetCompatibilityVersion(CompatibilityVersion.Version_2_2)
        .AddSessionStateTempDataProvider();

    services.AddSession();
}

public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseCookiePolicy();
    app.UseSession();
    app.UseMvc();
}
```

The order of middleware is important. In the preceding example, an `InvalidOperationException` exception occurs when `UseSession` is invoked after `UseMvc`. For more information, see Middleware Ordering.

> **IMPORTANT**
>
> If targeting .NET Framework and using the session-based TempData provider, add the Microsoft.AspNetCore.Session package to the project.

Query strings

A limited amount of data can be passed from one request to another by adding it to the new request's query string. This is useful for capturing state in a persistent manner that allows links with embedded state to be shared through email or social networks. Because URL query strings are public, never use query strings for sensitive data.

In addition to unintended sharing, including data in query strings can create opportunities for Cross-Site Request Forgery (CSRF) attacks, which can trick users into visiting malicious sites while authenticated. Attackers can then steal user data from the app or take malicious actions on behalf of the user. Any preserved app or session state must protect against CSRF attacks. For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

Hidden fields

Data can be saved in hidden form fields and posted back on the next request. This is common in multi-page forms. Because the client can potentially tamper with the data, the app must always revalidate the data stored in hidden fields.

HttpContext.Items

The HttpContext.Items collection is used to store data while processing a single request. The collection's contents are discarded after a request is processed. The `Items` collection is often used to allow components or middleware to communicate when they operate at different points in time during a request and have no direct way to pass parameters.

In the following example, middleware adds `isVerified` to the `Items` collection.

```
app.Use(async (context, next) =>
{
    // perform some verification
    context.Items["isVerified"] = true;
    await next.Invoke();
});
```

Later in the pipeline, another middleware can access the value of `isVerified`:

```
app.Run(async (context) =>
{
    await context.Response.WriteAsync($"Verified: {context.Items["isVerified"]}");
});
```

For middleware that's only used by a single app, `string` keys are acceptable. Middleware shared between app instances should use unique object keys to avoid key collisions. The following example shows how to use a unique object key defined in a middleware class:

```
public class HttpContextItemsMiddleware
{
    private readonly RequestDelegate _next;
    public static readonly object HttpContextItemsMiddlewareKey = new Object();

    public HttpContextItemsMiddleware(RequestDelegate next)
    {
        _next = next;
    }

    public async Task Invoke(HttpContext httpContext)
    {
        httpContext.Items[HttpContextItemsMiddlewareKey] = "K-9";

        await _next(httpContext);
    }
}

public static class HttpContextItemsMiddlewareExtensions
{
    public static IApplicationBuilder
        UseHttpContextItemsMiddleware(this IApplicationBuilder builder)
    {
        return builder.UseMiddleware<HttpContextItemsMiddleware>();
    }
}
```

Other code can access the value stored in `HttpContext.Items` using the key exposed by the middleware class:

```
HttpContext.Items
    .TryGetValue(HttpContextItemsMiddleware.HttpContextItemsMiddlewareKey,
        out var middlewareSetValue);
SessionInfo_MiddlewareValue =
    middlewareSetValue?.ToString() ?? "Middleware value not set!";
```

This approach also has the advantage of eliminating the use of key strings in the code.

Cache

Caching is an efficient way to store and retrieve data. The app can control the lifetime of cached items.

Cached data isn't associated with a specific request, user, or session. **Be careful not to cache user-specific data that may be retrieved by other users' requests.**

For more information, see Response caching in ASP.NET Core.

Dependency Injection

Use Dependency Injection to make data available to all users:

1. Define a service containing the data. For example, a class named `MyAppData` is defined:

   ```
   public class MyAppData
   {
       // Declare properties and methods
   }
   ```

2. Add the service class to `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSingleton<MyAppData>();
}
```

3. Consume the data service class:

```
public class IndexModel : PageModel
{
    public IndexModel(MyAppData myService)
    {
        // Do something with the service
        //    Examples: Read data, store in a field or property
    }
}
```

Common errors

- "Unable to resolve service for type 'Microsoft.Extensions.Caching.Distributed.IDistributedCache' while attempting to activate 'Microsoft.AspNetCore.Session.DistributedSessionStore'."

  This is usually caused by failing to configure at least one `IDistributedCache` implementation. For more information, see Distributed caching in ASP.NET Core and Cache in-memory in ASP.NET Core.

- In the event that the session middleware fails to persist a session (for example, if the backing store isn't available), the middleware logs the exception and the request continues normally. This leads to unpredictable behavior.

  For example, a user stores a shopping cart in session. The user adds an item to the cart but the commit fails. The app doesn't know about the failure so it reports to the user that the item was added to their cart, which isn't true.

  The recommended approach to check for errors is to call `await feature.Session.CommitAsync();` from app code when the app is done writing to the session. `CommitAsync` throws an exception if the backing store is unavailable. If `CommitAsync` fails, the app can process the exception. `LoadAsync` throws under the same conditions where the data store is unavailable.

SignalR and session state

SignalR apps should not use session state to store information. SignalR apps can store per connection state in `Context.Items` in the hub.

Layout in ASP.NET Core

9/22/2020 • 5 minutes to read • Edit Online

By Steve Smith and Dave Brock

Pages and views frequently share visual and programmatic elements. This article demonstrates how to:

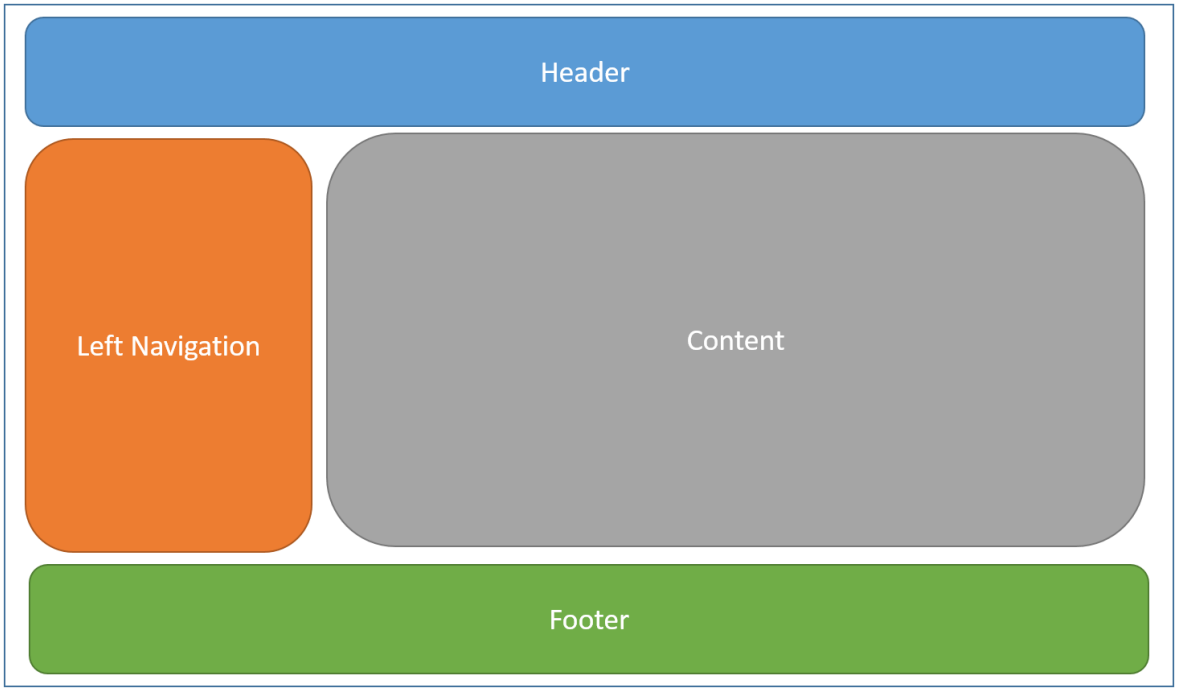
- Use common layouts.
- Share directives.
- Run common code before rendering pages or views.

This document discusses layouts for the two different approaches to ASP.NET Core MVC: Razor Pages and controllers with views. For this topic, the differences are minimal:

- Razor Pages are in the *Pages* folder.
- Controllers with views uses a *Views* folder for views.

What is a Layout

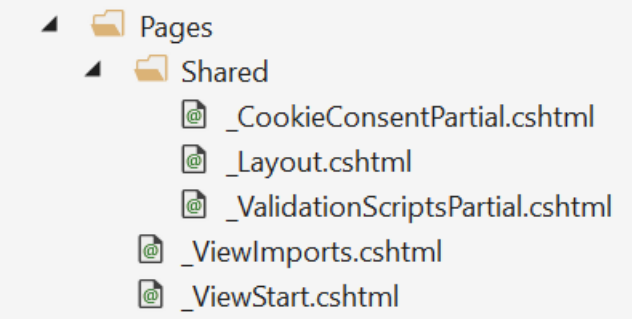
Most web apps have a common layout that provides the user with a consistent experience as they navigate from page to page. The layout typically includes common user interface elements such as the app header, navigation or menu elements, and footer.



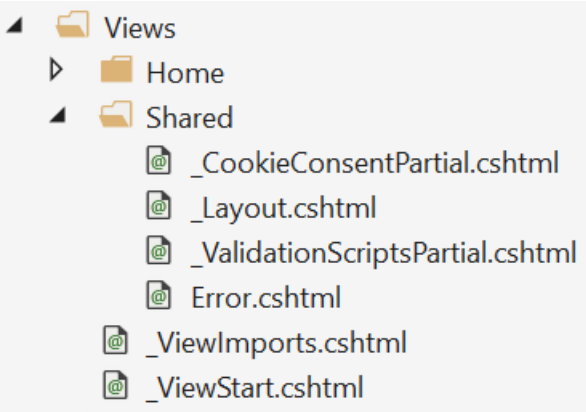
Common HTML structures such as scripts and stylesheets are also frequently used by many pages within an app. All of these shared elements may be defined in a *layout* file, which can then be referenced by any view used within the app. Layouts reduce duplicate code in views.

By convention, the default layout for an ASP.NET Core app is named *_Layout.cshtml*. The layout files for new ASP.NET Core projects created with the templates are:

- Razor Pages: *Pages/Shared/_Layout.cshtml*



- Controller with views: *Views/Shared/_Layout.cshtml*



The layout defines a top level template for views in the app. Apps don't require a layout. Apps can define more than one layout, with different views specifying different layouts.

The following code shows the layout file for a template created project with a controller and views:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - WebApplication1</title>

    <environment include="Development">
        <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
        <link rel="stylesheet" href="~/css/site.css" />
    </environment>
    <environment exclude="Development">
        <link rel="stylesheet"
href="https://ajax.aspnetcdn.com/ajax/bootstrap/3.3.7/css/bootstrap.min.css"
              asp-fallback-href="~/lib/bootstrap/dist/css/bootstrap.min.css"
              asp-fallback-test-class="sr-only" asp-fallback-test-property="position" asp-fallback-
test-value="absolute" />
        <link rel="stylesheet" href="~/css/site.min.css" asp-append-version="true" />
    </environment>
</head>
<body>
    <nav class="navbar navbar-inverse navbar-fixed-top">
        <div class="container">
            <div class="navbar-header">
                <button type="button" class="navbar-toggle" data-toggle="collapse" data-
target=".navbar-collapse">
                    <span class="sr-only">Toggle navigation</span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                </button>
                <a asp-page="/Index" class="navbar-brand">WebApplication1</a>
            </div>
            <div class="navbar-collapse collapse">
```

```
                <ul class="nav navbar-nav">
                    <li><a asp-page="/Index">Home</a></li>
                    <li><a asp-page="/About">About</a></li>
                    <li><a asp-page="/Contact">Contact</a></li>
                </ul>
            </div>
        </div>
    </nav>

    <partial name="_CookieConsentPartial" />

    <div class="container body-content">
        @RenderBody()
        <hr />
        <footer>
            <p>&copy; 2018 - WebApplication1</p>
        </footer>
    </div>

    <environment include="Development">
        <script src="~/lib/jquery/dist/jquery.js"></script>
        <script src="~/lib/bootstrap/dist/js/bootstrap.js"></script>
        <script src="~/js/site.js" asp-append-version="true"></script>
    </environment>
    <environment exclude="Development">
        <script src="https://ajax.aspnetcdn.com/ajax/jquery/jquery-3.3.1.min.js"
                asp-fallback-src="~/lib/jquery/dist/jquery.min.js"
                asp-fallback-test="window.jQuery"
                crossorigin="anonymous"
                integrity="sha384-tsQFqpEReu7ZLhBV2VZlAu7zcOV+rXbYlF2cqB8txI/8aZajjp4Bqd+V6D5IgvKT">
        </script>
        <script src="https://ajax.aspnetcdn.com/ajax/bootstrap/3.3.7/bootstrap.min.js"
                asp-fallback-src="~/lib/bootstrap/dist/js/bootstrap.min.js"
                asp-fallback-test="window.jQuery && window.jQuery.fn && window.jQuery.fn.modal"
                crossorigin="anonymous"
                integrity="sha384-Tc5IQib027qvyjSMfHjOMaLkfuWVxZxUPnCJA7l2mCWNIpG9mGCD8wGNIcPD7Txa">
        </script>
        <script src="~/js/site.min.js" asp-append-version="true"></script>
    </environment>

    @RenderSection("Scripts", required: false)
</body>
</html>
```

Specifying a Layout

Razor views have a `Layout` property. Individual views specify a layout by setting this property:

```
@{
    Layout = "_Layout";
}
```

The layout specified can use a full path (for example, */Pages/Shared/_Layout.cshtml* or */Views/Shared/_Layout.cshtml*) or a partial name (example: `_Layout`). When a partial name is provided, the Razor view engine searches for the layout file using its standard discovery process. The folder where the handler method (or controller) exists is searched first, followed by the *Shared* folder. This discovery process is identical to the process used to discover partial views.

By default, every layout must call `RenderBody`. Wherever the call to `RenderBody` is placed, the contents of the view will be rendered.

Sections

A layout can optionally reference one or more *sections*, by calling `RenderSection`. Sections provide a way to organize where certain page elements should be placed. Each call to `RenderSection` can specify whether that section is required or optional:

```
<script type="text/javascript" src="~/scripts/global.js"></script>

@RenderSection("Scripts", required: false)
```

If a required section isn't found, an exception is thrown. Individual views specify the content to be rendered within a section using the `@section` Razor syntax. If a page or view defines a section, it must be rendered (or an error will occur).

An example `@section` definition in Razor Pages view:

```
@section Scripts {
     <script type="text/javascript" src="~/scripts/main.js"></script>
}
```

In the preceding code, *scripts/main.js* is added to the `scripts` section on a page or view. Other pages or views in the same app might not require this script and wouldn't define a scripts section.

The following markup uses the Partial Tag Helper to render *_ValidationScriptsPartial.cshtml*:

```
@section Scripts {
    <partial name="_ValidationScriptsPartial" />
}
```

The preceding markup was generated by scaffolding Identity.

Sections defined in a page or view are available only in its immediate layout page. They cannot be referenced from partials, view components, or other parts of the view system.

Ignoring sections

By default, the body and all sections in a content page must all be rendered by the layout page. The Razor view engine enforces this by tracking whether the body and each section have been rendered.

To instruct the view engine to ignore the body or sections, call the `IgnoreBody` and `IgnoreSection` methods.

The body and every section in a Razor page must be either rendered or ignored.

Importing Shared Directives

Views and pages can use Razor directives to import namespaces and use dependency injection. Directives shared by many views may be specified in a common *_ViewImports.cshtml* file. The `_ViewImports` file supports the following directives:

- `@addTagHelper`
- `@removeTagHelper`
- `@tagHelperPrefix`
- `@using`
- `@model`
- `@inherits`
- `@inject`

The file doesn't support other Razor features, such as functions and section definitions.

A sample `_ViewImports.cshtml` file:

```
@using WebApplication1
@using WebApplication1.Models
@using WebApplication1.Models.AccountViewModels
@using WebApplication1.Models.ManageViewModels
@using Microsoft.AspNetCore.Identity
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
```

The *_ViewImports.cshtml* file for an ASP.NET Core MVC app is typically placed in the *Pages* (or *Views*) folder. A *_ViewImports.cshtml* file can be placed within any folder, in which case it will only be applied to pages or views within that folder and its subfolders. `_ViewImports` files are processed starting at the root level and then for each folder leading up to the location of the page or view itself. `_ViewImports` settings specified at the root level may be overridden at the folder level.

For example, suppose:

- The root level *_ViewImports.cshtml* file includes `@model MyModel1` and `@addTagHelper *, MyTagHelper1`.
- A subfolder *_ViewImports.cshtml* file includes `@model MyModel2` and `@addTagHelper *, MyTagHelper2`.

Pages and views in the subfolder will have access to both Tag Helpers and the `MyModel2` model.

If multiple *_ViewImports.cshtml* files are found in the file hierarchy, the combined behavior of the directives are:

- `@addTagHelper`, `@removeTagHelper`: all run, in order
- `@tagHelperPrefix`: the closest one to the view overrides any others
- `@model`: the closest one to the view overrides any others
- `@inherits`: the closest one to the view overrides any others
- `@using`: all are included; duplicates are ignored
- `@inject`: for each property, the closest one to the view overrides any others with the same property name

Running Code Before Each View

Code that needs to run before each view or page should be placed in the *_ViewStart.cshtml* file. By convention, the *_ViewStart.cshtml* file is located in the *Pages* (or *Views*) folder. The statements listed in *_ViewStart.cshtml* are run before every full view (not layouts, and not partial views). Like ViewImports.cshtml, *_ViewStart.cshtml* is hierarchical. If a *_ViewStart.cshtml* file is defined in the view or pages folder, it will be run after the one defined in the root of the *Pages* (or *Views*) folder (if any).

A sample *_ViewStart.cshtml* file:

```
@{
    Layout = "_Layout";
}
```

The file above specifies that all views will use the *_Layout.cshtml* layout.

_ViewStart.cshtml and *_ViewImports.cshtml* are **not** typically placed in the */Pages/Shared* (or */Views/Shared*) folder. The app-level versions of these files should be placed directly in the */Pages* (or */Views*) folder.

Razor syntax reference for ASP.NET Core

9/22/2020 • 18 minutes to read • Edit Online

By Rick Anderson, Taylor Mullen, and Dan Vicarel

Razor is a markup syntax for embedding server-based code into webpages. The Razor syntax consists of Razor markup, C#, and HTML. Files containing Razor generally have a *.cshtml* file extension. Razor is also found in Razor components files (*.razor*).

Rendering HTML

The default Razor language is HTML. Rendering HTML from Razor markup is no different than rendering HTML from an HTML file. HTML markup in *.cshtml* Razor files is rendered by the server unchanged.

Razor syntax

Razor supports C# and uses the `@` symbol to transition from HTML to C#. Razor evaluates C# expressions and renders them in the HTML output.

When an `@` symbol is followed by a Razor reserved keyword, it transitions into Razor-specific markup. Otherwise, it transitions into plain C#.

To escape an `@` symbol in Razor markup, use a second `@` symbol:

```
<p>@@Username</p>
```

The code is rendered in HTML with a single `@` symbol:

```
<p>@Username</p>
```

HTML attributes and content containing email addresses don't treat the `@` symbol as a transition character. The email addresses in the following example are untouched by Razor parsing:

```
<a href="mailto:Support@contoso.com">Support@contoso.com</a>
```

Implicit Razor expressions

Implicit Razor expressions start with `@` followed by C# code:

```
<p>@DateTime.Now</p>
<p>@DateTime.IsLeapYear(2016)</p>
```

With the exception of the C# `await` keyword, implicit expressions must not contain spaces. If the C# statement has a clear ending, spaces can be intermingled:

```
<p>@await DoSomething("hello", "world")</p>
```

Implicit expressions **cannot** contain C# generics, as the characters inside the brackets (`<>`) are interpreted as

an HTML tag. The following code is **not** valid:

```
<p>@GenericMethod<int>()</p>
```

The preceding code generates a compiler error similar to one of the following:

- The "int" element wasn't closed. All elements must be either self-closing or have a matching end tag.
- Cannot convert method group 'GenericMethod' to non-delegate type 'object'. Did you intend to invoke the method?`

Generic method calls must be wrapped in an explicit Razor expression or a Razor code block.

Explicit Razor expressions

Explicit Razor expressions consist of an `@` symbol with balanced parenthesis. To render last week's time, the following Razor markup is used:

```
<p>Last week this time: @(DateTime.Now - TimeSpan.FromDays(7))</p>
```

Any content within the `@()` parenthesis is evaluated and rendered to the output.

Implicit expressions, described in the previous section, generally can't contain spaces. In the following code, one week isn't subtracted from the current time:

```
<p>Last week: @DateTime.Now - TimeSpan.FromDays(7)</p>
```

The code renders the following HTML:

```
<p>Last week: 7/7/2016 4:39:52 PM - TimeSpan.FromDays(7)</p>
```

Explicit expressions can be used to concatenate text with an expression result:

```
@{
    var joe = new Person("Joe", 33);
}

<p>Age@(joe.Age)</p>
```

Without the explicit expression, `<p>Age@joe.Age</p>` is treated as an email address, and `<p>Age@joe.Age</p>` is rendered. When written as an explicit expression, `<p>Age33</p>` is rendered.

Explicit expressions can be used to render output from generic methods in *.cshtml* files. The following markup shows how to correct the error shown earlier caused by the brackets of a C# generic. The code is written as an explicit expression:

```
<p>@(GenericMethod<int>())</p>
```

Expression encoding

C# expressions that evaluate to a string are HTML encoded. C# expressions that evaluate to `IHtmlContent` are rendered directly through `IHtmlContent.WriteTo`. C# expressions that don't evaluate to `IHtmlContent` are converted to a string by `ToString` and encoded before they're rendered.

```
@("<span>Hello World</span>")
```

The preceding code renders the following HTML:

```
&lt;span&gt;Hello World&lt;/span&gt;
```

The HTML is shown in the browser as plain text:

Hello World

`HtmlHelper.Raw` output isn't encoded but rendered as HTML markup.

> **WARNING**
> Using `HtmlHelper.Raw` on unsanitized user input is a security risk. User input might contain malicious JavaScript or other exploits. Sanitizing user input is difficult. Avoid using `HtmlHelper.Raw` with user input.

```
@Html.Raw("<span>Hello World</span>")
```

The code renders the following HTML:

```
<span>Hello World</span>
```

Razor code blocks

Razor code blocks start with `@` and are enclosed by `{}`. Unlike expressions, C# code inside code blocks isn't rendered. Code blocks and expressions in a view share the same scope and are defined in order:

```
@{
    var quote = "The future depends on what you do today. - Mahatma Gandhi";
}

<p>@quote</p>

@{
    quote = "Hate cannot drive out hate, only love can do that. - Martin Luther King, Jr.";
}

<p>@quote</p>
```

The code renders the following HTML:

```
<p>The future depends on what you do today. - Mahatma Gandhi</p>
<p>Hate cannot drive out hate, only love can do that. - Martin Luther King, Jr.</p>
```

In code blocks, declare local functions with markup to serve as templating methods:

```
@{
    void RenderName(string name)
    {
        <p>Name: <strong>@name</strong></p>
    }

    RenderName("Mahatma Gandhi");
    RenderName("Martin Luther King, Jr.");
}
```

The code renders the following HTML:

```
<p>Name: <strong>Mahatma Gandhi</strong></p>
<p>Name: <strong>Martin Luther King, Jr.</strong></p>
```

Implicit transitions

The default language in a code block is C#, but the Razor Page can transition back to HTML:

```
@{
    var inCSharp = true;
    <p>Now in HTML, was in C# @inCSharp</p>
}
```

Explicit delimited transition

To define a subsection of a code block that should render HTML, surround the characters for rendering with the Razor `<text>` tag:

```
@for (var i = 0; i < people.Length; i++)
{
    var person = people[i];
    <text>Name: @person.Name</text>
}
```

Use this approach to render HTML that isn't surrounded by an HTML tag. Without an HTML or Razor tag, a Razor runtime error occurs.

The `<text>` tag is useful to control whitespace when rendering content:

- Only the content between the `<text>` tag is rendered.
- No whitespace before or after the `<text>` tag appears in the HTML output.

Explicit line transition

To render the rest of an entire line as HTML inside a code block, use `@:` syntax:

```
@for (var i = 0; i < people.Length; i++)
{
    var person = people[i];
    @:Name: @person.Name
}
```

Without the `@:` in the code, a Razor runtime error is generated.

Extra `@` characters in a Razor file can cause compiler errors at statements later in the block. These compiler errors can be difficult to understand because the actual error occurs before the reported error. This error is common after combining multiple implicit/explicit expressions into a single code block.

Control structures

Control structures are an extension of code blocks. All aspects of code blocks (transitioning to markup, inline C#) also apply to the following structures:

Conditionals `@if, else if, else, and @switch`

`@if` controls when code runs:

```
@if (value % 2 == 0)
{
    <p>The value was even.</p>
}
```

`else` and `else if` don't require the `@` symbol:

```
@if (value % 2 == 0)
{
    <p>The value was even.</p>
}
else if (value >= 1337)
{
    <p>The value is large.</p>
}
else
{
    <p>The value is odd and small.</p>
}
```

The following markup shows how to use a switch statement:

```
@switch (value)
{
    case 1:
        <p>The value is 1!</p>
        break;
    case 1337:
        <p>Your number is 1337!</p>
        break;
    default:
        <p>Your number wasn't 1 or 1337.</p>
        break;
}
```

Looping `@for, @foreach, @while, and @do while`

Templated HTML can be rendered with looping control statements. To render a list of people:

```
@{
    var people = new Person[]
    {
          new Person("Weston", 33),
          new Person("Johnathon", 41),
          ...
    };
}
```

The following looping statements are supported:

`@for`

```
@for (var i = 0; i < people.Length; i++)
{
    var person = people[i];
    <p>Name: @person.Name</p>
    <p>Age: @person.Age</p>
}
```

`@foreach`

```
@foreach (var person in people)
{
    <p>Name: @person.Name</p>
    <p>Age: @person.Age</p>
}
```

`@while`

```
@{ var i = 0; }
@while (i < people.Length)
{
    var person = people[i];
    <p>Name: @person.Name</p>
    <p>Age: @person.Age</p>

    i++;
}
```

`@do while`

```
@{ var i = 0; }
@do
{
    var person = people[i];
    <p>Name: @person.Name</p>
    <p>Age: @person.Age</p>

    i++;
} while (i < people.Length);
```

Compound `@using`

In C#, a `using` statement is used to ensure an object is disposed. In Razor, the same mechanism is used to create HTML Helpers that contain additional content. In the following code, HTML Helpers render a `<form>` tag with the `@using` statement:

```
@using (Html.BeginForm())
{
    <div>
        Email: <input type="email" id="Email" value="">
        <button>Register</button>
    </div>
}
```

`@try, catch, finally`

Exception handling is similar to C#:

```
@try
{
    throw new InvalidOperationException("You did something invalid.");
}
catch (Exception ex)
{
    <p>The exception message: @ex.Message</p>
}
finally
{
    <p>The finally statement.</p>
}
```

`@lock`

Razor has the capability to protect critical sections with lock statements:

```
@lock (SomeLock)
{
    // Do critical section work
}
```

Comments

Razor supports C# and HTML comments:

```
@{
    /* C# comment */
    // Another C# comment
}
<!-- HTML comment -->
```

The code renders the following HTML:

```
<!-- HTML comment -->
```

Razor comments are removed by the server before the webpage is rendered. Razor uses `@* *@` to delimit comments. The following code is commented out, so the server doesn't render any markup:

```
@*
    @{
        /* C# comment */
        // Another C# comment
    }
    <!-- HTML comment -->
*@
```

Directives

Razor directives are represented by implicit expressions with reserved keywords following the `@` symbol. A directive typically changes the way a view is parsed or enables different functionality.

Understanding how Razor generates code for a view makes it easier to understand how directives work.

```
@{
    var quote = "Getting old ain't for wimps! - Anonymous";
}

<div>Quote of the Day: @quote</div>
```

The code generates a class similar to the following:

```
public class _Views_Something_cshtml : RazorPage<dynamic>
{
    public override async Task ExecuteAsync()
    {
        var output = "Getting old ain't for wimps! - Anonymous";

        WriteLiteral("/r/n<div>Quote of the Day: ");
        Write(output);
        WriteLiteral("</div>");
    }
}
```

Later in this article, the section Inspect the Razor C# class generated for a view explains how to view this generated class.

`@attribute`

The `@attribute` directive adds the given attribute to the class of the generated page or view. The following example adds the `[Authorize]` attribute:

```
@attribute [Authorize]
```

`@code`

This scenario only applies to Razor components (.razor).

The `@code` block enables a Razor component to add C# members (fields, properties, and methods) to a component:

```
@code {
    // C# members (fields, properties, and methods)
}
```

For Razor components, `@code` is an alias of `@functions` and recommended over `@functions`. More than one `@code` block is permissible.

`@functions`

The `@functions` directive enables adding C# members (fields, properties, and methods) to the generated class:

```
@functions {
    // C# members (fields, properties, and methods)
}
```

In Razor components, use `@code` over `@functions` to add C# members.

For example:

```
@functions {
    public string GetHello()
    {
        return "Hello";
    }
}

<div>From method: @GetHello()</div>
```

The code generates the following HTML markup:

```
<div>From method: Hello</div>
```

The following code is the generated Razor C# class:

```
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc.Razor;

public class _Views_Home_Test_cshtml : RazorPage<dynamic>
{
    // Functions placed between here
    public string GetHello()
    {
        return "Hello";
    }
    // And here.
#pragma warning disable 1998
    public override async Task ExecuteAsync()
    {
        WriteLiteral("\r\n<div>From method: ");
        Write(GetHello());
        WriteLiteral("</div>\r\n");
    }
#pragma warning restore 1998
```

`@functions` methods serve as templating methods when they have markup:

```
@{
    RenderName("Mahatma Gandhi");
    RenderName("Martin Luther King, Jr.");
}

@functions {
    private void RenderName(string name)
    {
        <p>Name: <strong>@name</strong></p>
    }
}
```

The code renders the following HTML:

```
<p>Name: <strong>Mahatma Gandhi</strong></p>
<p>Name: <strong>Martin Luther King, Jr.</strong></p>
```

`@implements`

The `@implements` directive implements an interface for the generated class.

The following example implements System.IDisposable so that the Dispose method can be called:

```
@implements IDisposable

<h1>Example</h1>

@functions {
    private bool _isDisposed;

    ...

    public void Dispose() => _isDisposed = true;
}
```

`@inherits`

The `@inherits` directive provides full control of the class the view inherits:

```
@inherits TypeNameOfClassToInheritFrom
```

The following code is a custom Razor page type:

```
using Microsoft.AspNetCore.Mvc.Razor;

public abstract class CustomRazorPage<TModel> : RazorPage<TModel>
{
    public string CustomText { get; } =
        "Gardyloo! - A Scottish warning yelled from a window before dumping" +
        "a slop bucket on the street below.";
}
```

The `CustomText` is displayed in a view:

```
@inherits CustomRazorPage<TModel>

<div>Custom text: @CustomText</div>
```

The code renders the following HTML:

```
<div>
    Custom text: Gardyloo! - A Scottish warning yelled from a window before dumping
    a slop bucket on the street below.
</div>
```

`@model` and `@inherits` can be used in the same view. `@inherits` can be in a *_ViewImports.cshtml* file that the view imports:

```
@inherits CustomRazorPage<TModel>
```

The following code is an example of a strongly-typed view:

```
@inherits CustomRazorPage<TModel>

<div>The Login Email: @Model.Email</div>
<div>Custom text: @CustomText</div>
```

If "rick@contoso.com" is passed in the model, the view generates the following HTML markup:

```
<div>The Login Email: rick@contoso.com</div>
<div>
    Custom text: Gardyloo! - A Scottish warning yelled from a window before dumping
    a slop bucket on the street below.
</div>
```

`@inject`

The `@inject` directive enables the Razor Page to inject a service from the service container into a view. For more information, see Dependency injection into views.

`@layout`

This scenario only applies to Razor components (.razor).

The `@layout` directive specifies a layout for a Razor component. Layout components are used to avoid code duplication and inconsistency. For more information, see ASP.NET Core Blazor layouts.

`@model`

This scenario only applies to MVC views and Razor Pages (.cshtml).

The `@model` directive specifies the type of the model passed to a view or page:

```
@model TypeNameOfModel
```

In an ASP.NET Core MVC or Razor Pages app created with individual user accounts, *Views/Account/Login.cshtml* contains the following model declaration:

```
@model LoginViewModel
```

The class generated inherits from `RazorPage<dynamic>`:

```
public class _Views_Account_Login_cshtml : RazorPage<LoginViewModel>
```

Razor exposes a `Model` property for accessing the model passed to the view:

```
<div>The Login Email: @Model.Email</div>
```

The `@model` directive specifies the type of the `Model` property. The directive specifies the `T` in `RazorPage<T>` that the generated class that the view derives from. If the `@model` directive isn't specified, the `Model` property is of type `dynamic`. For more information, see Strongly typed models and the @model keyword.

`@namespace`

The `@namespace` directive:

- Sets the namespace of the class of the generated Razor page, MVC view, or Razor component.
- Sets the root derived namespaces of a pages, views, or components classes from the closest imports file in the directory tree, *_ViewImports.cshtml* (views or pages) or *_Imports.razor* (Razor components).

```
@namespace Your.Namespace.Here
```

For the Razor Pages example shown in the following table:

- Each page imports *Pages/_ViewImports.cshtml*.
- *Pages/_ViewImports.cshtml* contains `@namespace Hello.World`.
- Each page has `Hello.World` as the root of it's namespace.

PAGE	NAMESPACE
Pages/Index.cshtml	`Hello.World`
Pages/MorePages/Page.cshtml	`Hello.World.MorePages`
Pages/MorePages/EvenMorePages/Page.cshtml	`Hello.World.MorePages.EvenMorePages`

The preceding relationships apply to import files used with MVC views and Razor components.

When multiple import files have a `@namespace` directive, the file closest to the page, view, or component in the directory tree is used to set the root namespace.

If the *EvenMorePages* folder in the preceding example has an imports file with `@namespace Another.Planet` (or the *Pages/MorePages/EvenMorePages/Page.cshtml* file contains `@namespace Another.Planet`), the result is shown in the following table.

PAGE	NAMESPACE
Pages/Index.cshtml	`Hello.World`
Pages/MorePages/Page.cshtml	`Hello.World.MorePages`
Pages/MorePages/EvenMorePages/Page.cshtml	`Another.Planet`

`@page`

The `@page` directive has different effects depending on the type of the file where it appears. The directive:

- In a *.cshtml* file indicates that the file is a Razor Page. For more information, see Custom routes and Introduction to Razor Pages in ASP.NET Core.
- Specifies that a Razor component should handle requests directly. For more information, see ASP.NET Core Blazor routing.

The `@page` directive on the first line of a *.cshtml* file indicates that the file is a Razor Page. For more information, see Introduction to Razor Pages in ASP.NET Core.

`@section`

This scenario only applies to MVC views and Razor Pages (.cshtml).

The `@section` directive is used in conjunction with MVC and Razor Pages layouts to enable views or pages to render content in different parts of the HTML page. For more information, see Layout in ASP.NET Core.

`@using`

The `@using` directive adds the C# `using` directive to the generated view:

```
@using System.IO
@{
    var dir = Directory.GetCurrentDirectory();
}
<p>@dir</p>
```

In Razor components, `@using` also controls which components are in scope.

Directive attributes

Razor directive attributes are represented by implicit expressions with reserved keywords following the `@` symbol. A directive attribute typically changes the way an element is parsed or enables different functionality.

`@attributes`

This scenario only applies to Razor components (.razor).

`@attributes` allows a component to render non-declared attributes. For more information, see Create and use ASP.NET Core Razor components.

`@bind`

This scenario only applies to Razor components (.razor).

Data binding in components is accomplished with the `@bind` attribute. For more information, see ASP.NET Core Blazor data binding.

`@on{EVENT}`

This scenario only applies to Razor components (.razor).

Razor provides event handling features for components. For more information, see ASP.NET Core Blazor event handling.

`@on{EVENT}:preventDefault`

This scenario only applies to Razor components (.razor).

Prevents the default action for the event.

`@on{EVENT}:stopPropagation`

This scenario only applies to Razor components (.razor).

Stops event propagation for the event.

`@key`

This scenario only applies to Razor components (.razor).

The `@key` directive attribute causes the components diffing algorithm to guarantee preservation of elements or components based on the key's value. For more information, see Create and use ASP.NET Core Razor components.

`@ref`

This scenario only applies to Razor components (.razor).

Component references (`@ref`) provide a way to reference a component instance so that you can issue commands to that instance. For more information, see Create and use ASP.NET Core Razor components.

`@typeparam`

This scenario only applies to Razor components (.razor).

The `@typeparam` directive declares a generic type parameter for the generated component class. For more information, see ASP.NET Core Blazor templated components.

Templated Razor delegates

Razor templates allow you to define a UI snippet with the following format:

```
@<tag>...</tag>
```

The following example illustrates how to specify a templated Razor delegate as a Func<T,TResult>. The dynamic type is specified for the parameter of the method that the delegate encapsulates. An object type is specified as the return value of the delegate. The template is used with a List<T> of `Pet` that has a `Name` property.

```
public class Pet
{
    public string Name { get; set; }
}
```

```
@{
    Func<dynamic, object> petTemplate = @<p>You have a pet named <strong>@item.Name</strong>.</p>;

    var pets = new List<Pet>
    {
        new Pet { Name = "Rin Tin Tin" },
        new Pet { Name = "Mr. Bigglesworth" },
        new Pet { Name = "K-9" }
    };
}
```

The template is rendered with `pets` supplied by a `foreach` statement:

```
@foreach (var pet in pets)
{
    @petTemplate(pet)
}
```

Rendered output:

```
<p>You have a pet named <strong>Rin Tin Tin</strong>.</p>
<p>You have a pet named <strong>Mr. Bigglesworth</strong>.</p>
<p>You have a pet named <strong>K-9</strong>.</p>
```

You can also supply an inline Razor template as an argument to a method. In the following example, the `Repeat` method receives a Razor template. The method uses the template to produce HTML content with repeats of items supplied from a list:

```
@using Microsoft.AspNetCore.Html

@functions {
    public static IHtmlContent Repeat(IEnumerable<dynamic> items, int times,
        Func<dynamic, IHtmlContent> template)
    {
        var html = new HtmlContentBuilder();

        foreach (var item in items)
        {
            for (var i = 0; i < times; i++)
            {
                html.AppendHtml(template(item));
            }
        }

        return html;
    }
}
```

Using the list of pets from the prior example, the `Repeat` method is called with:

- List<T> of `Pet`.
- Number of times to repeat each pet.
- Inline template to use for the list items of an unordered list.

```
<ul>
    @Repeat(pets, 3, @<li>@item.Name</li>)
</ul>
```

Rendered output:

```
<ul>
    <li>Rin Tin Tin</li>
    <li>Rin Tin Tin</li>
    <li>Rin Tin Tin</li>
    <li>Mr. Bigglesworth</li>
    <li>Mr. Bigglesworth</li>
    <li>Mr. Bigglesworth</li>
    <li>K-9</li>
    <li>K-9</li>
    <li>K-9</li>
</ul>
```

Tag Helpers

This scenario only applies to MVC views and Razor Pages (.cshtml).

There are three directives that pertain to Tag Helpers.

DIRECTIVE	FUNCTION
`@addTagHelper`	Makes Tag Helpers available to a view.
`@removeTagHelper`	Removes Tag Helpers previously added from a view.

DIRECTIVE	FUNCTION
`@tagHelperPrefix`	Specifies a tag prefix to enable Tag Helper support and to make Tag Helper usage explicit.

Razor reserved keywords

Razor keywords

- `page` (Requires ASP.NET Core 2.1 or later)
- `namespace`
- `functions`
- `inherits`
- `model`
- `section`
- `helper` (Not currently supported by ASP.NET Core)

Razor keywords are escaped with `@(Razor Keyword)` (for example, `@(functions)`).

C# Razor keywords

- `case`
- `do`
- `default`
- `for`
- `foreach`
- `if`
- `else`
- `lock`
- `switch`
- `try`
- `catch`
- `finally`
- `using`
- `while`

C# Razor keywords must be double-escaped with `@(@C# Razor Keyword)` (for example, `@(@case)`). The first `@` escapes the Razor parser. The second `@` escapes the C# parser.

Reserved keywords not used by Razor

- `class`

Inspect the Razor C# class generated for a view

With .NET Core SDK 2.1 or later, the Razor SDK handles compilation of Razor files. When building a project, the Razor SDK generates an *obj/<build_configuration>/<target_framework_moniker>/Razor* directory in the project root. The directory structure within the *Razor* directory mirrors the project's directory structure.

Consider the following directory structure in an ASP.NET Core 2.1 Razor Pages project targeting .NET Core 2.1:

```
Areas/
  Admin/
    Pages/
      Index.cshtml
      Index.cshtml.cs
Pages/
  Shared/
    _Layout.cshtml
  _ViewImports.cshtml
  _ViewStart.cshtml
  Index.cshtml
  Index.cshtml.cs
```

Building the project in *Debug* configuration yields the following *obj* directory:

```
obj/
  Debug/
    netcoreapp2.1/
      Razor/
        Areas/
          Admin/
            Pages/
              Index.g.cshtml.cs
        Pages/
          Shared/
            _Layout.g.cshtml.cs
          _ViewImports.g.cshtml.cs
          _ViewStart.g.cshtml.cs
          Index.g.cshtml.cs
```

To view the generated class for *Pages/Index.cshtml*, open *obj/Debug/netcoreapp2.1/Razor/Pages/Index.g.cshtml.cs*.

Add the following class to the ASP.NET Core MVC project:

```
#if V2
using Microsoft.AspNetCore.Mvc.Razor.Extensions;
using Microsoft.AspNetCore.Razor.Language;

public class CustomTemplateEngine : MvcRazorTemplateEngine
{
    public CustomTemplateEngine(RazorEngine engine, RazorProject project)
        : base(engine, project)
    {
    }

    public override RazorCSharpDocument GenerateCode(RazorCodeDocument codeDocument)
    {
        var csharpDocument = base.GenerateCode(codeDocument);
        var generatedCode = csharpDocument.GeneratedCode;

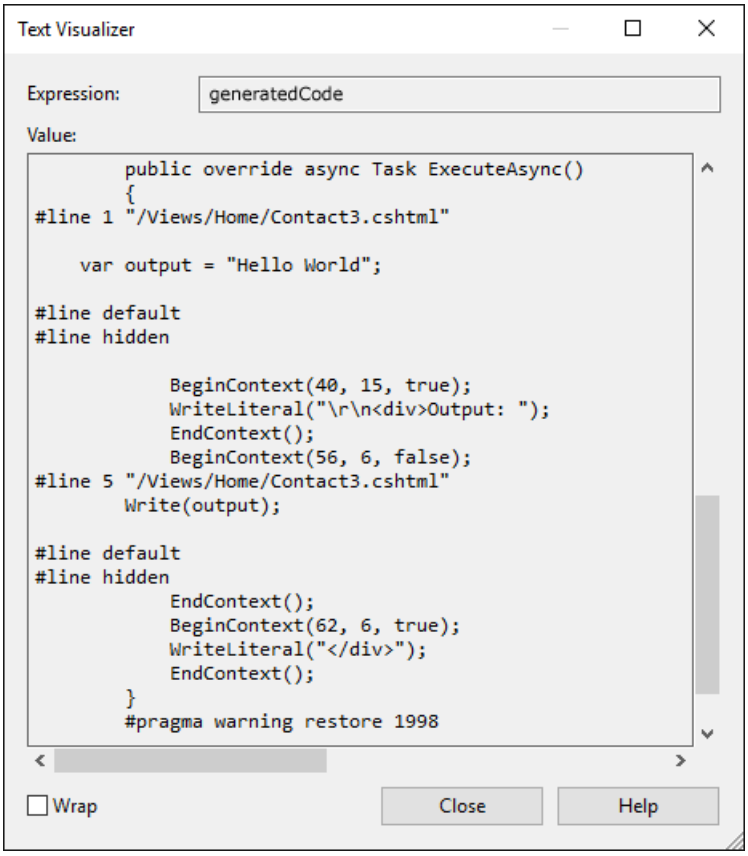
        // Look at generatedCode

        return csharpDocument;
    }
}
#endif
```

In `Startup.ConfigureServices`, override the `RazorTemplateEngine` added by MVC with the `CustomTemplateEngine` class:

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddMvc();
```

Set a breakpoint on the `return csharpDocument;` statement of `CustomTemplateEngine`. When program execution stops at the breakpoint, view the value of `generatedCode`.



View lookups and case sensitivity

The Razor view engine performs case-sensitive lookups for views. However, the actual lookup is determined by the underlying file system:

- File based source:
  - On operating systems with case insensitive file systems (for example, Windows), physical file provider lookups are case insensitive. For example, `return View("Test")` results in matches for */Views/Home/Test.cshtml*, */Views/home/test.cshtml*, and any other casing variant.
  - On case-sensitive file systems (for example, Linux, OSX, and with `EmbeddedFileProvider`), lookups are case-sensitive. For example, `return View("Test")` specifically matches */Views/Home/Test.cshtml*.
- Precompiled views: With ASP.NET Core 2.0 and later, looking up precompiled views is case insensitive on all operating systems. The behavior is identical to physical file provider's behavior on Windows. If two precompiled views differ only in case, the result of lookup is non-deterministic.

Developers are encouraged to match the casing of file and directory names to the casing of:

- Area, controller, and action names.
- Razor Pages.

Matching case ensures the deployments find their views regardless of the underlying file system.

Introduction to ASP.NET Web Programming Using the Razor Syntax provides many samples of programming with Razor syntax.

Create reusable UI using the Razor class library project in ASP.NET Core

9/22/2020 • 10 minutes to read • Edit Online

By Rick Anderson

Razor views, pages, controllers, page models, Razor components, View components, and data models can be built into a Razor class library (RCL). The RCL can be packaged and reused. Applications can include the RCL and override the views and pages it contains. When a view, partial view, or Razor Page is found in both the web app and the RCL, the Razor markup (*.cshtml* file) in the web app takes precedence.

View or download sample code (how to download)

Create a class library containing Razor UI

- Visual Studio
- .NET Core CLI

- From Visual Studio select **Create new a new project**.
- Select **Razor Class Library** > **Next**.
- Name the library (for example, "RazorClassLib"), > **Create**. To avoid a file name collision with the generated view library, ensure the library name doesn't end in `.Views`.
- Select **Support pages and views** if you need to support views. By default, only Razor Pages are supported. Select **Create**.

The Razor class library (RCL) template defaults to Razor component development by default. The **Support pages and views** option supports pages and views.

Add Razor files to the RCL.

The ASP.NET Core templates assume the RCL content is in the *Areas* folder. See RCL Pages layout to create an RCL that exposes content in `~/Pages` rather than `~/Areas/Pages`.

Reference RCL content

The RCL can be referenced by:

- NuGet package. See Creating NuGet packages and dotnet add package and Create and publish a NuGet package.
- *{ProjectName}.csproj*. See dotnet-add reference.

Override views, partial views, and pages

When a view, partial view, or Razor Page is found in both the web app and the RCL, the Razor markup (*.cshtml* file) in the web app takes precedence. For example, add *WebApp1/Areas/MyFeature/Pages/Page1.cshtml* to WebApp1, and Page1 in the WebApp1 will take precedence over Page1 in the RCL.

In the sample download, rename *WebApp1/Areas/MyFeature2* to *WebApp1/Areas/MyFeature* to test precedence.

Copy the *RazorUIClassLib/Areas/MyFeature/Pages/Shared/_Message.cshtml* partial view to

WebApp1/Areas/MyFeature/Pages/Shared/_Message.cshtml. Update the markup to indicate the new location. Build and run the app to verify the app's version of the partial is being used.

RCL Pages layout

To reference RCL content as though it is part of the web app's *Pages* folder, create the RCL project with the following file structure:

- *RazorUIClassLib/Pages*
- *RazorUIClassLib/Pages/Shared*

Suppose *RazorUIClassLib/Pages/Shared* contains two partial files: *_Header.cshtml* and *_Footer.cshtml*. The `<partial>` tags could be added to *_Layout.cshtml* file:

```
<body>
  <partial name="_Header">
  @RenderBody()
  <partial name="_Footer">
</body>
```

Create an RCL with static assets

An RCL may require companion static assets that can be referenced by either the RCL or the consuming app of the RCL. ASP.NET Core allows creating RCLs that include static assets that are available to a consuming app.

To include companion assets as part of an RCL, create a *wwwroot* folder in the class library and include any required files in that folder.

When packing an RCL, all companion assets in the *wwwroot* folder are automatically included in the package.

Use the `dotnet pack` command rather than the NuGet.exe version `nuget pack`.

Exclude static assets

To exclude static assets, add the desired exclusion path to the `$(DefaultItemExcludes)` property group in the project file. Separate entries with a semicolon (`;`).

In the following example, the *lib.css* stylesheet in the *wwwroot* folder isn't considered a static asset and isn't included in the published RCL:

```
<PropertyGroup>
  <DefaultItemExcludes>$(DefaultItemExcludes);wwwroot\lib.css</DefaultItemExcludes>
</PropertyGroup>
```

Typescript integration

To include TypeScript files in an RCL:

1. Place the TypeScript files (*.ts*) outside of the *wwwroot* folder. For example, place the files in a *Client* folder.
2. Configure the TypeScript build output for the *wwwroot* folder. Set the `TypescriptOutDir` property inside of a `PropertyGroup` in the project file:

   ```
   <TypescriptOutDir>wwwroot</TypescriptOutDir>
   ```

3. Include the TypeScript target as a dependency of the `ResolveCurrentProjectStaticWebAssets` target by adding the following target inside of a `PropertyGroup` in the project file:

```
<ResolveCurrentProjectStaticWebAssetsInputsDependsOn>
  CompileTypeScript;
  $(ResolveCurrentProjectStaticWebAssetsInputs)
</ResolveCurrentProjectStaticWebAssetsInputsDependsOn>
```

Consume content from a referenced RCL

The files included in the *wwwroot* folder of the RCL are exposed to either the RCL or the consuming app under the prefix `_content/{LIBRARY NAME}/`. For example, a library named *Razor.Class.Lib* results in a path to static content at `_content/Razor.Class.Lib/`. When producing a NuGet package and the assembly name isn't the same as the package ID, use the package ID for `{LIBRARY NAME}`.

The consuming app references static assets provided by the library with `<script>`, `<style>`, `<img>`, and other HTML tags. The consuming app must have static file support enabled in `Startup.Configure`:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    ...

    app.UseStaticFiles();

    ...
}
```

When running the consuming app from build output (`dotnet run`), static web assets are enabled by default in the Development environment. To support assets in other environments when running from build output, call `UseStaticWebAssets` on the host builder in *Program.cs*:

```
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Hosting;

public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStaticWebAssets();
                webBuilder.UseStartup<Startup>();
            });
}
```

Calling `UseStaticWebAssets` isn't required when running an app from published output (`dotnet publish`).

Multi-project development flow

When the consuming app runs:

- The assets in the RCL stay in their original folders. The assets aren't moved to the consuming app.
- Any change within the RCL's *wwwroot* folder is reflected in the consuming app after the RCL is rebuilt and without rebuilding the consuming app.

When the RCL is built, a manifest is produced that describes the static web asset locations. The consuming app reads the manifest at runtime to consume the assets from referenced projects and packages. When a new asset is added to an RCL, the RCL must be rebuilt to update its manifest before a consuming app can access the new

asset.

Publish

When the app is published, the companion assets from all referenced projects and packages are copied into the *wwwroot* folder of the published app under `_content/{LIBRARY NAME}/`.

Razor views, pages, controllers, page models, Razor components, View components, and data models can be built into a Razor class library (RCL). The RCL can be packaged and reused. Applications can include the RCL and override the views and pages it contains. When a view, partial view, or Razor Page is found in both the web app and the RCL, the Razor markup (*.cshtml* file) in the web app takes precedence.

View or download sample code (how to download)

Create a class library containing Razor UI

- Visual Studio
- .NET Core CLI

- From the Visual Studio **File** menu, select **New** > **Project**.
- Select **ASP.NET Core Web Application**.
- Name the library (for example, "RazorClassLib") > **OK**. To avoid a file name collision with the generated view library, ensure the library name doesn't end in `.Views`.
- Verify **ASP.NET Core 2.1** or later is selected.
- Select **Razor Class Library** > **OK**.

An RCL has the following project file:

```
<Project Sdk="Microsoft.NET.Sdk.Razor">

  <PropertyGroup>
    <TargetFramework>netstandard2.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.Mvc" Version="2.2.0" />
  </ItemGroup>

</Project>
```

Add Razor files to the RCL.

The ASP.NET Core templates assume the RCL content is in the *Areas* folder. See RCL Pages layout to create an RCL that exposes content in `~/Pages` rather than `~/Areas/Pages`.

Reference RCL content

The RCL can be referenced by:

- NuGet package. See Creating NuGet packages and dotnet add package and Create and publish a NuGet package.
- *{ProjectName}.csproj*. See dotnet-add reference.

Walkthrough: Create an RCL project and use from a Razor Pages project

You can download the complete project and test it rather than creating it. The sample download contains

additional code and links that make the project easy to test. You can leave feedback in this GitHub issue with your comments on download samples versus step-by-step instructions.

Test the download app

If you haven't downloaded the completed app and would rather create the walkthrough project, skip to the next section.

- Visual Studio
- .NET Core CLI

Open the *.sln* file in Visual Studio. Run the app.

Follow the instructions in Test WebApp1

Create an RCL

In this section, an RCL is created. Razor files are added to the RCL.

- Visual Studio
- .NET Core CLI

Create the RCL project:

- From the Visual Studio **File** menu, select **New** > **Project**.
- Select **ASP.NET Core Web Application**.
- Name the app **RazorUIClassLib** > **OK**.
- Verify **ASP.NET Core 2.1** or later is selected.
- Select **Razor Class Library** > **OK**.
- Add a Razor partial view file named *RazorUIClassLib/Areas/MyFeature/Pages/Shared/_Message.cshtml*.

Add Razor files and folders to the project

- Replace the markup in *RazorUIClassLib/Areas/MyFeature/Pages/Shared/_Message.cshtml* with the following code:

```
<h3>_Message.cshtml partial view.</h3>

<p>RazorUIClassLib\Areas\MyFeature\Pages\Shared\_Message.cshtml</p>
```

- Replace the markup in *RazorUIClassLib/Areas/MyFeature/Pages/Page1.cshtml* with the following code:

```
@page
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<h2>Hello from a Razor UI class library!</h2>
<p> From  RazorUIClassLib\Areas\MyFeature\Pages\Page1.cshtml</p>

<partial name="_Message" />
```

`@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers` is required to use the partial view (`<partial name="_Message" />`). Rather than including the `@addTagHelper` directive, you can add a *_ViewImports.cshtml* file. For example:

```
dotnet new viewimports -o RazorUIClassLib/Areas/MyFeature/Pages
```

For more information on *_ViewImports.cshtml*, see Importing Shared Directives

- Build the class library to verify there are no compiler errors:

```
dotnet build RazorUIClassLib
```

The build output contains *RazorUIClassLib.dll* and *RazorUIClassLib.Views.dll*. *RazorUIClassLib.Views.dll* contains the compiled Razor content.

Use the Razor UI library from a Razor Pages project

- Visual Studio
- .NET Core CLI

Create the Razor Pages web app:

- From **Solution Explorer**, right-click the solution > **Add** > **New Project**.
- Select **ASP.NET Core Web Application**.
- Name the app **WebApp1**.
- Verify **ASP.NET Core 2.1** or later is selected.
- Select **Web Application** > **OK**.
- From **Solution Explorer**, right-click on **WebApp1** and select **Set as StartUp Project**.
- From **Solution Explorer**, right-click on **WebApp1** and select **Build Dependencies** > **Project Dependencies**.
- Check **RazorUIClassLib** as a dependency of **WebApp1**.
- From **Solution Explorer**, right-click on **WebApp1** and select **Add** > **Reference**.
- In the **Reference Manager** dialog, check **RazorUIClassLib** > **OK**.

Run the app.

Test WebApp1

Browse to `/MyFeature/Page1` to verify that the Razor UI class library is in use.

Override views, partial views, and pages

When a view, partial view, or Razor Page is found in both the web app and the RCL, the Razor markup (*.cshtml* file) in the web app takes precedence. For example, add *WebApp1/Areas/MyFeature/Pages/Page1.cshtml* to WebApp1, and Page1 in the WebApp1 will take precedence over Page1 in the RCL.

In the sample download, rename *WebApp1/Areas/MyFeature2* to *WebApp1/Areas/MyFeature* to test precedence.

Copy the *RazorUIClassLib/Areas/MyFeature/Pages/Shared/_Message.cshtml* partial view to *WebApp1/Areas/MyFeature/Pages/Shared/_Message.cshtml*. Update the markup to indicate the new location. Build and run the app to verify the app's version of the partial is being used.

RCL Pages layout

To reference RCL content as though it is part of the web app's *Pages* folder, create the RCL project with the following file structure:

- *RazorUIClassLib/Pages*
- *RazorUIClassLib/Pages/Shared*

Suppose *RazorUIClassLib/Pages/Shared* contains two partial files: *_Header.cshtml* and *_Footer.cshtml*. The `<partial>` tags could be added to *_Layout.cshtml* file:

```
<body>
  <partial name="_Header">
  @RenderBody()
  <partial name="_Footer">
</body>
```

ASP.NET Core built-in Tag Helpers

9/22/2020 • 2 minutes to read • Edit Online

By Peter Kellner

For an overview of Tag Helpers, see Tag Helpers in ASP.NET Core.

There are built-in Tag Helpers which aren't listed in this document. The unlisted Tag Helpers are used internally by the Razor view engine. The Tag Helper for the `~` (tilde) character is unlisted. The tilde Tag Helper expands to the root path of the website.

Built-in ASP.NET Core Tag Helpers

Anchor Tag Helper

Cache Tag Helper

Component Tag Helper

Distributed Cache Tag Helper

Environment Tag Helper

Form Tag Helper

Form Action Tag Helper

Image Tag Helper

Input Tag Helper

Label Tag Helper

Link Tag Helper

Partial Tag Helper

Script Tag Helper

Select Tag Helper

Textarea Tag Helper

Validation Message Tag Helper

Validation Summary Tag Helper

Tag Helpers in ASP.NET Core

9/22/2020 • 12 minutes to read • Edit Online

By Rick Anderson

What are Tag Helpers

Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files. For example, the built-in `ImageTagHelper` can append a version number to the image name. Whenever the image changes, the server generates a new unique version for the image, so clients are guaranteed to get the current image (instead of a stale cached image). There are many built-in Tag Helpers for common tasks - such as creating forms, links, loading assets and more - and even more available in public GitHub repositories and as NuGet packages. Tag Helpers are authored in C#, and they target HTML elements based on element name, attribute name, or parent tag. For example, the built-in `LabelTagHelper` can target the HTML `<label>` element when the `LabelTagHelper` attributes are applied. If you're familiar with HTML Helpers, Tag Helpers reduce the explicit transitions between HTML and C# in Razor views. In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. Tag Helpers compared to HTML Helpers explains the differences in more detail.

What Tag Helpers provide

An HTML-friendly development experience For the most part, Razor markup using Tag Helpers looks like standard HTML. Front-end designers conversant with HTML/CSS/JavaScript can edit Razor without learning C# Razor syntax.

A rich IntelliSense environment for creating HTML and Razor markup This is in sharp contrast to HTML Helpers, the previous approach to server-side creation of markup in Razor views. Tag Helpers compared to HTML Helpers explains the differences in more detail. IntelliSense support for Tag Helpers explains the IntelliSense environment. Even developers experienced with Razor C# syntax are more productive using Tag Helpers than writing C# Razor markup.

A way to make you more productive and able to produce more robust, reliable, and maintainable code using information only available on the server For example, historically the mantra on updating images was to change the name of the image when you change the image. Images should be aggressively cached for performance reasons, and unless you change the name of an image, you risk clients getting a stale copy. Historically, after an image was edited, the name had to be changed and each reference to the image in the web app needed to be updated. Not only is this very labor intensive, it's also error prone (you could miss a reference, accidentally enter the wrong string, etc.) The built-in `ImageTagHelper` can do this for you automatically. The `ImageTagHelper` can append a version number to the image name, so whenever the image changes, the server automatically generates a new unique version for the image. Clients are guaranteed to get the current image. This robustness and labor savings comes essentially free by using the `ImageTagHelper`.

Most built-in Tag Helpers target standard HTML elements and provide server-side attributes

for the element. For example, the `<input>` element used in many views in the *Views/Account* folder contains the `asp-for` attribute. This attribute extracts the name of the specified model property into the rendered HTML. Consider a Razor view with the following model:

```
public class Movie
{
    public int ID { get; set; }
    public string Title { get; set; }
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; }
    public decimal Price { get; set; }
}
```

The following Razor markup:

```
<label asp-for="Movie.Title"></label>
```

Generates the following HTML:

```
<label for="Movie_Title">Title</label>
```

The `asp-for` attribute is made available by the `For` property in the LabelTagHelper. See Author Tag Helpers for more information.

Managing Tag Helper scope

Tag Helpers scope is controlled by a combination of `@addTagHelper`, `@removeTagHelper`, and the "!" opt-out character.

`@addTagHelper` makes Tag Helpers available

If you create a new ASP.NET Core web app named *AuthoringTagHelpers*, the following *Views/_ViewImports.cshtml* file will be added to your project:

```
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@addTagHelper *, AuthoringTagHelpers
```

The `@addTagHelper` directive makes Tag Helpers available to the view. In this case, the view file is *Pages/_ViewImports.cshtml*, which by default is inherited by all files in the *Pages* folder and subfolders; making Tag Helpers available. The code above uses the wildcard syntax ("*") to specify that all Tag Helpers in the specified assembly (*Microsoft.AspNetCore.Mvc.TagHelpers*) will be available to every view file in the *Views* directory or subdirectory. The first parameter after `@addTagHelper` specifies the Tag Helpers to load (we are using "*" for all Tag Helpers), and the second parameter "Microsoft.AspNetCore.Mvc.TagHelpers" specifies the assembly containing the Tag Helpers. *Microsoft.AspNetCore.Mvc.TagHelpers* is the assembly for the built-in ASP.NET Core Tag Helpers.

To expose all of the Tag Helpers in this project (which creates an assembly named *AuthoringTagHelpers*), you would use the following:

```
@using AuthoringTagHelpers
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@addTagHelper *, AuthoringTagHelpers
```

If your project contains an `EmailTagHelper` with the default namespace (`AuthoringTagHelpers.TagHelpers.EmailTagHelper`), you can provide the fully qualified name (FQN) of the Tag Helper:

```
@using AuthoringTagHelpers
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@addTagHelper AuthoringTagHelpers.TagHelpers.EmailTagHelper, AuthoringTagHelpers
```

To add a Tag Helper to a view using an FQN, you first add the FQN (`AuthoringTagHelpers.TagHelpers.EmailTagHelper`), and then the assembly name (*AuthoringTagHelpers*). Most developers prefer to use the "*" wildcard syntax. The wildcard syntax allows you to insert the wildcard character "*" as the suffix in an FQN. For example, any of the following directives will bring in the `EmailTagHelper` :

```
@addTagHelper AuthoringTagHelpers.TagHelpers.E*, AuthoringTagHelpers
@addTagHelper AuthoringTagHelpers.TagHelpers.Email*, AuthoringTagHelpers
```

As mentioned previously, adding the `@addTagHelper` directive to the *Views/_ViewImports.cshtml* file makes the Tag Helper available to all view files in the *Views* directory and subdirectories. You can use the `@addTagHelper` directive in specific view files if you want to opt-in to exposing the Tag Helper to only those views.

`@removeTagHelper` removes Tag Helpers

The `@removeTagHelper` has the same two parameters as `@addTagHelper` , and it removes a Tag Helper that was previously added. For example, `@removeTagHelper` applied to a specific view removes the specified Tag Helper from the view. Using `@removeTagHelper` in a *Views/Folder/_ViewImports.cshtml* file removes the specified Tag Helper from all of the views in *Folder*.

Controlling Tag Helper scope with the *_ViewImports.cshtml* file

You can add a *_ViewImports.cshtml* to any view folder, and the view engine applies the directives from both that file and the *Views/_ViewImports.cshtml* file. If you added an empty *Views/Home/_ViewImports.cshtml* file for the *Home* views, there would be no change because the *_ViewImports.cshtml* file is additive. Any `@addTagHelper` directives you add to the *Views/Home/_ViewImports.cshtml* file (that are not in the default *Views/_ViewImports.cshtml* file) would expose those Tag Helpers to views only in the *Home* folder.

Opting out of individual elements

You can disable a Tag Helper at the element level with the Tag Helper opt-out character ("!"). For example, `Email` validation is disabled in the `<span>` with the Tag Helper opt-out character:

```
<!span asp-validation-for="Email" class="text-danger"></!span>
```

You must apply the Tag Helper opt-out character to the opening and closing tag. (The Visual Studio editor automatically adds the opt-out character to the closing tag when you add one

to the opening tag). After you add the opt-out character, the element and Tag Helper attributes are no longer displayed in a distinctive font.

Using `@tagHelperPrefix` to make Tag Helper usage explicit

The `@tagHelperPrefix` directive allows you to specify a tag prefix string to enable Tag Helper support and to make Tag Helper usage explicit. For example, you could add the following markup to the *Views/_ViewImports.cshtml* file:

```
@tagHelperPrefix th:
```

In the code image below, the Tag Helper prefix is set to `th:`, so only those elements using the prefix `th:` support Tag Helpers (Tag Helper-enabled elements have a distinctive font). The `<label>` and `<input>` elements have the Tag Helper prefix and are Tag Helper-enabled, while the `<span>` element doesn't.

```
<div class="form-group">
    <th:label asp-for="Password" class="col-md-2"></th:label>
    <div class="col-md-10">
        <th:input asp-for="Password" class="form-control" />
        <span asp-validation-for="Password" class="text-danger"></span>
    </div>
</div>
```

The same hierarchy rules that apply to `@addTagHelper` also apply to `@tagHelperPrefix`.

Self-closing Tag Helpers

Many Tag Helpers can't be used as self-closing tags. Some Tag Helpers are designed to be self-closing tags. Using a Tag Helper that was not designed to be self-closing suppresses the rendered output. Self-closing a Tag Helper results in a self-closing tag in the rendered output. For more information, see this note in Authoring Tag Helpers.

C# in Tag Helpers attribute/declaration

Tag Helpers do not allow C# in the element's attribute or tag declaration area. For example, the following code is not valid:

```
<input asp-for="LastName"
       @(Model?.LicenseId == null ? "disabled" : string.Empty) />
```

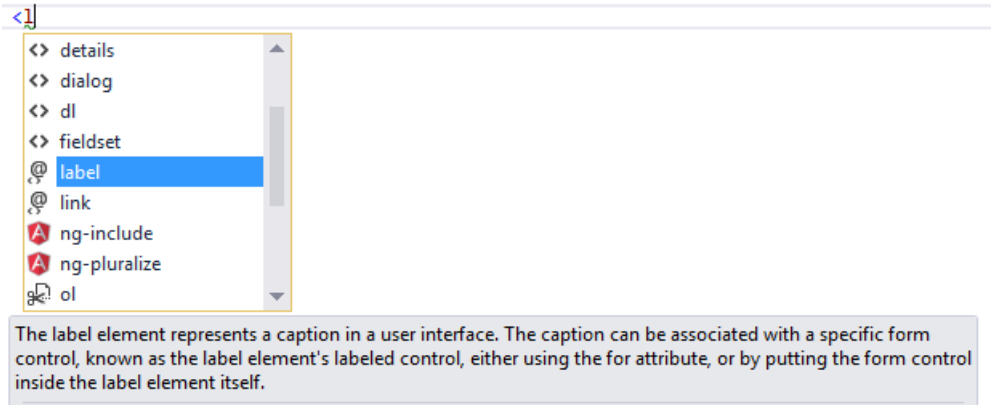
The preceding code can be written as:

```
<input asp-for="LastName"
       disabled="@(Model?.LicenseId == null)" />
```

IntelliSense support for Tag Helpers

When you create a new ASP.NET Core web app in Visual Studio, it adds the NuGet package "Microsoft.AspNetCore.Razor.Tools". This is the package that adds Tag Helper tooling.

Consider writing an HTML `<label>` element. As soon as you enter `<l` in the Visual Studio editor, IntelliSense displays matching elements:



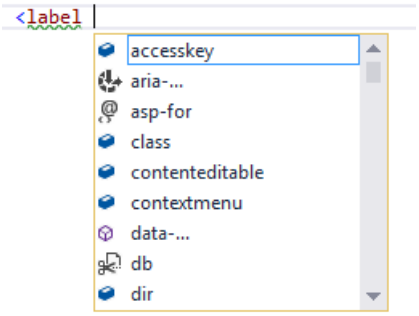
Not only do you get HTML help, but the icon (the "@" symbol with "<>" under it).

identifies the element as targeted by Tag Helpers. Pure HTML elements (such as the `fieldset`) display the "<>" icon.

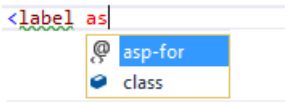
A pure HTML `<label>` tag displays the HTML tag (with the default Visual Studio color theme) in a brown font, the attributes in red, and the attribute values in blue.

```
<label class="col-md-2">Email</label>
```

After you enter `<label`, IntelliSense lists the available HTML/CSS attributes and the Tag Helper-targeted attributes:



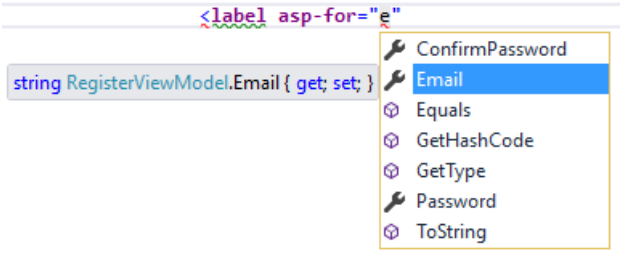
IntelliSense statement completion allows you to enter the tab key to complete the statement with the selected value:



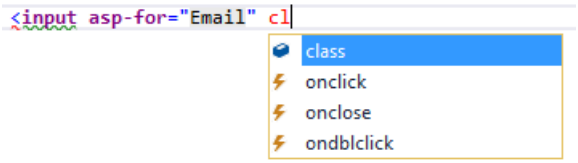
As soon as a Tag Helper attribute is entered, the tag and attribute fonts change. Using the default Visual Studio "Blue" or "Light" color theme, the font is bold purple. If you're using the "Dark" theme the font is bold teal. The images in this document were taken using the default theme.

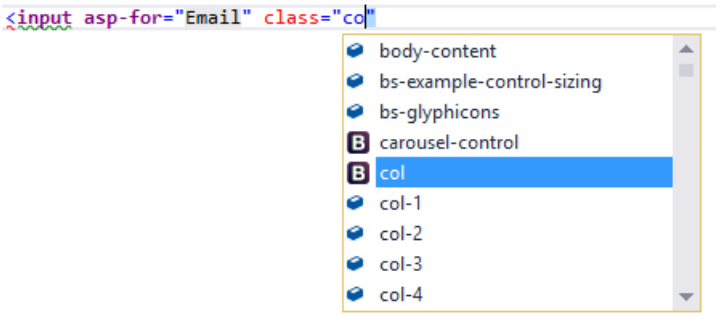
```
<label asp-for
```

You can enter the Visual Studio *CompleteWord* shortcut (Ctrl +spacebar is the default inside the double quotes (""), and you are now in C#, just like you would be in a C# class. IntelliSense displays all the methods and properties on the page model. The methods and properties are available because the property type is `ModelExpression`. In the image below, I'm editing the `Register` view, so the `RegisterViewModel` is available.



IntelliSense lists the properties and methods available to the model on the page. The rich IntelliSense environment helps you select the CSS class:





Tag Helpers compared to HTML Helpers

Tag Helpers attach to HTML elements in Razor views, while HTML Helpers are invoked as methods interspersed with HTML in Razor views. Consider the following Razor markup, which creates an HTML label with the CSS class "caption":

```
@Html.Label("FirstName", "First Name:", new {@class="caption"})
```

The at (`@`) symbol tells Razor this is the start of code. The next two parameters ("FirstName" and "First Name:") are strings, so IntelliSense can't help. The last argument:

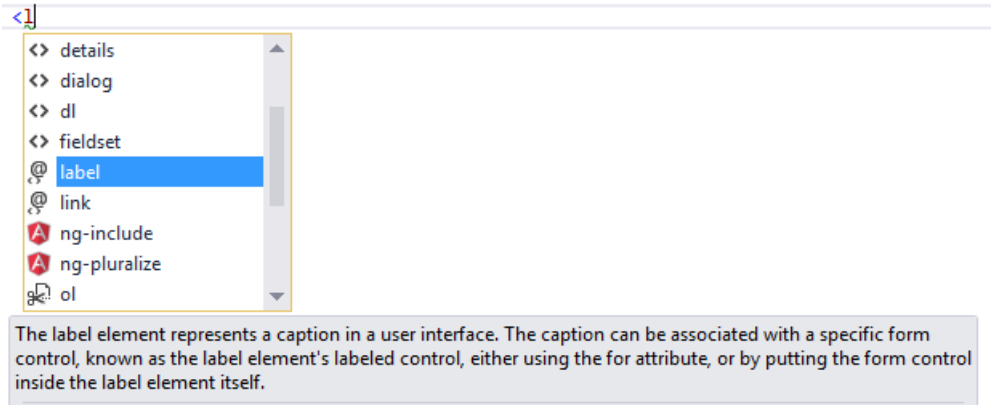
```
new {@class="caption"}
```

Is an anonymous object used to represent attributes. Because `class` is a reserved keyword in C#, you use the `@` symbol to force C# to interpret `@class=` as a symbol (property name). To a front-end designer (someone familiar with HTML/CSS/JavaScript and other client technologies but not familiar with C# and Razor), most of the line is foreign. The entire line must be authored with no help from IntelliSense.

Using the `LabelTagHelper`, the same markup can be written as:

```
<label class="caption" asp-for="FirstName"></label>
```

With the Tag Helper version, as soon as you enter `<l` in the Visual Studio editor, IntelliSense displays matching elements:



IntelliSense helps you write the entire line.

The following code image shows the Form portion of the *Views/Account/Register.cshtml* Razor view generated from the ASP.NET 4.5.x MVC template included with Visual Studio.

```
@using (Html.BeginForm("Register", "Account", FormMethod.Post, new { @class = "form-horizo
{
    @Html.AntiForgeryToken()
    <h4>Create a new account.</h4>
    <hr />
    @Html.ValidationSummary("", new { @class = "text-danger" })
    <div class="form-group">
        @Html.LabelFor(m => m.Email, new { @class = "col-md-2 control-label" })
        <div class="col-md-10">
            @Html.TextBoxFor(m => m.Email, new { @class = "form-control" })
        </div>
    </div>
    <div class="form-group">
        @Html.LabelFor(m => m.Password, new { @class = "col-md-2 control-label" })
        <div class="col-md-10">
            @Html.PasswordFor(m => m.Password, new { @class = "form-control" })
        </div>
    </div>
    <div class="form-group">
        @Html.LabelFor(m => m.ConfirmPassword, new { @class = "col-md-2 control-label" })
        <div class="col-md-10">
            @Html.PasswordFor(m => m.ConfirmPassword, new { @class = "form-control" })
        </div>
    </div>
    <div class="form-group">
        <div class="col-md-offset-2 col-md-10">
            <input type="submit" class="btn btn-default" value="Register" />
        </div>
    </div>
}
```

The Visual Studio editor displays C# code with a grey background. For example, the `AntiForgeryToken` HTML Helper:

```
@Html.AntiForgeryToken()
```

is displayed with a grey background. Most of the markup in the Register view is C#. Compare that to the equivalent approach using Tag Helpers:

```
<form asp-controller="Account" asp-action="Register" method="post" class="form-hori
    <h4>Create a new account.</h4>
    <hr />
    <div asp-validation-summary="ValidationSummary.All" class="text-danger"></div>
    <div class="form-group">
        <label asp-for="Email" class="col-md-2 control-label"></label>
        <div class="col-md-10">
            <input asp-for="Email" class="form-control" />
            <span asp-validation-for="Email" class="text-danger"></span>
        </div>
    </div>
    <div class="form-group">
        <label asp-for="Password" class="col-md-2 control-label"></label>
        <div class="col-md-10">
            <input asp-for="Password" class="form-control" />
            <span asp-validation-for="Password" class="text-danger"></span>
        </div>
    </div>
    <div class="form-group">
        <label asp-for="ConfirmPassword" class="col-md-2 control-label"></label>
        <div class="col-md-10">
            <input asp-for="ConfirmPassword" class="form-control" />
            <span asp-validation-for="ConfirmPassword" class="text-danger"></span>
        </div>
    </div>
    <div class="form-group">
        <div class="col-md-offset-2 col-md-10">
            <button type="submit" class="btn btn-default">Register</button>
        </div>
    </div>
</form>
```

The markup is much cleaner and easier to read, edit, and maintain than the HTML Helpers approach. The C# code is reduced to the minimum that the server needs to know about. The Visual Studio editor displays markup targeted by a Tag Helper in a distinctive font.

Consider the *Email* group:

```
<div class="form-group">
    <label asp-for="Email" class="col-md-2 control-label"></label>
    <div class="col-md-10">
        <input asp-for="Email" class="form-control" />
        <span asp-validation-for="Email" class="text-danger"></span>
    </div>
</div>
```

Each of the "asp-" attributes has a value of "Email", but "Email" isn't a string. In this context, "Email" is the C# model expression property for the `RegisterViewModel`.

The Visual Studio editor helps you write **all** of the markup in the Tag Helper approach of the register form, while Visual Studio provides no help for most of the code in the HTML Helpers approach. IntelliSense support for Tag Helpers goes into detail on working with Tag Helpers in the Visual Studio editor.

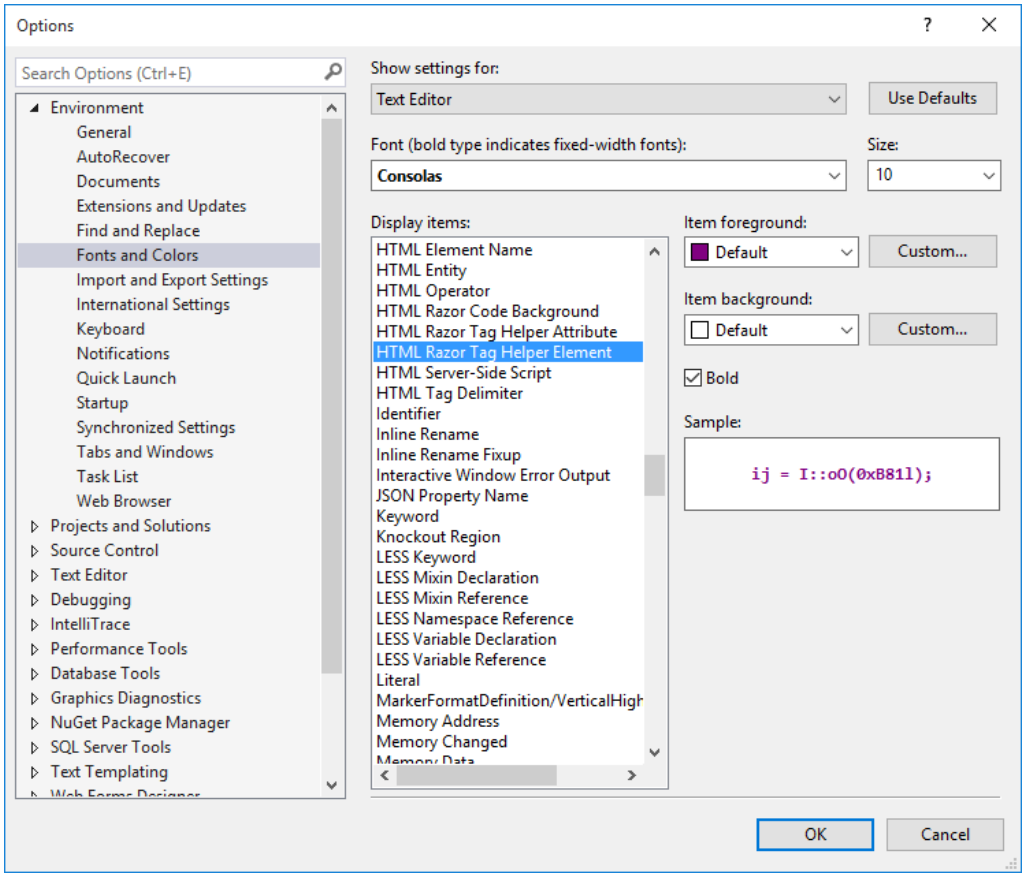
Tag Helpers compared to Web Server Controls

- Tag Helpers don't own the element they're associated with; they simply participate in the rendering of the element and content. ASP.NET /previous-versions/dotnet/netframework-3.0/7698y1f0(v=vs.85) are declared and invoked on a page.
- /previous-versions/zsyt68f1(v=vs.140) have a non-trivial lifecycle that can make developing and debugging difficult.
- Web Server controls allow you to add functionality to the client Document Object Model (DOM) elements by using a client control. Tag Helpers have no DOM.

- Web Server controls include automatic browser detection. Tag Helpers have no knowledge of the browser.
- Multiple Tag Helpers can act on the same element (see Avoiding Tag Helper conflicts) while you typically can't compose Web Server controls.
- Tag Helpers can modify the tag and content of HTML elements that they're scoped to, but don't directly modify anything else on a page. Web Server controls have a less specific scope and can perform actions that affect other parts of your page; enabling unintended side effects.
- Web Server controls use type converters to convert strings into objects. With Tag Helpers, you work natively in C#, so you don't need to do type conversion.
- Web Server controls use System.ComponentModel to implement the run-time and design-time behavior of components and controls. `System.ComponentModel` includes the base classes and interfaces for implementing attributes and type converters, binding to data sources, and licensing components. Contrast that to Tag Helpers, which typically derive from `TagHelper`, and the `TagHelper` base class exposes only two methods, `Process` and `ProcessAsync`.

Customizing the Tag Helper element font

You can customize the font and colorization from **Tools** > **Options** > **Environment** > **Fonts and Colors**:



Built-in ASP.NET Core Tag Helpers

Anchor Tag Helper

Cache Tag Helper

Component Tag Helper

Distributed Cache Tag Helper

Environment Tag Helper

Form Tag Helper

Form Action Tag Helper

Image Tag Helper

Input Tag Helper

Label Tag Helper

Link Tag Helper

Partial Tag Helper

Script Tag Helper

Select Tag Helper

Textarea Tag Helper

Validation Message Tag Helper

Validation Summary Tag Helper

Author Tag Helpers in ASP.NET Core

9/22/2020 • 16 minutes to read • Edit Online

View or download sample code (how to download)

Get started with Tag Helpers

This tutorial provides an introduction to programming Tag Helpers. Introduction to Tag Helpers describes the benefits that Tag Helpers provide.

A tag helper is any class that implements the `ITagHelper` interface. However, when you author a tag helper, you generally derive from `TagHelper`, doing so gives you access to the `Process` method.

1. Create a new ASP.NET Core project called **AuthoringTagHelpers**. You won't need authentication for this project.
2. Create a folder to hold the Tag Helpers called *TagHelpers*. The *TagHelpers* folder is *not* required, but it's a reasonable convention. Now let's get started writing some simple tag helpers.

A minimal Tag Helper

In this section, you write a tag helper that updates an email tag. For example:

```
<email>Support</email>
```

The server will use our email tag helper to convert that markup into the following:

```
<a href="mailto:Support@contoso.com">Support@contoso.com</a>
```

That is, an anchor tag that makes this an email link. You might want to do this if you are writing a blog engine and need it to send email for marketing, support, and other contacts, all to the same domain.

1. Add the following `EmailTagHelper` class to the *TagHelpers* folder.

```
using Microsoft.AspNetCore.Razor.TagHelpers;
using System.Threading.Tasks;

namespace AuthoringTagHelpers.TagHelpers
{
    public class EmailTagHelper : TagHelper
    {
        public override void Process(TagHelperContext context, TagHelperOutput output)
        {
            output.TagName = "a";    // Replaces <email> with <a> tag
        }
    }
}
```

- Tag helpers use a naming convention that targets elements of the root class name (minus the *TagHelper* portion of the class name). In this example, the root name of **EmailTagHelper** is *email*,

so the `<email>` tag will be targeted. This naming convention should work for most tag helpers, later on I'll show how to override it.

- The `EmailTagHelper` class derives from `TagHelper`. The `TagHelper` class provides methods and properties for writing Tag Helpers.
- The overridden `Process` method controls what the tag helper does when executed. The `TagHelper` class also provides an asynchronous version (`ProcessAsync`) with the same parameters.
- The context parameter to `Process` (and `ProcessAsync`) contains information associated with the execution of the current HTML tag.
- The output parameter to `Process` (and `ProcessAsync`) contains a stateful HTML element representative of the original source used to generate an HTML tag and content.
- Our class name has a suffix of **TagHelper**, which is *not* required, but it's considered a best practice convention. You could declare the class as:

```
public class Email : TagHelper
```

2. To make the `EmailTagHelper` class available to all our Razor views, add the `addTagHelper` directive to the *Views/_ViewImports.cshtml* file:

```
@using AuthoringTagHelpers
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@addTagHelper *, AuthoringTagHelpers
```

The code above uses the wildcard syntax to specify all the tag helpers in our assembly will be available. The first string after `@addTagHelper` specifies the tag helper to load (Use "*" for all tag helpers), and the second string "AuthoringTagHelpers" specifies the assembly the tag helper is in. Also, note that the second line brings in the ASP.NET Core MVC tag helpers using the wildcard syntax (those helpers are discussed in Introduction to Tag Helpers.) It's the `@addTagHelper` directive that makes the tag helper available to the Razor view. Alternatively, you can provide the fully qualified name (FQN) of a tag helper as shown below:

```
@using AuthoringTagHelpers
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@addTagHelper AuthoringTagHelpers.TagHelpers.EmailTagHelper, AuthoringTagHelpers
```

To add a tag helper to a view using a FQN, you first add the FQN (`AuthoringTagHelpers.TagHelpers.EmailTagHelper`), and then the **assembly name** (*AuthoringTagHelpers*, not necessarily the `namespace`). Most developers will prefer to use the wildcard syntax. Introduction to Tag Helpers goes into detail on tag helper adding, removing, hierarchy, and wildcard syntax.

1. Update the markup in the *Views/Home/Contact.cshtml* file with these changes:

```
@{
    ViewData["Title"] = "Contact";
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<address>
    One Microsoft Way<br />
    Redmond, WA 98052<br />
    <abbr title="Phone">P:</abbr>
    425.555.0100
</address>

<address>
    <strong>Support:</strong><email>Support</email><br />
    <strong>Marketing:</strong><email>Marketing</email>
</address>
```

2. Run the app and use your favorite browser to view the HTML source so you can verify that the email tags are replaced with anchor markup (For example, `<a>Support</a>`). *Support* and *Marketing* are rendered as a links, but they don't have an `href` attribute to make them functional. We'll fix that in the next section.

SetAttribute and SetContent

In this section, we'll update the `EmailTagHelper` so that it will create a valid anchor tag for email. We'll update it to take information from a Razor view (in the form of a `mail-to` attribute) and use that in generating the anchor.

Update the `EmailTagHelper` class with the following:

```
public class EmailTagHelper : TagHelper
{
    private const string EmailDomain = "contoso.com";

    // Can be passed via <email mail-to="..." />.
    // PascalCase gets translated into kebab-case.
    public string MailTo { get; set; }

    public override void Process(TagHelperContext context, TagHelperOutput output)
    {
        output.TagName = "a";    // Replaces <email> with <a> tag

        var address = MailTo + "@" + EmailDomain;
        output.Attributes.SetAttribute("href", "mailto:" + address);
        output.Content.SetContent(address);
    }
}
```

- Pascal-cased class and property names for tag helpers are translated into their kebab case. Therefore, to use the `MailTo` attribute, you'll use `<email mail-to="value"/>` equivalent.
- The last line sets the completed content for our minimally functional tag helper.
- The highlighted line shows the syntax for adding attributes:

```
public override void Process(TagHelperContext context, TagHelperOutput output)
{
    output.TagName = "a";    // Replaces <email> with <a> tag

    var address = MailTo + "@" + EmailDomain;
    output.Attributes.SetAttribute("href", "mailto:" + address);
    output.Content.SetContent(address);
}
```

That approach works for the attribute "href" as long as it doesn't currently exist in the attributes collection. You can also use the `output.Attributes.Add` method to add a tag helper attribute to the end of the collection of tag attributes.

1. Update the markup in the *Views/Home/Contact.cshtml* file with these changes:

```
@{
    ViewData["Title"] = "Contact Copy";
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<address>
    One Microsoft Way Copy Version <br />
    Redmond, WA 98052-6399<br />
    <abbr title="Phone">P:</abbr>
    425.555.0100
</address>

<address>
    <strong>Support:</strong><email mail-to="Support"></email><br />
    <strong>Marketing:</strong><email mail-to="Marketing"></email>
</address>
```

2. Run the app and verify that it generates the correct links.

NOTE

If you were to write the email tag self-closing (`<email mail-to="Rick" />`), the final output would also be self-closing. To enable the ability to write the tag with only a start tag (`<email mail-to="Rick">`) you must mark the class with the following:

```
[HtmlTargetElement("email", TagStructure = TagStructure.WithoutEndTag)]
public class EmailVoidTagHelper : TagHelper
{
    private const string EmailDomain = "contoso.com";
    // Code removed for brevity
```

With a self-closing email tag helper, the output would be `<a href="mailto:Rick@contoso.com" />`. Self-closing anchor tags are not valid HTML, so you wouldn't want to create one, but you might want to create a tag helper that's self-closing. Tag helpers set the type of the `TagMode` property after reading a tag.

ProcessAsync

In this section, we'll write an asynchronous email helper.

1. Replace the `EmailTagHelper` class with the following code:

```
public class EmailTagHelper : TagHelper
{
    private const string EmailDomain = "contoso.com";
    public override async Task ProcessAsync(TagHelperContext context, TagHelperOutput output)
    {
        output.TagName = "a";                                   // Replaces <email> with <a> tag
        var content = await output.GetChildContentAsync();
        var target = content.GetContent() + "@" + EmailDomain;
        output.Attributes.SetAttribute("href", "mailto:" + target);
        output.Content.SetContent(target);
    }
}
```

Notes:

- This version uses the asynchronous `ProcessAsync` method. The asynchronous `GetChildContentAsync` returns a `Task` containing the `TagHelperContent`.
- Use the `output` parameter to get contents of the HTML element.

2. Make the following change to the *Views/Home/Contact.cshtml* file so the tag helper can get the target email.

```
@{
    ViewData["Title"] = "Contact";
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<address>
    One Microsoft Way<br />
    Redmond, WA 98052<br />
    <abbr title="Phone">P:</abbr>
    425.555.0100
</address>

<address>
    <strong>Support:</strong><email>Support</email><br />
    <strong>Marketing:</strong><email>Marketing</email>
</address>
```

3. Run the app and verify that it generates valid email links.

RemoveAll, PreContent.SetHtmlContent and PostContent.SetHtmlContent

1. Add the following `BoldTagHelper` class to the *TagHelpers* folder.

```
using Microsoft.AspNetCore.Razor.TagHelpers;

namespace AuthoringTagHelpers.TagHelpers
{
    [HtmlTargetElement(Attributes = "bold")]
    public class BoldTagHelper : TagHelper
    {
        public override void Process(TagHelperContext context, TagHelperOutput output)
        {
            output.Attributes.RemoveAll("bold");
            output.PreContent.SetHtmlContent("<strong>");
            output.PostContent.SetHtmlContent("</strong>");
        }
    }
}
```

- The `[HtmlTargetElement]` attribute passes an attribute parameter that specifies that any HTML element that contains an HTML attribute named "bold" will match, and the `Process` override method in the class will run. In our sample, the `Process` method removes the "bold" attribute and surrounds the containing markup with `<strong></strong>`.
- Because you don't want to replace the existing tag content, you must write the opening `<strong>` tag with the `PreContent.SetHtmlContent` method and the closing `</strong>` tag with the `PostContent.SetHtmlContent` method.

2. Modify the *About.cshtml* view to contain a `bold` attribute value. The completed code is shown below.

```
@{
    ViewData["Title"] = "About";
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<p bold>Use this area to provide additional information.</p>

<bold> Is this bold?</bold>
```

3. Run the app. You can use your favorite browser to inspect the source and verify the markup.

   The `[HtmlTargetElement]` attribute above only targets HTML markup that provides an attribute name of "bold". The `<bold>` element wasn't modified by the tag helper.

4. Comment out the `[HtmlTargetElement]` attribute line and it will default to targeting `<bold>` tags, that is, HTML markup of the form `<bold>`. Remember, the default naming convention will match the class name **Bold**TagHelper to `<bold>` tags.

5. Run the app and verify that the `<bold>` tag is processed by the tag helper.

Decorating a class with multiple `[HtmlTargetElement]` attributes results in a logical-OR of the targets. For example, using the code below, a bold tag or a bold attribute will match.

```
[HtmlTargetElement("bold")]
[HtmlTargetElement(Attributes = "bold")]
public class BoldTagHelper : TagHelper
{
    public override void Process(TagHelperContext context, TagHelperOutput output)
    {
        output.Attributes.RemoveAll("bold");
        output.PreContent.SetHtmlContent("<strong>");
        output.PostContent.SetHtmlContent("</strong>");
    }
}
```

When multiple attributes are added to the same statement, the runtime treats them as a logical-AND. For example, in the code below, an HTML element must be named "bold" with an attribute named "bold" (`<bold bold />`) to match.

```
[HtmlTargetElement("bold", Attributes = "bold")]
```

You can also use the `[HtmlTargetElement]` to change the name of the targeted element. For example if you wanted the `BoldTagHelper` to target `<MyBold>` tags, you would use the following attribute:

```
[HtmlTargetElement("MyBold")]
```

Pass a model to a Tag Helper

1. Add a *Models* folder.
2. Add the following `WebsiteContext` class to the *Models* folder:

```
using System;

namespace AuthoringTagHelpers.Models
{
    public class WebsiteContext
    {
        public Version Version { get; set; }
        public int CopyrightYear { get; set; }
        public bool Approved { get; set; }
        public int TagsToShow { get; set; }
    }
}
```

3. Add the following `WebsiteInformationTagHelper` class to the *TagHelpers* folder.

```
using System;
using AuthoringTagHelpers.Models;
using Microsoft.AspNetCore.Razor.TagHelpers;

namespace AuthoringTagHelpers.TagHelpers
{
    public class WebsiteInformationTagHelper : TagHelper
    {
        public WebsiteContext Info { get; set; }

      public override void Process(TagHelperContext context, TagHelperOutput output)
      {
         output.TagName = "section";
         output.Content.SetHtmlContent(
$@"<ul><li><strong>Version:</strong> {Info.Version}</li>
<li><strong>Copyright Year:</strong> {Info.CopyrightYear}</li>
<li><strong>Approved:</strong> {Info.Approved}</li>
<li><strong>Number of tags to show:</strong> {Info.TagsToShow}</li></ul>");
         output.TagMode = TagMode.StartTagAndEndTag;
      }
   }
}
```

- As mentioned previously, tag helpers translates Pascal-cased C# class names and properties for tag helpers into kebab case. Therefore, to use the `WebsiteInformationTagHelper` in Razor, you'll write `<website-information />`.
- You are not explicitly identifying the target element with the `[HtmlTargetElement]` attribute, so the default of `website-information` will be targeted. If you applied the following attribute (note it's not kebab case but matches the class name):

```
[HtmlTargetElement("WebsiteInformation")]
```

The kebab case tag `<website-information />` wouldn't match. If you want use the `[HtmlTargetElement]` attribute, you would use kebab case as shown below:

```
[HtmlTargetElement("Website-Information")]
```

- Elements that are self-closing have no content. For this example, the Razor markup will use a self-closing tag, but the tag helper will be creating a section element (which isn't self-closing and you are writing content inside the `section` element). Therefore, you need to set `TagMode` to `StartTagAndEndTag` to write output. Alternatively, you can comment out the line setting `TagMode` and write markup with a closing tag. (Example markup is provided later in this tutorial.)
- The `$` (dollar sign) in the following line uses an interpolated string:

```
$@"<ul><li><strong>Version:</strong> {Info.Version}</li>
```

4. Add the following markup to the *About.cshtml* view. The highlighted markup displays the web site information.

```
@using AuthoringTagHelpers.Models
@{
    ViewData["Title"] = "About";
    WebsiteContext webContext = new WebsiteContext {
                                    Version = new Version(1, 3),
                                    CopyrightYear = 1638,
                                    Approved = true,
                                    TagsToShow = 131 };
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<p bold>Use this area to provide additional information.</p>

<bold> Is this bold?</bold>

<h3> web site info </h3>
<website-information info="webContext" />
```

> **NOTE**
>
> In the Razor markup shown below:
>
> ```
> <website-information info="webContext" />
> ```
>
> Razor knows the `info` attribute is a class, not a string, and you want to write C# code. Any non-string tag helper attribute should be written without the `@` character.

5. Run the app, and navigate to the About view to see the web site information.

> **NOTE**
>
> You can use the following markup with a closing tag and remove the line with `TagMode.StartTagAndEndTag` in the tag helper:
>
> ```
> <website-information info="webContext" >
> </website-information>
> ```

Condition Tag Helper

The condition tag helper renders output when passed a true value.

1. Add the following `ConditionTagHelper` class to the *TagHelpers* folder.

```
using Microsoft.AspNetCore.Razor.TagHelpers;

namespace AuthoringTagHelpers.TagHelpers
{
    [HtmlTargetElement(Attributes = nameof(Condition))]
    public class ConditionTagHelper : TagHelper
    {
        public bool Condition { get; set; }

        public override void Process(TagHelperContext context, TagHelperOutput output)
        {
            if (!Condition)
            {
                output.SuppressOutput();
            }
        }
    }
}
```

2. Replace the contents of the *Views/Home/Index.cshtml* file with the following markup:

```
@using AuthoringTagHelpers.Models
@model WebsiteContext

@{
    ViewData["Title"] = "Home Page";
}

<div>
    <h3>Information about our website (outdated):</h3>
    <Website-InforMation info="Model" />
    <div condition="Model.Approved">
        <p>
            This website has <strong surround="em">@Model.Approved</strong> been approved yet.
            Visit www.contoso.com for more information.
        </p>
    </div>
</div>
```

3. Replace the `Index` method in the `Home` controller with the following code:

```
public IActionResult Index(bool approved = false)
{
    return View(new WebsiteContext
    {
        Approved = approved,
        CopyrightYear = 2015,
        Version = new Version(1, 3, 3, 7),
        TagsToShow = 20
    });
}
```

4. Run the app and browse to the home page. The markup in the conditional `div` won't be rendered. Append the query string `?approved=true` to the URL (for example, `http://localhost:1235/Home/Index?approved=true`). `approved` is set to true and the conditional markup will

be displayed.

> **NOTE**
>
> Use the nameof operator to specify the attribute to target rather than specifying a string as you did with the bold tag helper:

```
[HtmlTargetElement(Attributes = nameof(Condition))]
 //   [HtmlTargetElement(Attributes = "condition")]
 public class ConditionTagHelper : TagHelper
{
   public bool Condition { get; set; }

   public override void Process(TagHelperContext context, TagHelperOutput output)
   {
      if (!Condition)
      {
         output.SuppressOutput();
      }
   }
}
```

> The nameof operator will protect the code should it ever be refactored (we might want to change the name to `RedCondition`).

Avoid Tag Helper conflicts

In this section, you write a pair of auto-linking tag helpers. The first will replace markup containing a URL starting with HTTP to an HTML anchor tag containing the same URL (and thus yielding a link to the URL). The second will do the same for a URL starting with WWW.

Because these two helpers are closely related and you may refactor them in the future, we'll keep them in the same file.

1. Add the following `AutoLinkerHttpTagHelper` class to the *TagHelpers* folder.

```
[HtmlTargetElement("p")]
public class AutoLinkerHttpTagHelper : TagHelper
{
    public override async Task ProcessAsync(TagHelperContext context, TagHelperOutput output)
    {
        var childContent = await output.GetChildContentAsync();
        // Find Urls in the content and replace them with their anchor tag equivalent.
        output.Content.SetHtmlContent(Regex.Replace(
             childContent.GetContent(),
             @"\b(?:https?://)(\S+)\b",
              "<a target=\"_blank\" href=\"$0\">$0</a>"));  // http link version}
    }
}
```

> **NOTE**
>
> The `AutoLinkerHttpTagHelper` class targets `p` elements and uses Regex to create the anchor.

2. Add the following markup to the end of the *Views/Home/Contact.cshtml* file:

```
@{
    ViewData["Title"] = "Contact";
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<address>
    One Microsoft Way<br />
    Redmond, WA 98052<br />
    <abbr title="Phone">P:</abbr>
    425.555.0100
</address>

<address>
    <strong>Support:</strong><email>Support</email><br />
    <strong>Marketing:</strong><email>Marketing</email>
</address>

<p>Visit us at http://docs.asp.net or at www.microsoft.com</p>
```

3. Run the app and verify that the tag helper renders the anchor correctly.

4. Update the `AutoLinker` class to include the `AutoLinkerWwwTagHelper` which will convert www text to an anchor tag that also contains the original www text. The updated code is highlighted below:

```
    [HtmlTargetElement("p")]
    public class AutoLinkerHttpTagHelper : TagHelper
    {
        public override async Task ProcessAsync(TagHelperContext context, TagHelperOutput output)
        {
            var childContent = await output.GetChildContentAsync();
            // Find Urls in the content and replace them with their anchor tag equivalent.
            output.Content.SetHtmlContent(Regex.Replace(
                 childContent.GetContent(),
                 @"\b(?:https?://)(\S+)\b",
                  "<a target=\"_blank\" href=\"$0\">$0</a>"));  // http link version}
        }
    }

    [HtmlTargetElement("p")]
    public class AutoLinkerWwwTagHelper : TagHelper
    {
        public override async Task ProcessAsync(TagHelperContext context, TagHelperOutput output)
        {
            var childContent = await output.GetChildContentAsync();
            // Find Urls in the content and replace them with their anchor tag equivalent.
            output.Content.SetHtmlContent(Regex.Replace(
                childContent.GetContent(),
                 @"\b(www\.)(\S+)\b",
                 "<a target=\"_blank\" href=\"http://$0\">$0</a>"));  // www version
        }
    }
}
```

5. Run the app. Notice the www text is rendered as a link but the HTTP text isn't. If you put a break point in both classes, you can see that the HTTP tag helper class runs first. The problem is that the tag helper output is cached, and when the WWW tag helper is run, it overwrites the cached output from the HTTP tag helper. Later in the tutorial we'll see how to control the order that tag helpers run in. We'll fix the code with the following:

```
public class AutoLinkerHttpTagHelper : TagHelper
{
    public override async Task ProcessAsync(TagHelperContext context, TagHelperOutput output)
    {
        var childContent = output.Content.IsModified ? output.Content.GetContent() :
            (await output.GetChildContentAsync()).GetContent();

        // Find Urls in the content and replace them with their anchor tag equivalent.
        output.Content.SetHtmlContent(Regex.Replace(
             childContent,
             @"\b(?:https?://)(\S+)\b",
              "<a target=\"_blank\" href=\"$0\">$0</a>"));  // http link version}
    }
}

[HtmlTargetElement("p")]
public class AutoLinkerWwwTagHelper : TagHelper
{
    public override async Task ProcessAsync(TagHelperContext context, TagHelperOutput output)
    {
        var childContent = output.Content.IsModified ? output.Content.GetContent() :
            (await output.GetChildContentAsync()).GetContent();

        // Find Urls in the content and replace them with their anchor tag equivalent.
        output.Content.SetHtmlContent(Regex.Replace(
             childContent,
             @"\b(www\.)(\S+)\b",
             "<a target=\"_blank\" href=\"http://$0\">$0</a>"));  // www version
    }
}
```

NOTE

In the first edition of the auto-linking tag helpers, you got the content of the target with the following code:

```
var childContent = await output.GetChildContentAsync();
```

That is, you call `GetChildContentAsync` using the `TagHelperOutput` passed into the `ProcessAsync` method. As mentioned previously, because the output is cached, the last tag helper to run wins. You fixed that problem with the following code:

```
var childContent = output.Content.IsModified ? output.Content.GetContent() :
    (await output.GetChildContentAsync()).GetContent();
```

The code above checks to see if the content has been modified, and if it has, it gets the content from the output buffer.

6. Run the app and verify that the two links work as expected. While it might appear our auto linker tag helper is correct and complete, it has a subtle problem. If the WWW tag helper runs first, the www links won't be correct. Update the code by adding the `Order` overload to control the order that the tag runs in. The `Order` property determines the execution order relative to other tag helpers targeting the same element. The default order value is zero and instances with lower values are executed first.

```
public class AutoLinkerHttpTagHelper : TagHelper
{
    // This filter must run before the AutoLinkerWwwTagHelper as it searches and replaces http and
    // the AutoLinkerWwwTagHelper adds http to the markup.
    public override int Order
    {
        get  {  return int.MinValue;   }
    }
```

The preceding code guarantees that the HTTP tag helper runs before the WWW tag helper. Change `Order` to `MaxValue` and verify that the markup generated for the WWW tag is incorrect.

Inspect and retrieve child content

The tag helpers provide several properties to retrieve content.

- The result of `GetChildContentAsync` can be appended to `output.Content`.
- You can inspect the result of `GetChildContentAsync` with `GetContent`.
- If you modify `output.Content`, the TagHelper body won't be executed or rendered unless you call `GetChildContentAsync` as in our auto-linker sample:

```
public class AutoLinkerHttpTagHelper : TagHelper
{
    public override async Task ProcessAsync(TagHelperContext context, TagHelperOutput output)
    {
        var childContent = output.Content.IsModified ? output.Content.GetContent() :
            (await output.GetChildContentAsync()).GetContent();

        // Find Urls in the content and replace them with their anchor tag equivalent.
        output.Content.SetHtmlContent(Regex.Replace(
             childContent,
             @"\b(?:https?://)(\S+)\b",
              "<a target=\"_blank\" href=\"$0\">$0</a>"));  // http link version}
    }
}
```

- Multiple calls to `GetChildContentAsync` returns the same value and doesn't re-execute the `TagHelper` body unless you pass in a false parameter indicating not to use the cached result.

Load minified partial view TagHelper

In production environments, performance can be improved by loading minified partial views. To take advantage of minified partial view in production:

- Create/set up a pre-build process that minifies partial views.
- Use the following code to load minified partial views in non-development environments.

```
public class MinifiedVersionPartialTagHelper : PartialTagHelper
    {
        public MinifiedVersionPartialTagHelper(ICompositeViewEngine viewEngine,
                                IViewBufferScope viewBufferScope)
                               : base(viewEngine, viewBufferScope)
        {

        }

        public override Task ProcessAsync(TagHelperContext context, TagHelperOutput output)
        {
            // Append ".min" to load the minified partial view.
            if (!IsDevelopment())
            {
                Name += ".min";
            }

            return base.ProcessAsync(context, output);
        }

        private bool IsDevelopment()
        {
            return Environment.GetEnvironmentVariable("ASPNETCORE_ENVIRONMENT")
                                                == EnvironmentName.Development;
        }
    }
```

Tag Helpers in forms in ASP.NET Core

9/22/2020 • 18 minutes to read • Edit Online

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

NOTE

With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

ATTRIBUTE	DESCRIPTION
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"` .
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the **HTML Helper alternatives to Input Tag Helper** section for details.
- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to process
this request. Please review the following specific error details and modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type 'RegisterViewModel'
could be found (are you missing a using directive or an assembly reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

.NET TYPE	INPUT TYPE
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

ATTRIBUTE	INPUT TYPE
[EmailAddress]	type="email"
[Url]	type="url"
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

```
  <form method="post" action="/Demo/RegisterInput">
      Email:
      <input type="email" data-val="true"
             data-val-email="The Email Address field is not a valid email address."
             data-val-required="The Email Address field is required."
             id="Email" name="Email" value=""><br>
      Password:
      <input type="password" data-val="true"
             data-val-required="The Password field is required."
             id="Password" name="Password"><br>
      <button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"`.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="@Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    Address: <input asp-for="Address.AddressLine1" /><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1" value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The *Views/Shared/EditorTemplates/String.cshtml* template:

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The *Views/Shared/EditorTemplates/ToDoItem.cshtml* template:

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
</td>

@*
    This template replaces the following Razor which evaluates the indexer three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> **NOTE**
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type with a maximum length of
&#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type with a minimum length of
&#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.
- Less markup in source code
- Strong typing with the model property.

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on a HTML span element.

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> **NOTE**
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side

validation is disabled), MVC places that error message as the body of the `<span>` element.

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

ASP-VALIDATION-SUMMARY	VALIDATION MESSAGES DISPLAYED
ValidationSummary.All	Property and model level
ValidationSummary.ModelOnly	Model
ValidationSummary.None	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    Email:  <input asp-for="Email" /> <br />
    <span asp-validation-for="Email"></span><br />
    Password: <input asp-for="Password" /><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

```
<form action="/DemoReg/Register" method="post">
  <div class="validation-summary-valid" data-valmsg-summary="true">
  <ul><li style="display:none"></li></ul></div>
  Email:  <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"  },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

```
[HttpPost]
[ValidateAntiForgeryToken]
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

> **NOTE**
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

```
    public class CountryEnumViewModel
    {
        public CountryEnum EnumCountry { get; set; }
    }
}
```

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

```
<form method="post" action="/Home/IndexEnum">
       <select data-val="true" data-val-required="The EnumCountry field is required."
               id="EnumCountry" name="EnumCountry">
           <option value="0">United Mexican States</option>
           <option value="1">United States of America</option>
           <option value="2">Canada</option>
           <option value="3">France</option>
           <option value="4">Germany</option>
           <option selected="selected" value="5">Spain</option>
       </select>
       <br /><button type="submit">Register</button>
       <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
  </form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America" };
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }

    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

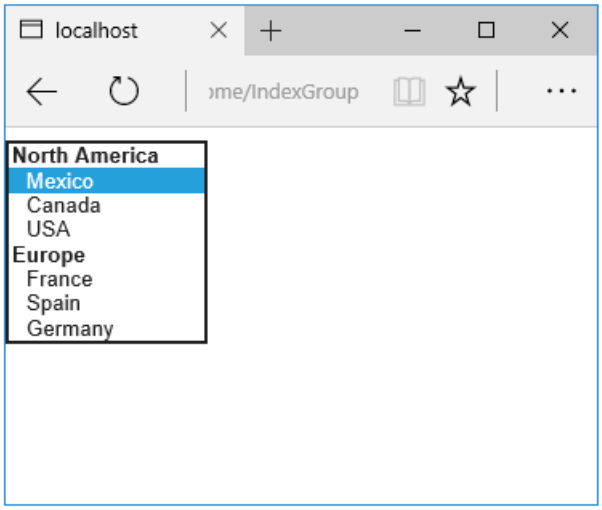
The two groups are shown below:



The generated HTML:

```
<form method="post" action="/Home/IndexGroup">
     <select id="Country" name="Country">
         <optgroup label="North America">
             <option value="MEX">Mexico</option>
             <option value="CAN">Canada</option>
             <option value="US">USA</option>
         </optgroup>
         <optgroup label="Europe">
             <option value="FR">France</option>
             <option value="ES">Spain</option>
             <option value="DE">Germany</option>
         </optgroup>
     </select>
     <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The *Views/Shared/EditorTemplates/CountryViewModel.cshtml* template:

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
 </form>
```

Tag Helper Components in ASP.NET Core

9/22/2020 • 5 minutes to read • Edit Online

By Scott Addie and Fiyaz Bin Hasan

A Tag Helper Component is a Tag Helper that allows you to conditionally modify or add HTML elements from server-side code. This feature is available in ASP.NET Core 2.0 or later.

ASP.NET Core includes two built-in Tag Helper Components: `head` and `body`. They're located in the Microsoft.AspNetCore.Mvc.Razor.TagHelpers namespace and can be used in both MVC and Razor Pages. Tag Helper Components don't require registration with the app in *_ViewImports.cshtml*.

View or download sample code (how to download)

Use cases

Two common use cases of Tag Helper Components include:

1. Injecting a `<link>` into the `<head>`.
2. Injecting a `<script>` into the `<body>`.

The following sections describe these use cases.

Inject into HTML head element

Inside the HTML `<head>` element, CSS files are commonly imported with the HTML `<link>` element. The following code injects a `<link>` element into the `<head>` element using the `head` Tag Helper Component:

```
using System;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Razor.TagHelpers;

namespace RazorPagesSample.TagHelpers
{
    public class AddressStyleTagHelperComponent : TagHelperComponent
    {
        private readonly string _style =
            @"<link rel=""stylesheet"" href=""/css/address.css"" />";

        public override int Order => 1;

        public override Task ProcessAsync(TagHelperContext context,
                                          TagHelperOutput output)
        {
            if (string.Equals(context.TagName, "head",
                              StringComparison.OrdinalIgnoreCase))
            {
                output.PostContent.AppendHtml(_style);
            }

            return Task.CompletedTask;
        }
    }
}
```

In the preceding code:

- `AddressStyleTagHelperComponent` implements TagHelperComponent. The abstraction:

    - Allows initialization of the class with a TagHelperContext.
    - Enables the use of Tag Helper Components to add or modify HTML elements.
- The Order property defines the order in which the Components are rendered. `Order` is necessary when there are multiple usages of Tag Helper Components in an app.
- ProcessAsync compares the execution context's TagName property value to `head`. If the comparison evaluates to true, the content of the `_style` field is injected into the HTML `<head>` element.

Inject into HTML body element

The `body` Tag Helper Component can inject a `<script>` element into the `<body>` element. The following code demonstrates this technique:

```
using System;
using System.IO;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Razor.TagHelpers;

namespace RazorPagesSample.TagHelpers
{
    public class AddressScriptTagHelperComponent : TagHelperComponent
    {
        public override int Order => 2;

        public override async Task ProcessAsync(TagHelperContext context,
                                                TagHelperOutput output)
        {
            if (string.Equals(context.TagName, "body",
                              StringComparison.OrdinalIgnoreCase))
            {
                var script = await File.ReadAllTextAsync(
                    "TagHelpers/Templates/AddressToolTipScript.html");
                output.PostContent.AppendHtml(script);
            }
        }
    }
}
```

A separate HTML file is used to store the `<script>` element. The HTML file makes the code cleaner and more maintainable. The preceding code reads the contents of *TagHelpers/Templates/AddressToolTipScript.html* and appends it with the Tag Helper output. The *AddressToolTipScript.html* file includes the following markup:

```
<script>
$("address[printable]").hover(function() {
    $(this).attr({
        "data-toggle": "tooltip",
        "data-placement": "right",
        "title": "Home of Microsoft!"
    });
});
</script>
```

The preceding code binds a Bootstrap tooltip widget to any `<address>` element that includes a `printable` attribute. The effect is visible when a mouse pointer hovers over the element.

Register a Component

A Tag Helper Component must be added to the app's Tag Helper Components collection. There are three ways to add to the collection:

- Registration via services container

- Registration via Razor file
- Registration via Page Model or controller

Registration via services container

If the Tag Helper Component class isn't managed with ITagHelperComponentManager, it must be registered with the dependency injection (DI) system. The following `Startup.ConfigureServices` code registers the `AddressStyleTagHelperComponent` and `AddressScriptTagHelperComponent` classes with a transient lifetime:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);

    services.AddTransient<ITagHelperComponent,
        AddressScriptTagHelperComponent>();
    services.AddTransient<ITagHelperComponent,
        AddressStyleTagHelperComponent>();
}
```

Registration via Razor file

If the Tag Helper Component isn't registered with DI, it can be registered from a Razor Pages page or an MVC view. This technique is used for controlling the injected markup and the component execution order from a Razor file.

`ITagHelperComponentManager` is used to add Tag Helper Components or remove them from the app. The following code demonstrates this technique with `AddressTagHelperComponent`:

```
@using RazorPagesSample.TagHelpers;
@using Microsoft.AspNetCore.Mvc.Razor.TagHelpers;
@inject ITagHelperComponentManager manager;

@{
    string markup;

    if (Model.IsWeekend)
    {
        markup = "<em class='text-warning'>Office closed today!</em>";
    }
    else
    {
        markup = "<em class='text-info'>Office open today!</em>";
    }

    manager.Components.Add(new AddressTagHelperComponent(markup, 1));
}
```

In the preceding code:

- The `@inject` directive provides an instance of `ITagHelperComponentManager`. The instance is assigned to a variable named `manager` for access downstream in the Razor file.
- An instance of `AddressTagHelperComponent` is added to the app's Tag Helper Components collection.

`AddressTagHelperComponent` is modified to accommodate a constructor that accepts the `markup` and `order` parameters:

```
private readonly string _markup;

public override int Order { get; }

public AddressTagHelperComponent(string markup = "", int order = 1)
{
    _markup = markup;
    Order = order;
}
```

The provided `markup` parameter is used in `ProcessAsync` as follows:

```
public override async Task ProcessAsync(TagHelperContext context,
                                        TagHelperOutput output)
{
    if (string.Equals(context.TagName, "address",
            StringComparison.OrdinalIgnoreCase) &&
        output.Attributes.ContainsName("printable"))
    {
        TagHelperContent childContent = await output.GetChildContentAsync();
        string content = childContent.GetContent();
        output.Content.SetHtmlContent(
            $"<div>{content}<br>{_markup}</div>{_printableButton}");
    }
}
```

Registration via Page Model or controller

If the Tag Helper Component isn't registered with DI, it can be registered from a Razor Pages page model or an MVC controller. This technique is useful for separating C# logic from Razor files.

Constructor injection is used to access an instance of `ITagHelperComponentManager`. The Tag Helper Component is added to the instance's Tag Helper Components collection. The following Razor Pages page model demonstrates this technique with `AddressTagHelperComponent`:

```
using System;
using Microsoft.AspNetCore.Mvc.Razor.TagHelpers;
using Microsoft.AspNetCore.Mvc.RazorPages;
using RazorPagesSample.TagHelpers;

public class IndexModel : PageModel
{
    private readonly ITagHelperComponentManager _tagHelperComponentManager;

    public bool IsWeekend
    {
        get
        {
            var dayOfWeek = DateTime.Now.DayOfWeek;

            return dayOfWeek == DayOfWeek.Saturday ||
                   dayOfWeek == DayOfWeek.Sunday;
        }
    }

    public IndexModel(ITagHelperComponentManager tagHelperComponentManager)
    {
        _tagHelperComponentManager = tagHelperComponentManager;
    }

    public void OnGet()
    {
        string markup;

        if (IsWeekend)
        {
            markup = "<em class='text-warning'>Office closed today!</em>";
        }
        else
        {
            markup = "<em class='text-info'>Office open today!</em>";
        }

        _tagHelperComponentManager.Components.Add(
            new AddressTagHelperComponent(markup, 1));
    }
}
```

In the preceding code:

- Constructor injection is used to access an instance of `ITagHelperComponentManager`.
- An instance of `AddressTagHelperComponent` is added to the app's Tag Helper Components collection.

Create a Component

To create a custom Tag Helper Component:

- Create a public class deriving from TagHelperComponentTagHelper.
- Apply an `[HtmlTargetElement]` attribute to the class. Specify the name of the target HTML element.
- *Optional*: Apply an `[EditorBrowsable(EditorBrowsableState.Never)]` attribute to the class to suppress the type's display in IntelliSense.

The following code creates a custom Tag Helper Component that targets the `<address>` HTML element:

```
using System.ComponentModel;
using Microsoft.AspNetCore.Mvc.Razor.TagHelpers;
using Microsoft.AspNetCore.Razor.TagHelpers;
using Microsoft.Extensions.Logging;

namespace RazorPagesSample.TagHelpers
{
    [HtmlTargetElement("address")]
    [EditorBrowsable(EditorBrowsableState.Never)]
    public class AddressTagHelperComponentTagHelper : TagHelperComponentTagHelper
    {
        public AddressTagHelperComponentTagHelper(
            ITagHelperComponentManager componentManager,
            ILoggerFactory loggerFactory) : base(componentManager, loggerFactory)
        {
        }
    }
}
```

Use the custom `address` Tag Helper Component to inject HTML markup as follows:

```
public class AddressTagHelperComponent : TagHelperComponent
{
    private readonly string _printableButton =
        "<button type='button' class='btn btn-info' onclick=\"window.open(" +
        "'https://binged.it/2AXRRYw')\">" +
        "<span class='glyphicon glyphicon-road' aria-hidden='true'></span>" +
        "</button>";

    public override int Order => 3;

    public override async Task ProcessAsync(TagHelperContext context,
                                            TagHelperOutput output)
    {
        if (string.Equals(context.TagName, "address",
                StringComparison.OrdinalIgnoreCase) &&
            output.Attributes.ContainsName("printable"))
        {
            var content = await output.GetChildContentAsync();
            output.Content.SetHtmlContent(
                $"<div>{content.GetContent()}</div>{_printableButton}");
        }
    }
}
```

The preceding `ProcessAsync` method injects the HTML provided to SetHtmlContent into the matching `<address>` element. The injection occurs when:

- The execution context's `TagName` property value equals `address`.
- The corresponding `<address>` element has a `printable` attribute.

For example, the `if` statement evaluates to true when processing the following `<address>` element:

```
<address printable>
    One Microsoft Way<br />
    Redmond, WA 98052-6399<br />
    <abbr title="Phone">P:</abbr>
    425.555.0100
</address>
```

Anchor Tag Helper in ASP.NET Core

9/22/2020 • 6 minutes to read • Edit Online

By Peter Kellner and Scott Addie

The Anchor Tag Helper enhances the standard HTML anchor (`<a ... ></a>`) tag by adding new attributes. By convention, the attribute names are prefixed with `asp-`. The rendered anchor element's `href` attribute value is determined by the values of the `asp-` attributes.

For an overview of Tag Helpers, see Tag Helpers in ASP.NET Core.

View or download sample code (how to download)

SpeakerController is used in samples throughout this document:

```
using Microsoft.AspNetCore.Mvc;
using System.Collections.Generic;
using System.Linq;

public class SpeakerController : Controller
{
    private List<Speaker> Speakers =
        new List<Speaker>
        {
            new Speaker {SpeakerId = 10},
            new Speaker {SpeakerId = 11},
            new Speaker {SpeakerId = 12}
        };

    [Route("Speaker/{id:int}")]
    public IActionResult Detail(int id) =>
        View(Speakers.FirstOrDefault(a => a.SpeakerId == id));

    [Route("/Speaker/Evaluations",
           Name = "speakerevals")]
    public IActionResult Evaluations() => View();

    [Route("/Speaker/EvaluationsCurrent",
           Name = "speakerevalscurrent")]
    public IActionResult Evaluations(
        int speakerId,
        bool currentYear) => View();

    public IActionResult Index() => View(Speakers);
}

public class Speaker
{
    public int SpeakerId { get; set; }
}
```

Anchor Tag Helper attributes

asp-controller

The asp-controller attribute assigns the controller used for generating the URL. The following markup lists all speakers:

```
<a asp-controller="Speaker"
   asp-action="Index">All Speakers</a>
```

The generated HTML:

```
<a href="/Speaker">All Speakers</a>
```

If the `asp-controller` attribute is specified and `asp-action` isn't, the default `asp-action` value is the controller action associated with the currently executing view. If `asp-action` is omitted from the preceding markup, and the Anchor Tag Helper is used in *HomeController*'s *Index* view (*/Home*), the generated HTML is:

```
<a href="/Home">All Speakers</a>
```

asp-action

The asp-action attribute value represents the controller action name included in the generated `href` attribute. The following markup sets the generated `href` attribute value to the speaker evaluations page:

```
<a asp-controller="Speaker"
   asp-action="Evaluations">Speaker Evaluations</a>
```

The generated HTML:

```
<a href="/Speaker/Evaluations">Speaker Evaluations</a>
```

If no `asp-controller` attribute is specified, the default controller calling the view executing the current view is used.

If the `asp-action` attribute value is `Index`, then no action is appended to the URL, leading to the invocation of the default `Index` action. The action specified (or defaulted), must exist in the controller referenced in `asp-controller`.

asp-route-{value}

The asp-route-{value} attribute enables a wildcard route prefix. Any value occupying the `{value}` placeholder is interpreted as a potential route parameter. If a default route isn't found, this route prefix is appended to the generated `href` attribute as a request parameter and value. Otherwise, it's substituted in the route template.

Consider the following controller action:

```
public IActionResult AnchorTagHelper(int id)
{
    var speaker = new Speaker
    {
        SpeakerId = id
    };

    return View(speaker);
}
```

With a default route template defined in *Startup.Configure*:

```
app.UseMvc(routes =>
{
    // need route and attribute on controller: [Area("Blogs")]
    routes.MapRoute(name: "mvcAreaRoute",
                    template: "{area:exists}/{controller=Home}/{action=Index}");

    // default route for non-areas
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");
});
```

The MVC view uses the model, provided by the action, as follows:

```
@model Speaker
<!DOCTYPE html>
<html>
<body>
    <a asp-controller="Speaker"
       asp-action="Detail"
       asp-route-id="@Model.SpeakerId">SpeakerId: @Model.SpeakerId</a>
</body>
</html>
```

The default route's `{id?}` placeholder was matched. The generated HTML:

```
<a href="/Speaker/Detail/12">SpeakerId: 12</a>
```

Assume the route prefix isn't part of the matching routing template, as with the following MVC view:

```
@model Speaker
<!DOCTYPE html>
<html>
<body>
    <a asp-controller="Speaker"
       asp-action="Detail"
       asp-route-speakerid="@Model.SpeakerId">SpeakerId: @Model.SpeakerId</a>
<body>
</html>
```

The following HTML is generated because `speakerid` wasn't found in the matching route:

```
<a href="/Speaker/Detail?speakerid=12">SpeakerId: 12</a>
```

If either `asp-controller` or `asp-action` aren't specified, then the same default processing is followed as is in the `asp-route` attribute.

asp-route

The asp-route attribute is used for creating a URL linking directly to a named route. Using routing attributes, a route can be named as shown in the `SpeakerController` and used in its `Evaluations` action:

```
[Route("/Speaker/Evaluations",
       Name = "speakerevals")]
public IActionResult Evaluations() => View();
```

In the following markup, the `asp-route` attribute references the named route:

```
<a asp-route="speakerevals">Speaker Evaluations</a>
```

The Anchor Tag Helper generates a route directly to that controller action using the URL */Speaker/Evaluations*. The generated HTML:

```
<a href="/Speaker/Evaluations">Speaker Evaluations</a>
```

If `asp-controller` or `asp-action` is specified in addition to `asp-route`, the route generated may not be what you expect. To avoid a route conflict, `asp-route` shouldn't be used with the `asp-controller` and `asp-action` attributes.

asp-all-route-data

The asp-all-route-data attribute supports the creation of a dictionary of key-value pairs. The key is the parameter name, and the value is the parameter value.

In the following example, a dictionary is initialized and passed to a Razor view. Alternatively, the data could be passed in with your model.

```
@{
var parms = new Dictionary<string, string>
            {
                { "speakerId", "11" },
                { "currentYear", "true" }
            };
}

<a asp-route="speakerevalscurrent"
   asp-all-route-data="parms">Speaker Evaluations</a>
```

The preceding code generates the following HTML:

```
<a href="/Speaker/EvaluationsCurrent?speakerId=11&currentYear=true">Speaker Evaluations</a>
```

The `asp-all-route-data` dictionary is flattened to produce a querystring meeting the requirements of the overloaded `Evaluations` action:

```
[Route("/Speaker/EvaluationsCurrent",
       Name = "speakerevalscurrent")]
public IActionResult Evaluations(
    int speakerId,
    bool currentYear) => View();
```

If any keys in the dictionary match route parameters, those values are substituted in the route as appropriate. The other non-matching values are generated as request parameters.

asp-fragment

The asp-fragment attribute defines a URL fragment to append to the URL. The Anchor Tag Helper adds the hash character (#). Consider the following markup:

```
<a asp-controller="Speaker"
   asp-action="Evaluations"
   asp-fragment="SpeakerEvaluations">Speaker Evaluations</a>
```

The generated HTML:

```
<a href="/Speaker/Evaluations#SpeakerEvaluations">Speaker Evaluations</a>
```

Hash tags are useful when building client-side apps. They can be used for easy marking and searching in JavaScript, for example.

asp-area

The asp-area attribute sets the area name used to set the appropriate route. The following examples depict how the `asp-area` attribute causes a remapping of routes.

Usage in Razor Pages

Razor Pages areas are supported in ASP.NET Core 2.1 or later.

Consider the following directory hierarchy:

- {Project name}
  - wwwroot
  - Areas
    - Sessions
      - Pages
        - *_ViewStart.cshtml*
        - *Index.cshtml*
        - *Index.cshtml.cs*
  - Pages

The markup to reference the *Sessions* area *Index* Razor Page is:

```
<a asp-area="Sessions"
   asp-page="/Index">View Sessions</a>
```

The generated HTML:

```
<a href="/Sessions">View Sessions</a>
```

TIP

To support areas in a Razor Pages app, do one of the following in `Startup.ConfigureServices`:

- Set the compatibility version to 2.1 or later.
- Set the RazorPagesOptions.AllowAreas property to `true`:

```
services.AddMvc()
        .AddRazorPagesOptions(options => options.AllowAreas = true);
```

Usage in MVC

Consider the following directory hierarchy:

- {Project name}
  - wwwroot
  - Areas

- Blogs
  - Controllers
    - *HomeController.cs*
  - Views
    - Home
      - *AboutBlog.cshtml*
      - *Index.cshtml*
    - *_ViewStart.cshtml*
- Controllers

Setting `asp-area` to "Blogs" prefixes the directory *Areas/Blogs* to the routes of the associated controllers and views for this anchor tag. The markup to reference the *AboutBlog* view is:

```
<a asp-area="Blogs"
   asp-controller="Home"
   asp-action="AboutBlog">About Blog</a>
```

The generated HTML:

```
<a href="/Blogs/Home/AboutBlog">About Blog</a>
```

TIP

To support areas in an MVC app, the route template must include a reference to the area, if it exists. That template is represented by the second parameter of the `routes.MapRoute` method call in *Startup.Configure*:

```
app.UseMvc(routes =>
{
    // need route and attribute on controller: [Area("Blogs")]
    routes.MapRoute(name: "mvcAreaRoute",
                    template: "{area:exists}/{controller=Home}/{action=Index}");

    // default route for non-areas
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");
});
```

asp-protocol

The asp-protocol attribute is for specifying a protocol (such as `https`) in your URL. For example:

```
<a asp-protocol="https"
   asp-controller="Home"
   asp-action="About">About</a>
```

The generated HTML:

```
<a href="https://localhost/Home/About">About</a>
```

The host name in the example is localhost. The Anchor Tag Helper uses the website's public domain when generating the URL.

asp-host

The asp-host attribute is for specifying a host name in your URL. For example:

```
<a asp-protocol="https"
   asp-host="microsoft.com"
   asp-controller="Home"
   asp-action="About">About</a>
```

The generated HTML:

```
<a href="https://microsoft.com/Home/About">About</a>
```

asp-page

The asp-page attribute is used with Razor Pages. Use it to set an anchor tag's `href` attribute value to a specific page. Prefixing the page name with a forward slash ("/") creates the URL.

The following sample points to the attendee Razor Page:

```
<a asp-page="/Attendee">All Attendees</a>
```

The generated HTML:

```
<a href="/Attendee">All Attendees</a>
```

The `asp-page` attribute is mutually exclusive with the `asp-route`, `asp-controller`, and `asp-action` attributes. However, `asp-page` can be used with `asp-route-{value}` to control routing, as the following markup demonstrates:

```
<a asp-page="/Attendee"
   asp-route-attendeeid="10">View Attendee</a>
```

The generated HTML:

```
<a href="/Attendee?attendeeid=10">View Attendee</a>
```

asp-page-handler

The asp-page-handler attribute is used with Razor Pages. It's intended for linking to specific page handlers.

Consider the following page handler:

```
public void OnGetProfile(int attendeeId)
{
    ViewData["AttendeeId"] = attendeeId;

    // code omitted for brevity
}
```

The page model's associated markup links to the `OnGetProfile` page handler. Note the `On<Verb>` prefix of the page handler method name is omitted in the `asp-page-handler` attribute value. When the method is asynchronous, the `Async` suffix is omitted, too.

```
<a asp-page="/Attendee"
   asp-page-handler="Profile"
   asp-route-attendeeid="12">Attendee Profile</a>
```

The generated HTML:

```
<a href="/Attendee?attendeeid=12&handler=Profile">Attendee Profile</a>
```

Cache Tag Helper in ASP.NET Core MVC

9/22/2020 • 4 minutes to read • Edit Online

By Peter Kellner

The Cache Tag Helper provides the ability to improve the performance of your ASP.NET Core app by caching its content to the internal ASP.NET Core cache provider.

For an overview of Tag Helpers, see Tag Helpers in ASP.NET Core.

The following Razor markup caches the current date:

```
<cache>@DateTime.Now</cache>
```

The first request to the page that contains the Tag Helper displays the current date. Additional requests show the cached value until the cache expires (default 20 minutes) or until the cached date is evicted from the cache.

Cache Tag Helper Attributes

enabled

ATTRIBUTE TYPE	EXAMPLES	DEFAULT
Boolean	`true`, `false`	`true`

`enabled` determines if the content enclosed by the Cache Tag Helper is cached. The default is `true`. If set to `false`, the rendered output is **not** cached.

Example:

```
<cache enabled="true">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

expires-on

ATTRIBUTE TYPE	EXAMPLE
`DateTimeOffset`	`@new DateTime(2025,1,29,17,02,0)`

`expires-on` sets an absolute expiration date for the cached item.

The following example caches the contents of the Cache Tag Helper until 5:02 PM on January 29, 2025:

```
<cache expires-on="@new DateTime(2025,1,29,17,02,0)">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

expires-after

ATTRIBUTE TYPE	EXAMPLE	DEFAULT
`TimeSpan`	`@TimeSpan.FromSeconds(120)`	20 minutes

`expires-after` sets the length of time from the first request time to cache the contents.

Example:

```
<cache expires-after="@TimeSpan.FromSeconds(120)">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

The Razor View Engine sets the default `expires-after` value to twenty minutes.

expires-sliding

ATTRIBUTE TYPE	EXAMPLE
`TimeSpan`	`@TimeSpan.FromSeconds(60)`

Sets the time that a cache entry should be evicted if its value hasn't been accessed.

Example:

```
<cache expires-sliding="@TimeSpan.FromSeconds(60)">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

vary-by-header

ATTRIBUTE TYPE	EXAMPLES
String	`User-Agent`, `User-Agent,content-encoding`

`vary-by-header` accepts a comma-delimited list of header values that trigger a cache refresh when they change.

The following example monitors the header value `User-Agent`. The example caches the content for every different `User-Agent` presented to the web server:

```
<cache vary-by-header="User-Agent">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

vary-by-query

ATTRIBUTE TYPE	EXAMPLES
String	`Make`, `Make,Model`

`vary-by-query` accepts a comma-delimited list of Keys in a query string (Query) that trigger a cache refresh when the value of any listed key changes.

The following example monitors the values of `Make` and `Model`. The example caches the content for every different `Make` and `Model` presented to the web server:

```
<cache vary-by-query="Make,Model">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

vary-by-route

ATTRIBUTE TYPE	EXAMPLES
String	`Make`, `Make,Model`

`vary-by-route` accepts a comma-delimited list of route parameter names that trigger a cache refresh when the route data parameter value changes.

Example:

Startup.cs:

```
routes.MapRoute(
    name: "default",
    template: "{controller=Home}/{action=Index}/{Make?}/{Model?}");
```

Index.cshtml:

```
<cache vary-by-route="Make,Model">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

vary-by-cookie

ATTRIBUTE TYPE	EXAMPLES
String	`.AspNetCore.Identity.Application`, `.AspNetCore.Identity.Application,HairColor`

`vary-by-cookie` accepts a comma-delimited list of cookie names that trigger a cache refresh when the cookie values change.

The following example monitors the cookie associated with ASP.NET Core Identity. When a user is authenticated, a change in the Identity cookie triggers a cache refresh:

```
<cache vary-by-cookie=".AspNetCore.Identity.Application">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

vary-by-user

ATTRIBUTE TYPE	EXAMPLES	DEFAULT
Boolean	`true`, `false`	`true`

`vary-by-user` specifies whether or not the cache resets when the signed-in user (or Context Principal) changes. The current user is also known as the Request Context Principal and can be viewed in a Razor view by referencing `@User.Identity.Name`.

The following example monitors the current logged in user to trigger a cache refresh:

```
<cache vary-by-user="true">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

Using this attribute maintains the contents in cache through a sign-in and sign-out cycle. When the value is set to `true`, an authentication cycle invalidates the cache for the authenticated user. The cache is invalidated because a new unique cookie value is generated when a user is authenticated. Cache is maintained for the anonymous state when no cookie is present or the cookie has expired. If the user is **not** authenticated, the cache is maintained.

vary-by

ATTRIBUTE TYPE	EXAMPLE
String	`@Model`

`vary-by` allows for customization of what data is cached. When the object referenced by the attribute's string value changes, the content of the Cache Tag Helper is updated. Often, a string-concatenation of model values are assigned to this attribute. Effectively, this results in a scenario where an update to any of the concatenated values invalidates the cache.

The following example assumes the controller method rendering the view sums the integer value of the two route parameters, `myParam1` and `myParam2`, and returns the sum as the single model property. When this sum changes, the content of the Cache Tag Helper is rendered and cached again.

Action:

```
public IActionResult Index(string myParam1, string myParam2, string myParam3)
{
    int num1;
    int num2;
    int.TryParse(myParam1, out num1);
    int.TryParse(myParam2, out num2);
    return View(viewName, num1 + num2);
}
```

Index.cshtml:

```
<cache vary-by="@Model">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

priority

ATTRIBUTE TYPE	EXAMPLES	DEFAULT
`CacheItemPriority`	`High`, `Low`, `NeverRemove`, `Normal`	`Normal`

`priority` provides cache eviction guidance to the built-in cache provider. The web server evicts `Low` cache entries first when it's under memory pressure.

Example:

```
<cache priority="High">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

The `priority` attribute doesn't guarantee a specific level of cache retention. `CacheItemPriority` is only a suggestion. Setting this attribute to `NeverRemove` doesn't guarantee that cached items are always retained. See the topics in the Additional Resources section for more information.

The Cache Tag Helper is dependent on the memory cache service. The Cache Tag Helper adds the service if it hasn't been added.

Component Tag Helper in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

By Daniel Roth and Luke Latham

To render a component from a page or view, use the Component Tag Helper.

Prerequisites

Follow the guidance in the *Prepare the app to use components in pages and views* section of the Integrate ASP.NET Core Razor components into Razor Pages and MVC apps article.

Component Tag Helper

The following Component Tag Helper renders the `Counter` component in a page or view:

```
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@using {APP ASSEMBLY}.Pages

...

<component type="typeof(Counter)" render-mode="ServerPrerendered" />
```

The preceding example assumes that the `Counter` component is in the app's *Pages* folder. The placeholder `{APP ASSEMBLY}` is the app's assembly name (for example, `@using BlazorSample.Pages`).

The Component Tag Helper can also pass parameters to components. Consider the following `ColorfulCheckbox` component that sets the check box label's color and size:

```
<label style="font-size:@(Size)px;color:@Color">
    <input @bind="Value"
           id="survey"
           name="blazor"
           type="checkbox" />
    Enjoying Blazor?
</label>

@code {
    [Parameter]
    public bool Value { get; set; }

    [Parameter]
    public int Size { get; set; } = 8;

    [Parameter]
    public string Color { get; set; }

    protected override void OnInitialized()
    {
        Size += 10;
    }
}
```

The `Size` (`int`) and `Color` (`string`) component parameters can be set by the Component Tag Helper:

```
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@using {APP ASSEMBLY}.Shared

...

<component type="typeof(ColorfulCheckbox)" render-mode="ServerPrerendered"
    param-Size="14" param-Color="@("blue")" />
```

The preceding example assumes that the `ColorfulCheckbox` component is in the app's *Shared* folder. The placeholder `{APP ASSEMBLY}` is the app's assembly name (for example, `@using BlazorSample.Shared`).

The following HTML is rendered in the page or view:

```
<label style="font-size:24px;color:blue">
    <input id="survey" name="blazor" type="checkbox">
    Enjoying Blazor?
</label>
```

Passing a quoted string requires an explicit Razor expression, as shown for `param-Color` in the preceding example. The Razor parsing behavior for a `string` type value doesn't apply to a `param-*` attribute because the attribute is an `object` type.

The parameter type must be JSON serializable, which typically means that the type must have a default constructor and settable properties. For example, you can specify a value for `Size` and `Color` in the preceding example because the types of `Size` and `Color` are primitive types (`int` and `string`), which are supported by the JSON serializer.

In the following example, a class object is passed to the component:

MyClass.cs:

```
public class MyClass
{
    public MyClass()
    {
    }

    public int MyInt { get; set; } = 999;
    public string MyString { get; set; } = "Initial value";
}
```

The class must have a public parameterless constructor.

Shared/MyComponent.razor:

```
<h2>MyComponent</h2>

<p>Int: @MyObject.MyInt</p>
<p>String: @MyObject.MyString</p>

@code
{
    [Parameter]
    public MyClass MyObject { get; set; }
}
```

Pages/MyPage.cshtml:

```
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@using {APP ASSEMBLY}
@using {APP ASSEMBLY}.Shared

...

@{
    var myObject = new MyClass();
    myObject.MyInt = 7;
    myObject.MyString = "Set by MyPage";
}

<component type="typeof(MyComponent)" render-mode="ServerPrerendered"
    param-MyObject="@myObject" />
```

The preceding example assumes that the `MyComponent` component is in the app's *Shared* folder. The placeholder `{APP ASSEMBLY}` is the app's assembly name (for example, `@using BlazorSample` and `@using BlazorSample.Shared`). `MyClass` is in the app's namespace.

RenderMode configures whether the component:

- Is prerendered into the page.
- Is rendered as static HTML on the page or if it includes the necessary information to bootstrap a Blazor app from the user agent.

RENDER MODE	DESCRIPTION
ServerPrerendered	Renders the component into static HTML and includes a marker for a Blazor Server app. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Server	Renders a marker for a Blazor Server app. Output from the component isn't included. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Static	Renders the component into static HTML.

While pages and views can use components, the converse isn't true. Components can't use view- and page-specific features, such as partial views and sections. To use logic from a partial view in a component, factor out the partial view logic into a component.

Rendering server components from a static HTML page isn't supported.

Distributed Cache Tag Helper in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

By Peter Kellner

The Distributed Cache Tag Helper provides the ability to dramatically improve the performance of your ASP.NET Core app by caching its content to a distributed cache source.

For an overview of Tag Helpers, see Tag Helpers in ASP.NET Core.

The Distributed Cache Tag Helper inherits from the same base class as the Cache Tag Helper. All of the Cache Tag Helper attributes are available to the Distributed Tag Helper.

The Distributed Cache Tag Helper uses constructor injection. The IDistributedCache interface is passed into the Distributed Cache Tag Helper's constructor. If no concrete implementation of `IDistributedCache` is created in `Startup.ConfigureServices` (*Startup.cs*), the Distributed Cache Tag Helper uses the same in-memory provider for storing cached data as the Cache Tag Helper.

Distributed Cache Tag Helper Attributes

Attributes shared with the Cache Tag Helper

- `enabled`
- `expires-on`
- `expires-after`
- `expires-sliding`
- `vary-by-header`
- `vary-by-query`
- `vary-by-route`
- `vary-by-cookie`
- `vary-by-user`
- `vary-by priority`

The Distributed Cache Tag Helper inherits from the same class as Cache Tag Helper. For descriptions of these attributes, see the Cache Tag Helper.

name

ATTRIBUTE TYPE	EXAMPLE
String	`my-distributed-cache-unique-key-101`

`name` is required. The `name` attribute is used as a key for each stored cache instance. Unlike the Cache Tag Helper that assigns a cache key to each instance based on the Razor page name and location in the Razor page, the Distributed Cache Tag Helper only bases its key on the attribute `name`.

Example:

```
<distributed-cache name="my-distributed-cache-unique-key-101">
    Time Inside Cache Tag Helper: @DateTime.Now
</distributed-cache>
```

Distributed Cache Tag Helper IDistributedCache implementations

There are two implementations of IDistributedCache built in to ASP.NET Core. One is based on SQL Server, and the other is based on Redis. Third-party implementations are also available, such as NCache. Details of these implementations can be found at Distributed caching in ASP.NET Core. Both implementations involve setting an instance of `IDistributedCache` in `Startup`.

There are no tag attributes specifically associated with using any specific implementation of `IDistributedCache`.

Environment Tag Helper in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

By Peter Kellner and Hisham Bin Ateya

The Environment Tag Helper conditionally renders its enclosed content based on the current hosting environment. The Environment Tag Helper's single attribute, `names`, is a comma-separated list of environment names. If any of the provided environment names match the current environment, the enclosed content is rendered.

For an overview of Tag Helpers, see Tag Helpers in ASP.NET Core.

Environment Tag Helper Attributes

names

`names` accepts a single hosting environment name or a comma-separated list of hosting environment names that trigger the rendering of the enclosed content.

Environment values are compared to the current value returned by IHostingEnvironment.EnvironmentName. The comparison ignores case.

The following example uses an Environment Tag Helper. The content is rendered if the hosting environment is Staging or Production:

```
<environment names="Staging,Production">
    <strong>HostingEnvironment.EnvironmentName is Staging or Production</strong>
</environment>
```

include and exclude attributes

`include` & `exclude` attributes control rendering the enclosed content based on the included or excluded hosting environment names.

include

The `include` property exhibits similar behavior to the `names` attribute. An environment listed in the `include` attribute value must match the app's hosting environment (IHostingEnvironment.EnvironmentName) to render the content of the `<environment>` tag.

```
<environment include="Staging,Production">
    <strong>HostingEnvironment.EnvironmentName is Staging or Production</strong>
</environment>
```

exclude

In contrast to the `include` attribute, the content of the `<environment>` tag is rendered when the hosting environment doesn't match an environment listed in the `exclude` attribute value.

```
<environment exclude="Development">
    <strong>HostingEnvironment.EnvironmentName is not Development</strong>
</environment>
```

Tag Helpers in forms in ASP.NET Core

9/22/2020 • 18 minutes to read • Edit Online

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

NOTE

With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

ATTRIBUTE	DESCRIPTION
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"` .
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the **HTML Helper alternatives to Input Tag Helper** section for details.
- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to process
this request. Please review the following specific error details and modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type 'RegisterViewModel'
could be found (are you missing a using directive or an assembly reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

.NET TYPE	INPUT TYPE
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

ATTRIBUTE	INPUT TYPE
[EmailAddress]	type="email"
[Url]	type="url"
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

```
  <form method="post" action="/Demo/RegisterInput">
      Email:
      <input type="email" data-val="true"
             data-val-email="The Email Address field is not a valid email address."
             data-val-required="The Email Address field is required."
             id="Email" name="Email" value=""><br>
      Password:
      <input type="password" data-val="true"
             data-val-required="The Password field is required."
             id="Password" name="Password"><br>
      <button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"`.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="@Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    Address: <input asp-for="Address.AddressLine1" /><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1" value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The *Views/Shared/EditorTemplates/String.cshtml* template:

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The *Views/Shared/EditorTemplates/ToDoItem.cshtml* template:

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
</td>

@*
    This template replaces the following Razor which evaluates the indexer three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> **NOTE**
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type with a maximum length of
&#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type with a minimum length of
&#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.
- Less markup in source code
- Strong typing with the model property.

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on a HTML span element.

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> **NOTE**
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side

validation is disabled), MVC places that error message as the body of the `<span>` element.

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

ASP-VALIDATION-SUMMARY	VALIDATION MESSAGES DISPLAYED
ValidationSummary.All	Property and model level
ValidationSummary.ModelOnly	Model
ValidationSummary.None	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    Email:  <input asp-for="Email" /> <br />
    <span asp-validation-for="Email"></span><br />
    Password: <input asp-for="Password" /><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

```
<form action="/DemoReg/Register" method="post">
  <div class="validation-summary-valid" data-valmsg-summary="true">
  <ul><li style="display:none"></li></ul></div>
  Email:  <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"  },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

```
[HttpPost]
[ValidateAntiForgeryToken]
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

> **NOTE**
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

```
    public class CountryEnumViewModel
    {
        public CountryEnum EnumCountry { get; set; }
    }
}
```

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

```
<form method="post" action="/Home/IndexEnum">
       <select data-val="true" data-val-required="The EnumCountry field is required."
               id="EnumCountry" name="EnumCountry">
           <option value="0">United Mexican States</option>
           <option value="1">United States of America</option>
           <option value="2">Canada</option>
           <option value="3">France</option>
           <option value="4">Germany</option>
           <option selected="selected" value="5">Spain</option>
       </select>
       <br /><button type="submit">Register</button>
       <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
  </form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America" };
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }

    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

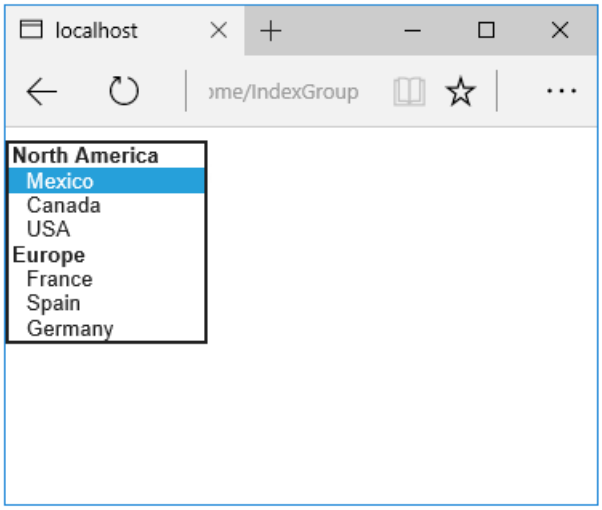
The two groups are shown below:



The generated HTML:

```
<form method="post" action="/Home/IndexGroup">
     <select id="Country" name="Country">
         <optgroup label="North America">
             <option value="MEX">Mexico</option>
             <option value="CAN">Canada</option>
             <option value="US">USA</option>
         </optgroup>
         <optgroup label="Europe">
             <option value="FR">France</option>
             <option value="ES">Spain</option>
             <option value="DE">Germany</option>
         </optgroup>
     </select>
     <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The *Views/Shared/EditorTemplates/CountryViewModel.cshtml* template:

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
 </form>
```

Tag Helpers in forms in ASP.NET Core

9/22/2020 • 18 minutes to read • Edit Online

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

NOTE

With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

ATTRIBUTE	DESCRIPTION
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"` .
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the **HTML Helper alternatives to Input Tag Helper** section for details.
- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to process
this request. Please review the following specific error details and modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type 'RegisterViewModel'
could be found (are you missing a using directive or an assembly reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

.NET TYPE	INPUT TYPE
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

ATTRIBUTE	INPUT TYPE
[EmailAddress]	type="email"
[Url]	type="url"
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

```
  <form method="post" action="/Demo/RegisterInput">
      Email:
      <input type="email" data-val="true"
             data-val-email="The Email Address field is not a valid email address."
             data-val-required="The Email Address field is required."
             id="Email" name="Email" value=""><br>
      Password:
      <input type="password" data-val="true"
             data-val-required="The Password field is required."
             id="Password" name="Password"><br>
      <button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"`.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="@Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    Address: <input asp-for="Address.AddressLine1" /><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1" value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The *Views/Shared/EditorTemplates/String.cshtml* template:

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The *Views/Shared/EditorTemplates/ToDoItem.cshtml* template:

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
</td>

@*
    This template replaces the following Razor which evaluates the indexer three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> **NOTE**
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type with a maximum length of
&#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type with a minimum length of
&#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.
- Less markup in source code
- Strong typing with the model property.

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on a HTML span element.

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> **NOTE**
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side

validation is disabled), MVC places that error message as the body of the `<span>` element.

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

ASP-VALIDATION-SUMMARY	VALIDATION MESSAGES DISPLAYED
ValidationSummary.All	Property and model level
ValidationSummary.ModelOnly	Model
ValidationSummary.None	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    Email:  <input asp-for="Email" /> <br />
    <span asp-validation-for="Email"></span><br />
    Password: <input asp-for="Password" /><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

```
<form action="/DemoReg/Register" method="post">
  <div class="validation-summary-valid" data-valmsg-summary="true">
  <ul><li style="display:none"></li></ul></div>
  Email:  <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"  },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

```
[HttpPost]
[ValidateAntiForgeryToken]
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

> **NOTE**
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

```
    public class CountryEnumViewModel
    {
        public CountryEnum EnumCountry { get; set; }
    }
}
```

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

```
<form method="post" action="/Home/IndexEnum">
       <select data-val="true" data-val-required="The EnumCountry field is required."
               id="EnumCountry" name="EnumCountry">
           <option value="0">United Mexican States</option>
           <option value="1">United States of America</option>
           <option value="2">Canada</option>
           <option value="3">France</option>
           <option value="4">Germany</option>
           <option selected="selected" value="5">Spain</option>
       </select>
       <br /><button type="submit">Register</button>
       <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
  </form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America" };
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }

    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

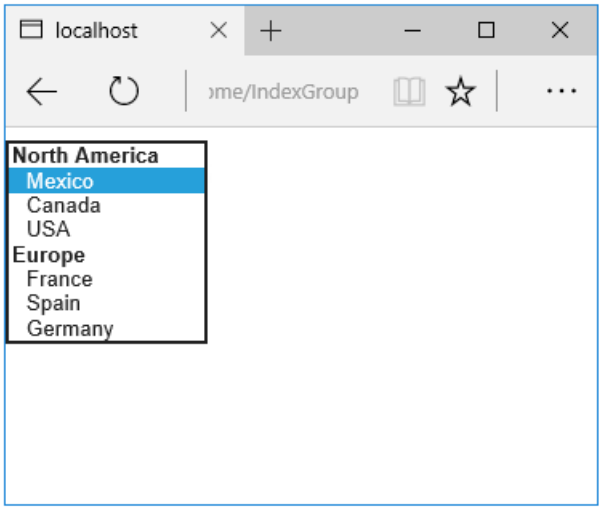
The two groups are shown below:



The generated HTML:

```
<form method="post" action="/Home/IndexGroup">
     <select id="Country" name="Country">
         <optgroup label="North America">
             <option value="MEX">Mexico</option>
             <option value="CAN">Canada</option>
             <option value="US">USA</option>
         </optgroup>
         <optgroup label="Europe">
             <option value="FR">France</option>
             <option value="ES">Spain</option>
             <option value="DE">Germany</option>
         </optgroup>
     </select>
     <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The *Views/Shared/EditorTemplates/CountryViewModel.cshtml* template:

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
 </form>
```

Image Tag Helper in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

By Peter Kellner

The Image Tag Helper enhances the `<img>` tag to provide cache-busting behavior for static image files.

A cache-busting string is a unique value representing the hash of the static image file appended to the asset's URL. The unique string prompts clients (and some proxies) to reload the image from the host web server and not from the client's cache.

If the image source (`src`) is a static file on the host web server:

- A unique cache-busting string is appended as a query parameter to the image source.
- If the file on the host web server changes, a unique request URL is generated that includes the updated request parameter.

For an overview of Tag Helpers, see Tag Helpers in ASP.NET Core.

Image Tag Helper Attributes

src

To activate the Image Tag Helper, the `src` attribute is required on the `<img>` element.

The image source (`src`) must point to a physical static file on the server. If the `src` is a remote URI, the cache-busting query string parameter isn't generated.

asp-append-version

When `asp-append-version` is specified with a `true` value along with a `src` attribute, the Image Tag Helper is invoked.

The following example uses an Image Tag Helper:

```
<img src="~/images/asplogo.png" asp-append-version="true">
```

If the static file exists in the directory */wwwroot/images/*, the generated HTML is similar to the following (the hash will be different):

```
<img src="/images/asplogo.png?v=Kl_dqr9NVtnMdsM2MUg4qthUnWZm5T1fCEimBPWDNgM">
```

The value assigned to the parameter `v` is the hash value of the *asplogo.png* file on disk. If the web server is unable to obtain read access to the static file, no `v` parameter is added to the `src` attribute in the rendered markup.

Hash caching behavior

The Image Tag Helper uses the cache provider on the local web server to store the calculated `Sha512` hash of a given file. If the file is requested multiple times, the hash isn't recalculated. The cache is invalidated by a file watcher that's attached to the file when the file's `Sha512` hash is calculated. When the file changes on disk, a new hash is calculated and cached.

Tag Helpers in forms in ASP.NET Core

9/22/2020 • 18 minutes to read • Edit Online

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

NOTE

With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

ATTRIBUTE	DESCRIPTION
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"` .
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the **HTML Helper alternatives to Input Tag Helper** section for details.
- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to process
this request. Please review the following specific error details and modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type 'RegisterViewModel'
could be found (are you missing a using directive or an assembly reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

.NET TYPE	INPUT TYPE
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

ATTRIBUTE	INPUT TYPE
[EmailAddress]	type="email"
[Url]	type="url"
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

```
  <form method="post" action="/Demo/RegisterInput">
      Email:
      <input type="email" data-val="true"
             data-val-email="The Email Address field is not a valid email address."
             data-val-required="The Email Address field is required."
             id="Email" name="Email" value=""><br>
      Password:
      <input type="password" data-val="true"
             data-val-required="The Password field is required."
             id="Password" name="Password"><br>
      <button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"`.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="@Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    Address: <input asp-for="Address.AddressLine1" /><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1" value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The *Views/Shared/EditorTemplates/String.cshtml* template:

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The *Views/Shared/EditorTemplates/ToDoItem.cshtml* template:

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
</td>

@*
    This template replaces the following Razor which evaluates the indexer three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> **NOTE**
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type with a maximum length of
&#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type with a minimum length of
&#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.
- Less markup in source code
- Strong typing with the model property.

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on a HTML span element.

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> **NOTE**
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side

validation is disabled), MVC places that error message as the body of the `<span>` element.

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

ASP-VALIDATION-SUMMARY	VALIDATION MESSAGES DISPLAYED
ValidationSummary.All	Property and model level
ValidationSummary.ModelOnly	Model
ValidationSummary.None	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    Email:  <input asp-for="Email" /> <br />
    <span asp-validation-for="Email"></span><br />
    Password: <input asp-for="Password" /><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

```
<form action="/DemoReg/Register" method="post">
  <div class="validation-summary-valid" data-valmsg-summary="true">
  <ul><li style="display:none"></li></ul></div>
  Email:  <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"  },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

```
[HttpPost]
[ValidateAntiForgeryToken]
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

> **NOTE**
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

```
    public class CountryEnumViewModel
    {
        public CountryEnum EnumCountry { get; set; }
    }
}
```

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

```
<form method="post" action="/Home/IndexEnum">
       <select data-val="true" data-val-required="The EnumCountry field is required."
               id="EnumCountry" name="EnumCountry">
           <option value="0">United Mexican States</option>
           <option value="1">United States of America</option>
           <option value="2">Canada</option>
           <option value="3">France</option>
           <option value="4">Germany</option>
           <option selected="selected" value="5">Spain</option>
       </select>
       <br /><button type="submit">Register</button>
       <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
  </form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America" };
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }

    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

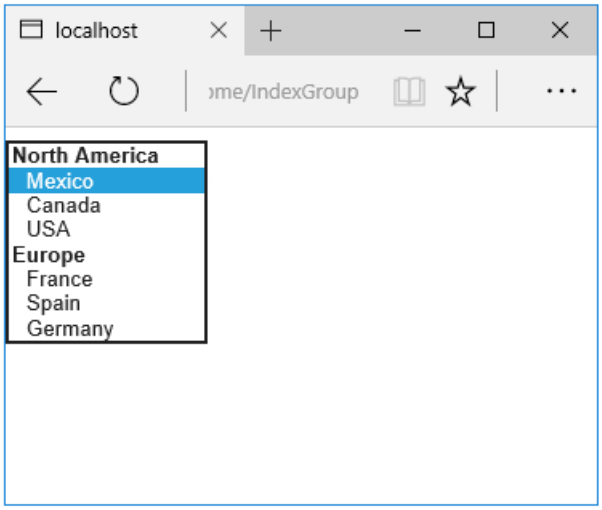
The two groups are shown below:



The generated HTML:

```
<form method="post" action="/Home/IndexGroup">
     <select id="Country" name="Country">
         <optgroup label="North America">
             <option value="MEX">Mexico</option>
             <option value="CAN">Canada</option>
             <option value="US">USA</option>
         </optgroup>
         <optgroup label="Europe">
             <option value="FR">France</option>
             <option value="ES">Spain</option>
             <option value="DE">Germany</option>
         </optgroup>
     </select>
     <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The *Views/Shared/EditorTemplates/CountryViewModel.cshtml* template:

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
 </form>
```

Tag Helpers in forms in ASP.NET Core

9/22/2020 • 18 minutes to read • Edit Online

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

NOTE

With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

ATTRIBUTE	DESCRIPTION
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"` .
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the **HTML Helper alternatives to Input Tag Helper** section for details.
- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to process
this request. Please review the following specific error details and modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type 'RegisterViewModel'
could be found (are you missing a using directive or an assembly reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

.NET TYPE	INPUT TYPE
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

ATTRIBUTE	INPUT TYPE
[EmailAddress]	type="email"
[Url]	type="url"
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

```
  <form method="post" action="/Demo/RegisterInput">
      Email:
      <input type="email" data-val="true"
             data-val-email="The Email Address field is not a valid email address."
             data-val-required="The Email Address field is required."
             id="Email" name="Email" value=""><br>
      Password:
      <input type="password" data-val="true"
             data-val-required="The Password field is required."
             id="Password" name="Password"><br>
      <button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"`.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="@Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    Address: <input asp-for="Address.AddressLine1" /><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1" value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The *Views/Shared/EditorTemplates/String.cshtml* template:

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The *Views/Shared/EditorTemplates/ToDoItem.cshtml* template:

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
</td>

@*
    This template replaces the following Razor which evaluates the indexer three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> **NOTE**
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type with a maximum length of
&#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type with a minimum length of
&#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.
- Less markup in source code
- Strong typing with the model property.

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on a HTML span element.

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> **NOTE**
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side

validation is disabled), MVC places that error message as the body of the `<span>` element.

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

ASP-VALIDATION-SUMMARY	VALIDATION MESSAGES DISPLAYED
ValidationSummary.All	Property and model level
ValidationSummary.ModelOnly	Model
ValidationSummary.None	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    Email:  <input asp-for="Email" /> <br />
    <span asp-validation-for="Email"></span><br />
    Password: <input asp-for="Password" /><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

```
<form action="/DemoReg/Register" method="post">
  <div class="validation-summary-valid" data-valmsg-summary="true">
  <ul><li style="display:none"></li></ul></div>
  Email:  <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"  },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

```
[HttpPost]
[ValidateAntiForgeryToken]
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

> **NOTE**
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

```
    public class CountryEnumViewModel
    {
        public CountryEnum EnumCountry { get; set; }
    }
}
```

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

```
<form method="post" action="/Home/IndexEnum">
       <select data-val="true" data-val-required="The EnumCountry field is required."
               id="EnumCountry" name="EnumCountry">
           <option value="0">United Mexican States</option>
           <option value="1">United States of America</option>
           <option value="2">Canada</option>
           <option value="3">France</option>
           <option value="4">Germany</option>
           <option selected="selected" value="5">Spain</option>
       </select>
       <br /><button type="submit">Register</button>
       <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
  </form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America" };
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }

    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

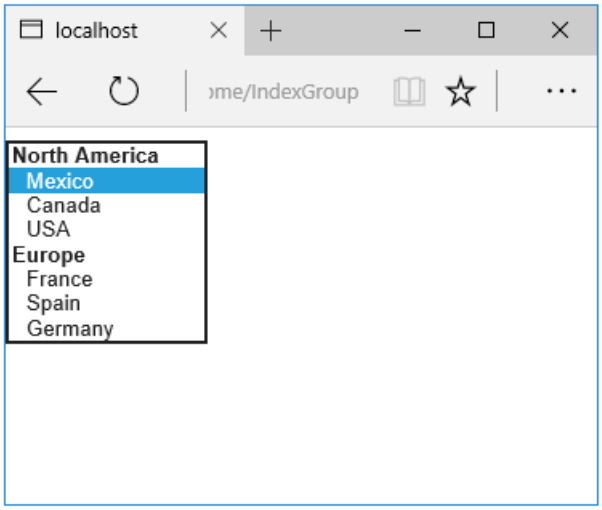
The two groups are shown below:



The generated HTML:

```
<form method="post" action="/Home/IndexGroup">
     <select id="Country" name="Country">
         <optgroup label="North America">
             <option value="MEX">Mexico</option>
             <option value="CAN">Canada</option>
             <option value="US">USA</option>
         </optgroup>
         <optgroup label="Europe">
             <option value="FR">France</option>
             <option value="ES">Spain</option>
             <option value="DE">Germany</option>
         </optgroup>
     </select>
     <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The *Views/Shared/EditorTemplates/CountryViewModel.cshtml* template:

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
 </form>
```

Link Tag Helper in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

By Rick Anderson

The Link Tag Helper generates a link to a primary or fall back CSS file. Typically the primary CSS file is on a Content Delivery Network (CDN).

A CDN:

- Provides several performance advantages vs hosting the asset with the web app.
- Should not be relied on as the only source for the asset. CDNs are not always available, therefore a reliable fallback should be used. Typically the fallback is the site hosting the web app.

The Link Tag Helper allows you to specify a CDN for the CSS file and a fallback when the CDN is not available. The Link Tag Helper provides the performance advantage of a CDN with the robustness of local hosting.

The following Razor markup shows the `head` element of a layout file created with the ASP.NET Core web app template:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - WebLinkTH</title>

    <environment include="Development">
        <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    </environment>
    <environment exclude="Development">
        <link rel="stylesheet"
              href="https://cdnjs.cloudflare.com/ajax/libs/twitter-bootstrap/4.1.3/css/bootstrap.min.css"
              asp-fallback-href="~/lib/bootstrap/dist/css/bootstrap.min.css"
              asp-fallback-test-class="sr-only" asp-fallback-test-property="position"
              asp-fallback-test-value="absolute"
              crossorigin="anonymous"
              integrity="sha256-eSi1q2PG6J7g7ib17yAaWMcrr5GrtohYChqibrV7PBE=" />
    </environment>
    <link rel="stylesheet" href="~/css/site.css" />
</head>
```

The following is rendered HTML from the preceding code (in a non-Development environment):

```
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>Home page - WebLinkTH</title>
    <link rel="stylesheet" href="https://cdnjs.cloudflare.com/ajax/libs/twitter-
bootstrap/4.1.3/css/bootstrap.min.css"
          crossorigin="anonymous" integrity="sha256-eS<snip>BE=" />
    <meta name="x-stylesheet-fallback-test" content="" class="sr-only" />
    <script>
        !function (a, b, c, d) {
            var e, f = document,
                g = f.getElementsByTagName("SCRIPT"),
                h = g[g.length - 1].previousElementSibling,
                i = f.defaultView && f.defaultView.getComputedStyle ? f.defaultView.getComputedStyle(h) :
h.currentStyle;
            if (i && i[a] !== b) for (e = 0; e < c.length; e++)
                f.write('<link href="' + c[e] + '" ' + d + "/>")
        }
            ("position", "absolute", ["\/lib\/bootstrap\/dist\/css\/bootstrap.min.css"],
                "rel=\u0022stylesheet\u0022 crossorigin=\u0022anonymous\u0022 integrity=\abc<snip>BE=\u0022
");
    </script>

    <link rel="stylesheet" href="/css/site.css" />
</head>
```

In the preceding code, the Link Tag Helper generated the `<meta name="x-stylesheet-fallback-test" content="" class="sr-only" />` element and the following JavaScript which is used to verify the requested *bootstrap.min.css* file is available on the CDN. In this case, the CSS file was available so the Tag Helper generated the `<link />` element with the CDN CSS file.

Commonly used Link Tag Helper attributes

See Link Tag Helper for all the Link Tag Helper attributes, properties, and methods.

href

Preferred address of the linked resource. The address is passed thought to the generated HTML in all cases.

asp-fallback-href

The URL of a CSS stylesheet to fallback to in the case the primary URL fails.

asp-fallback-test-class

The class name defined in the stylesheet to use for the fallback test. For more information, see FallbackTestClass.

asp-fallback-test-property

The CSS property name to use for the fallback test. For more information, see FallbackTestProperty.

asp-fallback-test-value

The CSS property value to use for the fallback test. For more information, see FallbackTestValue.

Partial Tag Helper in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

By Scott Addie

For an overview of Tag Helpers, see Tag Helpers in ASP.NET Core.

View or download sample code (how to download)

Overview

The Partial Tag Helper is used for rendering a partial view in Razor Pages and MVC apps. Consider that it:

- Requires ASP.NET Core 2.1 or later.
- Is an alternative to HTML Helper syntax.
- Renders the partial view asynchronously.

The HTML Helper options for rendering a partial view include:

- `@await Html.PartialAsync`
- `@await Html.RenderPartialAsync`
- `@Html.Partial`
- `@Html.RenderPartial`

The *Product* model is used in samples throughout this document:

```
namespace TagHelpersBuiltIn.Models
{
    public class Product
    {
        public int Number { get; set; }

        public string Name { get; set; }

        public string Description { get; set; }
    }
}
```

An inventory of the Partial Tag Helper attributes follows.

name

The `name` attribute is required. It indicates the name or the path of the partial view to be rendered. When a partial view name is provided, the view discovery process is initiated. That process is bypassed when an explicit path is provided. For all acceptable `name` values, see Partial view discovery.

The following markup uses an explicit path, indicating that *_ProductPartial.cshtml* is to be loaded from the *Shared* folder. Using the for attribute, a model is passed to the partial view for binding.

```
<partial name="Shared/_ProductPartial.cshtml" for="Product">
```

for

The `for` attribute assigns a ModelExpression to be evaluated against the current model. A `ModelExpression` infers the `@Model.` syntax. For example, `for="Product"` can be used instead of `for="@Model.Product"`. This default inference behavior is overridden by using the `@` symbol to define an inline expression.

The following markup loads *_ProductPartial.cshtml*:

```
<partial name="_ProductPartial" for="Product">
```

The partial view is bound to the associated page model's `Product` property:

```
using Microsoft.AspNetCore.Mvc.RazorPages;
using TagHelpersBuiltIn.Models;

namespace TagHelpersBuiltIn.Pages
{
    public class ProductModel : PageModel
    {
        public Product Product { get; set; }

        public void OnGet()
        {
            Product = new Product
            {
                Number = 1,
                Name = "Test product",
                Description = "This is a test product"
            };
        }
    }
}
```

model

The `model` attribute assigns a model instance to pass to the partial view. The `model` attribute can't be used with the for attribute.

In the following markup, a new `Product` object is instantiated and passed to the `model` attribute for binding:

```
<partial name="_ProductPartial"
         model='new Product { Number = 1, Name = "Test product", Description = "This is a test" }'>
```

view-data

The `view-data` attribute assigns a ViewDataDictionary to pass to the partial view. The following markup makes the entire ViewData collection accessible to the partial view:

```
@{
    ViewData["IsNumberReadOnly"] = true;
}

<partial name="_ProductViewDataPartial" for="Product" view-data="ViewData">
```

In the preceding code, the `IsNumberReadOnly` key value is set to `true` and added to the ViewData collection. Consequently, `ViewData["IsNumberReadOnly"]` is made accessible within the following partial view:

```
@model TagHelpersBuiltIn.Models.Product

<div class="form-group">
    <label asp-for="Number"></label>
    @if ((bool)ViewData["IsNumberReadOnly"])
    {
        <input asp-for="Number" type="number" class="form-control" readonly />
    }
    else
    {
        <input asp-for="Number" type="number" class="form-control" />
    }
</div>
<div class="form-group">
    <label asp-for="Name"></label>
    <input asp-for="Name" type="text" class="form-control" />
</div>
<div class="form-group">
    <label asp-for="Description"></label>
    <textarea asp-for="Description" rows="4" cols="50" class="form-control"></textarea>
</div>
```

In this example, the value of `ViewData["IsNumberReadOnly"]` determines whether the *Number* field is displayed as read only.

Migrate from an HTML Helper

Consider the following asynchronous HTML Helper example. A collection of products is iterated and displayed. Per the `PartialAsync` method's first parameter, the *_ProductPartial.cshtml* partial view is loaded. An instance of the `Product` model is passed to the partial view for binding.

```
@foreach (var product in Model.Products)
{
    @await Html.PartialAsync("_ProductPartial", product)
}
```

The following Partial Tag Helper achieves the same asynchronous rendering behavior as the `PartialAsync` HTML Helper. The `model` attribute is assigned a `Product` model instance for binding to the partial view.

```
@foreach (var product in Model.Products)
{
    <partial name="_ProductPartial" model="product" />
}
```

Script Tag Helper in ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

By Rick Anderson

The Script Tag Helper generates a link to a primary or fall back script file. Typically the primary script file is on a Content Delivery Network (CDN).

A CDN:

- Provides several performance advantages vs hosting the asset with the web app.
- Should not be relied on as the only source for the asset. CDNs are not always available, therefore a reliable fallback should be used. Typically the fallback is the site hosting the web app.

The Script Tag Helper allows you to specify a CDN for the script file and a fallback when the CDN is not available. The Script Tag Helper provides the performance advantage of a CDN with the robustness of local hosting.

The following Razor markup shows a `script` element with a fallback:

```
<script src="https://ajax.aspnetcdn.com/ajax/jquery/jquery-3.3.1.min.js"
        asp-fallback-src="~/lib/jquery/dist/jquery.min.js"
        asp-fallback-test="window.jQuery"
        crossorigin="anonymous"
        integrity="sha384-tsQFqpEReu7ZLhBV2VZlAu7zcOV+rXbYlF2cqB8txI/8aZajjp4Bqd+V6D5IgvKT">
</script>
```

Don't use the `<script>` element's defer attribute to defer loading the CDN script. The Script Tag Helper renders JavaScript that immediately executes the asp-fallback-test expression. The expression fails if loading the CDN script is deferred.

Commonly used Script Tag Helper attributes

See Script Tag Helper for all the Script Tag Helper attributes, properties, and methods.

asp-fallback-test

The script method defined in the primary script to use for the fallback test. For more information, see FallbackTestExpression.

asp-fallback-src

The URL of a Script tag to fallback to in the case the primary one fails. For more information, see FallbackSrc.

Tag Helpers in forms in ASP.NET Core

9/22/2020 • 18 minutes to read • Edit Online

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

NOTE

With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

ATTRIBUTE	DESCRIPTION
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"` .
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the **HTML Helper alternatives to Input Tag Helper** section for details.
- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to process
this request. Please review the following specific error details and modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type 'RegisterViewModel'
could be found (are you missing a using directive or an assembly reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

.NET TYPE	INPUT TYPE
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

ATTRIBUTE	INPUT TYPE
[EmailAddress]	type="email"
[Url]	type="url"
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

```
  <form method="post" action="/Demo/RegisterInput">
      Email:
      <input type="email" data-val="true"
             data-val-email="The Email Address field is not a valid email address."
             data-val-required="The Email Address field is required."
             id="Email" name="Email" value=""><br>
      Password:
      <input type="password" data-val="true"
             data-val-required="The Password field is required."
             id="Password" name="Password"><br>
      <button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"`.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="@Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    Address: <input asp-for="Address.AddressLine1" /><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1" value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The *Views/Shared/EditorTemplates/String.cshtml* template:

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The *Views/Shared/EditorTemplates/ToDoItem.cshtml* template:

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
</td>

@*
    This template replaces the following Razor which evaluates the indexer three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> **NOTE**
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type with a maximum length of
&#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type with a minimum length of
&#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.
- Less markup in source code
- Strong typing with the model property.

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on a HTML span element.

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> **NOTE**
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side

validation is disabled), MVC places that error message as the body of the `<span>` element.

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

ASP-VALIDATION-SUMMARY	VALIDATION MESSAGES DISPLAYED
ValidationSummary.All	Property and model level
ValidationSummary.ModelOnly	Model
ValidationSummary.None	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    Email:  <input asp-for="Email" /> <br />
    <span asp-validation-for="Email"></span><br />
    Password: <input asp-for="Password" /><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

```
<form action="/DemoReg/Register" method="post">
  <div class="validation-summary-valid" data-valmsg-summary="true">
  <ul><li style="display:none"></li></ul></div>
  Email:  <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"  },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

```
[HttpPost]
[ValidateAntiForgeryToken]
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

> **NOTE**
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

```
    public class CountryEnumViewModel
    {
        public CountryEnum EnumCountry { get; set; }
    }
}
```

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

```
<form method="post" action="/Home/IndexEnum">
       <select data-val="true" data-val-required="The EnumCountry field is required."
               id="EnumCountry" name="EnumCountry">
           <option value="0">United Mexican States</option>
           <option value="1">United States of America</option>
           <option value="2">Canada</option>
           <option value="3">France</option>
           <option value="4">Germany</option>
           <option selected="selected" value="5">Spain</option>
       </select>
       <br /><button type="submit">Register</button>
       <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
  </form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America" };
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }

    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

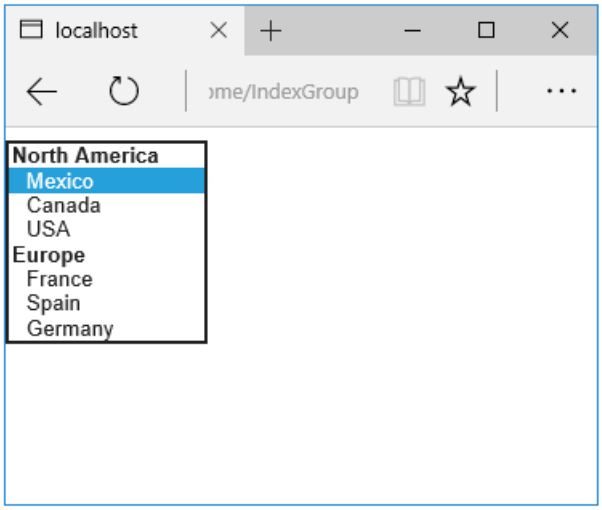
The two groups are shown below:



The generated HTML:

```
<form method="post" action="/Home/IndexGroup">
     <select id="Country" name="Country">
         <optgroup label="North America">
             <option value="MEX">Mexico</option>
             <option value="CAN">Canada</option>
             <option value="US">USA</option>
         </optgroup>
         <optgroup label="Europe">
             <option value="FR">France</option>
             <option value="ES">Spain</option>
             <option value="DE">Germany</option>
         </optgroup>
     </select>
     <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The *Views/Shared/EditorTemplates/CountryViewModel.cshtml* template:

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
 </form>
```

Tag Helpers in forms in ASP.NET Core

9/22/2020 • 18 minutes to read • Edit Online

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

NOTE

With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

ATTRIBUTE	DESCRIPTION
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"` .
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the **HTML Helper alternatives to Input Tag Helper** section for details.
- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to process
this request. Please review the following specific error details and modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type 'RegisterViewModel'
could be found (are you missing a using directive or an assembly reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

.NET TYPE	INPUT TYPE
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

ATTRIBUTE	INPUT TYPE
[EmailAddress]	type="email"
[Url]	type="url"
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

```
  <form method="post" action="/Demo/RegisterInput">
      Email:
      <input type="email" data-val="true"
             data-val-email="The Email Address field is not a valid email address."
             data-val-required="The Email Address field is required."
             id="Email" name="Email" value=""><br>
      Password:
      <input type="password" data-val="true"
             data-val-required="The Password field is required."
             id="Password" name="Password"><br>
      <button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"`.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="@Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    Address: <input asp-for="Address.AddressLine1" /><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1" value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The *Views/Shared/EditorTemplates/String.cshtml* template:

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The *Views/Shared/EditorTemplates/ToDoItem.cshtml* template:

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
</td>

@*
    This template replaces the following Razor which evaluates the indexer three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> **NOTE**
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type with a maximum length of
&#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type with a minimum length of
&#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.
- Less markup in source code
- Strong typing with the model property.

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on a HTML span element.

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> **NOTE**
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side

validation is disabled), MVC places that error message as the body of the `<span>` element.

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

ASP-VALIDATION-SUMMARY	VALIDATION MESSAGES DISPLAYED
ValidationSummary.All	Property and model level
ValidationSummary.ModelOnly	Model
ValidationSummary.None	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    Email:  <input asp-for="Email" /> <br />
    <span asp-validation-for="Email"></span><br />
    Password: <input asp-for="Password" /><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

```
<form action="/DemoReg/Register" method="post">
  <div class="validation-summary-valid" data-valmsg-summary="true">
  <ul><li style="display:none"></li></ul></div>
  Email:  <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"  },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

```
[HttpPost]
[ValidateAntiForgeryToken]
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

> **NOTE**
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

```
    public class CountryEnumViewModel
    {
        public CountryEnum EnumCountry { get; set; }
    }
}
```

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

```
<form method="post" action="/Home/IndexEnum">
       <select data-val="true" data-val-required="The EnumCountry field is required."
               id="EnumCountry" name="EnumCountry">
           <option value="0">United Mexican States</option>
           <option value="1">United States of America</option>
           <option value="2">Canada</option>
           <option value="3">France</option>
           <option value="4">Germany</option>
           <option selected="selected" value="5">Spain</option>
       </select>
       <br /><button type="submit">Register</button>
       <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
  </form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America" };
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }

    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

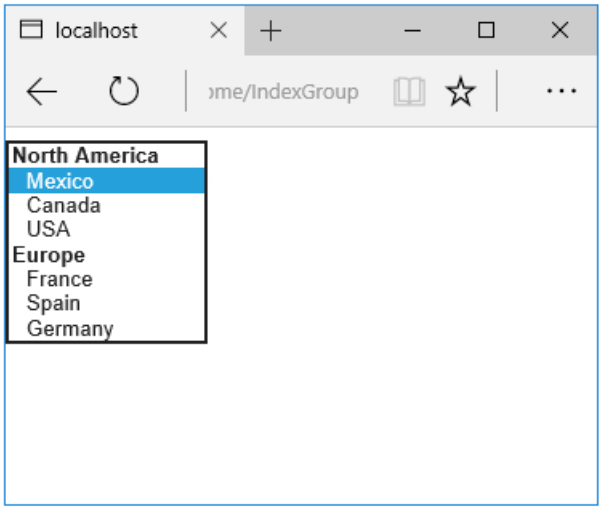
The two groups are shown below:



The generated HTML:

```
<form method="post" action="/Home/IndexGroup">
     <select id="Country" name="Country">
         <optgroup label="North America">
             <option value="MEX">Mexico</option>
             <option value="CAN">Canada</option>
             <option value="US">USA</option>
         </optgroup>
         <optgroup label="Europe">
             <option value="FR">France</option>
             <option value="ES">Spain</option>
             <option value="DE">Germany</option>
         </optgroup>
     </select>
     <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The *Views/Shared/EditorTemplates/CountryViewModel.cshtml* template:

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
 </form>
```

Tag Helpers in forms in ASP.NET Core

9/22/2020 • 18 minutes to read • Edit Online

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

NOTE

With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

ATTRIBUTE	DESCRIPTION
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"` .
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the **HTML Helper alternatives to Input Tag Helper** section for details.
- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to process
this request. Please review the following specific error details and modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type 'RegisterViewModel'
could be found (are you missing a using directive or an assembly reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

.NET TYPE	INPUT TYPE
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

ATTRIBUTE	INPUT TYPE
[EmailAddress]	type="email"
[Url]	type="url"
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

```
  <form method="post" action="/Demo/RegisterInput">
      Email:
      <input type="email" data-val="true"
             data-val-email="The Email Address field is not a valid email address."
             data-val-required="The Email Address field is required."
             id="Email" name="Email" value=""><br>
      Password:
      <input type="password" data-val="true"
             data-val-required="The Password field is required."
             id="Password" name="Password"><br>
      <button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"`.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="@Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    Address: <input asp-for="Address.AddressLine1" /><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1" value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The *Views/Shared/EditorTemplates/String.cshtml* template:

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The *Views/Shared/EditorTemplates/ToDoItem.cshtml* template:

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
</td>

@*
    This template replaces the following Razor which evaluates the indexer three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> **NOTE**
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type with a maximum length of
&#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type with a minimum length of
&#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.
- Less markup in source code
- Strong typing with the model property.

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on a HTML span element.

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> **NOTE**
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side

validation is disabled), MVC places that error message as the body of the `<span>` element.

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

ASP-VALIDATION-SUMMARY	VALIDATION MESSAGES DISPLAYED
ValidationSummary.All	Property and model level
ValidationSummary.ModelOnly	Model
ValidationSummary.None	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    Email:  <input asp-for="Email" /> <br />
    <span asp-validation-for="Email"></span><br />
    Password: <input asp-for="Password" /><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

```
<form action="/DemoReg/Register" method="post">
  <div class="validation-summary-valid" data-valmsg-summary="true">
  <ul><li style="display:none"></li></ul></div>
  Email:  <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"  },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

```
[HttpPost]
[ValidateAntiForgeryToken]
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

> **NOTE**
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

```
    public class CountryEnumViewModel
    {
        public CountryEnum EnumCountry { get; set; }
    }
}
```

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

```
<form method="post" action="/Home/IndexEnum">
       <select data-val="true" data-val-required="The EnumCountry field is required."
               id="EnumCountry" name="EnumCountry">
           <option value="0">United Mexican States</option>
           <option value="1">United States of America</option>
           <option value="2">Canada</option>
           <option value="3">France</option>
           <option value="4">Germany</option>
           <option selected="selected" value="5">Spain</option>
       </select>
       <br /><button type="submit">Register</button>
       <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
  </form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America" };
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }

    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

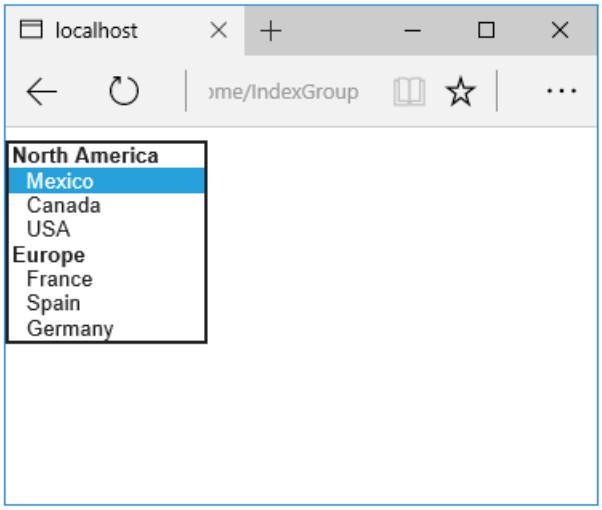
The two groups are shown below:



The generated HTML:

```
<form method="post" action="/Home/IndexGroup">
     <select id="Country" name="Country">
         <optgroup label="North America">
             <option value="MEX">Mexico</option>
             <option value="CAN">Canada</option>
             <option value="US">USA</option>
         </optgroup>
         <optgroup label="Europe">
             <option value="FR">France</option>
             <option value="ES">Spain</option>
             <option value="DE">Germany</option>
         </optgroup>
     </select>
     <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The *Views/Shared/EditorTemplates/CountryViewModel.cshtml* template:

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
 </form>
```

Tag Helpers in forms in ASP.NET Core

9/22/2020 • 18 minutes to read • Edit Online

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app

with a route named `register` could use the following markup for the registration page:

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

> **NOTE**
> With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

ATTRIBUTE	DESCRIPTION
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"`.
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or

button are selected:

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the **HTML Helper alternatives to Input Tag Helper** section for details.
- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to process
this request. Please review the following specific error details and modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type 'RegisterViewModel'
could be found (are you missing a using directive or an assembly reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

.NET TYPE	INPUT TYPE
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"

.NET TYPE	INPUT TYPE
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

ATTRIBUTE	INPUT TYPE
[EmailAddress]	type="email"
[Url]	type="url"
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

```
<form method="post" action="/Demo/RegisterInput">
    Email:
    <input type="email" data-val="true"
           data-val-email="The Email Address field is not a valid email address."
           data-val-required="The Email Address field is required."
           id="Email" name="Email" value=""><br>
    Password:
    <input type="password" data-val="true"
           data-val-required="The Password field is required."
           id="Password" name="Password"><br>
    <button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
 </form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"` .

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="@Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    Email:  <input asp-for="Email" /> <br />
    Password: <input asp-for="Password" /><br />
    Address: <input asp-for="Address.AddressLine1" /><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1" value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The *Views/Shared/EditorTemplates/String.cshtml* template:

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The *Views/Shared/EditorTemplates/ToDoItem.cshtml* template:

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
</td>

@*
    This template replaces the following Razor which evaluates the indexer three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> **NOTE**
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.

- HTML Helper alternative: `Html.TextAreaFor`

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type with a maximum length
of &#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type with a minimum length
of &#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.
- Less markup in source code
- Strong typing with the model property.

Sample:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on a HTML span element.

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> **NOTE**
>
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side validation is disabled), MVC places that error message as the body of the `<span>` element.

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

ASP-VALIDATION-SUMMARY	VALIDATION MESSAGES DISPLAYED
ValidationSummary.All	Property and model level
ValidationSummary.ModelOnly	Model
ValidationSummary.None	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    Email:  <input asp-for="Email" /> <br />
    <span asp-validation-for="Email"></span><br />
    Password: <input asp-for="Password" /><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

```
<form action="/DemoReg/Register" method="post">
  <div class="validation-summary-valid" data-valmsg-summary="true">
  <ul><li style="display:none"></li></ul></div>
  Email:  <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true"><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"  },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

```
[HttpPost]
[ValidateAntiForgeryToken]
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
   </form>
```

> **NOTE**
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

```
    public class CountryEnumViewModel
    {
        public CountryEnum EnumCountry { get; set; }
    }
}
```

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

```
  <form method="post" action="/Home/IndexEnum">
        <select data-val="true" data-val-required="The EnumCountry field is required."
                id="EnumCountry" name="EnumCountry">
            <option value="0">United Mexican States</option>
            <option value="1">United States of America</option>
            <option value="2">Canada</option>
            <option value="3">France</option>
            <option value="4">Germany</option>
            <option selected="selected" value="5">Spain</option>
        </select>
        <br /><button type="submit">Register</button>
        <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
    </form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America" };
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }

    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

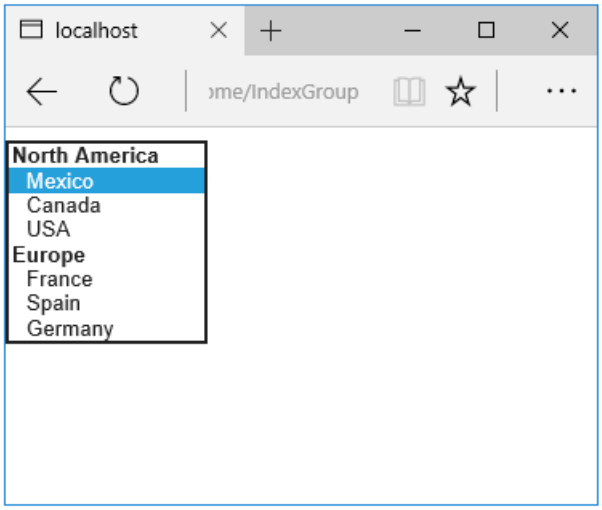
The two groups are shown below:



The generated HTML:

```
<form method="post" action="/Home/IndexGroup">
     <select id="Country" name="Country">
         <optgroup label="North America">
             <option value="MEX">Mexico</option>
             <option value="CAN">Canada</option>
             <option value="US">USA</option>
         </optgroup>
         <optgroup label="Europe">
             <option value="FR">France</option>
             <option value="ES">Spain</option>
             <option value="DE">Germany</option>
         </optgroup>
     </select>
     <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The *Views/Shared/EditorTemplates/CountryViewModel.cshtml* template:

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed for brevity>">
 </form>
```

Share controllers, views, Razor Pages and more with Application Parts

9/22/2020 • 7 minutes to read • Edit Online

By Rick Anderson

View or download sample code (how to download)

An *Application Part* is an abstraction over the resources of an app. Application Parts allow ASP.NET Core to discover controllers, view components, tag helpers, Razor Pages, razor compilation sources, and more. AssemblyPart is an Application part. `AssemblyPart` encapsulates an assembly reference and exposes types and compilation references.

Feature providers work with application parts to populate the features of an ASP.NET Core app. The main use case for application parts is to configure an app to discover (or avoid loading) ASP.NET Core features from an assembly. For example, you might want to share common functionality between multiple apps. Using Application Parts, you can share an assembly (DLL) containing controllers, views, Razor Pages, razor compilation sources, Tag Helpers, and more with multiple apps. Sharing an assembly is preferred to duplicating code in multiple projects.

ASP.NET Core apps load features from ApplicationPart. The AssemblyPart class represents an application part that's backed by an assembly.

Load ASP.NET Core features

Use the Microsoft.AspNetCore.Mvc.ApplicationParts and AssemblyPart classes to discover and load ASP.NET Core features (controllers, view components, etc.). The ApplicationPartManager tracks the application parts and feature providers available. `ApplicationPartManager` is configured in `Startup.ConfigureServices`:

```
// Requires using System.Reflection;
public void ConfigureServices(IServiceCollection services)
{
    var assembly = typeof(MySharedController).Assembly;
    services.AddControllersWithViews()
        .AddApplicationPart(assembly)
        .AddRazorRuntimeCompilation();

    services.Configure<MvcRazorRuntimeCompilationOptions>(options =>
    { options.FileProviders.Add(new EmbeddedFileProvider(assembly)); });
}
```

The following code provides an alternative approach to configuring `ApplicationPartManager` using `AssemblyPart`:

```
// Requires using System.Reflection;
// Requires using Microsoft.AspNetCore.Mvc.ApplicationParts;
public void ConfigureServices(IServiceCollection services)
{
    var assembly = typeof(MySharedController).GetTypeInfo().Assembly;
    // This creates an AssemblyPart, but does not create any related parts for items such as views.
    var part = new AssemblyPart(assembly);
    services.AddControllersWithViews()
        .ConfigureApplicationPartManager(apm => apm.ApplicationParts.Add(part));
}
```

The preceding two code samples load the `SharedController` from an assembly. The `SharedController` is not in the

app's project. See the WebAppParts solution sample download.

Include views

Use a Razor class library to include views in the assembly.

Prevent loading resources

Application parts can be used to *avoid* loading resources in a particular assembly or location. Add or remove members of the Microsoft.AspNetCore.Mvc.ApplicationParts collection to hide or make available resources. The order of the entries in the `ApplicationParts` collection isn't important. Configure the `ApplicationPartManager` before using it to configure services in the container. For example, configure the `ApplicationPartManager` before invoking `AddControllersAsServices`. Call `Remove` on the `ApplicationParts` collection to remove a resource.

The `ApplicationPartManager` includes parts for:

- The app's assembly and dependent assemblies.
- `Microsoft.AspNetCore.Mvc.ApplicationParts.CompiledRazorAssemblyPart`
- `Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation`
- `Microsoft.AspNetCore.Mvc.TagHelpers`.
- `Microsoft.AspNetCore.Mvc.Razor`.

Feature providers

Application feature providers examine application parts and provide features for those parts. There are built-in feature providers for the following ASP.NET Core features:

- ControllerFeatureProvider
- TagHelperFeatureProvider
- MetadataReferenceFeatureProvider
- ViewsFeatureProvider
- `internal class` RazorCompiledItemFeatureProvider

Feature providers inherit from IApplicationFeatureProvider<TFeature>, where `T` is the type of the feature. Feature providers can be implemented for any of the previously listed feature types. The order of feature providers in the `ApplicationPartManager.FeatureProviders` can impact run time behavior. Later added providers can react to actions taken by earlier added providers.

Display available features

The features available to an app can be enumerated by requesting an `ApplicationPartManager` through dependency injection:

```
using AppPartsSample.ViewModels;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.ApplicationParts;
using Microsoft.AspNetCore.Mvc.Controllers;
using System.Linq;
using Microsoft.AspNetCore.Mvc.Razor.Compilation;
using Microsoft.AspNetCore.Mvc.Razor.TagHelpers;
using Microsoft.AspNetCore.Mvc.ViewComponents;

namespace AppPartsSample.Controllers
{
    public class FeaturesController : Controller
    {
        private readonly ApplicationPartManager _partManager;

        public FeaturesController(ApplicationPartManager partManager)
        {
            _partManager = partManager;
        }

        public IActionResult Index()
        {
            var viewModel = new FeaturesViewModel();

            var controllerFeature = new ControllerFeature();
            _partManager.PopulateFeature(controllerFeature);
            viewModel.Controllers = controllerFeature.Controllers.ToList();

            var tagHelperFeature = new TagHelperFeature();
            _partManager.PopulateFeature(tagHelperFeature);
            viewModel.TagHelpers = tagHelperFeature.TagHelpers.ToList();

            var viewComponentFeature = new ViewComponentFeature();
            _partManager.PopulateFeature(viewComponentFeature);
            viewModel.ViewComponents = viewComponentFeature.ViewComponents.ToList();

            return View(viewModel);
        }
    }
}
```

The download sample uses the preceding code to display the app features:

```
Controllers:
    - FeaturesController
    - HomeController
    - HelloController
    - GenericController`1
    - GenericController`1
Tag Helpers:
    - PrerenderTagHelper
    - AnchorTagHelper
    - CacheTagHelper
    - DistributedCacheTagHelper
    - EnvironmentTagHelper
    - Additional Tag Helpers omitted for brevity.
View Components:
    - SampleViewComponent
```

Discovery in application parts

HTTP 404 errors are not uncommon when developing with application parts. These errors are typically caused by missing an essential requirement for how applications parts are discovered. If your app returns an HTTP 404 error,

verify the following requirements have been met:

- The `applicationName` setting needs to be set to the root assembly used for discovery. The root assembly used for discovery is normally the entry point assembly.
- The root assembly needs to have a reference to the parts used for discovery. The reference can be direct or transitive.
- The root assembly needs to reference the Web SDK. The framework has logic that stamps attributes into the root assembly that are used for discovery.

View or download sample code (how to download)

An *Application Part* is an abstraction over the resources of an app. Application Parts allow ASP.NET Core to discover controllers, view components, tag helpers, Razor Pages, razor compilation sources, and more. AssemblyPart is an Application part. `AssemblyPart` encapsulates an assembly reference and exposes types and compilation references.

Feature providers work with application parts to populate the features of an ASP.NET Core app. The main use case for application parts is to configure an app to discover (or avoid loading) ASP.NET Core features from an assembly. For example, you might want to share common functionality between multiple apps. Using Application Parts, you can share an assembly (DLL) containing controllers, views, Razor Pages, razor compilation sources, Tag Helpers, and more with multiple apps. Sharing an assembly is preferred to duplicating code in multiple projects.

ASP.NET Core apps load features from ApplicationPart. The AssemblyPart class represents an application part that's backed by an assembly.

Load ASP.NET Core features

Use the `ApplicationPart` and `AssemblyPart` classes to discover and load ASP.NET Core features (controllers, view components, etc.). The ApplicationPartManager tracks the application parts and feature providers available. `ApplicationPartManager` is configured in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    // Requires using System.Reflection;
    var assembly = typeof(MySharedController).GetTypeInfo().Assembly;
    services.AddMvc()
        .AddApplicationPart(assembly)
        .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

The following code provides an alternative approach to configuring `ApplicationPartManager` using `AssemblyPart`:

```
public void ConfigureServices(IServiceCollection services)
{
    // Requires using System.Reflection;
    // Requires using Microsoft.AspNetCore.Mvc.ApplicationParts;
    var assembly = typeof(MySharedController).GetTypeInfo().Assembly;
    var part = new AssemblyPart(assembly);
    services.AddMvc()
        .ConfigureApplicationPartManager(apm => apm.ApplicationParts.Add(part))
        .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

The preceding two code samples load the `SharedController` from an assembly. The `SharedController` is not in the application's project. See the WebAppParts solution sample download.

Include views

Use a Razor class library to include views in the assembly.

Prevent loading resources

Application parts can be used to *avoid* loading resources in a particular assembly or location. Add or remove members of the Microsoft.AspNetCore.Mvc.ApplicationParts collection to hide or make available resources. The order of the entries in the `ApplicationParts` collection isn't important. Configure the `ApplicationPartManager` before using it to configure services in the container. For example, configure the `ApplicationPartManager` before invoking `AddControllersAsServices`. Call `Remove` on the `ApplicationParts` collection to remove a resource.

The following code uses Microsoft.AspNetCore.Mvc.ApplicationParts to remove `MyDependentLibrary` from the app:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_2)
            .ConfigureApplicationPartManager(apm =>
            {
                var dependentLibrary = apm.ApplicationParts
                    .FirstOrDefault(part => part.Name == "MyDependentLibrary");

                if (dependentLibrary != null)
                {
                    apm.ApplicationParts.Remove(dependentLibrary);
                }
            });
}
```

The `ApplicationPartManager` includes parts for:

- The app's assembly and dependent assemblies.
- `Microsoft.AspNetCore.Mvc.TagHelpers`.
- `Microsoft.AspNetCore.Mvc.Razor`.

Application feature providers

Application feature providers examine application parts and provide features for those parts. There are built-in feature providers for the following ASP.NET Core features:

- Controllers
- Tag Helpers
- View Components

Feature providers inherit from IApplicationFeatureProvider<TFeature>, where `T` is the type of the feature. Feature providers can be implemented for any of the previously listed feature types. The order of feature providers in the `ApplicationPartManager.FeatureProviders` can impact run time behavior. Later added providers can react to actions taken by earlier added providers.

Display available features

The features available to an app can be enumerated by requesting an `ApplicationPartManager` through dependency injection:

```
using AppPartsSample.ViewModels;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.ApplicationParts;
using Microsoft.AspNetCore.Mvc.Controllers;
using System.Linq;
using Microsoft.AspNetCore.Mvc.Razor.Compilation;
using Microsoft.AspNetCore.Mvc.Razor.TagHelpers;
using Microsoft.AspNetCore.Mvc.ViewComponents;

namespace AppPartsSample.Controllers
{
    public class FeaturesController : Controller
    {
        private readonly ApplicationPartManager _partManager;

        public FeaturesController(ApplicationPartManager partManager)
        {
            _partManager = partManager;
        }

        public IActionResult Index()
        {
            var viewModel = new FeaturesViewModel();

            var controllerFeature = new ControllerFeature();
            _partManager.PopulateFeature(controllerFeature);
            viewModel.Controllers = controllerFeature.Controllers.ToList();

            var tagHelperFeature = new TagHelperFeature();
            _partManager.PopulateFeature(tagHelperFeature);
            viewModel.TagHelpers = tagHelperFeature.TagHelpers.ToList();

            var viewComponentFeature = new ViewComponentFeature();
            _partManager.PopulateFeature(viewComponentFeature);
            viewModel.ViewComponents = viewComponentFeature.ViewComponents.ToList();

            return View(viewModel);
        }
    }
}
```

The download sample uses the preceding code to display the app features:

```
Controllers:
    - FeaturesController
    - HomeController
    - HelloController
    - GenericController`1
    - GenericController`1
Tag Helpers:
    - PrerenderTagHelper
    - AnchorTagHelper
    - CacheTagHelper
    - DistributedCacheTagHelper
    - EnvironmentTagHelper
    - Additional Tag Helpers omitted for brevity.
View Components:
    - SampleViewComponent
```

Discovery in application parts

HTTP 404 errors are not uncommon when developing with application parts. These errors are typically caused by missing an essential requirement for how applications parts are discovered. If your app returns an HTTP 404 error,

verify the following requirements have been met:

- The `applicationName` setting needs to be set to the root assembly used for discovery. The root assembly used for discovery is normally the entry point assembly.
- The root assembly needs to have a reference to the parts used for discovery. The reference can be direct or transitive.
- The root assembly needs to reference the Web SDK.
  - The ASP.NET Core framework has custom build logic that stamps attributes into the root assembly that are used for discovery.

Work with the application model in ASP.NET Core

9/22/2020 • 10 minutes to read • Edit Online

By Steve Smith

ASP.NET Core MVC defines an *application model* representing the components of an MVC app. You can read and manipulate this model to modify how MVC elements behave. By default, MVC follows certain conventions to determine which classes are considered to be controllers, which methods on those classes are actions, and how parameters and routing behave. You can customize this behavior to suit your app's needs by creating your own conventions and applying them globally or as attributes.

Models and Providers

The ASP.NET Core MVC application model include both abstract interfaces and concrete implementation classes that describe an MVC application. This model is the result of MVC discovering the app's controllers, actions, action parameters, routes, and filters according to default conventions. By working with the application model, you can modify your app to follow different conventions from the default MVC behavior. The parameters, names, routes, and filters are all used as configuration data for actions and controllers.

The ASP.NET Core MVC Application Model has the following structure:

- ApplicationModel
  - Controllers (ControllerModel)
    - Actions (ActionModel)
      - Parameters (ParameterModel)

Each level of the model has access to a common `Properties` collection, and lower levels can access and overwrite property values set by higher levels in the hierarchy. The properties are persisted to the `ActionDescriptor.Properties` when the actions are created. Then when a request is being handled, any properties a convention added or modified can be accessed through `ActionContext.ActionDescriptor.Properties`. Using properties is a great way to configure your filters, model binders, etc. on a per-action basis.

> **NOTE**
> The `ActionDescriptor.Properties` collection isn't thread safe (for writes) once app startup has finished. Conventions are the best way to safely add data to this collection.

IApplicationModelProvider

ASP.NET Core MVC loads the application model using a provider pattern, defined by the IApplicationModelProvider interface. This section covers some of the internal implementation details of how this provider functions. This is an advanced topic - most apps that leverage the application model should do so by working with conventions.

Implementations of the `IApplicationModelProvider` interface "wrap" one another, with each implementation calling `OnProvidersExecuting` in ascending order based on its `Order` property. The `OnProvidersExecuted` method is then called in reverse order. The framework defines several providers:

First (`Order=-1000`):

- `DefaultApplicationModelProvider`

Then (`Order=-990`):

- `AuthorizationApplicationModelProvider`
- `CorsApplicationModelProvider`

> **NOTE**
> The order in which two providers with the same value for `Order` are called is undefined, and therefore shouldn't be relied upon.

> **NOTE**
> `IApplicationModelProvider` is an advanced concept for framework authors to extend. In general, apps should use conventions and frameworks should use providers. The key distinction is that providers always run before conventions.

The `DefaultApplicationModelProvider` establishes many of the default behaviors used by ASP.NET Core MVC. Its responsibilities include:

- Adding global filters to the context
- Adding controllers to the context
- Adding public controller methods as actions
- Adding action method parameters to the context
- Applying route and other attributes

Some built-in behaviors are implemented by the `DefaultApplicationModelProvider`. This provider is responsible for constructing the `ControllerModel`, which in turn references `ActionModel`, `PropertyModel`, and `ParameterModel` instances. The `DefaultApplicationModelProvider` class is an internal framework implementation detail that can and will change in the future.

The `AuthorizationApplicationModelProvider` is responsible for applying the behavior associated with the `AuthorizeFilter` and `AllowAnonymousFilter` attributes. Learn more about these attributes.

The `CorsApplicationModelProvider` implements behavior associated with the `IEnableCorsAttribute` and `IDisableCorsAttribute`, and the `DisableCorsAuthorizationFilter`. Learn more about CORS.

Conventions

The application model defines convention abstractions that provide a simpler way to customize the behavior of the models than overriding the entire model or provider. These abstractions are the recommended way to modify your app's behavior. Conventions provide a way for you to write code that will dynamically apply customizations. While filters provide a means of modifying the framework's behavior, customizations let you control how the whole app works together.

The following conventions are available:

- `IApplicationModelConvention`
- `IControllerModelConvention`
- `IActionModelConvention`
- `IParameterModelConvention`

Conventions are applied by adding them to MVC options or by implementing `Attribute`s and applying them to controllers, actions, or action parameters (similar to `Filters`). Unlike filters, conventions are only executed when the app is starting, not as part of each request.

Sample: Modifying the ApplicationModel

The following convention is used to add a property to the application model.

```
using Microsoft.AspNetCore.Mvc.ApplicationModels;

namespace AppModelSample.Conventions
{
    public class ApplicationDescription : IApplicationModelConvention
    {
        private readonly string _description;

        public ApplicationDescription(string description)
        {
            _description = description;
        }

        public void Apply(ApplicationModel application)
        {
            application.Properties["description"] = _description;
        }
    }
}
```

Application model conventions are applied as options when MVC is added in `ConfigureServices` in `Startup`.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc(options =>
    {
        options.Conventions.Add(new ApplicationDescription("My Application Description"));
        options.Conventions.Add(new NamespaceRoutingConvention());
        //options.Conventions.Add(new IdsMustBeInRouteParameterModelConvention());
    });
}
```

Properties are accessible from the `ActionDescriptor` properties collection within controller actions:

```
public class AppModelController : Controller
{
    public string Description()
    {
        return "Description: " + ControllerContext.ActionDescriptor.Properties["description"];
    }
}
```

Sample: Modifying the ControllerModel Description

As in the previous example, the controller model can also be modified to include custom properties. These will override existing properties with the same name specified in the application model. The following convention attribute adds a description at the controller level:

```
using System;
using Microsoft.AspNetCore.Mvc.ApplicationModels;

namespace AppModelSample.Conventions
{
    public class ControllerDescriptionAttribute : Attribute, IControllerModelConvention
    {
        private readonly string _description;

        public ControllerDescriptionAttribute(string description)
        {
            _description = description;
        }

        public void Apply(ControllerModel controllerModel)
        {
            controllerModel.Properties["description"] = _description;
        }
    }
}
```

This convention is applied as an attribute on a controller.

```
[ControllerDescription("Controller Description")]
public class DescriptionAttributesController : Controller
{
    public string Index()
    {
        return "Description: " + ControllerContext.ActionDescriptor.Properties["description"];
    }
```

The "description" property is accessed in the same manner as in previous examples.

Sample: Modifying the ActionModel Description

A separate attribute convention can be applied to individual actions, overriding behavior already applied at the application or controller level.

```
using System;
using Microsoft.AspNetCore.Mvc.ApplicationModels;

namespace AppModelSample.Conventions
{
    public class ActionDescriptionAttribute : Attribute, IActionModelConvention
    {
        private readonly string _description;

        public ActionDescriptionAttribute(string description)
        {
            _description = description;
        }

        public void Apply(ActionModel actionModel)
        {
            actionModel.Properties["description"] = _description;
        }
    }
}
```

Applying this to an action within the previous example's controller demonstrates how it overrides the controller-level convention:

```
[ControllerDescription("Controller Description")]
public class DescriptionAttributesController : Controller
{
    public string Index()
    {
        return "Description: " + ControllerContext.ActionDescriptor.Properties["description"];
    }

    [ActionDescription("Action Description")]
    public string UseActionDescriptionAttribute()
    {
        return "Description: " + ControllerContext.ActionDescriptor.Properties["description"];
    }
}
```

Sample: Modifying the ParameterModel

The following convention can be applied to action parameters to modify their `BindingInfo`. The following convention requires that the parameter be a route parameter; other potential binding sources (such as query string values) are ignored.

```
using System;
using Microsoft.AspNetCore.Mvc.ApplicationModels;
using Microsoft.AspNetCore.Mvc.ModelBinding;

namespace AppModelSample.Conventions
{
    public class MustBeInRouteParameterModelConvention : Attribute, IParameterModelConvention
    {
        public void Apply(ParameterModel model)
        {
            if (model.BindingInfo == null)
            {
                model.BindingInfo = new BindingInfo();
            }
            model.BindingInfo.BindingSource = BindingSource.Path;
        }
    }
}
```

The attribute may be applied to any action parameter:

```
public class ParameterModelController : Controller
{
    // Will bind:  /ParameterModel/GetById/123
    // WON'T bind: /ParameterModel/GetById?id=123
    public string GetById([MustBeInRouteParameterModelConvention]int id)
    {
        return $"Bound to id: {id}";
    }
}
```

Sample: Modifying the ActionModel Name

The following convention modifies the `ActionModel` to update the *name* of the action to which it's applied. The new name is provided as a parameter to the attribute. This new name is used by routing, so it will affect the route used to reach this action method.

```
using System;
using Microsoft.AspNetCore.Mvc.ApplicationModels;

namespace AppModelSample.Conventions
{
    public class CustomActionNameAttribute : Attribute, IActionModelConvention
    {
        private readonly string _actionName;

        public CustomActionNameAttribute(string actionName)
        {
            _actionName = actionName;
        }

        public void Apply(ActionModel actionModel)
        {
            // this name will be used by routing
            actionModel.ActionName = _actionName;
        }
    }
}
```

This attribute is applied to an action method in the `HomeController`:

```
// Route: /Home/MyCoolAction
[CustomActionName("MyCoolAction")]
public string SomeName()
{
    return ControllerContext.ActionDescriptor.ActionName;
}
```

Even though the method name is `SomeName`, the attribute overrides the MVC convention of using the method name and replaces the action name with `MyCoolAction`. Thus, the route used to reach this action is `/Home/MyCoolAction`.

> **NOTE**
>
> This example is essentially the same as using the built-in ActionName attribute.

Sample: Custom Routing Convention

You can use an `IApplicationModelConvention` to customize how routing works. For example, the following convention will incorporate Controllers' namespaces into their routes, replacing `.` in the namespace with `/` in the route:

```
using Microsoft.AspNetCore.Mvc.ApplicationModels;
using System.Linq;

namespace AppModelSample.Conventions
{
    public class NamespaceRoutingConvention : IApplicationModelConvention
    {
        public void Apply(ApplicationModel application)
        {
            foreach (var controller in application.Controllers)
            {
                var hasAttributeRouteModels = controller.Selectors
                    .Any(selector => selector.AttributeRouteModel != null);

                if (!hasAttributeRouteModels
                    && controller.ControllerName.Contains("Namespace")) // affect one controller in this sample
                {
                    // Replace the . in the namespace with a / to create the attribute route
                    // Ex: MySite.Admin namespace will correspond to MySite/Admin attribute route
                    // Then attach [controller], [action] and optional {id?} token.
                    // [Controller] and [action] is replaced with the controller and action
                    // name to generate the final template
                    controller.Selectors[0].AttributeRouteModel = new AttributeRouteModel()
                    {
                        Template = controller.ControllerType.Namespace.Replace('.', '/') +
"/[controller]/[action]/{id?}"
                    };
                }
            }

            // You can continue to put attribute route templates for the controller actions depending on the
way you want them to behave
        }
    }
}
```

The convention is added as an option in Startup.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc(options =>
    {
        options.Conventions.Add(new ApplicationDescription("My Application Description"));
        options.Conventions.Add(new NamespaceRoutingConvention());
        //options.Conventions.Add(new IdsMustBeInRouteParameterModelConvention());
    });
}
```

TIP

You can add conventions to your middleware by accessing `MvcOptions` using `services.Configure<MvcOptions>(c => c.Conventions.Add(YOURCONVENTION));`

This sample applies this convention to routes that are not using attribute routing where the controller has "Namespace" in its name. The following controller demonstrates this convention:

```
using Microsoft.AspNetCore.Mvc;

namespace AppModelSample.Controllers
{
    public class NamespaceRoutingController : Controller
    {
        // using NamespaceRoutingConvention
        // route: /AppModelSample/Controllers/NamespaceRouting/Index
        public string Index()
        {
            return "This demonstrates namespace routing.";
        }
    }
}
```

Application Model Usage in WebApiCompatShim

ASP.NET Core MVC uses a different set of conventions from ASP.NET Web API 2. Using custom conventions, you can modify an ASP.NET Core MVC app's behavior to be consistent with that of a Web API app. Microsoft ships the WebApiCompatShim specifically for this purpose.

> **NOTE**
> Learn more about migration from ASP.NET Web API.

To use the Web API Compatibility Shim, you need to add the package to your project and then add the conventions to MVC by calling `AddWebApiConventions` in `Startup`:

```
services.AddMvc().AddWebApiConventions();
```

The conventions provided by the shim are only applied to parts of the app that have had certain attributes applied to them. The following four attributes are used to control which controllers should have their conventions modified by the shim's conventions:

- UseWebApiActionConventionsAttribute
- UseWebApiOverloadingAttribute
- UseWebApiParameterConventionsAttribute
- UseWebApiRoutesAttribute

Action Conventions

The `UseWebApiActionConventionsAttribute` is used to map the HTTP method to actions based on their name (for instance, `Get` would map to `HttpGet`). It only applies to actions that don't use attribute routing.

Overloading

The `UseWebApiOverloadingAttribute` is used to apply the `WebApiOverloadingApplicationModelConvention` convention. This convention adds an `OverloadActionConstraint` to the action selection process, which limits candidate actions to those for which the request satisfies all non-optional parameters.

Parameter Conventions

The `UseWebApiParameterConventionsAttribute` is used to apply the `WebApiParameterConventionsApplicationModelConvention` action convention. This convention specifies that simple types used as action parameters are bound from the URI by default, while complex types are bound from the request body.

Routes

The `UseWebApiRoutesAttribute` controls whether the `WebApiApplicationModelConvention` controller convention is applied. When enabled, this convention is used to add support for areas to the route.

In addition to a set of conventions, the compatibility package includes a `System.Web.Http.ApiController` base class that replaces the one provided by Web API. This allows your controllers written for Web API and inheriting from its `ApiController` to work as they were designed, while running on ASP.NET Core MVC. All of the `UseWebApi*` attributes listed earlier are applied to the base controller class. The `ApiController` exposes properties, methods, and result types that are compatible with those found in Web API.

Using ApiExplorer to Document Your App

The application model exposes an `ApiExplorer` property at each level that can be used to traverse the app's structure. This can be used to generate help pages for your Web APIs using tools like Swagger. The `ApiExplorer` property exposes an `IsVisible` property that can be set to specify which parts of your app's model should be exposed. You can configure this setting using a convention:

```
using Microsoft.AspNetCore.Mvc.ApplicationModels;

namespace AppModelSample.Conventions
{
    public class EnableApiExplorerApplicationConvention : IApplicationModelConvention
    {
        public void Apply(ApplicationModel application)
        {
            application.ApiExplorer.IsVisible = true;
        }
    }
}
```

Using this approach (and additional conventions if required), you can enable or disable API visibility at any level within your app.

Areas in ASP.NET Core

9/22/2020 • 14 minutes to read • Edit Online

By Dhananjay Kumar and Rick Anderson

Areas are an ASP.NET feature used to organize related functionality into a group as a separate:

- Namespace for routing.
- Folder structure for views and Razor Pages.

Using areas creates a hierarchy for the purpose of routing by adding another route parameter, `area`, to `controller` and `action` or a Razor Page `page`.

Areas provide a way to partition an ASP.NET Core Web app into smaller functional groups, each with its own set of Razor Pages, controllers, views, and models. An area is effectively a structure inside an app. In an ASP.NET Core web project, logical components like Pages, Model, Controller, and View are kept in different folders. The ASP.NET Core runtime uses naming conventions to create the relationship between these components. For a large app, it may be advantageous to partition the app into separate high level areas of functionality. For instance, an e-commerce app with multiple business units, such as checkout, billing, and search. Each of these units have their own area to contain views, controllers, Razor Pages, and models.

Consider using Areas in a project when:

- The app is made of multiple high-level functional components that can be logically separated.
- You want to partition the app so that each functional area can be worked on independently.

View or download sample code (how to download). The download sample provides a basic app for testing areas.

If you're using Razor Pages, see Areas with Razor Pages in this document.

Areas for controllers with views

A typical ASP.NET Core web app using areas, controllers, and views contains the following:

- An Area folder structure.
- Controllers with the `[Area]` attribute to associate the controller with the area:

```
[Area("Products")]
public class ManageController : Controller
{
```

- The area route added to startup:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(
        name: "MyArea",
        pattern: "{area:exists}/{controller=Home}/{action=Index}/{id?}");

    endpoints.MapControllerRoute(
        name: "default",
        pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

Area folder structure

Consider an app that has two logical groups, *Products* and *Services*. Using areas, the folder structure would be similar to the following:

- Project name
  - Areas
    - Products
      - Controllers
        - HomeController.cs
        - ManageController.cs
      - Views
        - Home
          - Index.cshtml
        - Manage
          - Index.cshtml
          - About.cshtml
    - Services
      - Controllers
        - HomeController.cs
      - Views
        - Home
          - Index.cshtml

While the preceding layout is typical when using Areas, only the view files are required to use this folder structure. View discovery searches for a matching area view file in the following order:

```
/Areas/<Area-Name>/Views/<Controller-Name>/<Action-Name>.cshtml
/Areas/<Area-Name>/Views/Shared/<Action-Name>.cshtml
/Views/Shared/<Action-Name>.cshtml
/Pages/Shared/<Action-Name>.cshtml
```

Associate the controller with an Area

Area controllers are designated with the [Area] attribute:

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.Docs.Samples;

namespace MVCareas.Areas.Products.Controllers
{
    [Area("Products")]
    public class ManageController : Controller
    {
        public IActionResult Index()
        {
            ViewData["routeInfo"] = ControllerContext.MyDisplayRouteInfo();
            return View();
        }

        public IActionResult About()
        {
            ViewData["routeInfo"] = ControllerContext.MyDisplayRouteInfo();
            return View();
        }
    }
}
```

Add Area route

Area routes typically use conventional routing rather than attribute routing. Conventional routing is order-dependent. In general, routes with areas should be placed earlier in the route table as they're more specific than routes without an area.

`{area:...}` can be used as a token in route templates if url space is uniform across all areas:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }
    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllerRoute(
            name: "MyArea",
            pattern: "{area:exists}/{controller=Home}/{action=Index}/{id?}");

        endpoints.MapControllerRoute(
            name: "default",
            pattern: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

In the preceding code, `exists` applies a constraint that the route must match an area. Using `{area:...}` with `MapControllerRoute`:

- Is the least complicated mechanism to adding routing to areas.

- Matches all controllers with the `[Area("Area name")]` attribute.

The following code uses MapAreaControllerRoute to create two named area routes:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }
    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapAreaControllerRoute(
            name: "MyAreaProducts",
            areaName: "Products",
            pattern: "Products/{controller=Home}/{action=Index}/{id?}");

        endpoints.MapAreaControllerRoute(
            name: "MyAreaServices",
            areaName: "Services",
            pattern: "Services/{controller=Home}/{action=Index}/{id?}");

        endpoints.MapControllerRoute(
            name: "default",
            pattern: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

For more information, see Area routing.

Link generation with MVC areas

The following code from the sample download shows link generation with the area specified:

```
<li>Anchor Tag Helper links</li>
<ul>
    <li>
        <a asp-area="Products" asp-controller="Home" asp-action="About">
            Products/Home/About
        </a>
    </li>
    <li>
        <a asp-area="Services" asp-controller="Home" asp-action="About">
            Services About
        </a>
    </li>
    <li>
        <a asp-area="" asp-controller="Home" asp-action="About">
            /Home/About
        </a>
    </li>
</ul>
<li>Html.ActionLink generated links</li>
<ul>
    <li>
        @Html.ActionLink("Product/Manage/About", "About", "Manage",
                                                 new { area = "Products" })
    </li>
</ul>
<li>Url.Action generated links</li>
<ul>
    <li>
        <a href='@Url.Action("About", "Manage", new { area = "Products" })'>
            Products/Manage/About
        </a>
    </li>
</ul>
```

The sample download includes a partial view that contains:

- The preceding links.
- Links similar to the preceding except `area` is not specified.

The partial view is referenced in the layout file, so every page in the app displays the generated links. The links generated without specifying the area are only valid when referenced from a page in the same area and controller.

When the area or controller is not specified, routing depends on the ambient values. The current route values of the current request are considered ambient values for link generation. In many cases for the sample app, using the ambient values generates incorrect links with the markup that doesn't specify the area.

For more information, see Routing to controller actions.

Shared layout for Areas using the _ViewStart.cshtml file

To share a common layout for the entire app, keep the *_ViewStart.cshtml* in the application root folder. For more information, see Layout in ASP.NET Core

Application root folder

The application root folder is the folder containing *Startup.cs* in web app created with the ASP.NET Core templates.

_ViewImports.cshtml

/Views/_ViewImports.cshtml, for MVC, and */Pages/_ViewImports.cshtml* for Razor Pages, is not imported to views in areas. Use one of the following approaches to provide view imports to all views:

- Add *_ViewImports.cshtml* to the application root folder. A *_ViewImports.cshtml* in the application root folder will apply to all views in the app.
- Copy the *_ViewImports.cshtml* file to the appropriate view folder under areas.

The *_ViewImports.cshtml* file typically contains Tag Helpers imports, `@using`, and `@inject` statements. For more information, see Importing Shared Directives.

Change default area folder where views are stored

The following code changes the default area folder from `"Areas"` to `"MyAreas"`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<RazorViewEngineOptions>(options =>
    {
        options.AreaViewLocationFormats.Clear();
        options.AreaViewLocationFormats.Add("/MyAreas/{2}/Views/{1}/{0}.cshtml");
        options.AreaViewLocationFormats.Add("/MyAreas/{2}/Views/Shared/{0}.cshtml");
        options.AreaViewLocationFormats.Add("/Views/Shared/{0}.cshtml");
    });

    services.AddControllersWithViews();
}
```

Areas with Razor Pages

Areas with Razor Pages require an `Areas/<area name>/Pages` folder in the root of the app. The following folder structure is used with the sample app:

- Project name
  - Areas
    - Products
      - Pages
        - _ViewImports
        - About
        - Index
    - Services
      - Pages
        - Manage
          - About
          - Index

Link generation with Razor Pages and areas

The following code from the sample download shows link generation with the area specified (for example, `asp-area="Products"`):

```
<li>Anchor Tag Helper links</li>
<ul>
    <li>
        <a asp-area="Products" asp-page="/About">
            Products/About
        </a>
    </li>
    <li>
        <a asp-area="Services" asp-page="/Manage/About">
            Services/Manage/About
        </a>
    </li>
    <li>
        <a asp-area="" asp-page="/About">
            /About
        </a>
    </li>
</ul>
<li>Url.Page generated links</li>
<ul>
    <li>
        <a href='@Url.Page("/Manage/About", new { area = "Services" })'>
            Services/Manage/About
        </a>
    </li>
    <li>
        <a href='@Url.Page("/About", new { area = "Products" })'>
            Products/About
        </a>
    </li>
</ul>
```

The sample download includes a partial view that contains the preceding links and the same links without specifying the area. The partial view is referenced in the layout file, so every page in the app displays the generated links. The links generated without specifying the area are only valid when referenced from a page in the same area.

When the area is not specified, routing depends on the *ambient* values. The current route values of the current request are considered ambient values for link generation. In many cases for the sample app, using the ambient values generates incorrect links. For example, consider the links generated from the following code:

```
<li>
    <a asp-page="/Manage/About">
        Services/Manage/About
    </a>
</li>
<li>
    <a asp-page="/About">
        /About
    </a>
</li>
```

For the preceding code:

- The link generated from `<a asp-page="/Manage/About">` is correct only when the last request was for a page in `Services` area. For example, `/Services/Manage/`, `/Services/Manage/Index`, or `/Services/Manage/About`.
- The link generated from `<a asp-page="/About">` is correct only when the last request was for a page in `/Home`.

- The code is from the sample download.

Import namespace and Tag Helpers with _ViewImports file

A *_ViewImports.cshtml* file can be added to each area *Pages* folder to import the namespace and Tag Helpers to each Razor Page in the folder.

Consider the *Services* area of the sample code, which doesn't contain a *_ViewImports.cshtml* file. The following markup shows the */Services/Manage/About* Razor Page:

```
@page
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@model RPareas.Areas.Services.Pages.Manage.AboutModel
@{
    ViewData["Title"] = "Srv Mng About";
}

<a asp-area="Products" asp-page="/Index">
    Products/Index
</a>
```

In the preceding markup:

- The fully qualified domain name must be used to specify the model (`@model RPareas.Areas.Services.Pages.Manage.AboutModel`).
- Tag Helpers are enabled by `@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers`

In the sample download, the Products area contains the following *_ViewImports.cshtml* file:

```
@namespace RPareas.Areas.Products.Pages
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
```

The following markup shows the */Products/About* Razor Page:

```
@page
@model AboutModel
@{
    ViewData["Title"] = "Prod About";
}
```

In the preceding file, the namespace and `@addTagHelper` directive is imported to the file by the *Areas/Products/Pages/_ViewImports.cshtml* file.

For more information, see Managing Tag Helper scope and Importing Shared Directives.

Shared layout for Razor Pages Areas

To share a common layout for the entire app, move the *_ViewStart.cshtml* to the application root folder.

Publishing Areas

All *.cshtml files and files within the *wwwroot* directory are published to output when `<Project Sdk="Microsoft.NET.Sdk.Web">` is included in the *.csproj file.

Areas are an ASP.NET feature used to organize related functionality into a group as a separate namespace (for routing) and folder structure (for views). Using areas creates a hierarchy for the purpose of routing by adding another route parameter, `area`, to `controller` and `action` or a Razor Page `page`.

Areas provide a way to partition an ASP.NET Core Web app into smaller functional groups, each with its own set of Razor Pages, controllers, views, and models. An area is effectively a structure inside an app. In an

ASP.NET Core web project, logical components like Pages, Model, Controller, and View are kept in different folders. The ASP.NET Core runtime uses naming conventions to create the relationship between these components. For a large app, it may be advantageous to partition the app into separate high level areas of functionality. For instance, an e-commerce app with multiple business units, such as checkout, billing, and search. Each of these units have their own area to contain views, controllers, Razor Pages, and models.

Consider using Areas in a project when:

- The app is made of multiple high-level functional components that can be logically separated.
- You want to partition the app so that each functional area can be worked on independently.

View or download sample code (how to download). The download sample provides a basic app for testing areas.

If you're using Razor Pages, see Areas with Razor Pages in this document.

Areas for controllers with views

A typical ASP.NET Core web app using areas, controllers, and views contains the following:

- An Area folder structure.
- Controllers with the `[Area]` attribute to associate the controller with the area:

```
[Area("Products")]
public class ManageController : Controller
{
```

- The area route added to startup:

```
app.UseMvc(routes =>
{
    routes.MapRoute(
      name: "MyArea",
      template: "{area:exists}/{controller=Home}/{action=Index}/{id?}");

    routes.MapRoute(
       name: "default",
       template: "{controller=Home}/{action=Index}/{id?}");
});
```

Area folder structure

Consider an app that has two logical groups, *Products* and *Services*. Using areas, the folder structure would be similar to the following:

- Project name
  - Areas
    - Products
      - Controllers
        - HomeController.cs
        - ManageController.cs
      - Views
        - Home
          - Index.cshtml
        - Manage

        - Index.cshtml
        - About.cshtml
    - Services
        - Controllers
            - HomeController.cs
        - Views
            - Home
                - Index.cshtml

While the preceding layout is typical when using Areas, only the view files are required to use this folder structure. View discovery searches for a matching area view file in the following order:

```
/Areas/<Area-Name>/Views/<Controller-Name>/<Action-Name>.cshtml
/Areas/<Area-Name>/Views/Shared/<Action-Name>.cshtml
/Views/Shared/<Action-Name>.cshtml
/Pages/Shared/<Action-Name>.cshtml
```

Associate the controller with an Area

Area controllers are designated with the [Area] attribute:

```
using Microsoft.AspNetCore.Mvc;

namespace MVCareas.Areas.Products.Controllers
{
    [Area("Products")]
    public class ManageController : Controller
    {
        public IActionResult Index()
        {
            return View();
        }

        public IActionResult About()
        {
            return View();
        }
    }
}
```

Add Area route

Area routes typically use conventional routing rather than attribute routing. Conventional routing is order-dependent. In general, routes with areas should be placed earlier in the route table as they're more specific than routes without an area.

`{area:...}` can be used as a token in route templates if url space is uniform across all areas:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseMvc(routes =>
    {
        routes.MapRoute(
          name: "MyArea",
          template: "{area:exists}/{controller=Home}/{action=Index}/{id?}");

        routes.MapRoute(
           name: "default",
           template: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

In the preceding code, `exists` applies a constraint that the route must match an area. Using `{area:...}` is the least complicated mechanism to adding routing to areas.

The following code uses MapAreaRoute to create two named area routes:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseMvc(routes =>
    {
        routes.MapAreaRoute(
            name: "MyAreaProducts",
            areaName:"Products",
            template: "Products/{controller=Home}/{action=Index}/{id?}");

        routes.MapAreaRoute(
            name: "MyAreaServices",
            areaName: "Services",
            template: "Services/{controller=Home}/{action=Index}/{id?}");

        routes.MapRoute(
           name: "default",
           template: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

When using `MapAreaRoute` with ASP.NET Core 2.2, see this GitHub issue.

For more information, see Area routing.

Link generation with MVC areas

The following code from the sample download shows link generation with the area specified:

```
<li>Anchor Tag Helper links</li>
<ul>
    <li>
        <a asp-area="Products" asp-controller="Home" asp-action="About">
            Products/Home/About
        </a>
    </li>
    <li>
        <a asp-area="Services" asp-controller="Home" asp-action="About">
            Services About
        </a>
    </li>
    <li>
        <a asp-area="" asp-controller="Home" asp-action="About">
            /Home/About
        </a>
    </li>
</ul>
<li>Html.ActionLink generated links</li>
<ul>
    <li>
        @Html.ActionLink("Product/Manage/About", "About", "Manage",
                                                 new { area = "Products" })
    </li>
</ul>
<li>Url.Action generated links</li>
<ul>
    <li>
        <a href='@Url.Action("About", "Manage", new { area = "Products" })'>
            Products/Manage/About
        </a>
    </li>
</ul>
```

The links generated with the preceding code are valid anywhere in the app.

The sample download includes a partial view that contains the preceding links and the same links without specifying the area. The partial view is referenced in the layout file, so every page in the app displays the generated links. The links generated without specifying the area are only valid when referenced from a page in the same area and controller.

When the area or controller is not specified, routing depends on the *ambient* values. The current route values of the current request are considered ambient values for link generation. In many cases for the sample app, using the ambient values generates incorrect links.

For more information, see Routing to controller actions.

Shared layout for Areas using the _ViewStart.cshtml file

To share a common layout for the entire app, move the *_ViewStart.cshtml* to the application root folder.

_ViewImports.cshtml

In its standard location, */Views/_ViewImports.cshtml* doesn't apply to areas. To use common Tag Helpers, `@using`, or `@inject` in your area, ensure a proper *_ViewImports.cshtml* file applies to your area views. If you want the same behavior in all your views, move */Views/_ViewImports.cshtml* to the application root.

Change default area folder where views are stored

The following code changes the default area folder from `"Areas"` to `"MyAreas"`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<RazorViewEngineOptions>(options =>
    {
        options.AreaViewLocationFormats.Clear();
        options.AreaViewLocationFormats.Add("/MyAreas/{2}/Views/{1}/{0}.cshtml");
        options.AreaViewLocationFormats.Add("/MyAreas/{2}/Views/Shared/{0}.cshtml");
        options.AreaViewLocationFormats.Add("/Views/Shared/{0}.cshtml");
    });

    services.AddMvc();
}
```

Areas with Razor Pages

Areas with Razor Pages require an `Areas/<area name>/Pages` folder in the root of the app. The following folder structure is used with the sample app:

- Project name
  - Areas
    - Products
      - Pages
        - _ViewImports
        - About
        - Index
    - Services
      - Pages
        - Manage
          - About
          - Index

Link generation with Razor Pages and areas

The following code from the sample download shows link generation with the area specified (for example, `asp-area="Products"`):

```
<li>Anchor Tag Helper links</li>
<ul>
    <li>
        <a asp-area="Products" asp-page="/About">
            Products/About
        </a>
    </li>
    <li>
        <a asp-area="Services" asp-page="/Manage/About">
            Services/Manage/About
        </a>
    </li>
    <li>
        <a asp-area="" asp-page="/About">
            /About
        </a>
    </li>
</ul>
<li>Url.Page generated links</li>
<ul>
    <li>
        <a href='@Url.Page("/Manage/About", new { area = "Services" })'>
            Services/Manage/About
        </a>
    </li>
    <li>
        <a href='@Url.Page("/About", new { area = "Products" })'>
            Products/About
        </a>
    </li>
</ul>
```

The links generated with the preceding code are valid anywhere in the app.

The sample download includes a partial view that contains the preceding links and the same links without specifying the area. The partial view is referenced in the layout file, so every page in the app displays the generated links. The links generated without specifying the area are only valid when referenced from a page in the same area.

When the area is not specified, routing depends on the *ambient* values. The current route values of the current request are considered ambient values for link generation. In many cases for the sample app, using the ambient values generates incorrect links. For example, consider the links generated from the following code:

```
<li>
    <a asp-page="/Manage/About">
        Services/Manage/About
    </a>
</li>
<li>
    <a asp-page="/About">
        /About
    </a>
</li>
```

For the preceding code:

- The link generated from `<a asp-page="/Manage/About">` is correct only when the last request was for a page in `Services` area. For example, `/Services/Manage/`, `/Services/Manage/Index`, or `/Services/Manage/About`.
- The link generated from `<a asp-page="/About">` is correct only when the last request was for a page in

`/Home`.

- The code is from the sample download.

Import namespace and Tag Helpers with _ViewImports file

A *_ViewImports.cshtml* file can be added to each area *Pages* folder to import the namespace and Tag Helpers to each Razor Page in the folder.

Consider the *Services* area of the sample code, which doesn't contain a *_ViewImports.cshtml* file. The following markup shows the */Services/Manage/About* Razor Page:

```
@page
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@model RPareas.Areas.Services.Pages.Manage.AboutModel
@{
    ViewData["Title"] = "Srv Mng About";
}

<h2>/Services/Manage/About</h2>

<a asp-area="Products" asp-page="/Index">
    Products/Index
</a>
```

In the preceding markup:

- The fully qualified domain name must be used to specify the model (`@model RPareas.Areas.Services.Pages.Manage.AboutModel`).
- Tag Helpers are enabled by `@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers`

In the sample download, the Products area contains the following *_ViewImports.cshtml* file:

```
@namespace RPareas.Areas.Products.Pages
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
```

The following markup shows the */Products/About* Razor Page:

```
@page
@model AboutModel
@{
    ViewData["Title"] = "Prod About";
}

<h2>Products/About</h2>

<a asp-area="Services" asp-page="/Manage/About">
    Services/Manage/About
</a>
```

In the preceding file, the namespace and `@addTagHelper` directive is imported to the file by the *Areas/Products/Pages/_ViewImports.cshtml* file.

For more information, see Managing Tag Helper scope and Importing Shared Directives.

Shared layout for Razor Pages Areas

To share a common layout for the entire app, move the *_ViewStart.cshtml* to the application root folder.

Publishing Areas

All *.cshtml files and files within the *wwwroot* directory are published to output when

`<Project Sdk="Microsoft.NET.Sdk.Web">` is included in the *.csproj file.

Filters in ASP.NET Core

9/22/2020 • 44 minutes to read • Edit Online

By Kirk Larkin, Rick Anderson, Tom Dykstra, and Steve Smith

Filters in ASP.NET Core allow code to be run before or after specific stages in the request processing pipeline.

Built-in filters handle tasks such as:

- Authorization (preventing access to resources a user isn't authorized for).
- Response caching (short-circuiting the request pipeline to return a cached response).

Custom filters can be created to handle cross-cutting concerns. Examples of cross-cutting concerns include error handling, caching, configuration, authorization, and logging. Filters avoid duplicating code. For example, an error handling exception filter could consolidate error handling.

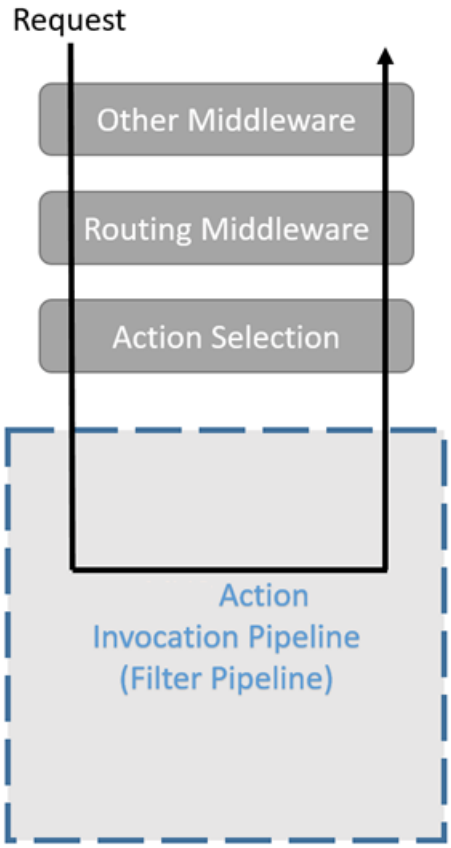
This document applies to Razor Pages, API controllers, and controllers with views. Filters don't work directly with Razor components. A filter can only indirectly affect a component when:

- The component is embedded in a page or view.
- The page or controller/view uses the filter.

View or download sample (how to download).

How filters work

Filters run within the *ASP.NET Core action invocation pipeline*, sometimes referred to as the *filter pipeline*. The filter pipeline runs after ASP.NET Core selects the action to execute.

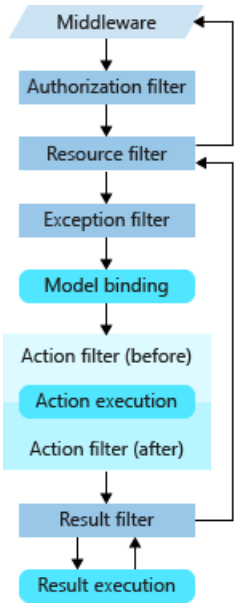


Filter types

Each filter type is executed at a different stage in the filter pipeline:

- Authorization filters run first and are used to determine whether the user is authorized for the request. Authorization filters short-circuit the pipeline if the request is not authorized.
- Resource filters:
  - Run after authorization.
  - OnResourceExecuting runs code before the rest of the filter pipeline. For example, `OnResourceExecuting` runs code before model binding.
  - OnResourceExecuted runs code after the rest of the pipeline has completed.
- Action filters:
  - Run code immediately before and after an action method is called.
  - Can change the arguments passed into an action.
  - Can change the result returned from the action.
  - Are **not** supported in Razor Pages.
- Exception filters apply global policies to unhandled exceptions that occur before the response body has been written to.
- Result filters run code immediately before and after the execution of action results. They run only when the action method has executed successfully. They are useful for logic that must surround view or formatter execution.

The following diagram shows how filter types interact in the filter pipeline.



Implementation

Filters support both synchronous and asynchronous implementations through different interface definitions.

Synchronous filters run code before and after their pipeline stage. For example, OnActionExecuting is called before the action method is called. OnActionExecuted is called after the action method returns.

```
public class MySampleActionFilter : IActionFilter
{
    public void OnActionExecuting(ActionExecutingContext context)
    {
        // Do something before the action executes.
        MyDebug.Write(MethodBase.GetCurrentMethod(), context.HttpContext.Request.Path);
    }

    public void OnActionExecuted(ActionExecutedContext context)
    {
        // Do something after the action executes.
        MyDebug.Write(MethodBase.GetCurrentMethod(), context.HttpContext.Request.Path);
    }
}
```

In the preceding code, MyDebug is a utility function in the sample download.

Asynchronous filters define an `On-Stage-ExecutionAsync` method. For example, OnActionExecutionAsync:

```
public class SampleAsyncActionFilter : IAsyncActionFilter
{
    public async Task OnActionExecutionAsync(
        ActionExecutingContext context,
        ActionExecutionDelegate next)
    {
        // Do something before the action executes.

        // next() calls the action method.
        var resultContext = await next();
        // resultContext.Result is set.
        // Do something after the action executes.
    }
}
```

In the preceding code, the `SampleAsyncActionFilter` has an ActionExecutionDelegate (`next`) that executes the action method.

Multiple filter stages

Interfaces for multiple filter stages can be implemented in a single class. For example, the ActionFilterAttribute class implements:

- Synchronous: IActionFilter and IResultFilter
- Asynchronous: IAsyncActionFilter and IAsyncResultFilter
- IOrderedFilter

Implement **either** the synchronous or the async version of a filter interface, **not** both. The runtime checks first to see if the filter implements the async interface, and if so, it calls that. If not, it calls the synchronous interface's method(s). If both asynchronous and synchronous interfaces are implemented in one class, only the async method is called. When using abstract classes like ActionFilterAttribute, override only the synchronous methods or the asynchronous methods for each filter type.

Built-in filter attributes

ASP.NET Core includes built-in attribute-based filters that can be subclassed and customized. For example, the following result filter adds a header to the response:

```
public class AddHeaderAttribute : ResultFilterAttribute
{
    private readonly string _name;
    private readonly string _value;

    public AddHeaderAttribute(string name, string value)
    {
        _name = name;
        _value = value;
    }

    public override void OnResultExecuting(ResultExecutingContext context)
    {
        context.HttpContext.Response.Headers.Add( _name, new string[] { _value });
        base.OnResultExecuting(context);
    }
}
```

Attributes allow filters to accept arguments, as shown in the preceding example. Apply the `AddHeaderAttribute` to a controller or action method and specify the name and value of the HTTP header:

```
[AddHeader("Author", "Rick Anderson")]
public class SampleController : Controller
{
    public IActionResult Index()
    {
        return Content("Examine the headers using the F12 developer tools.");
    }
```

Use a tool such as the browser developer tools to examine the headers. Under **Response Headers**, `author: Rick Anderson` is displayed.

The following code implements an `ActionFilterAttribute` that:

- Reads the title and name from the configuration system. Unlike the previous sample, the following code doesn't require filter parameters to be added to the code.
- Adds the title and name to the response header.

```
public class MyActionFilterAttribute : ActionFilterAttribute
{
    private readonly PositionOptions _settings;

    public MyActionFilterAttribute(IOptions<PositionOptions> options)
    {
        _settings = options.Value;
        Order = 1;
    }

    public override void OnResultExecuting(ResultExecutingContext context)
    {
        context.HttpContext.Response.Headers.Add(_settings.Title,
                                                 new string[] { _settings.Name });
        base.OnResultExecuting(context);
    }
}
```

The configuration options are provided from the configuration system using the options pattern. For example, from the *appsettings.json* file:

```
{
  "Position": {
    "Title": "Editor",
    "Name": "Joe Smith"
  },
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*"
}
```

In the `StartUp.ConfigureServices`:

- The `PositionOptions` class is added to the service container with the `"Position"` configuration area.
- The `MyActionFilterAttribute` is added to the service container.

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<PositionOptions>(
             Configuration.GetSection("Position"));
    services.AddScoped<MyActionFilterAttribute>();

    services.AddControllersWithViews();
}
```

The following code shows the `PositionOptions` class:

```
public class PositionOptions
{
    public string Title { get; set; }
    public string Name { get; set; }
}
```

The following code applies the `MyActionFilterAttribute` to the `Index2` method:

```
[AddHeader("Author", "Rick Anderson")]
public class SampleController : Controller
{
    public IActionResult Index()
    {
        return Content("Examine the headers using the F12 developer tools.");
    }

    [ServiceFilter(typeof(MyActionFilterAttribute))]
    public IActionResult Index2()
    {
        return Content("Header values by configuration.");
    }
```

Under **Response Headers**, `author: Rick Anderson`, and `Editor: Joe Smith` is displayed when the `Sample/Index2` endpoint is called.

The following code applies the `MyActionFilterAttribute` and the `AddHeaderAttribute` to the Razor Page:

```
[AddHeader("Author", "Rick Anderson")]
[ServiceFilter(typeof(MyActionFilterAttribute))]
public class IndexModel : PageModel
{
    public void OnGet()
    {
    }
}
```

Filters cannot be applied to Razor Page handler methods. They can be applied either to the Razor Page model or globally.

Several of the filter interfaces have corresponding attributes that can be used as base classes for custom implementations.

Filter attributes:

- ActionFilterAttribute
- ExceptionFilterAttribute
- ResultFilterAttribute
- FormatFilterAttribute
- ServiceFilterAttribute
- TypeFilterAttribute

Filter scopes and order of execution

A filter can be added to the pipeline at one of three *scopes*:

- Using an attribute on a controller action. Filter attributes cannot be applied to Razor Pages handler methods.
- Using an attribute on a controller or Razor Page.
- Globally for all controllers, actions, and Razor Pages as shown in the following code:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews(options =>
   {
        options.Filters.Add(typeof(MySampleActionFilter));
    });
}
```

Default order of execution

When there are multiple filters for a particular stage of the pipeline, scope determines the default order of filter execution. Global filters surround class filters, which in turn surround method filters.

As a result of filter nesting, the *after* code of filters runs in the reverse order of the *before* code. The filter sequence:

- The *before* code of global filters.
  - The *before* code of controller and Razor Page filters.
    - The *before* code of action method filters.
    - The *after* code of action method filters.
  - The *after* code of controller and Razor Page filters.
- The *after* code of global filters.

The following example that illustrates the order in which filter methods are called for synchronous action filters.

SEQUENCE	FILTER SCOPE	FILTER METHOD
1	Global	`OnActionExecuting`
2	Controller or Razor Page	`OnActionExecuting`
3	Method	`OnActionExecuting`
4	Method	`OnActionExecuted`
5	Controller or Razor Page	`OnActionExecuted`
6	Global	`OnActionExecuted`

Controller level filters

Every controller that inherits from the Controller base class includes Controller.OnActionExecuting, Controller.OnActionExecutionAsync, and Controller.OnActionExecuted `OnActionExecuted` methods. These methods:

- Wrap the filters that run for a given action.
- `OnActionExecuting` is called before any of the action's filters.
- `OnActionExecuted` is called after all of the action filters.
- `OnActionExecutionAsync` is called before any of the action's filters. Code in the filter after `next` runs after the action method.

For example, in the download sample, `MySampleActionFilter` is applied globally in startup.

The `TestController`:

- Applies the `SampleActionFilterAttribute` (`[SampleActionFilter]`) to the `FilterTest2` action.
- Overrides `OnActionExecuting` and `OnActionExecuted`.

```
public class TestController : Controller
{
    [SampleActionFilter(Order = int.MinValue)]
    public IActionResult FilterTest2()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    public override void OnActionExecuting(ActionExecutingContext context)
    {
        // Do something before the action executes.
        MyDebug.Write(MethodBase.GetCurrentMethod(), HttpContext.Request.Path);
        base.OnActionExecuting(context);
    }

    public override void OnActionExecuted(ActionExecutedContext context)
    {
        // Do something after the action executes.
        MyDebug.Write(MethodBase.GetCurrentMethod(), HttpContext.Request.Path);
        base.OnActionExecuted(context);
    }
}
```

MyDisplayRouteInfo is provided by the Rick.Docs.Samples.RouteInfo NuGet package and displays route information.

Navigating to `https://localhost:5001/Test2/FilterTest2` runs the following code:

- `TestController.OnActionExecuting`
  - `MySampleActionFilter.OnActionExecuting`
    - `SampleActionFilterAttribute.OnActionExecuting`
      - `TestController.FilterTest2`
    - `SampleActionFilterAttribute.OnActionExecuted`
  - `MySampleActionFilter.OnActionExecuted`
- `TestController.OnActionExecuted`

Controller level filters set the Order property to `int.MinValue`. Controller level filters can **not** be set to run after filters applied to methods. Order is explained in the next section.

For Razor Pages, see Implement Razor Page filters by overriding filter methods.

Overriding the default order

The default sequence of execution can be overridden by implementing IOrderedFilter. `IOrderedFilter` exposes the Order property that takes precedence over scope to determine the order of execution. A filter with a lower `Order` value:

- Runs the *before* code before that of a filter with a higher value of `Order`.
- Runs the *after* code after that of a filter with a higher `Order` value.

The `Order` property is set with a constructor parameter:

```
[SampleActionFilter(Order = int.MinValue)]
```

Consider the two action filters in the following controller:

```
[MyAction2Filter]
public class Test2Controller : Controller
{
    public IActionResult FilterTest2()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    public override void OnActionExecuting(ActionExecutingContext context)
    {
        // Do something before the action executes.
        MyDebug.Write(MethodBase.GetCurrentMethod(), HttpContext.Request.Path);
        base.OnActionExecuting(context);
    }

    public override void OnActionExecuted(ActionExecutedContext context)
    {
        // Do something after the action executes.
        MyDebug.Write(MethodBase.GetCurrentMethod(), HttpContext.Request.Path);
        base.OnActionExecuted(context);
    }
}
```

A global filter is added in `StartUp.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews(options =>
   {
        options.Filters.Add(typeof(MySampleActionFilter));
    });
}
```

The 3 filters run in the following order:

- `Test2Controller.OnActionExecuting`
  - `MySampleActionFilter.OnActionExecuting`
    - `MyAction2FilterAttribute.OnActionExecuting`
      - `Test2Controller.FilterTest2`
    - `MySampleActionFilter.OnActionExecuted`
  - `MyAction2FilterAttribute.OnResultExecuting`
- `Test2Controller.OnActionExecuted`

The `Order` property overrides scope when determining the order in which filters run. Filters are sorted first by order, then scope is used to break ties. All of the built-in filters implement `IOrderedFilter` and set the default `Order` value to 0. As mentioned previously, controller level filters set the Order property to `int.MinValue` For built-in filters, scope determines order unless `Order` is set to a non-zero value.

In the preceding code, `MySampleActionFilter` has global scope so it runs before `MyAction2FilterAttribute`, which has controller scope. To make `MyAction2FilterAttribute` run first, set the order to `int.MinValue`:

```
[MyAction2Filter(int.MinValue)]
public class Test2Controller : Controller
{
    public IActionResult FilterTest2()
    {
        return ControllerContext.MyDisplayRouteInfo();
    }

    public override void OnActionExecuting(ActionExecutingContext context)
    {
        // Do something before the action executes.
        MyDebug.Write(MethodBase.GetCurrentMethod(), HttpContext.Request.Path);
        base.OnActionExecuting(context);
    }

    public override void OnActionExecuted(ActionExecutedContext context)
    {
        // Do something after the action executes.
        MyDebug.Write(MethodBase.GetCurrentMethod(), HttpContext.Request.Path);
        base.OnActionExecuted(context);
    }
}
```

To make the global filter `MySampleActionFilter` run first, set `Order` to `int.MinValue`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews(options =>
   {
        options.Filters.Add(typeof(MySampleActionFilter),
                            int.MinValue);
    });
}
```

Cancellation and short-circuiting

The filter pipeline can be short-circuited by setting the Result property on the ResourceExecutingContext parameter provided to the filter method. For instance, the following Resource filter prevents the rest of the pipeline from executing:

```
public class ShortCircuitingResourceFilterAttribute : Attribute, IResourceFilter
{
    public void OnResourceExecuting(ResourceExecutingContext context)
    {
        context.Result = new ContentResult()
        {
            Content = "Resource unavailable - header not set."
        };
    }

    public void OnResourceExecuted(ResourceExecutedContext context)
    {
    }
}
```

In the following code, both the `ShortCircuitingResourceFilter` and the `AddHeader` filter target the `SomeResource` action method. The `ShortCircuitingResourceFilter`:

- Runs first, because it's a Resource Filter and `AddHeader` is an Action Filter.
- Short-circuits the rest of the pipeline.

Therefore the `AddHeader` filter never runs for the `SomeResource` action. This behavior would be the same if both filters were applied at the action method level, provided the `ShortCircuitingResourceFilter` ran first. The `ShortCircuitingResourceFilter` runs first because of its filter type, or by explicit use of `Order` property.

```
[AddHeader("Author", "Rick Anderson")]
public class SampleController : Controller
{
    public IActionResult Index()
    {
        return Content("Examine the headers using the F12 developer tools.");
    }
```

Dependency injection

Filters can be added by type or by instance. If an instance is added, that instance is used for every request. If a type is added, it's type-activated. A type-activated filter means:

- An instance is created for each request.
- Any constructor dependencies are populated by dependency injection (DI).

Filters that are implemented as attributes and added directly to controller classes or action methods cannot have constructor dependencies provided by dependency injection (DI). Constructor dependencies cannot be provided by DI because:

- Attributes must have their constructor parameters supplied where they're applied.
- This is a limitation of how attributes work.

The following filters support constructor dependencies provided from DI:

- ServiceFilterAttribute
- TypeFilterAttribute
- IFilterFactory implemented on the attribute.

The preceding filters can be applied to a controller or action method:

Loggers are available from DI. However, avoid creating and using filters purely for logging purposes. The built-in framework logging typically provides what's needed for logging. Logging added to filters:

- Should focus on business domain concerns or behavior specific to the filter.
- Should **not** log actions or other framework events. The built-in filters log actions and framework events.

ServiceFilterAttribute

Service filter implementation types are registered in `ConfigureServices`. A ServiceFilterAttribute retrieves an instance of the filter from DI.

The following code shows the `AddHeaderResultServiceFilter`:

```
public class AddHeaderResultServiceFilter : IResultFilter
{
    private ILogger _logger;
    public AddHeaderResultServiceFilter(ILoggerFactory loggerFactory)
    {
        _logger = loggerFactory.CreateLogger<AddHeaderResultServiceFilter>();
    }

    public void OnResultExecuting(ResultExecutingContext context)
    {
        var headerName = "OnResultExecuting";
        context.HttpContext.Response.Headers.Add(
            headerName, new string[] { "ResultExecutingSuccessfully" });
        _logger.LogInformation("Header added: {HeaderName}", headerName);
    }

    public void OnResultExecuted(ResultExecutedContext context)
    {
        // Can't add to headers here because response has started.
        _logger.LogInformation("AddHeaderResultServiceFilter.OnResultExecuted");
    }
}
```

In the following code, `AddHeaderResultServiceFilter` is added to the DI container:

```
public void ConfigureServices(IServiceCollection services)
{
    // Add service filters.
    services.AddScoped<AddHeaderResultServiceFilter>();
    services.AddScoped<SampleActionFilterAttribute>();

    services.AddControllersWithViews(options =>
   {
        options.Filters.Add(new AddHeaderAttribute("GlobalAddHeader",
            "Result filter added to MvcOptions.Filters"));         // An instance
        options.Filters.Add(typeof(MySampleActionFilter));         // By type
        options.Filters.Add(new SampleGlobalActionFilter());       // An instance
    });
}
```

In the following code, the `ServiceFilter` attribute retrieves an instance of the `AddHeaderResultServiceFilter` filter from DI:

```
[ServiceFilter(typeof(AddHeaderResultServiceFilter))]
public IActionResult Index()
{
    return View();
}
```

When using `ServiceFilterAttribute`, setting ServiceFilterAttribute.IsReusable:

- Provides a hint that the filter instance *may* be reused outside of the request scope it was created within. The ASP.NET Core runtime doesn't guarantee:
  - That a single instance of the filter will be created.
  - The filter will not be re-requested from the DI container at some later point.
- Should not be used with a filter that depends on services with a lifetime other than singleton.

ServiceFilterAttribute implements IFilterFactory. `IFilterFactory` exposes the CreateInstance method for creating an IFilterMetadata instance. `CreateInstance` loads the specified type from DI.

TypeFilterAttribute

TypeFilterAttribute is similar to ServiceFilterAttribute, but its type isn't resolved directly from the DI container. It instantiates the type by using Microsoft.Extensions.DependencyInjection.ObjectFactory.

Because `TypeFilterAttribute` types aren't resolved directly from the DI container:

- Types that are referenced using the `TypeFilterAttribute` don't need to be registered with the DI container. They do have their dependencies fulfilled by the DI container.
- `TypeFilterAttribute` can optionally accept constructor arguments for the type.

When using `TypeFilterAttribute`, setting TypeFilterAttribute.IsReusable:

- Provides hint that the filter instance *may* be reused outside of the request scope it was created within. The ASP.NET Core runtime provides no guarantees that a single instance of the filter will be created.
- Should not be used with a filter that depends on services with a lifetime other than singleton.

The following example shows how to pass arguments to a type using `TypeFilterAttribute`:

```
[TypeFilter(typeof(LogConstantFilter),
    Arguments = new object[] { "Method 'Hi' called" })]
public IActionResult Hi(string name)
{
    return Content($"Hi {name}");
}
```

Authorization filters

Authorization filters:

- Are the first filters run in the filter pipeline.
- Control access to action methods.
- Have a before method, but no after method.

Custom authorization filters require a custom authorization framework. Prefer configuring the authorization policies or writing a custom authorization policy over writing a custom filter. The built-in authorization filter:

- Calls the authorization system.
- Does not authorize requests.

Do **not** throw exceptions within authorization filters:

- The exception will not be handled.
- Exception filters will not handle the exception.

Consider issuing a challenge when an exception occurs in an authorization filter.

Learn more about Authorization.

Resource filters

Resource filters:

- Implement either the IResourceFilter or IAsyncResourceFilter interface.
- Execution wraps most of the filter pipeline.
- Only Authorization filters run before resource filters.

Resource filters are useful to short-circuit most of the pipeline. For example, a caching filter can avoid the rest

of the pipeline on a cache hit.

Resource filter examples:

- The short-circuiting resource filter shown previously.
- DisableFormValueModelBindingAttribute:
  - Prevents model binding from accessing the form data.
  - Used for large file uploads to prevent the form data from being read into memory.

Action filters

Action filters do **not** apply to Razor Pages. Razor Pages supports IPageFilter and IAsyncPageFilter . For more information, see Filter methods for Razor Pages.

Action filters:

- Implement either the IActionFilter or IAsyncActionFilter interface.
- Their execution surrounds the execution of action methods.

The following code shows a sample action filter:

```
public class MySampleActionFilter : IActionFilter
{
    public void OnActionExecuting(ActionExecutingContext context)
    {
        // Do something before the action executes.
        MyDebug.Write(MethodBase.GetCurrentMethod(), context.HttpContext.Request.Path);
    }

    public void OnActionExecuted(ActionExecutedContext context)
    {
        // Do something after the action executes.
        MyDebug.Write(MethodBase.GetCurrentMethod(), context.HttpContext.Request.Path);
    }
}
```

The ActionExecutingContext provides the following properties:

- ActionArguments - enables reading the inputs to an action method.
- Controller - enables manipulating the controller instance.
- Result - setting `Result` short-circuits execution of the action method and subsequent action filters.

Throwing an exception in an action method:

- Prevents running of subsequent filters.
- Unlike setting `Result`, is treated as a failure instead of a successful result.

The ActionExecutedContext provides `Controller` and `Result` plus the following properties:

- Canceled - True if the action execution was short-circuited by another filter.
- Exception - Non-null if the action or a previously run action filter threw an exception. Setting this property to null:
  - Effectively handles the exception.
  - `Result` is executed as if it was returned from the action method.

For an `IAsyncActionFilter`, a call to the ActionExecutionDelegate:

- Executes any subsequent action filters and the action method.
- Returns `ActionExecutedContext`.

To short-circuit, assign Microsoft.AspNetCore.Mvc.Filters.ActionExecutingContext.Result to a result instance and don't call `next` (the `ActionExecutionDelegate`).

The framework provides an abstract ActionFilterAttribute that can be subclassed.

The `OnActionExecuting` action filter can be used to:

- Validate model state.
- Return an error if the state is invalid.

```
public class ValidateModelAttribute : ActionFilterAttribute
{
    public override void OnActionExecuting(ActionExecutingContext
                                           context)
    {
        if (!context.ModelState.IsValid)
        {
            context.Result = new BadRequestObjectResult(
                                                context.ModelState);
        }
    }
```

> **NOTE**
> Controllers annotated with the `[ApiController]` attribute automatically validate model state and return a 400 response. For more information, see Automatic HTTP 400 responses.

The `OnActionExecuted` method runs after the action method:

- And can see and manipulate the results of the action through the Result property.
- Canceled is set to true if the action execution was short-circuited by another filter.
- Exception is set to a non-null value if the action or a subsequent action filter threw an exception. Setting `Exception` to null:
  - Effectively handles an exception.
  - `ActionExecutedContext.Result` is executed as if it were returned normally from the action method.

```
public class ValidateModelAttribute : ActionFilterAttribute
{
    public override void OnActionExecuting(ActionExecutingContext
                                           context)
    {
        if (!context.ModelState.IsValid)
        {
            context.Result = new BadRequestObjectResult(
                                                context.ModelState);
        }
    }

    public override void OnActionExecuted(ActionExecutedContext
                                          context)
    {
        var result = context.Result;
        // Do something with Result.
        if (context.Canceled == true)
        {
            // Action execution was short-circuited by another filter.
        }

        if(context.Exception != null)
        {
            // Exception thrown by action or action filter.
            // Set to null to handle the exception.
            context.Exception = null;
        }
        base.OnActionExecuted(context);
    }
}
```

Exception filters

Exception filters:

- Implement IExceptionFilter or IAsyncExceptionFilter.
- Can be used to implement common error handling policies.

The following sample exception filter uses a custom error view to display details about exceptions that occur when the app is in development:

```
public class CustomExceptionFilter : IExceptionFilter
{
    private readonly IWebHostEnvironment _hostingEnvironment;
    private readonly IModelMetadataProvider _modelMetadataProvider;

    public CustomExceptionFilter(
        IWebHostEnvironment hostingEnvironment,
        IModelMetadataProvider modelMetadataProvider)
    {
        _hostingEnvironment = hostingEnvironment;
        _modelMetadataProvider = modelMetadataProvider;
    }

    public void OnException(ExceptionContext context)
    {
        if (!_hostingEnvironment.IsDevelopment())
        {
            return;
        }
        var result = new ViewResult {ViewName = "CustomError"};
        result.ViewData = new ViewDataDictionary(_modelMetadataProvider,
                                                 context.ModelState);
        result.ViewData.Add("Exception", context.Exception);
        // TODO: Pass additional detailed data via ViewData
        context.Result = result;
    }
}
```

The following code tests the exception filter:

```
[TypeFilter(typeof(CustomExceptionFilter))]
public class FailingController : Controller
{
    [AddHeader("Failing Controller",
               "Won't appear when exception is handled")]
    public IActionResult Index()
    {
        throw new Exception("Testing custom exception filter.");
    }
}
```

Exception filters:

- Don't have before and after events.
- Implement OnException or OnExceptionAsync.
- Handle unhandled exceptions that occur in Razor Page or controller creation, model binding, action filters, or action methods.
- Do **not** catch exceptions that occur in resource filters, result filters, or MVC result execution.

To handle an exception, set the ExceptionHandled property to `true` or write a response. This stops propagation of the exception. An exception filter can't turn an exception into a "success". Only an action filter can do that.

Exception filters:

- Are good for trapping exceptions that occur within actions.
- Are not as flexible as error handling middleware.

Prefer middleware for exception handling. Use exception filters only where error handling *differs* based on which action method is called. For example, an app might have action methods for both API endpoints and for views/HTML. The API endpoints could return error information as JSON, while the view-based actions could

return an error page as HTML.

Result filters

Result filters:

- Implement an interface:
  - IResultFilter or IAsyncResultFilter
  - IAlwaysRunResultFilter or IAsyncAlwaysRunResultFilter
- Their execution surrounds the execution of action results.

IResultFilter and IAsyncResultFilter

The following code shows a result filter that adds an HTTP header:

```
public class AddHeaderResultServiceFilter : IResultFilter
{
    private ILogger _logger;
    public AddHeaderResultServiceFilter(ILoggerFactory loggerFactory)
    {
        _logger = loggerFactory.CreateLogger<AddHeaderResultServiceFilter>();
    }

    public void OnResultExecuting(ResultExecutingContext context)
    {
        var headerName = "OnResultExecuting";
        context.HttpContext.Response.Headers.Add(
            headerName, new string[] { "ResultExecutingSuccessfully" });
        _logger.LogInformation("Header added: {HeaderName}", headerName);
    }

    public void OnResultExecuted(ResultExecutedContext context)
    {
        // Can't add to headers here because response has started.
        _logger.LogInformation("AddHeaderResultServiceFilter.OnResultExecuted");
    }
}
```

The kind of result being executed depends on the action. An action returning a view includes all razor processing as part of the ViewResult being executed. An API method might perform some serialization as part of the execution of the result. Learn more about action results.

Result filters are only executed when an action or action filter produces an action result. Result filters are not executed when:

- An authorization filter or resource filter short-circuits the pipeline.
- An exception filter handles an exception by producing an action result.

The Microsoft.AspNetCore.Mvc.Filters.IResultFilter.OnResultExecuting method can short-circuit execution of the action result and subsequent result filters by setting Microsoft.AspNetCore.Mvc.Filters.ResultExecutingContext.Cancel to `true`. Write to the response object when short-circuiting to avoid generating an empty response. Throwing an exception in `IResultFilter.OnResultExecuting`:

- Prevents execution of the action result and subsequent filters.
- Is treated as a failure instead of a successful result.

When the Microsoft.AspNetCore.Mvc.Filters.IResultFilter.OnResultExecuted method runs, the response has probably already been sent to the client. If the response has already been sent to the client, it cannot be changed.

`ResultExecutedContext.Canceled` is set to `true` if the action result execution was short-circuited by another filter.

`ResultExecutedContext.Exception` is set to a non-null value if the action result or a subsequent result filter threw an exception. Setting `Exception` to null effectively handles an exception and prevents the exception from being thrown again later in the pipeline. There is no reliable way to write data to a response when handling an exception in a result filter. If the headers have been flushed to the client when an action result throws an exception, there's no reliable mechanism to send a failure code.

For an IAsyncResultFilter, a call to `await next` on the ResultExecutionDelegate executes any subsequent result filters and the action result. To short-circuit, set ResultExecutingContext.Cancel to `true` and don't call the `ResultExecutionDelegate`:

```
public class MyAsyncResponseFilter : IAsyncResultFilter
{
    public async Task OnResultExecutionAsync(ResultExecutingContext context,
                                             ResultExecutionDelegate next)
    {
        if (!(context.Result is EmptyResult))
        {
            await next();
        }
        else
        {
            context.Cancel = true;
        }

    }
}
```

The framework provides an abstract `ResultFilterAttribute` that can be subclassed. The AddHeaderAttribute class shown previously is an example of a result filter attribute.

IAlwaysRunResultFilter and IAsyncAlwaysRunResultFilter

The IAlwaysRunResultFilter and IAsyncAlwaysRunResultFilter interfaces declare an IResultFilter implementation that runs for all action results. This includes action results produced by:

- Authorization filters and resource filters that short-circuit.
- Exception filters.

For example, the following filter always runs and sets an action result (ObjectResult) with a *422 Unprocessable Entity* status code when content negotiation fails:

```
public class UnprocessableResultFilter : Attribute, IAlwaysRunResultFilter
{
    public void OnResultExecuting(ResultExecutingContext context)
    {
        if (context.Result is StatusCodeResult statusCodeResult &&
            statusCodeResult.StatusCode == 415)
        {
            context.Result = new ObjectResult("Can't process this!")
            {
                StatusCode = 422,
            };
        }
    }

    public void OnResultExecuted(ResultExecutedContext context)
    {
    }
}
```

IFilterFactory

IFilterFactory implements IFilterMetadata. Therefore, an `IFilterFactory` instance can be used as an `IFilterMetadata` instance anywhere in the filter pipeline. When the runtime prepares to invoke the filter, it attempts to cast it to an `IFilterFactory`. If that cast succeeds, the CreateInstance method is called to create the `IFilterMetadata` instance that is invoked. This provides a flexible design, since the precise filter pipeline doesn't need to be set explicitly when the app starts.

`IFilterFactory` can be implemented using custom attribute implementations as another approach to creating filters:

```
public class AddHeaderWithFactoryAttribute : Attribute, IFilterFactory
{
    // Implement IFilterFactory
    public IFilterMetadata CreateInstance(IServiceProvider serviceProvider)
    {
        return new InternalAddHeaderFilter();
    }

    private class InternalAddHeaderFilter : IResultFilter
    {
        public void OnResultExecuting(ResultExecutingContext context)
        {
            context.HttpContext.Response.Headers.Add(
                "Internal", new string[] { "My header" });
        }

        public void OnResultExecuted(ResultExecutedContext context)
        {
        }
    }

    public bool IsReusable
    {
        get
        {
            return false;
        }
    }
}
```

The filter is applied in the following code:

```
[AddHeader("Author", "Rick Anderson")]
public class SampleController : Controller
{
    public IActionResult Index()
    {
        return Content("Examine the headers using the F12 developer tools.");
    }

    [ServiceFilter(typeof(MyActionFilterAttribute))]
    public IActionResult Index2()
    {
        return Content("Header values by configuration.");
    }

    [ShortCircuitingResourceFilter]
    public IActionResult SomeResource()
    {
        return Content("Successful access to resource - header is set.");
    }

    [AddHeaderWithFactory]
    public IActionResult HeaderWithFactory()
    {
        return Content("Examine the headers using the F12 developer tools.");
    }
}
```

Test the preceding code by running the download sample:

- Invoke the F12 developer tools.
- Navigate to `https://localhost:5001/Sample/HeaderWithFactory`.

The F12 developer tools display the following response headers added by the sample code:

- **author:** `Rick Anderson`
- **globaladdheader:** `Result filter added to MvcOptions.Filters`
- **internal:** `My header`

The preceding code creates the **internal:** `My header` response header.

IFilterFactory implemented on an attribute

Filters that implement `IFilterFactory` are useful for filters that:

- Don't require passing parameters.
- Have constructor dependencies that need to be filled by DI.

TypeFilterAttribute implements IFilterFactory. `IFilterFactory` exposes the CreateInstance method for creating an IFilterMetadata instance. `CreateInstance` loads the specified type from the services container (DI).

```
public class SampleActionFilterAttribute : TypeFilterAttribute
{
    public SampleActionFilterAttribute()
                        :base(typeof(SampleActionFilterImpl))
    {
    }

    private class SampleActionFilterImpl : IActionFilter
    {
        private readonly ILogger _logger;
        public SampleActionFilterImpl(ILoggerFactory loggerFactory)
        {
            _logger = loggerFactory.CreateLogger<SampleActionFilterAttribute>();
        }

        public void OnActionExecuting(ActionExecutingContext context)
        {
           _logger.LogInformation("SampleActionFilterAttribute.OnActionExecuting");
        }

        public void OnActionExecuted(ActionExecutedContext context)
        {
            _logger.LogInformation("SampleActionFilterAttribute.OnActionExecuted");
        }
    }
}
```

The following code shows three approaches to applying the `[SampleActionFilter]`:

```
[SampleActionFilter]
public IActionResult FilterTest()
{
    return Content("From FilterTest");
}

[TypeFilter(typeof(SampleActionFilterAttribute))]
public IActionResult TypeFilterTest()
{
    return Content("From TypeFilterTest");
}

// ServiceFilter must be registered in ConfigureServices or
// System.InvalidOperationException: No service for type '<filter>'
// has been registered. Is thrown.
[ServiceFilter(typeof(SampleActionFilterAttribute))]
public IActionResult ServiceFilterTest()
{
    return Content("From ServiceFilterTest");
}
```

In the preceding code, decorating the method with `[SampleActionFilter]` is the preferred approach to applying the `SampleActionFilter`.

Using middleware in the filter pipeline

Resource filters work like middleware in that they surround the execution of everything that comes later in the pipeline. But filters differ from middleware in that they're part of the runtime, which means that they have access to context and constructs.

To use middleware as a filter, create a type with a `Configure` method that specifies the middleware to inject into the filter pipeline. The following example uses the localization middleware to establish the current culture for a request:

```
public class LocalizationPipeline
{
    public void Configure(IApplicationBuilder applicationBuilder)
    {
        var supportedCultures = new[]
        {
            new CultureInfo("en-US"),
            new CultureInfo("fr")
        };

        var options = new RequestLocalizationOptions
        {
            DefaultRequestCulture = new RequestCulture(
                                    culture: "en-US",
                                    uiCulture: "en-US"),
            SupportedCultures = supportedCultures,
            SupportedUICultures = supportedCultures
        };
        options.RequestCultureProviders = new[]
            { new RouteDataRequestCultureProvider() {
                Options = options } };

        applicationBuilder.UseRequestLocalization(options);
    }
}
```

Use the MiddlewareFilterAttribute to run the middleware:

```
[Route("{culture}/[controller]/[action]")]
[MiddlewareFilter(typeof(LocalizationPipeline))]
public IActionResult CultureFromRouteData()
{
    return Content(
          $"CurrentCulture:{CultureInfo.CurrentCulture.Name},"
        + $"CurrentUICulture:{CultureInfo.CurrentUICulture.Name}");
}
```

Middleware filters run at the same stage of the filter pipeline as Resource filters, before model binding and after the rest of the pipeline.

Next actions

- See Filter methods for Razor Pages.
- To experiment with filters, download, test, and modify the GitHub sample.

By Kirk Larkin, Rick Anderson, Tom Dykstra, and Steve Smith

Filters in ASP.NET Core allow code to be run before or after specific stages in the request processing pipeline.

Built-in filters handle tasks such as:

- Authorization (preventing access to resources a user isn't authorized for).
- Response caching (short-circuiting the request pipeline to return a cached response).

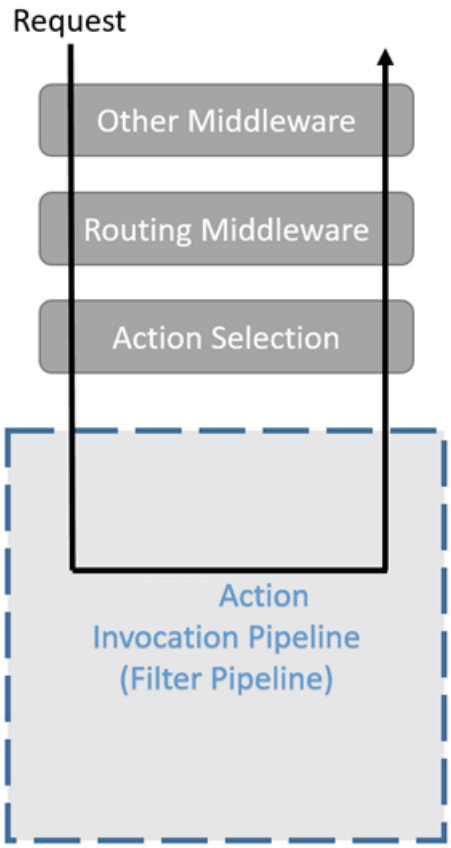
Custom filters can be created to handle cross-cutting concerns. Examples of cross-cutting concerns include error handling, caching, configuration, authorization, and logging. Filters avoid duplicating code. For example, an error handling exception filter could consolidate error handling.

This document applies to Razor Pages, API controllers, and controllers with views.

View or download sample (how to download).

How filters work

Filters run within the *ASP.NET Core action invocation pipeline*, sometimes referred to as the *filter pipeline*. The filter pipeline runs after ASP.NET Core selects the action to execute.

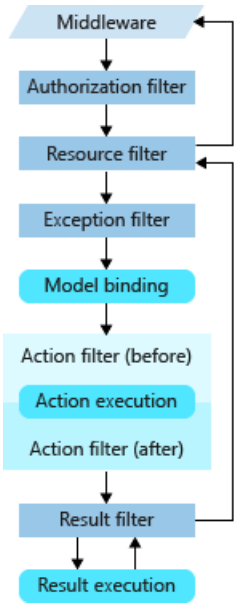


Filter types

Each filter type is executed at a different stage in the filter pipeline:

- Authorization filters run first and are used to determine whether the user is authorized for the request. Authorization filters short-circuit the pipeline if the request is unauthorized.
- Resource filters:
  - Run after authorization.
  - OnResourceExecuting can run code before the rest of the filter pipeline. For example, `OnResourceExecuting` can run code before model binding.
  - OnResourceExecuted can run code after the rest of the pipeline has completed.
- Action filters can run code immediately before and after an individual action method is called. They can be used to manipulate the arguments passed into an action and the result returned from the action. Action filters are **not** supported in Razor Pages.
- Exception filters are used to apply global policies to unhandled exceptions that occur before anything has been written to the response body.
- Result filters can run code immediately before and after the execution of individual action results. They run only when the action method has executed successfully. They are useful for logic that must surround view or formatter execution.

The following diagram shows how filter types interact in the filter pipeline.



Implementation

Filters support both synchronous and asynchronous implementations through different interface definitions.

Synchronous filters can run code before (`On-Stage-Executing`) and after (`On-Stage-Executed`) their pipeline stage. For example, `OnActionExecuting` is called before the action method is called. `OnActionExecuted` is called after the action method returns.

```
public class MySampleActionFilter : IActionFilter
{
    public void OnActionExecuting(ActionExecutingContext context)
    {
        // Do something before the action executes.
    }

    public void OnActionExecuted(ActionExecutedContext context)
    {
        // Do something after the action executes.
    }
}
```

Asynchronous filters define an `On-Stage-ExecutionAsync` method:

```
public class SampleAsyncActionFilter : IAsyncActionFilter
{
    public async Task OnActionExecutionAsync(
        ActionExecutingContext context,
        ActionExecutionDelegate next)
    {
        // Do something before the action executes.

        // next() calls the action method.
        var resultContext = await next();
        // resultContext.Result is set.
        // Do something after the action executes.
    }
}
```

In the preceding code, the `SampleAsyncActionFilter` has an ActionExecutionDelegate (`next`) that executes the action method. Each of the `On-Stage-ExecutionAsync` methods take a `FilterType-ExecutionDelegate` that executes the filter's pipeline stage.

Multiple filter stages

Interfaces for multiple filter stages can be implemented in a single class. For example, the ActionFilterAttribute class implements `IActionFilter`, `IResultFilter`, and their async equivalents.

Implement **either** the synchronous or the async version of a filter interface, **not** both. The runtime checks first to see if the filter implements the async interface, and if so, it calls that. If not, it calls the synchronous interface's method(s). If both asynchronous and synchronous interfaces are implemented in one class, only the async method is called. When using abstract classes like ActionFilterAttribute override only the synchronous methods or the async method for each filter type.

Built-in filter attributes

ASP.NET Core includes built-in attribute-based filters that can be subclassed and customized. For example, the following result filter adds a header to the response:

```
public class AddHeaderAttribute : ResultFilterAttribute
{
    private readonly string _name;
    private readonly string _value;

    public AddHeaderAttribute(string name, string value)
    {
        _name = name;
        _value = value;
    }

    public override void OnResultExecuting(ResultExecutingContext context)
    {
        context.HttpContext.Response.Headers.Add( _name, new string[] { _value });
        base.OnResultExecuting(context);
    }
}
```

Attributes allow filters to accept arguments, as shown in the preceding example. Apply the `AddHeaderAttribute` to a controller or action method and specify the name and value of the HTTP header:

```
[AddHeader("Author", "Joe Smith")]
public class SampleController : Controller
{
    public IActionResult Index()
    {
        return Content("Examine the headers using the F12 developer tools.");
    }

    [ShortCircuitingResourceFilter]
    public IActionResult SomeResource()
    {
        return Content("Successful access to resource - header is set.");
    }
```

Several of the filter interfaces have corresponding attributes that can be used as base classes for custom implementations.

Filter attributes:

- ActionFilterAttribute
- ExceptionFilterAttribute
- ResultFilterAttribute
- FormatFilterAttribute
- ServiceFilterAttribute

- TypeFilterAttribute

Filter scopes and order of execution

A filter can be added to the pipeline at one of three *scopes*:

- Using an attribute on an action.
- Using an attribute on a controller.
- Globally for all controllers and actions as shown in the following code:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc(options =>
    {
        options.Filters.Add(new AddHeaderAttribute("GlobalAddHeader",
            "Result filter added to MvcOptions.Filters"));         // An instance
        options.Filters.Add(typeof(MySampleActionFilter));         // By type
        options.Filters.Add(new SampleGlobalActionFilter());       // An instance
    }).SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

The preceding code adds three filters globally using the MvcOptions.Filters collection.

Default order of execution

When there are multiple filters *of the same type*, scope determines the default order of filter execution. Global filters surround class filters. Class filters surround method filters.

As a result of filter nesting, the *after* code of filters runs in the reverse order of the *before* code. The filter sequence:

- The *before* code of global filters.
  - The *before* code of controller filters.
    - The *before* code of action method filters.
    - The *after* code of action method filters.
  - The *after* code of controller filters.
- The *after* code of global filters.

The following example that illustrates the order in which filter methods are called for synchronous action filters.

SEQUENCE	FILTER SCOPE	FILTER METHOD
1	Global	`OnActionExecuting`
2	Controller	`OnActionExecuting`
3	Method	`OnActionExecuting`
4	Method	`OnActionExecuted`
5	Controller	`OnActionExecuted`
6	Global	`OnActionExecuted`

This sequence shows:

- The method filter is nested within the controller filter.
- The controller filter is nested within the global filter.

Controller and Razor Page level filters

Every controller that inherits from the Controller base class includes Controller.OnActionExecuting, Controller.OnActionExecutionAsync, and Controller.OnActionExecuted `OnActionExecuted` methods. These methods:

- Wrap the filters that run for a given action.
- `OnActionExecuting` is called before any of the action's filters.
- `OnActionExecuted` is called after all of the action filters.
- `OnActionExecutionAsync` is called before any of the action's filters. Code in the filter after `next` runs after the action method.

For example, in the download sample, `MySampleActionFilter` is applied globally in startup.

The `TestController`:

- Applies the `SampleActionFilterAttribute` (`[SampleActionFilter]`) to the `FilterTest2` action.
- Overrides `OnActionExecuting` and `OnActionExecuted`.

```
public class TestController : Controller
{
    [SampleActionFilter]
    public IActionResult FilterTest2()
    {
        return Content($"From FilterTest2");
    }

    public override void OnActionExecuting(ActionExecutingContext context)
    {
        // Do something before the action executes.
        base.OnActionExecuting(context);
    }

    public override void OnActionExecuted(ActionExecutedContext context)
    {
        // Do something after the action executes.
        base.OnActionExecuted(context);
    }
}
```

Navigating to `https://localhost:5001/Test/FilterTest2` runs the following code:

- `TestController.OnActionExecuting`
  - `MySampleActionFilter.OnActionExecuting`
    - `SampleActionFilterAttribute.OnActionExecuting`
      - `TestController.FilterTest2`
    - `SampleActionFilterAttribute.OnActionExecuted`
  - `MySampleActionFilter.OnActionExecuted`
- `TestController.OnActionExecuted`

For Razor Pages, see Implement Razor Page filters by overriding filter methods.

Overriding the default order

The default sequence of execution can be overridden by implementing IOrderedFilter. `IOrderedFilter` exposes the Order property that takes precedence over scope to determine the order of execution. A filter with a lower

`Order` value:

- Runs the *before* code before that of a filter with a higher value of `Order`.
- Runs the *after* code after that of a filter with a higher `Order` value.

The `Order` property can be set with a constructor parameter:

```
[MyFilter(Name = "Controller Level Attribute", Order=1)]
```

Consider the same 3 action filters shown in the preceding example. If the `Order` property of the controller and global filters is set to 1 and 2 respectively, the order of execution is reversed.

SEQUENCE	FILTER SCOPE	`ORDER` PROPERTY	FILTER METHOD
1	Method	0	`OnActionExecuting`
2	Controller	1	`OnActionExecuting`
3	Global	2	`OnActionExecuting`
4	Global	2	`OnActionExecuted`
5	Controller	1	`OnActionExecuted`
6	Method	0	`OnActionExecuted`

The `Order` property overrides scope when determining the order in which filters run. Filters are sorted first by order, then scope is used to break ties. All of the built-in filters implement `IOrderedFilter` and set the default `Order` value to 0. For built-in filters, scope determines order unless `Order` is set to a non-zero value.

Cancellation and short-circuiting

The filter pipeline can be short-circuited by setting the Result property on the ResourceExecutingContext parameter provided to the filter method. For instance, the following Resource filter prevents the rest of the pipeline from executing:

```
public class ShortCircuitingResourceFilterAttribute : Attribute, IResourceFilter
{
    public void OnResourceExecuting(ResourceExecutingContext context)
    {
        context.Result = new ContentResult()
        {
            Content = "Resource unavailable - header not set."
        };
    }

    public void OnResourceExecuted(ResourceExecutedContext context)
    {
    }
}
```

In the following code, both the `ShortCircuitingResourceFilter` and the `AddHeader` filter target the `SomeResource` action method. The `ShortCircuitingResourceFilter`:

- Runs first, because it's a Resource Filter and `AddHeader` is an Action Filter.

- Short-circuits the rest of the pipeline.

Therefore the `AddHeader` filter never runs for the `SomeResource` action. This behavior would be the same if both filters were applied at the action method level, provided the `ShortCircuitingResourceFilter` ran first. The `ShortCircuitingResourceFilter` runs first because of its filter type, or by explicit use of `Order` property.

```
[AddHeader("Author", "Joe Smith")]
public class SampleController : Controller
{
    public IActionResult Index()
    {
        return Content("Examine the headers using the F12 developer tools.");
    }

    [ShortCircuitingResourceFilter]
    public IActionResult SomeResource()
    {
        return Content("Successful access to resource - header is set.");
    }
```

Dependency injection

Filters can be added by type or by instance. If an instance is added, that instance is used for every request. If a type is added, it's type-activated. A type-activated filter means:

- An instance is created for each request.
- Any constructor dependencies are populated by dependency injection (DI).

Filters that are implemented as attributes and added directly to controller classes or action methods cannot have constructor dependencies provided by dependency injection (DI). Constructor dependencies cannot be provided by DI because:

- Attributes must have their constructor parameters supplied where they're applied.
- This is a limitation of how attributes work.

The following filters support constructor dependencies provided from DI:

- ServiceFilterAttribute
- TypeFilterAttribute
- IFilterFactory implemented on the attribute.

The preceding filters can be applied to a controller or action method:

Loggers are available from DI. However, avoid creating and using filters purely for logging purposes. The built-in framework logging typically provides what's needed for logging. Logging added to filters:

- Should focus on business domain concerns or behavior specific to the filter.
- Should **not** log actions or other framework events. The built in filters log actions and framework events.

ServiceFilterAttribute

Service filter implementation types are registered in `ConfigureServices`. A ServiceFilterAttribute retrieves an instance of the filter from DI.

The following code shows the `AddHeaderResultServiceFilter`:

```
public class AddHeaderResultServiceFilter : IResultFilter
{
    private ILogger _logger;
    public AddHeaderResultServiceFilter(ILoggerFactory loggerFactory)
    {
        _logger = loggerFactory.CreateLogger<AddHeaderResultServiceFilter>();
    }

    public void OnResultExecuting(ResultExecutingContext context)
    {
        var headerName = "OnResultExecuting";
        context.HttpContext.Response.Headers.Add(
            headerName, new string[] { "ResultExecutingSuccessfully" });
        _logger.LogInformation("Header added: {HeaderName}", headerName);
    }

    public void OnResultExecuted(ResultExecutedContext context)
    {
        // Can't add to headers here because response has started.
    }
}
```

In the following code, `AddHeaderResultServiceFilter` is added to the DI container:

```
public void ConfigureServices(IServiceCollection services)
{
    // Add service filters.
    services.AddScoped<AddHeaderResultServiceFilter>();
    services.AddScoped<SampleActionFilterAttribute>();

    services.AddMvc(options =>
    {
        options.Filters.Add(new AddHeaderAttribute("GlobalAddHeader",
            "Result filter added to MvcOptions.Filters"));         // An instance
        options.Filters.Add(typeof(MySampleActionFilter));         // By type
        options.Filters.Add(new SampleGlobalActionFilter());       // An instance
    }).SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

In the following code, the `ServiceFilter` attribute retrieves an instance of the `AddHeaderResultServiceFilter` filter from DI:

```
[ServiceFilter(typeof(AddHeaderResultServiceFilter))]
public IActionResult Index()
{
    return View();
}
```

When using `ServiceFilterAttribute`, setting ServiceFilterAttribute.IsReusable:

- Provides a hint that the filter instance *may* be reused outside of the request scope it was created within. The ASP.NET Core runtime doesn't guarantee:
  - That a single instance of the filter will be created.
  - The filter will not be re-requested from the DI container at some later point.
- Should not be used with a filter that depends on services with a lifetime other than singleton.

ServiceFilterAttribute implements IFilterFactory. `IFilterFactory` exposes the CreateInstance method for creating an IFilterMetadata instance. `CreateInstance` loads the specified type from DI.

TypeFilterAttribute

TypeFilterAttribute is similar to ServiceFilterAttribute, but its type isn't resolved directly from the DI container. It instantiates the type by using Microsoft.Extensions.DependencyInjection.ObjectFactory.

Because `TypeFilterAttribute` types aren't resolved directly from the DI container:

- Types that are referenced using the `TypeFilterAttribute` don't need to be registered with the DI container. They do have their dependencies fulfilled by the DI container.
- `TypeFilterAttribute` can optionally accept constructor arguments for the type.

When using `TypeFilterAttribute`, setting TypeFilterAttribute.IsReusable:

- Provides hint that the filter instance *may* be reused outside of the request scope it was created within. The ASP.NET Core runtime provides no guarantees that a single instance of the filter will be created.
- Should not be used with a filter that depends on services with a lifetime other than singleton.

The following example shows how to pass arguments to a type using `TypeFilterAttribute`:

```
[TypeFilter(typeof(LogConstantFilter),
    Arguments = new object[] { "Method 'Hi' called" })]
public IActionResult Hi(string name)
{
    return Content($"Hi {name}");
}
```

```
public class LogConstantFilter : IActionFilter
{
    private readonly string _value;
    private readonly ILogger<LogConstantFilter> _logger;

    public LogConstantFilter(string value, ILogger<LogConstantFilter> logger)
    {
        _logger = logger;
        _value = value;
    }

    public void OnActionExecuting(ActionExecutingContext context)
    {
        _logger.LogInformation(_value);
    }

    public void OnActionExecuted(ActionExecutedContext context)
    { }
}
```

Authorization filters

Authorization filters:

- Are the first filters run in the filter pipeline.
- Control access to action methods.
- Have a before method, but no after method.

Custom authorization filters require a custom authorization framework. Prefer configuring the authorization policies or writing a custom authorization policy over writing a custom filter. The built-in authorization filter:

- Calls the authorization system.
- Does not authorize requests.

Do **not** throw exceptions within authorization filters:

- The exception will not be handled.
- Exception filters will not handle the exception.

Consider issuing a challenge when an exception occurs in an authorization filter.

Learn more about Authorization.

Resource filters

Resource filters:

- Implement either the IResourceFilter or IAsyncResourceFilter interface.
- Execution wraps most of the filter pipeline.
- Only Authorization filters run before resource filters.

Resource filters are useful to short-circuit most of the pipeline. For example, a caching filter can avoid the rest of the pipeline on a cache hit.

Resource filter examples:

- The short-circuiting resource filter shown previously.
- DisableFormValueModelBindingAttribute:
  - Prevents model binding from accessing the form data.
  - Used for large file uploads to prevent the form data from being read into memory.

Action filters

> **IMPORTANT**
> Action filters do **not** apply to Razor Pages. Razor Pages supports IPageFilter and IAsyncPageFilter . For more information, see Filter methods for Razor Pages.

Action filters:

- Implement either the IActionFilter or IAsyncActionFilter interface.
- Their execution surrounds the execution of action methods.

The following code shows a sample action filter:

```
public class MySampleActionFilter : IActionFilter
{
    public void OnActionExecuting(ActionExecutingContext context)
    {
        // Do something before the action executes.
    }

    public void OnActionExecuted(ActionExecutedContext context)
    {
        // Do something after the action executes.
    }
}
```

The ActionExecutingContext provides the following properties:

- ActionArguments - enables the inputs to an action method be read.
- Controller - enables manipulating the controller instance.
- Result - setting `Result` short-circuits execution of the action method and subsequent action filters.

Throwing an exception in an action method:

- Prevents running of subsequent filters.
- Unlike setting `Result`, is treated as a failure instead of a successful result.

The ActionExecutedContext provides `Controller` and `Result` plus the following properties:

- Canceled - True if the action execution was short-circuited by another filter.
- Exception - Non-null if the action or a previously run action filter threw an exception. Setting this property to null:
  - Effectively handles the exception.
  - `Result` is executed as if it was returned from the action method.

For an `IAsyncActionFilter`, a call to the ActionExecutionDelegate:

- Executes any subsequent action filters and the action method.
- Returns `ActionExecutedContext`.

To short-circuit, assign Microsoft.AspNetCore.Mvc.Filters.ActionExecutingContext.Result to a result instance and don't call `next` (the `ActionExecutionDelegate`).

The framework provides an abstract ActionFilterAttribute that can be subclassed.

The `OnActionExecuting` action filter can be used to:

- Validate model state.
- Return an error if the state is invalid.

```
public class ValidateModelAttribute : ActionFilterAttribute
{
    public override void OnActionExecuting(ActionExecutingContext context)
    {
        if (!context.ModelState.IsValid)
        {
            context.Result = new BadRequestObjectResult(context.ModelState);
        }
    }
```

The `OnActionExecuted` method runs after the action method:

- And can see and manipulate the results of the action through the Result property.
- Canceled is set to true if the action execution was short-circuited by another filter.
- Exception is set to a non-null value if the action or a subsequent action filter threw an exception. Setting `Exception` to null:
  - Effectively handles an exception.
  - `ActionExecutedContext.Result` is executed as if it were returned normally from the action method.

```
public class ValidateModelAttribute : ActionFilterAttribute
{
    public override void OnActionExecuting(ActionExecutingContext context)
    {
        if (!context.ModelState.IsValid)
        {
            context.Result = new BadRequestObjectResult(context.ModelState);
        }
    }

    public override void OnActionExecuted(ActionExecutedContext context)
    {
        var result = context.Result;
        // Do something with Result.
        if (context.Canceled == true)
        {
            // Action execution was short-circuited by another filter.
        }

        if(context.Exception != null)
        {
            // Exception thrown by action or action filter.
            // Set to null to handle the exception.
            context.Exception = null;
        }
        base.OnActionExecuted(context);
    }
}
```

Exception filters

Exception filters:

- Implement IExceptionFilter or IAsyncExceptionFilter.
- Can be used to implement common error handling policies.

The following sample exception filter uses a custom error view to display details about exceptions that occur when the app is in development:

```
public class CustomExceptionFilter : IExceptionFilter
{
    private readonly IHostingEnvironment _hostingEnvironment;
    private readonly IModelMetadataProvider _modelMetadataProvider;

    public CustomExceptionFilter(
        IHostingEnvironment hostingEnvironment,
        IModelMetadataProvider modelMetadataProvider)
    {
        _hostingEnvironment = hostingEnvironment;
        _modelMetadataProvider = modelMetadataProvider;
    }

    public void OnException(ExceptionContext context)
    {
        if (!_hostingEnvironment.IsDevelopment())
        {
            return;
        }
        var result = new ViewResult {ViewName = "CustomError"};
        result.ViewData = new ViewDataDictionary(_modelMetadataProvider,
                                                 context.ModelState);
        result.ViewData.Add("Exception", context.Exception);
        // TODO: Pass additional detailed data via ViewData
        context.Result = result;
    }
}
```

Exception filters:

- Don't have before and after events.
- Implement OnException or OnExceptionAsync.
- Handle unhandled exceptions that occur in Razor Page or controller creation, model binding, action filters, or action methods.
- Do **not** catch exceptions that occur in resource filters, result filters, or MVC result execution.

To handle an exception, set the ExceptionHandled property to `true` or write a response. This stops propagation of the exception. An exception filter can't turn an exception into a "success". Only an action filter can do that.

Exception filters:

- Are good for trapping exceptions that occur within actions.
- Are not as flexible as error handling middleware.

Prefer middleware for exception handling. Use exception filters only where error handling *differs* based on which action method is called. For example, an app might have action methods for both API endpoints and for views/HTML. The API endpoints could return error information as JSON, while the view-based actions could return an error page as HTML.

Result filters

Result filters:

- Implement an interface:
  - IResultFilter or IAsyncResultFilter
  - IAlwaysRunResultFilter or IAsyncAlwaysRunResultFilter
- Their execution surrounds the execution of action results.

IResultFilter and IAsyncResultFilter

The following code shows a result filter that adds an HTTP header:

```
public class AddHeaderResultServiceFilter : IResultFilter
{
    private ILogger _logger;
    public AddHeaderResultServiceFilter(ILoggerFactory loggerFactory)
    {
        _logger = loggerFactory.CreateLogger<AddHeaderResultServiceFilter>();
    }

    public void OnResultExecuting(ResultExecutingContext context)
    {
        var headerName = "OnResultExecuting";
        context.HttpContext.Response.Headers.Add(
            headerName, new string[] { "ResultExecutingSuccessfully" });
        _logger.LogInformation("Header added: {HeaderName}", headerName);
    }

    public void OnResultExecuted(ResultExecutedContext context)
    {
        // Can't add to headers here because response has started.
    }
}
```

The kind of result being executed depends on the action. An action returning a view would include all razor processing as part of the ViewResult being executed. An API method might perform some serialization as part of the execution of the result. Learn more about action results.

Result filters are only executed when an action or action filter produces an action result. Result filters are not executed when:

- An authorization filter or resource filter short-circuits the pipeline.
- An exception filter handles an exception by producing an action result.

The Microsoft.AspNetCore.Mvc.Filters.IResultFilter.OnResultExecuting method can short-circuit execution of the action result and subsequent result filters by setting Microsoft.AspNetCore.Mvc.Filters.ResultExecutingContext.Cancel to `true`. Write to the response object when short-circuiting to avoid generating an empty response. Throwing an exception in `IResultFilter.OnResultExecuting` will:

- Prevent execution of the action result and subsequent filters.
- Be treated as a failure instead of a successful result.

When the Microsoft.AspNetCore.Mvc.Filters.IResultFilter.OnResultExecuted method runs, the response has likely already been sent to the client. If the response has already been sent to the client, it cannot be changed further.

`ResultExecutedContext.Canceled` is set to `true` if the action result execution was short-circuited by another filter.

`ResultExecutedContext.Exception` is set to a non-null value if the action result or a subsequent result filter threw an exception. Setting `Exception` to null effectively handles an exception and prevents the exception from being rethrown by ASP.NET Core later in the pipeline. There is no reliable way to write data to a response when handling an exception in a result filter. If the headers have been flushed to the client when an action result throws an exception, there's no reliable mechanism to send a failure code.

For an IAsyncResultFilter, a call to `await next` on the ResultExecutionDelegate executes any subsequent result filters and the action result. To short-circuit, set ResultExecutingContext.Cancel to `true` and don't call the `ResultExecutionDelegate`:

```
public class MyAsyncResponseFilter : IAsyncResultFilter
{
    public async Task OnResultExecutionAsync(ResultExecutingContext context,
                                             ResultExecutionDelegate next)
    {
        if (!(context.Result is EmptyResult))
        {
            await next();
        }
        else
        {
            context.Cancel = true;
        }

    }
}
```

The framework provides an abstract `ResultFilterAttribute` that can be subclassed. The AddHeaderAttribute class shown previously is an example of a result filter attribute.

IAlwaysRunResultFilter and IAsyncAlwaysRunResultFilter

The IAlwaysRunResultFilter and IAsyncAlwaysRunResultFilter interfaces declare an IResultFilter implementation that runs for all action results. This includes action results produced by:

- Authorization filters and resource filters that short-circuit.
- Exception filters.

For example, the following filter always runs and sets an action result (ObjectResult) with a *422 Unprocessable Entity* status code when content negotiation fails:

```
public class UnprocessableResultFilter : Attribute, IAlwaysRunResultFilter
{
    public void OnResultExecuting(ResultExecutingContext context)
    {
        if (context.Result is StatusCodeResult statusCodeResult &&
            statusCodeResult.StatusCode == 415)
        {
            context.Result = new ObjectResult("Can't process this!")
            {
                StatusCode = 422,
            };
        }
    }

    public void OnResultExecuted(ResultExecutedContext context)
    {
    }
}
```

IFilterFactory

IFilterFactory implements IFilterMetadata. Therefore, an `IFilterFactory` instance can be used as an `IFilterMetadata` instance anywhere in the filter pipeline. When the runtime prepares to invoke the filter, it attempts to cast it to an `IFilterFactory`. If that cast succeeds, the CreateInstance method is called to create the `IFilterMetadata` instance that is invoked. This provides a flexible design, since the precise filter pipeline doesn't need to be set explicitly when the app starts.

`IFilterFactory` can be implemented using custom attribute implementations as another approach to creating filters:

```
public class AddHeaderWithFactoryAttribute : Attribute, IFilterFactory
{
    // Implement IFilterFactory
    public IFilterMetadata CreateInstance(IServiceProvider serviceProvider)
    {
        return new InternalAddHeaderFilter();
    }

    private class InternalAddHeaderFilter : IResultFilter
    {
        public void OnResultExecuting(ResultExecutingContext context)
        {
            context.HttpContext.Response.Headers.Add(
                "Internal", new string[] { "My header" });
        }

        public void OnResultExecuted(ResultExecutedContext context)
        {
        }
    }

    public bool IsReusable
    {
        get
        {
            return false;
        }
    }
}
```

The preceding code can be tested by running the download sample:

- Invoke the F12 developer tools.
- Navigate to `https://localhost:5001/Sample/HeaderWithFactory`.

The F12 developer tools display the following response headers added by the sample code:

- **author:** `Joe Smith`
- **globaladdheader:** `Result filter added to MvcOptions.Filters`
- **internal:** `My header`

The preceding code creates the **internal:** `My header` response header.

IFilterFactory implemented on an attribute

Filters that implement `IFilterFactory` are useful for filters that:

- Don't require passing parameters.
- Have constructor dependencies that need to be filled by DI.

TypeFilterAttribute implements IFilterFactory. `IFilterFactory` exposes the CreateInstance method for creating an IFilterMetadata instance. `CreateInstance` loads the specified type from the services container (DI).

```
public class SampleActionFilterAttribute : TypeFilterAttribute
{
    public SampleActionFilterAttribute():base(typeof(SampleActionFilterImpl))
    {
    }

    private class SampleActionFilterImpl : IActionFilter
    {
        private readonly ILogger _logger;
        public SampleActionFilterImpl(ILoggerFactory loggerFactory)
        {
            _logger = loggerFactory.CreateLogger<SampleActionFilterAttribute>();
        }

        public void OnActionExecuting(ActionExecutingContext context)
        {
            _logger.LogInformation("Business action starting...");
            // perform some business logic work

        }

        public void OnActionExecuted(ActionExecutedContext context)
        {
            // perform some business logic work
            _logger.LogInformation("Business action completed.");
        }
    }
}
```

The following code shows three approaches to applying the `[SampleActionFilter]`:

```
[SampleActionFilter]
public IActionResult FilterTest()
{
    return Content($"From FilterTest");
}

[TypeFilter(typeof(SampleActionFilterAttribute))]
public IActionResult TypeFilterTest()
{
    return Content($"From ServiceFilterTest");
}

// ServiceFilter must be registered in ConfigureServices or
// System.InvalidOperationException: No service for type '<filter>' has been registered.
// Is thrown.
[ServiceFilter(typeof(SampleActionFilterAttribute))]
public IActionResult ServiceFilterTest()
{
    return Content($"From ServiceFilterTest");
}
```

In the preceding code, decorating the method with `[SampleActionFilter]` is the preferred approach to applying the `SampleActionFilter`.

Using middleware in the filter pipeline

Resource filters work like middleware in that they surround the execution of everything that comes later in the pipeline. But filters differ from middleware in that they're part of the ASP.NET Core runtime, which means that they have access to ASP.NET Core context and constructs.

To use middleware as a filter, create a type with a `Configure` method that specifies the middleware to inject

into the filter pipeline. The following example uses the localization middleware to establish the current culture for a request:

```
public class LocalizationPipeline
{
    public void Configure(IApplicationBuilder applicationBuilder)
    {
        var supportedCultures = new[]
        {
            new CultureInfo("en-US"),
            new CultureInfo("fr")
        };

        var options = new RequestLocalizationOptions
        {

            DefaultRequestCulture = new RequestCulture(culture: "en-US",
                                                       uiCulture: "en-US"),
            SupportedCultures = supportedCultures,
            SupportedUICultures = supportedCultures
        };
        options.RequestCultureProviders = new[]
            { new RouteDataRequestCultureProvider() { Options = options } };

        applicationBuilder.UseRequestLocalization(options);
    }
}
```

Use the MiddlewareFilterAttribute to run the middleware:

```
[Route("{culture}/[controller]/[action]")]
[MiddlewareFilter(typeof(LocalizationPipeline))]
public IActionResult CultureFromRouteData()
{
    return Content($"CurrentCulture:{CultureInfo.CurrentCulture.Name},"
        + $"CurrentUICulture:{CultureInfo.CurrentUICulture.Name}");
}
```

Middleware filters run at the same stage of the filter pipeline as Resource filters, before model binding and after the rest of the pipeline.

ASP.NET Core Razor SDK

9/22/2020 • 8 minutes to read • Edit Online

By Rick Anderson

Overview

The .NET Core 2.1 SDK or later includes the `Microsoft.NET.Sdk.Razor` MSBuild SDK (Razor SDK). The Razor SDK:

- Is required to build, package, and publish projects containing Razor files for ASP.NET Core MVC-based or Blazor projects.
- Includes a set of predefined targets, properties, and items that allow customizing the compilation of Razor (*.cshtml* or *.razor*) files.

The Razor SDK includes `Content` items with `Include` attributes set to the `**\*.cshtml` and `**\*.razor` globbing patterns. Matching files are published.

- Standardizes the experience around building, packaging, and publishing projects containing Razor files for ASP.NET Core MVC-based projects.
- Includes a set of predefined targets, properties, and items that allow customizing the compilation of Razor files.

The Razor SDK includes a `Content` item with an `Include` attribute set to the `**\*.cshtml` globbing pattern. Matching files are published.

Prerequisites

.NET Core 2.1 SDK or later

Use the Razor SDK

Most web apps aren't required to explicitly reference the Razor SDK.

To use the Razor SDK to build class libraries containing Razor views or Razor Pages, we recommend starting with the Razor class library (RCL) project template. An RCL that's used to build Blazor (*.razor*) files minimally requires a reference to the Microsoft.AspNetCore.Components package. An RCL that's used to build Razor views or pages (*.cshtml* files) minimally requires targeting `netcoreapp3.0` or later and has a `FrameworkReference` to the Microsoft.AspNetCore.App metapackage in its project file.

To use the Razor SDK to build class libraries containing Razor views or Razor Pages:

- Use `Microsoft.NET.Sdk.Razor` instead of `Microsoft.NET.Sdk`:

```
<Project SDK="Microsoft.NET.Sdk.Razor">
  <!-- omitted for brevity -->
</Project>
```

- Typically, a package reference to `Microsoft.AspNetCore.Mvc` is required to receive additional dependencies that are required to build and compile Razor Pages and Razor views. At a minimum, your project should add package references to:
  - `Microsoft.AspNetCore.Razor.Design`

- `Microsoft.AspNetCore.Mvc.Razor.Extensions`
- `Microsoft.AspNetCore.Mvc.Razor`

The `Microsoft.AspNetCore.Razor.Design` package provides the Razor compilation tasks and targets for the project.

The preceding packages are included in `Microsoft.AspNetCore.Mvc`. The following markup shows a project file that uses the Razor SDK to build Razor files for an ASP.NET Core Razor Pages app:

```
<Project Sdk="Microsoft.NET.Sdk.Razor">

  <PropertyGroup>
    <TargetFramework>netcoreapp2.1</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.Mvc" Version="2.1.3" />
  </ItemGroup>

</Project>
```

WARNING

The `Microsoft.AspNetCore.Razor.Design` and `Microsoft.AspNetCore.Mvc.Razor.Extensions` packages are included in the Microsoft.AspNetCore.App metapackage. However, the version-less `Microsoft.AspNetCore.App` package reference provides a metapackage to the app that doesn't include the latest version of `Microsoft.AspNetCore.Razor.Design`. Projects must reference a consistent version of `Microsoft.AspNetCore.Razor.Design` (or `Microsoft.AspNetCore.Mvc`) so that the latest build-time fixes for Razor are included. For more information, see this GitHub issue.

Properties

The following properties control the Razor's SDK behavior as part of a project build:

- `RazorCompileOnBuild`: When `true`, compiles and emits the Razor assembly as part of building the project. Defaults to `true`.
- `RazorCompileOnPublish`: When `true`, compiles and emits the Razor assembly as part of publishing the project. Defaults to `true`.

The properties and items in the following table are used to configure inputs and output to the Razor SDK.

WARNING

Starting with ASP.NET Core 3.0, MVC Views or Razor Pages aren't served by default if the `RazorCompileOnBuild` or `RazorCompileOnPublish` MSBuild properties in the project file are disabled. Applications must add an explicit reference to the Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation package if the app relies on runtime compilation to process *.cshtml* files.

ITEMS	DESCRIPTION
`RazorGenerate`	Item elements (*.cshtml* files) that are inputs to code generation.
`RazorComponent`	Item elements (*.razor* files) that are inputs to Razor component code generation.

ITEMS	DESCRIPTION
`RazorCompile`	Item elements (*.cs* files) that are inputs to Razor compilation targets. Use this `ItemGroup` to specify additional files to be compiled into the Razor assembly.
`RazorTargetAssemblyAttribute`	Item elements used to code generate attributes for the Razor assembly. For example: `RazorAssemblyAttribute` `Include="System.Reflection.AssemblyMetadataAttribute"` `_Parameter1="BuildSource"` `_Parameter2="https://docs.microsoft.com/">`
`RazorEmbeddedResource`	Item elements added as embedded resources to the generated Razor assembly.

PROPERTY	DESCRIPTION
`RazorTargetName`	File name (without extension) of the assembly produced by Razor.
`RazorOutputPath`	The Razor output directory.
`RazorCompileToolset`	Used to determine the toolset used to build the Razor assembly. Valid values are `Implicit`, `RazorSDK`, and `PrecompilationTool`.
EnableDefaultContentItems	Default is `true`. When `true`, includes *web.config*, *.json*, and *.cshtml* files as content in the project. When referenced via `Microsoft.NET.Sdk.Web`, files under *wwwroot* and config files are also included.
`EnableDefaultRazorGenerateItems`	When `true`, includes *.cshtml* files from `Content` items in `RazorGenerate` items.
`GenerateRazorTargetAssemblyInfo`	When `true`, generates a *.cs* file containing attributes specified by `RazorAssemblyAttribute` and includes the file in the compile output.
`EnableDefaultRazorTargetAssemblyInfoAttributes`	When `true`, adds a default set of assembly attributes to `RazorAssemblyAttribute`.
`CopyRazorGenerateFilesToPublishDirectory`	When `true`, copies `RazorGenerate` items (*.cshtml*) files to the publish directory. Typically, Razor files aren't required for a published app if they participate in compilation at build-time or publish-time. Defaults to `false`.
`PreserveCompilationReferences`	When `true`, copy reference assembly items to the publish directory. Typically, reference assemblies aren't required for a published app if Razor compilation occurs at build-time or publish-time. Set to `true` if your published app requires runtime compilation. For example, set the value to `true` if the app modifies *.cshtml* files at runtime or uses embedded views. Defaults to `false`.

PROPERTY	DESCRIPTION
`IncludeRazorContentInPack`	When `true`, all Razor content items (*.cshtml* files) are marked for inclusion in the generated NuGet package. Defaults to `false`.
`EmbedRazorGenerateSources`	When `true`, adds RazorGenerate (*.cshtml*) items as embedded files to the generated Razor assembly. Defaults to `false`.
`UseRazorBuildServer`	When `true`, uses a persistent build server process to offload code generation work. Defaults to the value of `UseSharedCompilation`.
`GenerateMvcApplicationPartsAssemblyAttributes`	When `true`, the SDK generates additional attributes used by MVC at runtime to perform application part discovery.
`DefaultWebContentItemExcludes`	A globbing pattern for item elements that are to be excluded from the `Content` item group in projects targeting the Web or Razor SDK
`ExcludeConfigFilesFromBuildOutput`	When `true`, *.config* and *.json* files do not get copied to the build output directory.
`AddRazorSupportForMvc`	When `true`, configures the Razor SDK to add support for the MVC configuration that is required when building applications containing MVC views or Razor Pages. This property is implicitly set for .NET Core 3.0 or later projects targeting the Web SDK
`RazorLangVersion`	The version of the Razor Language to target.

PROPERTY	DESCRIPTION
`RazorTargetName`	File name (without extension) of the assembly produced by Razor.
`RazorOutputPath`	The Razor output directory.
`RazorCompileToolset`	Used to determine the toolset used to build the Razor assembly. Valid values are `Implicit`, `RazorSDK`, and `PrecompilationTool`.
EnableDefaultContentItems	Default is `true`. When `true`, includes *web.config*, *.json*, and *.cshtml* files as content in the project. When referenced via `Microsoft.NET.Sdk.Web`, files under *wwwroot* and config files are also included.
`EnableDefaultRazorGenerateItems`	When `true`, includes *.cshtml* files from `Content` items in `RazorGenerate` items.
`GenerateRazorTargetAssemblyInfo`	When `true`, generates a *.cs* file containing attributes specified by `RazorAssemblyAttribute` and includes the file in the compile output.

PROPERTY	DESCRIPTION
`EnableDefaultRazorTargetAssemblyInfoAttributes`	When `true`, adds a default set of assembly attributes to `RazorAssemblyAttribute`.
`CopyRazorGenerateFilesToPublishDirectory`	When `true`, copies `RazorGenerate` items (*.cshtml*) files to the publish directory. Typically, Razor files aren't required for a published app if they participate in compilation at build-time or publish-time. Defaults to `false`.
`CopyRefAssembliesToPublishDirectory`	When `true`, copy reference assembly items to the publish directory. Typically, reference assemblies aren't required for a published app if Razor compilation occurs at build-time or publish-time. Set to `true` if your published app requires runtime compilation. For example, set the value to `true` if the app modifies *.cshtml* files at runtime or uses embedded views. Defaults to `false`.
`IncludeRazorContentInPack`	When `true`, all Razor content items (*.cshtml* files) are marked for inclusion in the generated NuGet package. Defaults to `false`.
`EmbedRazorGenerateSources`	When `true`, adds RazorGenerate (*.cshtml*) items as embedded files to the generated Razor assembly. Defaults to `false`.
`UseRazorBuildServer`	When `true`, uses a persistent build server process to offload code generation work. Defaults to the value of `UseSharedCompilation`.
`GenerateMvcApplicationPartsAssemblyAttributes`	When `true`, the SDK generates additional attributes used by MVC at runtime to perform application part discovery.
`DefaultWebContentItemExcludes`	A globbing pattern for item elements that are to be excluded from the `Content` item group in projects targeting the Web or Razor SDK
`ExcludeConfigFilesFromBuildOutput`	When `true`, *.config* and *.json* files do not get copied to the build output directory.
`AddRazorSupportForMvc`	When `true`, configures the Razor SDK to add support for the MVC configuration that is required when building applications containing MVC views or Razor Pages. This property is implicitly set for .NET Core 3.0 or later projects targeting the Web SDK
`RazorLangVersion`	The version of the Razor Language to target.

For more information on properties, see MSBuild properties.

Targets

The Razor SDK defines two primary targets:

- `RazorGenerate`: Code generates *.cs* files from `RazorGenerate` item elements. Use the `RazorGenerateDependsOn` property to specify additional targets that can run before or after this target.
- `RazorCompile`: Compiles generated *.cs* files in to a Razor assembly. Use the `RazorCompileDependsOn` to specify

additional targets that can run before or after this target.

- `RazorComponentGenerate`: Code generates *.cs* files for `RazorComponent` item elements. Use the `RazorComponentGenerateDependsOn` property to specify additional targets that can run before or after this target.

Runtime compilation of Razor views

- By default, the Razor SDK doesn't publish reference assemblies that are required to perform runtime compilation. This results in compilation failures when the application model relies on runtime compilation—for example, the app uses embedded views or changes views after the app is published. Set `CopyRefAssembliesToPublishDirectory` to `true` to continue publishing reference assemblies.
- For a web app, ensure your app is targeting the `Microsoft.NET.Sdk.Web` SDK.

Razor language version

When targeting the `Microsoft.NET.Sdk.Web` SDK, the Razor language version is inferred from the app's target framework version. For projects targeting the `Microsoft.NET.Sdk.Razor` SDK or in the rare case that the app requires a different Razor language version than the inferred value, a version can be configured by setting the `<RazorLangVersion>` property in the app's project file:

```
<PropertyGroup>
  <RazorLangVersion>{VERSION}</RazorLangVersion>
</PropertyGroup>
```

Razor's language version is tightly integrated with the version of the runtime that it was built for. Targeting a language version that isn't designed for the runtime is unsupported and likely produces build errors.

View components in ASP.NET Core

9/22/2020 • 11 minutes to read • Edit Online

By Rick Anderson

View or download sample code (how to download)

View components

View components are similar to partial views, but they're much more powerful. View components don't use model binding, and only depend on the data provided when calling into it. This article was written using controllers and views, but view components also work with Razor Pages.

A view component:

- Renders a chunk rather than a whole response.
- Includes the same separation-of-concerns and testability benefits found between a controller and view.
- Can have parameters and business logic.
- Is typically invoked from a layout page.

View components are intended anywhere you have reusable rendering logic that's too complex for a partial view, such as:

- Dynamic navigation menus
- Tag cloud (where it queries the database)
- Login panel
- Shopping cart
- Recently published articles
- Sidebar content on a typical blog
- A login panel that would be rendered on every page and show either the links to log out or log in, depending on the log in state of the user

A view component consists of two parts: the class (typically derived from ViewComponent) and the result it returns (typically a view). Like controllers, a view component can be a POCO, but most developers will want to take advantage of the methods and properties available by deriving from `ViewComponent`.

When considering if view components meet an app's specifications, consider using Razor Components instead. Razor Components also combine markup with C# code to produce reusable UI units. Razor Components are designed for developer productivity when providing client-side UI logic and composition. For more information, see Create and use ASP.NET Core Razor components.

Creating a view component

This section contains the high-level requirements to create a view component. Later in the article, we'll examine each step in detail and create a view component.

The view component class

A view component class can be created by any of the following:

- Deriving from *ViewComponent*
- Decorating a class with the `[ViewComponent]` attribute, or deriving from a class with the `[ViewComponent]`

attribute

- Creating a class where the name ends with the suffix *ViewComponent*

Like controllers, view components must be public, non-nested, and non-abstract classes. The view component name is the class name with the "ViewComponent" suffix removed. It can also be explicitly specified using the `ViewComponentAttribute.Name` property.

A view component class:

- Fully supports constructor dependency injection
- Doesn't take part in the controller lifecycle, which means you can't use filters in a view component

View component methods

A view component defines its logic in an `InvokeAsync` method that returns a `Task<IViewComponentResult>` or in a synchronous `Invoke` method that returns an `IViewComponentResult`. Parameters come directly from invocation of the view component, not from model binding. A view component never directly handles a request. Typically, a view component initializes a model and passes it to a view by calling the `View` method. In summary, view component methods:

- Define an `InvokeAsync` method that returns a `Task<IViewComponentResult>` or a synchronous `Invoke` method that returns an `IViewComponentResult`.
- Typically initializes a model and passes it to a view by calling the `ViewComponent` `View` method.
- Parameters come from the calling method, not HTTP. There's no model binding.
- Are not reachable directly as an HTTP endpoint. They're invoked from your code (usually in a view). A view component never handles a request.
- Are overloaded on the signature rather than any details from the current HTTP request.

View search path

The runtime searches for the view in the following paths:

- /Views/{Controller Name}/Components/{View Component Name}/{View Name}
- /Views/Shared/Components/{View Component Name}/{View Name}
- /Pages/Shared/Components/{View Component Name}/{View Name}

The search path applies to projects using controllers + views and Razor Pages.

The default view name for a view component is *Default*, which means your view file will typically be named *Default.cshtml*. You can specify a different view name when creating the view component result or when calling the `View` method.

We recommend you name the view file *Default.cshtml* and use the *Views/Shared/Components/{View Component Name}/{View Name}* path. The `PriorityList` view component used in this sample uses *Views/Shared/Components/PriorityList/Default.cshtml* for the view component view.

Customize the view search path

To customize the view search path, modify Razor's ViewLocationFormats collection. For example, to search for views within the path "/Components/{View Component Name}/{View Name}", add a new item to the collection:

```
services.AddMvc()
    .AddRazorOptions(options =>
    {
        options.ViewLocationFormats.Add("/{0}.cshtml");
    })
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

In the preceding code, the placeholder "{0}" represents the path "Components/{View Component Name}/{View Name}".

Invoking a view component

To use the view component, call the following inside a view:

```
@await Component.InvokeAsync("Name of view component", {Anonymous Type Containing Parameters})
```

The parameters will be passed to the `InvokeAsync` method. The `PriorityList` view component developed in the article is invoked from the *Views/ToDo/Index.cshtml* view file. In the following, the `InvokeAsync` method is called with two parameters:

```
@await Component.InvokeAsync("PriorityList", new { maxPriority = 4, isDone = true })
```

Invoking a view component as a Tag Helper

For ASP.NET Core 1.1 and higher, you can invoke a view component as a Tag Helper:

```
<vc:priority-list max-priority="2" is-done="false">
</vc:priority-list>
```

Pascal-cased class and method parameters for Tag Helpers are translated into their kebab case. The Tag Helper to invoke a view component uses the `<vc></vc>` element. The view component is specified as follows:

```
<vc:[view-component-name]
  parameter1="parameter1 value"
  parameter2="parameter2 value">
</vc:[view-component-name]>
```

To use a view component as a Tag Helper, register the assembly containing the view component using the `@addTagHelper` directive. If your view component is in an assembly called `MyWebApp`, add the following directive to the *_ViewImports.cshtml* file:

```
@addTagHelper *, MyWebApp
```

You can register a view component as a Tag Helper to any file that references the view component. See Managing Tag Helper Scope for more information on how to register Tag Helpers.

The `InvokeAsync` method used in this tutorial:

```
@await Component.InvokeAsync("PriorityList", new { maxPriority = 4, isDone = true })
```

In Tag Helper markup:

```
<vc:priority-list max-priority="2" is-done="false">
</vc:priority-list>
```

In the sample above, the `PriorityList` view component becomes `priority-list`. The parameters to the view component are passed as attributes in kebab case.

Invoking a view component directly from a controller

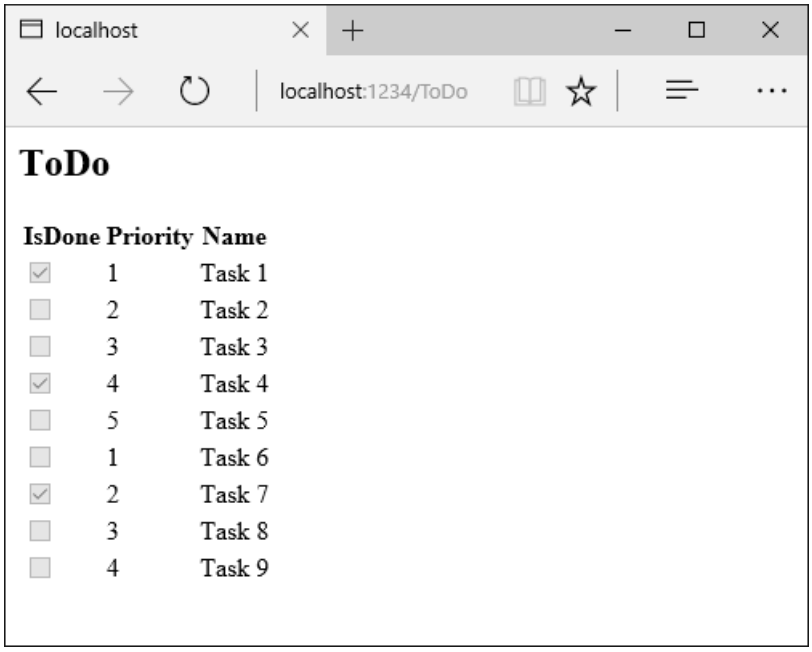
View components are typically invoked from a view, but you can invoke them directly from a controller method. While view components don't define endpoints like controllers, you can easily implement a controller action that returns the content of a `ViewComponentResult`.

In this example, the view component is called directly from the controller:

```
public IActionResult IndexVC()
{
    return ViewComponent("PriorityList", new { maxPriority = 3, isDone = false });
}
```

Walkthrough: Creating a simple view component

Download, build and test the starter code. It's a simple project with a `ToDo` controller that displays a list of *ToDo* items.



Add a ViewComponent class

Create a *ViewComponents* folder and add the following `PriorityListViewComponent` class:

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using ViewComponentSample.Models;

namespace ViewComponentSample.ViewComponents
{
    public class PriorityListViewComponent : ViewComponent
    {
        private readonly ToDoContext db;

        public PriorityListViewComponent(ToDoContext context)
        {
            db = context;
        }

        public async Task<IViewComponentResult> InvokeAsync(
        int maxPriority, bool isDone)
        {
            var items = await GetItemsAsync(maxPriority, isDone);
            return View(items);
        }
        private Task<List<TodoItem>> GetItemsAsync(int maxPriority, bool isDone)
        {
            return db.ToDo.Where(x => x.IsDone == isDone &&
                                 x.Priority <= maxPriority).ToListAsync();
        }
    }
}
```

Notes on the code:

- View component classes can be contained in **any** folder in the project.
- Because the class name PriorityList**ViewComponent** ends with the suffix **ViewComponent**, the runtime will use the string "PriorityList" when referencing the class component from a view. I'll explain that in more detail later.
- The `[ViewComponent]` attribute can change the name used to reference a view component. For example, we could've named the class `XYZ` and applied the `ViewComponent` attribute:

  ```
  [ViewComponent(Name = "PriorityList")]
     public class XYZ : ViewComponent
  ```

- The `[ViewComponent]` attribute above tells the view component selector to use the name `PriorityList` when looking for the views associated with the component, and to use the string "PriorityList" when referencing the class component from a view. I'll explain that in more detail later.
- The component uses dependency injection to make the data context available.
- `InvokeAsync` exposes a method which can be called from a view, and it can take an arbitrary number of arguments.
- The `InvokeAsync` method returns the set of `ToDo` items that satisfy the `isDone` and `maxPriority` parameters.

Create the view component Razor view

- Create the *Views/Shared/Components* folder. This folder **must** be named *Components*.

- Create the *Views/Shared/Components/PriorityList* folder. This folder name must match the name of the view component class, or the name of the class minus the suffix (if we followed convention and used the *ViewComponent* suffix in the class name). If you used the `ViewComponent` attribute, the class name would need to match the attribute designation.

- Create a *Views/Shared/Components/PriorityList/Default.cshtml* Razor view:

  ```
  @model IEnumerable<ViewComponentSample.Models.TodoItem>

  <h3>Priority Items</h3>
  <ul>
      @foreach (var todo in Model)
      {
          <li>@todo.Name</li>
      }
  </ul>
  ```

  The Razor view takes a list of `TodoItem` and displays them. If the view component `InvokeAsync` method doesn't pass the name of the view (as in our sample), *Default* is used for the view name by convention. Later in the tutorial, I'll show you how to pass the name of the view. To override the default styling for a specific controller, add a view to the controller-specific view folder (for example *Views/ToDo/Components/PriorityList/Default.cshtml)*.

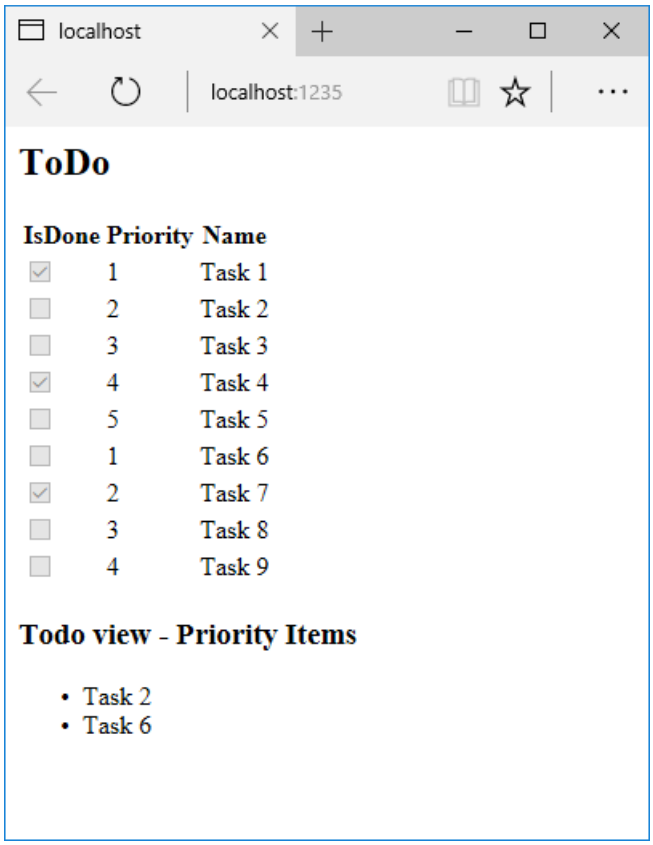
  If the view component is controller-specific, you can add it to the controller-specific folder (*Views/ToDo/Components/PriorityList/Default.cshtml*).

- Add a `div` containing a call to the priority list component to the bottom of the *Views/ToDo/index.cshtml* file:

  ```
  </table>
  <div>
      @await Component.InvokeAsync("PriorityList", new { maxPriority = 2, isDone = false })
  </div>
  ```

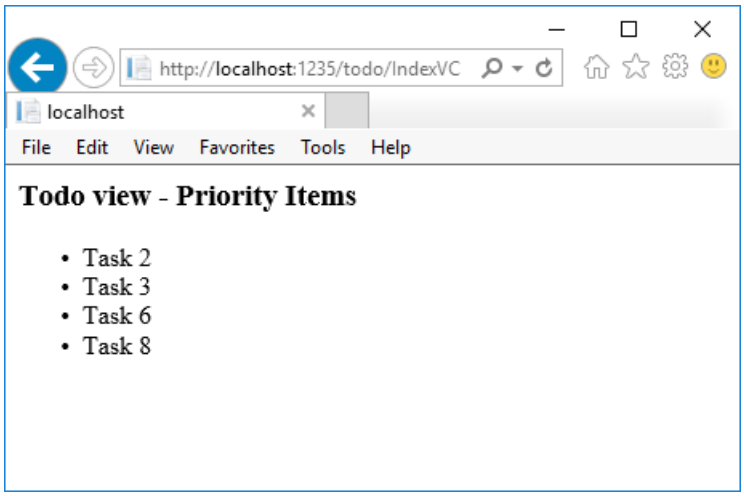
The markup `@await Component.InvokeAsync` shows the syntax for calling view components. The first argument is the name of the component we want to invoke or call. Subsequent parameters are passed to the component. `InvokeAsync` can take an arbitrary number of arguments.

Test the app. The following image shows the ToDo list and the priority items:



You can also call the view component directly from the controller:

```
public IActionResult IndexVC()
{
    return ViewComponent("PriorityList", new { maxPriority = 3, isDone = false });
}
```



Specifying a view name

A complex view component might need to specify a non-default view under some conditions. The following code shows how to specify the "PVC" view from the `InvokeAsync` method. Update the `InvokeAsync` method in the `PriorityListViewComponent` class.

```
public async Task<IViewComponentResult> InvokeAsync(
    int maxPriority, bool isDone)
{
    string MyView = "Default";
    // If asking for all completed tasks, render with the "PVC" view.
    if (maxPriority > 3 && isDone == true)
    {
        MyView = "PVC";
    }
    var items = await GetItemsAsync(maxPriority, isDone);
    return View(MyView, items);
}
```

Copy the *Views/Shared/Components/PriorityList/Default.cshtml* file to a view named *Views/Shared/Components/PriorityList/PVC.cshtml*. Add a heading to indicate the PVC view is being used.

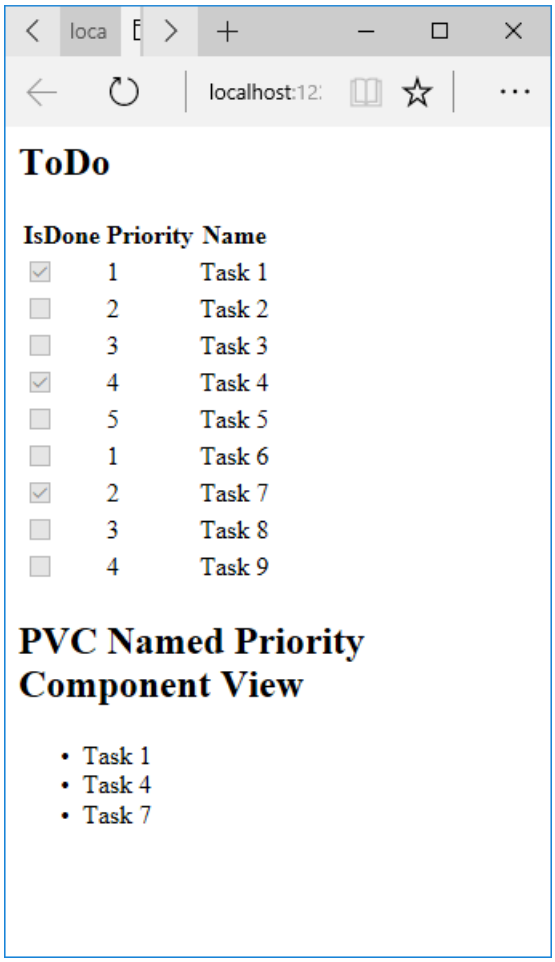
```
@model IEnumerable<ViewComponentSample.Models.TodoItem>

<h2> PVC Named Priority Component View</h2>
<h4>@ViewBag.PriorityMessage</h4>
<ul>
    @foreach (var todo in Model)
    {
        <li>@todo.Name</li>
    }
</ul>
```

Update *Views/ToDo/Index.cshtml*:

```
@await Component.InvokeAsync("PriorityList", new { maxPriority = 4, isDone = true })
```

Run the app and verify PVC view.



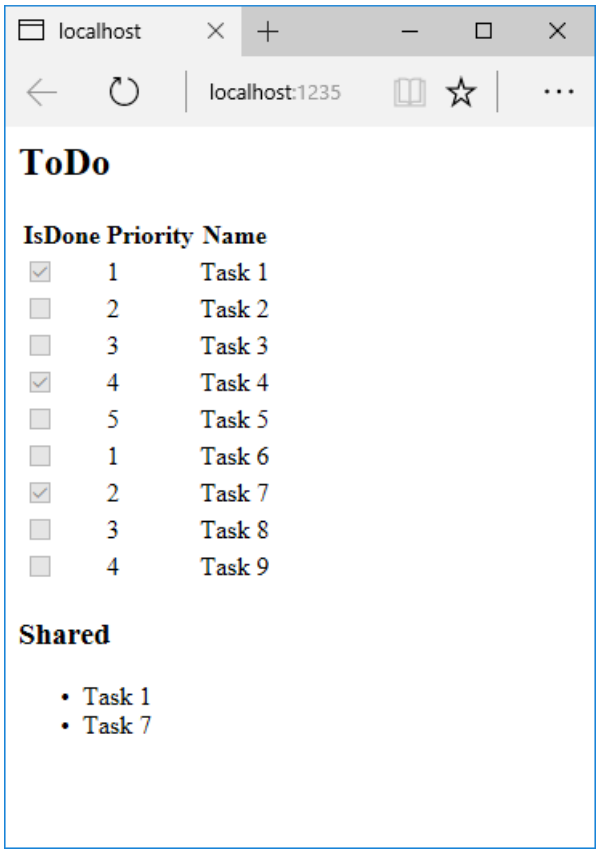
If the PVC view isn't rendered, verify you are calling the view component with a priority of 4 or higher.

Examine the view path

- Change the priority parameter to three or less so the priority view isn't returned.
- Temporarily rename the *Views/ToDo/Components/PriorityList/Default.cshtml* to *1Default.cshtml*.
- Test the app, you'll get the following error:

```
An unhandled exception occurred while processing the request.
InvalidOperationException: The view 'Components/PriorityList/Default' wasn't found. The following
locations were searched:
/Views/ToDo/Components/PriorityList/Default.cshtml
/Views/Shared/Components/PriorityList/Default.cshtml
EnsureSuccessful
```

- Copy *Views/ToDo/Components/PriorityList/1Default.cshtml* to *Views/Shared/Components/PriorityList/Default.cshtml*.
- Add some markup to the *Shared* ToDo view component view to indicate the view is from the *Shared* folder.
- Test the **Shared** component view.



Avoiding hard-coded strings

If you want compile time safety, you can replace the hard-coded view component name with the class name. Create the view component without the "ViewComponent" suffix:

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using ViewComponentSample.Models;

namespace ViewComponentSample.ViewComponents
{
    public class PriorityList : ViewComponent
    {
        private readonly ToDoContext db;

        public PriorityList(ToDoContext context)
        {
            db = context;
        }

        public async Task<IViewComponentResult> InvokeAsync(
        int maxPriority, bool isDone)
        {
            var items = await GetItemsAsync(maxPriority, isDone);
            return View(items);
        }
        private Task<List<TodoItem>> GetItemsAsync(int maxPriority, bool isDone)
        {
            return db.ToDo.Where(x => x.IsDone == isDone &&
                                 x.Priority <= maxPriority).ToListAsync();
        }
    }
}
```

Add a `using` statement to your Razor view file, and use the `nameof` operator:

```
@using ViewComponentSample.Models
@using ViewComponentSample.ViewComponents
@model IEnumerable<TodoItem>

    <h2>ToDo nameof</h2>
    <!-- Markup removed for brevity.  -->

    <div>

        @*
            Note:
            To use the below line, you need to #define no_suffix in ViewComponents/PriorityList.cs or it
won't compile.
            By doing so it will cause a problem to index as there will be multiple viewcomponents
            with the same name after the compiler removes the suffix "ViewComponent"
        *@

        @*@await Component.InvokeAsync(nameof(PriorityList), new { maxPriority = 4, isDone = true })*@
    </div>
```

Perform synchronous work

The framework handles invoking a synchronous `Invoke` method if you don't need to perform asynchronous work. The following method creates a synchronous `Invoke` view component:

```
public class PriorityList : ViewComponent
{
    public IViewComponentResult Invoke(int maxPriority, bool isDone)
    {
        var items = new List<string> { $"maxPriority: {maxPriority}", $"isDone: {isDone}" };
        return View(items);
    }
}
```

The view component's Razor file lists the strings passed to the `Invoke` method (*Views/Home/Components/PriorityList/Default.cshtml*):

```
@model List<string>

<h3>Priority Items</h3>
<ul>
    @foreach (var item in Model)
    {
        <li>@item</li>
    }
</ul>
```

The view component is invoked in a Razor file (for example, *Views/Home/Index.cshtml*) using one of the following approaches:

- IViewComponentHelper
- Tag Helper

To use the IViewComponentHelper approach, call `Component.InvokeAsync`:

The view component is invoked in a Razor file (for example, *Views/Home/Index.cshtml*) with IViewComponentHelper.

Call `Component.InvokeAsync`:

```
@await Component.InvokeAsync(nameof(PriorityList), new { maxPriority = 4, isDone = true })
```

To use the Tag Helper, register the assembly containing the View Component using the `@addTagHelper` directive (the view component is in an assembly called `MyWebApp`):

```
@addTagHelper *, MyWebApp
```

Use the view component Tag Helper in the Razor markup file:

```
<vc:priority-list max-priority="999" is-done="false">
</vc:priority-list>
```

The method signature of `PriorityList.Invoke` is synchronous, but Razor finds and calls the method with `Component.InvokeAsync` in the markup file.

All view component parameters are required

Each parameter in a view component is a required attribute. See this GitHub issue. If any parameter is omitted:

- The `InvokeAsync` method signature won't match, therefore the method won't execute.
- The ViewComponent won't render any markup.
- No errors will be thrown.

Razor file compilation in ASP.NET Core

9/22/2020 • 5 minutes to read • Edit Online

By Rick Anderson

Razor files with a *.cshtml* extension are compiled at both build and publish time using the Razor SDK. Runtime compilation may be optionally enabled by configuring your project.

Razor compilation

Build-time and publish-time compilation of Razor files is enabled by default by the Razor SDK. When enabled, runtime compilation complements build-time compilation, allowing Razor files to be updated if they're edited.

Enable runtime compilation at project creation

The Razor Pages and MVC project templates include an option to enable runtime compilation when the project is created. This option is supported in ASP.NET Core 3.1 and later.

- Visual Studio
- .NET Core CLI

In the **Create a new ASP.NET Core web application** dialog:

1. Select either the **Web Application** or the **Web Application (Model-View-Controller)** project template.
2. Select the **Enable Razor runtime compilation** check box.

Enable runtime compilation in an existing project

To enable runtime compilation for all environments in an existing project:

1. Install the Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation NuGet package.
2. Update the project's `Startup.ConfigureServices` method to include a call to AddRazorRuntimeCompilation. For example:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages()
        .AddRazorRuntimeCompilation();

    // code omitted for brevity
}
```

Conditionally enable runtime compilation in an existing project

Runtime compilation can be enabled such that it's only available for local development. Conditionally enabling in this manner ensures that the published output:

- Uses compiled views.
- Doesn't enable file watchers in production.

To enable runtime compilation only in the Development environment:

1. Install the Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation NuGet package.
2. Modify the launch profile `environmentVariables` section in *launchSettings.json*:
   - Verify `ASPNETCORE_ENVIRONMENT` is set to `"Development"`.
   - Set `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES` to `"Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation"`.

In the following example, runtime compilation is enabled in the Development environment for the `IIS Express` and `RazorPagesApp` launch profiles:

```
{
    "iisSettings": {
      "windowsAuthentication": false,
      "anonymousAuthentication": true,
      "iisExpress": {
        "applicationUrl": "http://localhost:57676",
        "sslPort": 44364
      }
    },
    "profiles": {
      "IIS Express": {
        "commandName": "IISExpress",
        "launchBrowser": true,
        "environmentVariables": {
          "ASPNETCORE_ENVIRONMENT": "Development",
          "ASPNETCORE_HOSTINGSTARTUPASSEMBLIES": "Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation"
        }
      },
      "RazorPagesApp": {
        "commandName": "Project",
        "launchBrowser": true,
        "applicationUrl": "https://localhost:5001;http://localhost:5000",
        "environmentVariables": {
          "ASPNETCORE_ENVIRONMENT": "Development",
          "ASPNETCORE_HOSTINGSTARTUPASSEMBLIES": "Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation"
        }
      }
    }
  }
```

No code changes are needed in the project's `Startup` class. At runtime, ASP.NET Core searches for an assembly-level HostingStartup attribute in `Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation`. The `HostingStartup` attribute specifies the app startup code to execute. That startup code enables runtime compilation.

Enable runtime compilation for a Razor Class Library

Consider a scenario in which a Razor Pages project references a Razor Class Library (RCL) named *MyClassLib*. The RCL contains a *_Layout.cshtml* file that all of your team's MVC and Razor Pages projects consume. You want to enable runtime compilation for the *_Layout.cshtml* file in that RCL. Make the following changes in the Razor Pages project:

1. Enable runtime compilation with the instructions at Conditionally enable runtime compilation in an existing project.
2. Configure the runtime compilation options in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();

    services.Configure<MvcRazorRuntimeCompilationOptions>(options =>
    {
        var libraryPath = Path.GetFullPath(
            Path.Combine(HostEnvironment.ContentRootPath, "..", "MyClassLib"));
        options.FileProviders.Add(new PhysicalFileProvider(libraryPath));
    });
}
```

In the preceding code, an absolute path to the *MyClassLib* RCL is constructed. The PhysicalFileProvider API is used to locate directories and files at that absolute path. Finally, the `PhysicalFileProvider` instance is added to a file providers collection, which allows access to the RCL's *.cshtml* files.

- Views in ASP.NET Core MVC
- ASP.NET Core Razor SDK

Razor files with a *.cshtml* extension are compiled at both build and publish time using the Razor SDK. Runtime compilation may be optionally enabled by configuring your application.

Razor compilation

Build-time and publish-time compilation of Razor files is enabled by default by the Razor SDK. When enabled, runtime compilation complements build-time compilation, allowing Razor files to be updated if they're edited.

Runtime compilation

To enable runtime compilation for all environments and configuration modes:

1. Install the Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation NuGet package.
2. Update the project's `Startup.ConfigureServices` method to include a call to AddRazorRuntimeCompilation. For example:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages()
        .AddRazorRuntimeCompilation();

    // code omitted for brevity
}
```

Conditionally enable runtime compilation

Runtime compilation can be enabled such that it's only available for local development. Conditionally enabling in this manner ensures that the published output:

- Uses compiled views.
- Is smaller in size.
- Doesn't enable file watchers in production.

To enable runtime compilation based on the environment and configuration mode:

1. Conditionally reference the Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation package based on the active `Configuration` value:

   ```
   <PackageReference Include="Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation" Version="3.1.0"
   Condition="'$(Configuration)' == 'Debug'" />
   ```

2. Update the project's `Startup.ConfigureServices` method to include a call to `AddRazorRuntimeCompilation`. Conditionally execute `AddRazorRuntimeCompilation` such that it only runs in Debug mode when the `ASPNETCORE_ENVIRONMENT` variable is set to `Development`:

   ```
   public class Startup
   {
       public Startup(IConfiguration configuration, IWebHostEnvironment env)
       {
           Configuration = configuration;
           Env = env;
       }

       public IWebHostEnvironment Env { get; set; }
       public IConfiguration Configuration { get; }

       public void ConfigureServices(IServiceCollection services)
       {
           IMvcBuilder builder = services.AddRazorPages();

   #if DEBUG
               if (Env.IsDevelopment())
               {
                   builder.AddRazorRuntimeCompilation();
               }
   #endif
       }

       public void Configure(IApplicationBuilder app)
       {
           if (Env.IsDevelopment())
           {
               app.UseDeveloperExceptionPage();
           }
           else
           {
               app.UseExceptionHandler("/Error");
               app.UseHsts();
           }

           app.UseHttpsRedirection();
           app.UseStaticFiles();

           app.UseRouting();

           app.UseAuthorization();

           app.UseEndpoints(endpoints =>
           {
               endpoints.MapRazorPages();
           });
       }
   }
   ```

- Introduction to Razor Pages in ASP.NET Core
- Views in ASP.NET Core MVC
- ASP.NET Core Razor SDK
- See the runtime compilation sample on GitHub for a sample that shows making runtime compilation work across projects.

A Razor file is compiled at runtime, when the associated Razor Page or MVC view is invoked. Razor files are compiled at both build and publish time using the Razor SDK.

Razor compilation

Build- and publish-time compilation of Razor files is enabled by default by the Razor SDK. Editing Razor files after they're updated is supported at build time. By default, only the compiled *Views.dll* and no *.cshtml* files or references assemblies required to compile Razor files are deployed with your app.

> **IMPORTANT**
>
> The precompilation tool has been deprecated, and will be removed in ASP.NET Core 3.0. We recommend migrating to Razor Sdk.
>
> The Razor SDK is effective only when no precompilation-specific properties are set in the project file. For instance, setting the *.csproj* file's `MvcRazorCompileOnPublish` property to `true` disables the Razor SDK.

Runtime compilation

Build-time compilation is supplemented by runtime compilation of Razor files. ASP.NET Core MVC will recompile Razor files when the contents of a *.cshtml* file change.

Upload files in ASP.NET Core

9/22/2020 • 66 minutes to read • Edit Online

By Steve Smith and Rutger Storm

ASP.NET Core supports uploading one or more files using buffered model binding for smaller files and unbuffered streaming for larger files.

View or download sample code (how to download)

Security considerations

Use caution when providing users with the ability to upload files to a server. Attackers may attempt to:

- Execute denial of service attacks.
- Upload viruses or malware.
- Compromise networks and servers in other ways.

Security steps that reduce the likelihood of a successful attack are:

- Upload files to a dedicated file upload area, preferably to a non-system drive. A dedicated location makes it easier to impose security restrictions on uploaded files. Disable execute permissions on the file upload location.†
- Do **not** persist uploaded files in the same directory tree as the app.†
- Use a safe file name determined by the app. Don't use a file name provided by the user or the untrusted file name of the uploaded file.† HTML encode the untrusted file name when displaying it. For example, logging the file name or displaying in UI (Razor automatically HTML encodes output).
- Allow only approved file extensions for the app's design specification.†
- Verify that client-side checks are performed on the server.† Client-side checks are easy to circumvent.
- Check the size of an uploaded file. Set a maximum size limit to prevent large uploads.†
- When files shouldn't be overwritten by an uploaded file with the same name, check the file name against the database or physical storage before uploading the file.
- **Run a virus/malware scanner on uploaded content before the file is stored.**

†The sample app demonstrates an approach that meets the criteria.

> **WARNING**
>
> Uploading malicious code to a system is frequently the first step to executing code that can:
>
> - Completely gain control of a system.
> - Overload a system with the result that the system crashes.
> - Compromise user or system data.
> - Apply graffiti to a public UI.
>
> For information on reducing the attack surface area when accepting files from users, see the following resources:
>
> - Unrestricted File Upload
> - Azure Security: Ensure appropriate controls are in place when accepting files from users

For more information on implementing security measures, including examples from the sample app, see the Validation section.

Storage scenarios

Common storage options for files include:

- Database
  - For small file uploads, a database is often faster than physical storage (file system or network share) options.
  - A database is often more convenient than physical storage options because retrieval of a database record for user data can concurrently supply the file content (for example, an avatar image).
  - A database is potentially less expensive than using a data storage service.
- Physical storage (file system or network share)
  - For large file uploads:
    - Database limits may restrict the size of the upload.
    - Physical storage is often less economical than storage in a database.
  - Physical storage is potentially less expensive than using a data storage service.
  - The app's process must have read and write permissions to the storage location. **Never grant execute permission.**
- Data storage service (for example, Azure Blob Storage)
  - Services usually offer improved scalability and resiliency over on-premises solutions that are usually subject to single points of failure.
  - Services are potentially lower cost in large storage infrastructure scenarios.

  For more information, see Quickstart: Use .NET to create a blob in object storage.

File upload scenarios

Two general approaches for uploading files are buffering and streaming.

Buffering

The entire file is read into an IFormFile, which is a C# representation of the file used to process or save the file.

The resources (disk, memory) used by file uploads depend on the number and size of concurrent file uploads. If an app attempts to buffer too many uploads, the site crashes when it runs out of memory or disk space. If the size or frequency of file uploads is exhausting app resources, use streaming.

> **NOTE**
> Any single buffered file exceeding 64 KB is moved from memory to a temp file on disk.

Buffering small files is covered in the following sections of this topic:

- Physical storage
- Database

Streaming

The file is received from a multipart request and directly processed or saved by the app. Streaming doesn't improve performance significantly. Streaming reduces the demands for memory or disk space when uploading files.

Streaming large files is covered in the Upload large files with streaming section.

Upload small files with buffered model binding to physical storage

To upload small files, use a multipart form or construct a POST request using JavaScript.

The following example demonstrates the use of a Razor Pages form to upload a single file (*Pages/BufferedSingleFileUploadPhysical.cshtml* in the sample app):

```
<form enctype="multipart/form-data" method="post">
    <dl>
        <dt>
            <label asp-for="FileUpload.FormFile"></label>
        </dt>
        <dd>
            <input asp-for="FileUpload.FormFile" type="file">
            <span asp-validation-for="FileUpload.FormFile"></span>
        </dd>
    </dl>
    <input asp-page-handler="Upload" class="btn" type="submit" value="Upload" />
</form>
```

The following example is analogous to the prior example except that:

- JavaScript's (Fetch API) is used to submit the form's data.
- There's no validation.

```
<form action="BufferedSingleFileUploadPhysical/?handler=Upload"
      enctype="multipart/form-data" onsubmit="AJAXSubmit(this);return false;"
      method="post">
    <dl>
        <dt>
            <label for="FileUpload_FormFile">File</label>
        </dt>
        <dd>
            <input id="FileUpload_FormFile" type="file"
                name="FileUpload.FormFile" />
        </dd>
    </dl>

    <input class="btn" type="submit" value="Upload" />

    <div style="margin-top:15px">
        <output name="result"></output>
    </div>
</form>

<script>
  async function AJAXSubmit (oFormElement) {
    var resultElement = oFormElement.elements.namedItem("result");
    const formData = new FormData(oFormElement);

    try {
    const response = await fetch(oFormElement.action, {
      method: 'POST',
      body: formData
    });

    if (response.ok) {
      window.location.href = '/';
    }

    resultElement.value = 'Result: ' + response.status + ' ' +
      response.statusText;
    } catch (error) {
      console.error('Error:', error);
    }
  }
</script>
```

To perform the form POST in JavaScript for clients that don't support the Fetch API, use one of the following approaches:

- Use a Fetch Polyfill (for example, window.fetch polyfill (github/fetch)).
- Use `XMLHttpRequest`. For example:

```
<script>
  "use strict";

  function AJAXSubmit (oFormElement) {
    var oReq = new XMLHttpRequest();
    oReq.onload = function(e) {
    oFormElement.elements.namedItem("result").value =
      'Result: ' + this.status + ' ' + this.statusText;
    };
    oReq.open("post", oFormElement.action);
    oReq.send(new FormData(oFormElement));
  }
</script>
```

In order to support file uploads, HTML forms must specify an encoding type (`enctype`) of `multipart/form-data`.

For a `files` input element to support uploading multiple files provide the `multiple` attribute on the `<input>` element:

```
<input asp-for="FileUpload.FormFiles" type="file" multiple>
```

The individual files uploaded to the server can be accessed through Model Binding using IFormFile. The sample app demonstrates multiple buffered file uploads for database and physical storage scenarios.

WARNING

Do **not** use the `FileName` property of IFormFile other than for display and logging. When displaying or logging, HTML encode the file name. An attacker can provide a malicious filename, including full paths or relative paths. Applications should:

- Remove the path from the user-supplied filename.
- Save the HTML-encoded, path-removed filename for UI or logging.
- Generate a new random filename for storage.

The following code removes the path from the file name:

```
string untrustedFileName = Path.GetFileName(pathName);
```

The examples provided thus far don't take into account security considerations. Additional information is provided by the following sections and the sample app:

- Security considerations
- Validation

When uploading files using model binding and IFormFile, the action method can accept:

- A single IFormFile.
- Any of the following collections that represent several files:
  - IFormFileCollection
  - IEnumerable<IFormFile>
  - List<IFormFile>

> **NOTE**
>
> Binding matches form files by name. For example, the HTML `name` value in `<input type="file" name="formFile">` must match the C# parameter/property bound (`FormFile`). For more information, see the Match name attribute value to parameter name of POST method section.

The following example:

- Loops through one or more uploaded files.
- Uses Path.GetTempFileName to return a full path for a file, including the file name.
- Saves the files to the local file system using a file name generated by the app.
- Returns the total number and size of files uploaded.

```
public async Task<IActionResult> OnPostUploadAsync(List<IFormFile> files)
{
    long size = files.Sum(f => f.Length);

    foreach (var formFile in files)
    {
        if (formFile.Length > 0)
        {
            var filePath = Path.GetTempFileName();

            using (var stream = System.IO.File.Create(filePath))
            {
                await formFile.CopyToAsync(stream);
            }
        }
    }

    // Process uploaded files
    // Don't rely on or trust the FileName property without validation.

    return Ok(new { count = files.Count, size });
}
```

Use `Path.GetRandomFileName` to generate a file name without a path. In the following example, the path is obtained from configuration:

```
foreach (var formFile in files)
{
    if (formFile.Length > 0)
    {
        var filePath = Path.Combine(_config["StoredFilesPath"],
            Path.GetRandomFileName());

        using (var stream = System.IO.File.Create(filePath))
        {
            await formFile.CopyToAsync(stream);
        }
    }
}
```

The path passed to the FileStream *must* include the file name. If the file name isn't provided, an UnauthorizedAccessException is thrown at runtime.

Files uploaded using the IFormFile technique are buffered in memory or on disk on the server before processing. Inside the action method, the IFormFile contents are accessible as a Stream. In addition to the local file system, files can be saved to a network share or to a file storage service, such as Azure Blob storage.

For another example that loops over multiple files for upload and uses safe file names, see *Pages/BufferedMultipleFileUploadPhysical.cshtml.cs* in the sample app.

> **WARNING**
>
> Path.GetTempFileName throws an IOException if more than 65,535 files are created without deleting previous temporary files. The limit of 65,535 files is a per-server limit. For more information on this limit on Windows OS, see the remarks in the following topics:
>
> - GetTempFileNameA function
> - GetTempFileName

Upload small files with buffered model binding to a database

To store binary file data in a database using Entity Framework, define a Byte array property on the entity:

```
public class AppFile
{
    public int Id { get; set; }
    public byte[] Content { get; set; }
}
```

Specify a page model property for the class that includes an IFormFile:

```
public class BufferedSingleFileUploadDbModel : PageModel
{
    ...

    [BindProperty]
    public BufferedSingleFileUploadDb FileUpload { get; set; }

    ...
}

public class BufferedSingleFileUploadDb
{
    [Required]
    [Display(Name="File")]
    public IFormFile FormFile { get; set; }
}
```

> **NOTE**
>
> IFormFile can be used directly as an action method parameter or as a bound model property. The prior example uses a bound model property.

The `FileUpload` is used in the Razor Pages form:

```
<form enctype="multipart/form-data" method="post">
    <dl>
        <dt>
            <label asp-for="FileUpload.FormFile"></label>
        </dt>
        <dd>
            <input asp-for="FileUpload.FormFile" type="file">
        </dd>
    </dl>
    <input asp-page-handler="Upload" class="btn" type="submit" value="Upload">
</form>
```

When the form is POSTed to the server, copy the IFormFile to a stream and save it as a byte array in the database. In the following example, `_dbContext` stores the app's database context:

```
public async Task<IActionResult> OnPostUploadAsync()
{
    using (var memoryStream = new MemoryStream())
    {
        await FileUpload.FormFile.CopyToAsync(memoryStream);

        // Upload the file if less than 2 MB
        if (memoryStream.Length < 2097152)
        {
            var file = new AppFile()
            {
                Content = memoryStream.ToArray()
            };

            _dbContext.File.Add(file);

            await _dbContext.SaveChangesAsync();
        }
        else
        {
            ModelState.AddModelError("File", "The file is too large.");
        }
    }

    return Page();
}
```

The preceding example is similar to a scenario demonstrated in the sample app:

- *Pages/BufferedSingleFileUploadDb.cshtml*
- *Pages/BufferedSingleFileUploadDb.cshtml.cs*

> **WARNING**
>
> Use caution when storing binary data in relational databases, as it can adversely impact performance.
>
> Don't rely on or trust the `FileName` property of IFormFile without validation. The `FileName` property should only be used for display purposes and only after HTML encoding.
>
> The examples provided don't take into account security considerations. Additional information is provided by the following sections and the sample app:

Upload large files with streaming

The following example demonstrates how to use JavaScript to stream a file to a controller action. The file's antiforgery token is generated using a custom filter attribute and passed to the client HTTP headers instead of in the request body. Because the action method processes the uploaded data directly, form model binding is disabled by another custom filter. Within the action, the form's contents are read using a `MultipartReader`, which reads each individual `MultipartSection`, processing the file or storing the contents as appropriate. After the multipart sections are read, the action performs its own model binding.

The initial page response loads the form and saves an antiforgery token in a cookie (via the `GenerateAntiforgeryTokenCookieAttribute` attribute). The attribute uses ASP.NET Core's built-in antiforgery support to set a cookie with a request token:

```
public class GenerateAntiforgeryTokenCookieAttribute : ResultFilterAttribute
{
    public override void OnResultExecuting(ResultExecutingContext context)
    {
        var antiforgery = context.HttpContext.RequestServices.GetService<IAntiforgery>();

        // Send the request token as a JavaScript-readable cookie
        var tokens = antiforgery.GetAndStoreTokens(context.HttpContext);

        context.HttpContext.Response.Cookies.Append(
            "RequestVerificationToken",
            tokens.RequestToken,
            new CookieOptions() { HttpOnly = false });
    }

    public override void OnResultExecuted(ResultExecutedContext context)
    {
    }
}
```

The `DisableFormValueModelBindingAttribute` is used to disable model binding:

```
[AttributeUsage(AttributeTargets.Class | AttributeTargets.Method)]
public class DisableFormValueModelBindingAttribute : Attribute, IResourceFilter
{
    public void OnResourceExecuting(ResourceExecutingContext context)
    {
        var factories = context.ValueProviderFactories;
        factories.RemoveType<FormValueProviderFactory>();
        factories.RemoveType<FormFileValueProviderFactory>();
        factories.RemoveType<JQueryFormValueProviderFactory>();
    }

    public void OnResourceExecuted(ResourceExecutedContext context)
    {
    }
}
```

In the sample app, `GenerateAntiforgeryTokenCookieAttribute` and `DisableFormValueModelBindingAttribute` are applied as filters to the page application models of `/StreamedSingleFileUploadDb` and `/StreamedSingleFileUploadPhysical` in `Startup.ConfigureServices` using Razor Pages conventions:

```
services.AddRazorPages(options =>
{
    options.Conventions
        .AddPageApplicationModelConvention("/StreamedSingleFileUploadDb",
            model =>
            {
                model.Filters.Add(
                    new GenerateAntiforgeryTokenCookieAttribute());
                model.Filters.Add(
                    new DisableFormValueModelBindingAttribute());
            });
    options.Conventions
        .AddPageApplicationModelConvention("/StreamedSingleFileUploadPhysical",
            model =>
            {
                model.Filters.Add(
                    new GenerateAntiforgeryTokenCookieAttribute());
                model.Filters.Add(
                    new DisableFormValueModelBindingAttribute());
            });
});
```

Since model binding doesn't read the form, parameters that are bound from the form don't bind (query, route, and header continue to work). The action method works directly with the `Request` property. A `MultipartReader` is used to read each section. Key/value data is stored in a `KeyValueAccumulator`. After the multipart sections are read, the contents of the `KeyValueAccumulator` are used to bind the form data to a model type.

The complete `StreamingController.UploadDatabase` method for streaming to a database with EF Core:

```
[HttpPost]
[DisableFormValueModelBinding]
[ValidateAntiForgeryToken]
public async Task<IActionResult> UploadDatabase()
{
    if (!MultipartRequestHelper.IsMultipartContentType(Request.ContentType))
    {
        ModelState.AddModelError("File",
            $"The request couldn't be processed (Error 1).");
        // Log error

        return BadRequest(ModelState);
    }

    // Accumulate the form data key-value pairs in the request (formAccumulator).
    var formAccumulator = new KeyValueAccumulator();
    var trustedFileNameForDisplay = string.Empty;
    var untrustedFileNameForStorage = string.Empty;
    var streamedFileContent = new byte[0];

    var boundary = MultipartRequestHelper.GetBoundary(
        MediaTypeHeaderValue.Parse(Request.ContentType),
        _defaultFormOptions.MultipartBoundaryLengthLimit);
    var reader = new MultipartReader(boundary, HttpContext.Request.Body);

    var section = await reader.ReadNextSectionAsync();

    while (section != null)
    {
        var hasContentDispositionHeader =
            ContentDispositionHeaderValue.TryParse(
                section.ContentDisposition, out var contentDisposition);

        if (hasContentDispositionHeader)
        {
            if (MultipartRequestHelper
```

```
            .HasFileContentDisposition(contentDisposition))
        {
            untrustedFileNameForStorage = contentDisposition.FileName.Value;
            // Don't trust the file name sent by the client. To display
            // the file name, HTML-encode the value.
            trustedFileNameForDisplay = WebUtility.HtmlEncode(
                    contentDisposition.FileName.Value);

            streamedFileContent =
                await FileHelpers.ProcessStreamedFile(section, contentDisposition,
                    ModelState, _permittedExtensions, _fileSizeLimit);

            if (!ModelState.IsValid)
            {
                return BadRequest(ModelState);
            }
        }
        else if (MultipartRequestHelper
            .HasFormDataContentDisposition(contentDisposition))
        {
            // Don't limit the key name length because the
            // multipart headers length limit is already in effect.
            var key = HeaderUtilities
                .RemoveQuotes(contentDisposition.Name).Value;
            var encoding = GetEncoding(section);

            if (encoding == null)
            {
                ModelState.AddModelError("File",
                    $"The request couldn't be processed (Error 2).");
                // Log error

                return BadRequest(ModelState);
            }

            using (var streamReader = new StreamReader(
                section.Body,
                encoding,
                detectEncodingFromByteOrderMarks: true,
                bufferSize: 1024,
                leaveOpen: true))
            {
                // The value length limit is enforced by
                // MultipartBodyLengthLimit
                var value = await streamReader.ReadToEndAsync();

                if (string.Equals(value, "undefined",
                    StringComparison.OrdinalIgnoreCase))
                {
                    value = string.Empty;
                }

                formAccumulator.Append(key, value);

                if (formAccumulator.ValueCount >
                    _defaultFormOptions.ValueCountLimit)
                {
                    // Form key count limit of
                    // _defaultFormOptions.ValueCountLimit
                    // is exceeded.
                    ModelState.AddModelError("File",
                        $"The request couldn't be processed (Error 3).");
                    // Log error

                    return BadRequest(ModelState);
                }
            }
        }
    }
```

```
        }

        // Drain any remaining section body that hasn't been consumed and
        // read the headers for the next section.
        section = await reader.ReadNextSectionAsync();
    }

    // Bind form data to the model
    var formData = new FormData();
    var formValueProvider = new FormValueProvider(
        BindingSource.Form,
        new FormCollection(formAccumulator.GetResults()),
        CultureInfo.CurrentCulture);
    var bindingSuccessful = await TryUpdateModelAsync(formData, prefix: "",
        valueProvider: formValueProvider);

    if (!bindingSuccessful)
    {
        ModelState.AddModelError("File",
            "The request couldn't be processed (Error 5).");
        // Log error

        return BadRequest(ModelState);
    }

    // **WARNING!**
    // In the following example, the file is saved without
    // scanning the file's contents. In most production
    // scenarios, an anti-virus/anti-malware scanner API
    // is used on the file before making the file available
    // for download or for use by other systems.
    // For more information, see the topic that accompanies
    // this sample app.

    var file = new AppFile()
    {
        Content = streamedFileContent,
        UntrustedName = untrustedFileNameForStorage,
        Note = formData.Note,
        Size = streamedFileContent.Length,
        UploadDT = DateTime.UtcNow
    };

    _context.File.Add(file);
    await _context.SaveChangesAsync();

    return Created(nameof(StreamingController), null);
}
```

`MultipartRequestHelper` (*Utilities/MultipartRequestHelper.cs*):

```
using System;
using System.IO;
using Microsoft.Net.Http.Headers;

namespace SampleApp.Utilities
{
    public static class MultipartRequestHelper
    {
        // Content-Type: multipart/form-data; boundary="----WebKitFormBoundarymx2fSWqWSd0OxQqq"
        // The spec at https://tools.ietf.org/html/rfc2046#section-5.1 states that 70 characters is a
reasonable limit.
        public static string GetBoundary(MediaTypeHeaderValue contentType, int lengthLimit)
        {
            var boundary = HeaderUtilities.RemoveQuotes(contentType.Boundary).Value;

            if (string.IsNullOrWhiteSpace(boundary))
            {
                throw new InvalidDataException("Missing content-type boundary.");
            }

            if (boundary.Length > lengthLimit)
            {
                throw new InvalidDataException(
                    $"Multipart boundary length limit {lengthLimit} exceeded.");
            }

            return boundary;
        }

        public static bool IsMultipartContentType(string contentType)
        {
            return !string.IsNullOrEmpty(contentType)
                   && contentType.IndexOf("multipart/", StringComparison.OrdinalIgnoreCase) >= 0;
        }

        public static bool HasFormDataContentDisposition(ContentDispositionHeaderValue contentDisposition)
        {
            // Content-Disposition: form-data; name="key";
            return contentDisposition != null
                && contentDisposition.DispositionType.Equals("form-data")
                && string.IsNullOrEmpty(contentDisposition.FileName.Value)
                && string.IsNullOrEmpty(contentDisposition.FileNameStar.Value);
        }

        public static bool HasFileContentDisposition(ContentDispositionHeaderValue contentDisposition)
        {
            // Content-Disposition: form-data; name="myfile1"; filename="Misc 002.jpg"
            return contentDisposition != null
                && contentDisposition.DispositionType.Equals("form-data")
                && (!string.IsNullOrEmpty(contentDisposition.FileName.Value)
                    || !string.IsNullOrEmpty(contentDisposition.FileNameStar.Value));
        }
    }
}
```

The complete `StreamingController.UploadPhysical` method for streaming to a physical location:

```
[HttpPost]
[DisableFormValueModelBinding]
[ValidateAntiForgeryToken]
public async Task<IActionResult> UploadPhysical()
{
    if (!MultipartRequestHelper.IsMultipartContentType(Request.ContentType))
    {
        ModelState.AddModelError("File",
            $"The request couldn't be processed (Error 1).");
```

```
            // Log error

            return BadRequest(ModelState);
        }

        var boundary = MultipartRequestHelper.GetBoundary(
            MediaTypeHeaderValue.Parse(Request.ContentType),
            _defaultFormOptions.MultipartBoundaryLengthLimit);
        var reader = new MultipartReader(boundary, HttpContext.Request.Body);
        var section = await reader.ReadNextSectionAsync();

        while (section != null)
        {
            var hasContentDispositionHeader =
                ContentDispositionHeaderValue.TryParse(
                    section.ContentDisposition, out var contentDisposition);

            if (hasContentDispositionHeader)
            {
                // This check assumes that there's a file
                // present without form data. If form data
                // is present, this method immediately fails
                // and returns the model error.
                if (!MultipartRequestHelper
                    .HasFileContentDisposition(contentDisposition))
                {
                    ModelState.AddModelError("File",
                        $"The request couldn't be processed (Error 2).");
                    // Log error

                    return BadRequest(ModelState);
                }
                else
                {
                    // Don't trust the file name sent by the client. To display
                    // the file name, HTML-encode the value.
                    var trustedFileNameForDisplay = WebUtility.HtmlEncode(
                            contentDisposition.FileName.Value);
                    var trustedFileNameForFileStorage = Path.GetRandomFileName();

                    // **WARNING!**
                    // In the following example, the file is saved without
                    // scanning the file's contents. In most production
                    // scenarios, an anti-virus/anti-malware scanner API
                    // is used on the file before making the file available
                    // for download or for use by other systems.
                    // For more information, see the topic that accompanies
                    // this sample.

                    var streamedFileContent = await FileHelpers.ProcessStreamedFile(
                        section, contentDisposition, ModelState,
                        _permittedExtensions, _fileSizeLimit);

                    if (!ModelState.IsValid)
                    {
                        return BadRequest(ModelState);
                    }

                    using (var targetStream = System.IO.File.Create(
                        Path.Combine(_targetFilePath, trustedFileNameForFileStorage)))
                    {
                        await targetStream.WriteAsync(streamedFileContent);

                        _logger.LogInformation(
                            "Uploaded file '{TrustedFileNameForDisplay}' saved to " +
                            "'{TargetFilePath}' as {TrustedFileNameForFileStorage}",
                            trustedFileNameForDisplay, _targetFilePath,
                            trustedFileNameForFileStorage);
                    }
```

```
            }
        }

        // Drain any remaining section body that hasn't been consumed and
        // read the headers for the next section.
        section = await reader.ReadNextSectionAsync();
    }

    return Created(nameof(StreamingController), null);
}
```

In the sample app, validation checks are handled by `FileHelpers.ProcessStreamedFile`.

Validation

The sample app's `FileHelpers` class demonstrates a several checks for buffered IFormFile and streamed file uploads. For processing IFormFile buffered file uploads in the sample app, see the `ProcessFormFile` method in the *Utilities/FileHelpers.cs* file. For processing streamed files, see the `ProcessStreamedFile` method in the same file.

> **WARNING**
>
> The validation processing methods demonstrated in the sample app don't scan the content of uploaded files. In most production scenarios, a virus/malware scanner API is used on the file before making the file available to users or other systems.
>
> Although the topic sample provides a working example of validation techniques, don't implement the `FileHelpers` class in a production app unless you:
>
> - Fully understand the implementation.
> - Modify the implementation as appropriate for the app's environment and specifications.
>
> **Never indiscriminately implement security code in an app without addressing these requirements.**

Content validation

Use a third party virus/malware scanning API on uploaded content.

Scanning files is demanding on server resources in high volume scenarios. If request processing performance is diminished due to file scanning, consider offloading the scanning work to a background service, possibly a service running on a server different from the app's server. Typically, uploaded files are held in a quarantined area until the background virus scanner checks them. When a file passes, the file is moved to the normal file storage location. These steps are usually performed in conjunction with a database record that indicates the scanning status of a file. By using such an approach, the app and app server remain focused on responding to requests.

File extension validation

The uploaded file's extension should be checked against a list of permitted extensions. For example:

```
private string[] permittedExtensions = { ".txt", ".pdf" };

var ext = Path.GetExtension(uploadedFileName).ToLowerInvariant();

if (string.IsNullOrEmpty(ext) || !permittedExtensions.Contains(ext))
{
    // The extension is invalid ... discontinue processing the file
}
```

File signature validation

A file's signature is determined by the first few bytes at the start of a file. These bytes can be used to indicate if the

extension matches the content of the file. The sample app checks file signatures for a few common file types. In the following example, the file signature for a JPEG image is checked against the file:

```
private static readonly Dictionary<string, List<byte[]>> _fileSignature =
    new Dictionary<string, List<byte[]>>
{
    { ".jpeg", new List<byte[]>
        {
            new byte[] { 0xFF, 0xD8, 0xFF, 0xE0 },
            new byte[] { 0xFF, 0xD8, 0xFF, 0xE2 },
            new byte[] { 0xFF, 0xD8, 0xFF, 0xE3 },
        }
    },
};

using (var reader = new BinaryReader(uploadedFileData))
{
    var signatures = _fileSignature[ext];
    var headerBytes = reader.ReadBytes(signatures.Max(m => m.Length));

    return signatures.Any(signature =>
        headerBytes.Take(signature.Length).SequenceEqual(signature));
}
```

To obtain additional file signatures, see the File Signatures Database and official file specifications.

File name security

Never use a client-supplied file name for saving a file to physical storage. Create a safe file name for the file using Path.GetRandomFileName or Path.GetTempFileName to create a full path (including the file name) for temporary storage.

Razor automatically HTML encodes property values for display. The following code is safe to use:

```
@foreach (var file in Model.DatabaseFiles) {
    <tr>
        <td>
            @file.UntrustedName
        </td>
    </tr>
}
```

Outside of Razor, always HtmlEncode file name content from a user's request.

Many implementations must include a check that the file exists; otherwise, the file is overwritten by a file of the same name. Supply additional logic to meet your app's specifications.

Size validation

Limit the size of uploaded files.

In the sample app, the size of the file is limited to 2 MB (indicated in bytes). The limit is supplied via Configuration from the *appsettings.json* file:

```
{
  "FileSizeLimit": 2097152
}
```

The `FileSizeLimit` is injected into `PageModel` classes:

```
public class BufferedSingleFileUploadPhysicalModel : PageModel
{
    private readonly long _fileSizeLimit;

    public BufferedSingleFileUploadPhysicalModel(IConfiguration config)
    {
        _fileSizeLimit = config.GetValue<long>("FileSizeLimit");
    }

    ...
}
```

When a file size exceeds the limit, the file is rejected:

```
if (formFile.Length > _fileSizeLimit)
{
    // The file is too large ... discontinue processing the file
}
```

Match name attribute value to parameter name of POST method

In non-Razor forms that POST form data or use JavaScript's `FormData` directly, the name specified in the form's element or `FormData` must match the name of the parameter in the controller's action.

In the following example:

- When using an `<input>` element, the `name` attribute is set to the value `battlePlans`:

  ```
  <input type="file" name="battlePlans" multiple>
  ```

- When using `FormData` in JavaScript, the name is set to the value `battlePlans`:

  ```
  var formData = new FormData();

  for (var file in files) {
    formData.append("battlePlans", file, file.name);
  }
  ```

Use a matching name for the parameter of the C# method (`battlePlans`):

- For a Razor Pages page handler method named `Upload`:

  ```
  public async Task<IActionResult> OnPostUploadAsync(List<IFormFile> battlePlans)
  ```

- For an MVC POST controller action method:

  ```
  public async Task<IActionResult> Post(List<IFormFile> battlePlans)
  ```

Server and app configuration

Multipart body length limit

MultipartBodyLengthLimit sets the limit for the length of each multipart body. Form sections that exceed this limit throw an InvalidDataException when parsed. The default is 134,217,728 (128 MB). Customize the limit using the MultipartBodyLengthLimit setting in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<FormOptions>(options =>
    {
        // Set the limit to 256 MB
        options.MultipartBodyLengthLimit = 268435456;
    });
}
```

RequestFormLimitsAttribute is used to set the MultipartBodyLengthLimit for a single page or action.

In a Razor Pages app, apply the filter with a convention in `Startup.ConfigureServices`:

```
services.AddRazorPages(options =>
{
    options.Conventions
        .AddPageApplicationModelConvention("/FileUploadPage",
            model.Filters.Add(
                new RequestFormLimitsAttribute()
                {
                    // Set the limit to 256 MB
                    MultipartBodyLengthLimit = 268435456
                });
});
```

In a Razor Pages app or an MVC app, apply the filter to the page model or action method:

```
// Set the limit to 256 MB
[RequestFormLimits(MultipartBodyLengthLimit = 268435456)]
public class BufferedSingleFileUploadPhysicalModel : PageModel
{
    ...
}
```

Kestrel maximum request body size

For apps hosted by Kestrel, the default maximum request body size is 30,000,000 bytes, which is approximately 28.6 MB. Customize the limit using the MaxRequestBodySize Kestrel server option:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.ConfigureKestrel((context, options) =>
            {
                // Handle requests up to 50 MB
                options.Limits.MaxRequestBodySize = 52428800;
            })
            .UseStartup<Startup>();
        });
```

RequestSizeLimitAttribute is used to set the MaxRequestBodySize for a single page or action.

In a Razor Pages app, apply the filter with a convention in `Startup.ConfigureServices`:

```
services.AddRazorPages(options =>
{
    options.Conventions
        .AddPageApplicationModelConvention("/FileUploadPage",
            model =>
            {
                // Handle requests up to 50 MB
                model.Filters.Add(
                    new RequestSizeLimitAttribute(52428800));
            });
});
```

In a Razor pages app or an MVC app, apply the filter to the page handler class or action method:

```
// Handle requests up to 50 MB
[RequestSizeLimit(52428800)]
public class BufferedSingleFileUploadPhysicalModel : PageModel
{
    ...
}
```

The `RequestSizeLimitAttribute` can also be applied using the `@attribute` Razor directive:

```
@attribute [RequestSizeLimitAttribute(52428800)]
```

Other Kestrel limits

Other Kestrel limits may apply for apps hosted by Kestrel:

- Maximum client connections
- Request and response data rates

IIS

The default request limit (`maxAllowedContentLength`) is 30,000,000 bytes, which is approximately 28.6 MB.
Customize the limit in the `web.config` file. In the following example, the limit is set to 50 MB (52,428,800 bytes):

```
<system.webServer>
  <security>
    <requestFiltering>
      <requestLimits maxAllowedContentLength="52428800" />
    </requestFiltering>
  </security>
</system.webServer>
```

The `maxAllowedContentLength` setting only applies to IIS. For more information, see Request Limits `<requestLimits>`.

Troubleshoot

Below are some common problems encountered when working with uploading files and their possible solutions.

Not Found error when deployed to an IIS server

The following error indicates that the uploaded file exceeds the server's configured content length:

```
HTTP 404.13 - Not Found
The request filtering module is configured to deny a request that exceeds the request content length.
```

For more information, see the IIS section.

Connection failure

A connection error and a reset server connection probably indicates that the uploaded file exceeds Kestrel's maximum request body size. For more information, see the Kestrel maximum request body size section. Kestrel client connection limits may also require adjustment.

Null Reference Exception with IFormFile

If the controller is accepting uploaded files using IFormFile but the value is `null`, confirm that the HTML form is specifying an `enctype` value of `multipart/form-data`. If this attribute isn't set on the `<form>` element, the file upload doesn't occur and any bound IFormFile arguments are `null`. Also confirm that the upload naming in form data matches the app's naming.

Stream was too long

The examples in this topic rely upon MemoryStream to hold the uploaded file's content. The size limit of a `MemoryStream` is `int.MaxValue`. If the app's file upload scenario requires holding file content larger than 50 MB, use an alternative approach that doesn't rely upon a single `MemoryStream` for holding an uploaded file's content.

ASP.NET Core supports uploading one or more files using buffered model binding for smaller files and unbuffered streaming for larger files.

View or download sample code (how to download)

Security considerations

Use caution when providing users with the ability to upload files to a server. Attackers may attempt to:

- Execute denial of service attacks.
- Upload viruses or malware.
- Compromise networks and servers in other ways.

Security steps that reduce the likelihood of a successful attack are:

- Upload files to a dedicated file upload area, preferably to a non-system drive. A dedicated location makes it easier to impose security restrictions on uploaded files. Disable execute permissions on the file upload location.†
- Do **not** persist uploaded files in the same directory tree as the app.†
- Use a safe file name determined by the app. Don't use a file name provided by the user or the untrusted file name of the uploaded file.† HTML encode the untrusted file name when displaying it. For example, logging the file name or displaying in UI (Razor automatically HTML encodes output).
- Allow only approved file extensions for the app's design specification.†
- Verify that client-side checks are performed on the server.† Client-side checks are easy to circumvent.
- Check the size of an uploaded file. Set a maximum size limit to prevent large uploads.†
- When files shouldn't be overwritten by an uploaded file with the same name, check the file name against the database or physical storage before uploading the file.
- **Run a virus/malware scanner on uploaded content before the file is stored.**

†The sample app demonstrates an approach that meets the criteria.

WARNING

Uploading malicious code to a system is frequently the first step to executing code that can:

- Completely gain control of a system.
- Overload a system with the result that the system crashes.
- Compromise user or system data.
- Apply graffiti to a public UI.

For information on reducing the attack surface area when accepting files from users, see the following resources:

- Unrestricted File Upload
- Azure Security: Ensure appropriate controls are in place when accepting files from users

For more information on implementing security measures, including examples from the sample app, see the Validation section.

Storage scenarios

Common storage options for files include:

- Database
  - For small file uploads, a database is often faster than physical storage (file system or network share) options.
  - A database is often more convenient than physical storage options because retrieval of a database record for user data can concurrently supply the file content (for example, an avatar image).
  - A database is potentially less expensive than using a data storage service.
- Physical storage (file system or network share)
  - For large file uploads:
    - Database limits may restrict the size of the upload.
    - Physical storage is often less economical than storage in a database.
  - Physical storage is potentially less expensive than using a data storage service.
  - The app's process must have read and write permissions to the storage location. **Never grant execute permission.**
- Data storage service (for example, Azure Blob Storage)
  - Services usually offer improved scalability and resiliency over on-premises solutions that are usually subject to single points of failure.
  - Services are potentially lower cost in large storage infrastructure scenarios.

  For more information, see Quickstart: Use .NET to create a blob in object storage.

File upload scenarios

Two general approaches for uploading files are buffering and streaming.

Buffering

The entire file is read into an IFormFile, which is a C# representation of the file used to process or save the file.

The resources (disk, memory) used by file uploads depend on the number and size of concurrent file uploads. If an app attempts to buffer too many uploads, the site crashes when it runs out of memory or disk space. If the size or frequency of file uploads is exhausting app resources, use streaming.

> **NOTE**
>
> Any single buffered file exceeding 64 KB is moved from memory to a temp file on disk.

Buffering small files is covered in the following sections of this topic:

- Physical storage
- Database

Streaming

The file is received from a multipart request and directly processed or saved by the app. Streaming doesn't improve performance significantly. Streaming reduces the demands for memory or disk space when uploading files.

Streaming large files is covered in the Upload large files with streaming section.

Upload small files with buffered model binding to physical storage

To upload small files, use a multipart form or construct a POST request using JavaScript.

The following example demonstrates the use of a Razor Pages form to upload a single file (*Pages/BufferedSingleFileUploadPhysical.cshtml* in the sample app):

```
<form enctype="multipart/form-data" method="post">
    <dl>
        <dt>
            <label asp-for="FileUpload.FormFile"></label>
        </dt>
        <dd>
            <input asp-for="FileUpload.FormFile" type="file">
            <span asp-validation-for="FileUpload.FormFile"></span>
        </dd>
    </dl>
    <input asp-page-handler="Upload" class="btn" type="submit" value="Upload" />
</form>
```

The following example is analogous to the prior example except that:

- JavaScript's (Fetch API) is used to submit the form's data.
- There's no validation.

```
<form action="BufferedSingleFileUploadPhysical/?handler=Upload"
      enctype="multipart/form-data" onsubmit="AJAXSubmit(this);return false;"
      method="post">
    <dl>
        <dt>
            <label for="FileUpload_FormFile">File</label>
        </dt>
        <dd>
            <input id="FileUpload_FormFile" type="file"
                name="FileUpload.FormFile" />
        </dd>
    </dl>

    <input class="btn" type="submit" value="Upload" />

    <div style="margin-top:15px">
        <output name="result"></output>
    </div>
</form>

<script>
  async function AJAXSubmit (oFormElement) {
    var resultElement = oFormElement.elements.namedItem("result");
    const formData = new FormData(oFormElement);

    try {
    const response = await fetch(oFormElement.action, {
      method: 'POST',
      body: formData
    });

    if (response.ok) {
      window.location.href = '/';
    }

    resultElement.value = 'Result: ' + response.status + ' ' +
      response.statusText;
    } catch (error) {
      console.error('Error:', error);
    }
  }
</script>
```

To perform the form POST in JavaScript for clients that don't support the Fetch API, use one of the following approaches:

- Use a Fetch Polyfill (for example, window.fetch polyfill (github/fetch)).
- Use `XMLHttpRequest`. For example:

```
  <script>
    "use strict";

    function AJAXSubmit (oFormElement) {
      var oReq = new XMLHttpRequest();
      oReq.onload = function(e) {
      oFormElement.elements.namedItem("result").value =
        'Result: ' + this.status + ' ' + this.statusText;
      };
      oReq.open("post", oFormElement.action);
      oReq.send(new FormData(oFormElement));
    }
  </script>
```

In order to support file uploads, HTML forms must specify an encoding type (`enctype`) of `multipart/form-data` .

For a `files` input element to support uploading multiple files provide the `multiple` attribute on the `<input>` element:

```
<input asp-for="FileUpload.FormFiles" type="file" multiple>
```

The individual files uploaded to the server can be accessed through Model Binding using IFormFile. The sample app demonstrates multiple buffered file uploads for database and physical storage scenarios.

WARNING

Do **not** use the `FileName` property of IFormFile other than for display and logging. When displaying or logging, HTML encode the file name. An attacker can provide a malicious filename, including full paths or relative paths. Applications should:

- Remove the path from the user-supplied filename.
- Save the HTML-encoded, path-removed filename for UI or logging.
- Generate a new random filename for storage.

The following code removes the path from the file name:

```
string untrustedFileName = Path.GetFileName(pathName);
```

The examples provided thus far don't take into account security considerations. Additional information is provided by the following sections and the sample app:

- Security considerations
- Validation

When uploading files using model binding and IFormFile, the action method can accept:

- A single IFormFile.
- Any of the following collections that represent several files:
  - IFormFileCollection
  - IEnumerable<IFormFile>
  - List<IFormFile>

NOTE

Binding matches form files by name. For example, the HTML `name` value in `<input type="file" name="formFile">` must match the C# parameter/property bound (`FormFile`). For more information, see the Match name attribute value to parameter name of POST method section.

The following example:

- Loops through one or more uploaded files.
- Uses Path.GetTempFileName to return a full path for a file, including the file name.
- Saves the files to the local file system using a file name generated by the app.
- Returns the total number and size of files uploaded.

```
public async Task<IActionResult> OnPostUploadAsync(List<IFormFile> files)
{
    long size = files.Sum(f => f.Length);

    foreach (var formFile in files)
    {
        if (formFile.Length > 0)
        {
            var filePath = Path.GetTempFileName();

            using (var stream = System.IO.File.Create(filePath))
            {
                await formFile.CopyToAsync(stream);
            }
        }
    }

    // Process uploaded files
    // Don't rely on or trust the FileName property without validation.

    return Ok(new { count = files.Count, size });
}
```

Use `Path.GetRandomFileName` to generate a file name without a path. In the following example, the path is obtained from configuration:

```
foreach (var formFile in files)
{
    if (formFile.Length > 0)
    {
        var filePath = Path.Combine(_config["StoredFilesPath"],
            Path.GetRandomFileName());

        using (var stream = System.IO.File.Create(filePath))
        {
            await formFile.CopyToAsync(stream);
        }
    }
}
```

The path passed to the FileStream *must* include the file name. If the file name isn't provided, an UnauthorizedAccessException is thrown at runtime.

Files uploaded using the IFormFile technique are buffered in memory or on disk on the server before processing. Inside the action method, the IFormFile contents are accessible as a Stream. In addition to the local file system, files can be saved to a network share or to a file storage service, such as Azure Blob storage.

For another example that loops over multiple files for upload and uses safe file names, see *Pages/BufferedMultipleFileUploadPhysical.cshtml.cs* in the sample app.

> **WARNING**
>
> Path.GetTempFileName throws an IOException if more than 65,535 files are created without deleting previous temporary files. The limit of 65,535 files is a per-server limit. For more information on this limit on Windows OS, see the remarks in the following topics:
>
> - GetTempFileNameA function
> - GetTempFileName

Upload small files with buffered model binding to a database

To store binary file data in a database using Entity Framework, define a Byte array property on the entity:

```
public class AppFile
{
    public int Id { get; set; }
    public byte[] Content { get; set; }
}
```

Specify a page model property for the class that includes an IFormFile:

```
public class BufferedSingleFileUploadDbModel : PageModel
{
    ...

    [BindProperty]
    public BufferedSingleFileUploadDb FileUpload { get; set; }

    ...
}

public class BufferedSingleFileUploadDb
{
    [Required]
    [Display(Name="File")]
    public IFormFile FormFile { get; set; }
}
```

> **NOTE**
>
> IFormFile can be used directly as an action method parameter or as a bound model property. The prior example uses a bound model property.

The `FileUpload` is used in the Razor Pages form:

```
<form enctype="multipart/form-data" method="post">
    <dl>
        <dt>
            <label asp-for="FileUpload.FormFile"></label>
        </dt>
        <dd>
            <input asp-for="FileUpload.FormFile" type="file">
        </dd>
    </dl>
    <input asp-page-handler="Upload" class="btn" type="submit" value="Upload">
</form>
```

When the form is POSTed to the server, copy the IFormFile to a stream and save it as a byte array in the database. In the following example, `_dbContext` stores the app's database context:

```
public async Task<IActionResult> OnPostUploadAsync()
{
    using (var memoryStream = new MemoryStream())
    {
        await FileUpload.FormFile.CopyToAsync(memoryStream);

        // Upload the file if less than 2 MB
        if (memoryStream.Length < 2097152)
        {
            var file = new AppFile()
            {
                Content = memoryStream.ToArray()
            };

            _dbContext.File.Add(file);

            await _dbContext.SaveChangesAsync();
        }
        else
        {
            ModelState.AddModelError("File", "The file is too large.");
        }
    }

    return Page();
}
```

The preceding example is similar to a scenario demonstrated in the sample app:

- *Pages/BufferedSingleFileUploadDb.cshtml*
- *Pages/BufferedSingleFileUploadDb.cshtml.cs*

WARNING

Use caution when storing binary data in relational databases, as it can adversely impact performance.

Don't rely on or trust the `FileName` property of IFormFile without validation. The `FileName` property should only be used for display purposes and only after HTML encoding.

The examples provided don't take into account security considerations. Additional information is provided by the following sections and the sample app:

- Security considerations
- Validation

Upload large files with streaming

The following example demonstrates how to use JavaScript to stream a file to a controller action. The file's antiforgery token is generated using a custom filter attribute and passed to the client HTTP headers instead of in the request body. Because the action method processes the uploaded data directly, form model binding is disabled by another custom filter. Within the action, the form's contents are read using a `MultipartReader`, which reads each individual `MultipartSection`, processing the file or storing the contents as appropriate. After the multipart sections are read, the action performs its own model binding.

The initial page response loads the form and saves an antiforgery token in a cookie (via the `GenerateAntiforgeryTokenCookieAttribute` attribute). The attribute uses ASP.NET Core's built-in antiforgery support to set a cookie with a request token:

```
public class GenerateAntiforgeryTokenCookieAttribute : ResultFilterAttribute
{
    public override void OnResultExecuting(ResultExecutingContext context)
    {
        var antiforgery = context.HttpContext.RequestServices.GetService<IAntiforgery>();

        // Send the request token as a JavaScript-readable cookie
        var tokens = antiforgery.GetAndStoreTokens(context.HttpContext);

        context.HttpContext.Response.Cookies.Append(
            "RequestVerificationToken",
            tokens.RequestToken,
            new CookieOptions() { HttpOnly = false });
    }

    public override void OnResultExecuted(ResultExecutedContext context)
    {
    }
}
```

The `DisableFormValueModelBindingAttribute` is used to disable model binding:

```
[AttributeUsage(AttributeTargets.Class | AttributeTargets.Method)]
public class DisableFormValueModelBindingAttribute : Attribute, IResourceFilter
{
    public void OnResourceExecuting(ResourceExecutingContext context)
    {
        var factories = context.ValueProviderFactories;
        factories.RemoveType<FormValueProviderFactory>();
        factories.RemoveType<FormFileValueProviderFactory>();
        factories.RemoveType<JQueryFormValueProviderFactory>();
    }

    public void OnResourceExecuted(ResourceExecutedContext context)
    {
    }
}
```

In the sample app, `GenerateAntiforgeryTokenCookieAttribute` and `DisableFormValueModelBindingAttribute` are applied as filters to the page application models of `/StreamedSingleFileUploadDb` and `/StreamedSingleFileUploadPhysical` in `Startup.ConfigureServices` using Razor Pages conventions:

```
services.AddRazorPages(options =>
{
    options.Conventions
        .AddPageApplicationModelConvention("/StreamedSingleFileUploadDb",
            model =>
            {
                model.Filters.Add(
                    new GenerateAntiforgeryTokenCookieAttribute());
                model.Filters.Add(
                    new DisableFormValueModelBindingAttribute());
            });
    options.Conventions
        .AddPageApplicationModelConvention("/StreamedSingleFileUploadPhysical",
            model =>
            {
                model.Filters.Add(
                    new GenerateAntiforgeryTokenCookieAttribute());
                model.Filters.Add(
                    new DisableFormValueModelBindingAttribute());
            });
});
```

Since model binding doesn't read the form, parameters that are bound from the form don't bind (query, route, and header continue to work). The action method works directly with the `Request` property. A `MultipartReader` is used to read each section. Key/value data is stored in a `KeyValueAccumulator`. After the multipart sections are read, the contents of the `KeyValueAccumulator` are used to bind the form data to a model type.

The complete `StreamingController.UploadDatabase` method for streaming to a database with EF Core:

```
[HttpPost]
[DisableFormValueModelBinding]
[ValidateAntiForgeryToken]
public async Task<IActionResult> UploadDatabase()
{
    if (!MultipartRequestHelper.IsMultipartContentType(Request.ContentType))
    {
        ModelState.AddModelError("File",
            $"The request couldn't be processed (Error 1).");
        // Log error

        return BadRequest(ModelState);
    }

    // Accumulate the form data key-value pairs in the request (formAccumulator).
    var formAccumulator = new KeyValueAccumulator();
    var trustedFileNameForDisplay = string.Empty;
    var untrustedFileNameForStorage = string.Empty;
    var streamedFileContent = new byte[0];

    var boundary = MultipartRequestHelper.GetBoundary(
        MediaTypeHeaderValue.Parse(Request.ContentType),
        _defaultFormOptions.MultipartBoundaryLengthLimit);
    var reader = new MultipartReader(boundary, HttpContext.Request.Body);

    var section = await reader.ReadNextSectionAsync();

    while (section != null)
    {
        var hasContentDispositionHeader =
            ContentDispositionHeaderValue.TryParse(
                section.ContentDisposition, out var contentDisposition);

        if (hasContentDispositionHeader)
        {
            if (MultipartRequestHelper
```

```
            .HasFileContentDisposition(contentDisposition))
        {
            untrustedFileNameForStorage = contentDisposition.FileName.Value;
            // Don't trust the file name sent by the client. To display
            // the file name, HTML-encode the value.
            trustedFileNameForDisplay = WebUtility.HtmlEncode(
                    contentDisposition.FileName.Value);

            streamedFileContent =
                await FileHelpers.ProcessStreamedFile(section, contentDisposition,
                    ModelState, _permittedExtensions, _fileSizeLimit);

            if (!ModelState.IsValid)
            {
                return BadRequest(ModelState);
            }
        }
        else if (MultipartRequestHelper
            .HasFormDataContentDisposition(contentDisposition))
        {
            // Don't limit the key name length because the
            // multipart headers length limit is already in effect.
            var key = HeaderUtilities
                .RemoveQuotes(contentDisposition.Name).Value;
            var encoding = GetEncoding(section);

            if (encoding == null)
            {
                ModelState.AddModelError("File",
                    $"The request couldn't be processed (Error 2).");
                // Log error

                return BadRequest(ModelState);
            }

            using (var streamReader = new StreamReader(
                section.Body,
                encoding,
                detectEncodingFromByteOrderMarks: true,
                bufferSize: 1024,
                leaveOpen: true))
            {
                // The value length limit is enforced by
                // MultipartBodyLengthLimit
                var value = await streamReader.ReadToEndAsync();

                if (string.Equals(value, "undefined",
                    StringComparison.OrdinalIgnoreCase))
                {
                    value = string.Empty;
                }

                formAccumulator.Append(key, value);

                if (formAccumulator.ValueCount >
                    _defaultFormOptions.ValueCountLimit)
                {
                    // Form key count limit of
                    // _defaultFormOptions.ValueCountLimit
                    // is exceeded.
                    ModelState.AddModelError("File",
                        $"The request couldn't be processed (Error 3).");
                    // Log error

                    return BadRequest(ModelState);
                }
            }
        }
    }
```

```
        }

        // Drain any remaining section body that hasn't been consumed and
        // read the headers for the next section.
        section = await reader.ReadNextSectionAsync();
    }

    // Bind form data to the model
    var formData = new FormData();
    var formValueProvider = new FormValueProvider(
        BindingSource.Form,
        new FormCollection(formAccumulator.GetResults()),
        CultureInfo.CurrentCulture);
    var bindingSuccessful = await TryUpdateModelAsync(formData, prefix: "",
        valueProvider: formValueProvider);

    if (!bindingSuccessful)
    {
        ModelState.AddModelError("File",
            "The request couldn't be processed (Error 5).");
        // Log error

        return BadRequest(ModelState);
    }

    // **WARNING!**
    // In the following example, the file is saved without
    // scanning the file's contents. In most production
    // scenarios, an anti-virus/anti-malware scanner API
    // is used on the file before making the file available
    // for download or for use by other systems.
    // For more information, see the topic that accompanies
    // this sample app.

    var file = new AppFile()
    {
        Content = streamedFileContent,
        UntrustedName = untrustedFileNameForStorage,
        Note = formData.Note,
        Size = streamedFileContent.Length,
        UploadDT = DateTime.UtcNow
    };

    _context.File.Add(file);
    await _context.SaveChangesAsync();

    return Created(nameof(StreamingController), null);
}
```

`MultipartRequestHelper` (*Utilities/MultipartRequestHelper.cs*):

```
using System;
using System.IO;
using Microsoft.Net.Http.Headers;

namespace SampleApp.Utilities
{
    public static class MultipartRequestHelper
    {
        // Content-Type: multipart/form-data; boundary="----WebKitFormBoundarymx2fSWqWSd0OxQqq"
        // The spec at https://tools.ietf.org/html/rfc2046#section-5.1 states that 70 characters is a
reasonable limit.
        public static string GetBoundary(MediaTypeHeaderValue contentType, int lengthLimit)
        {
            var boundary = HeaderUtilities.RemoveQuotes(contentType.Boundary).Value;

            if (string.IsNullOrWhiteSpace(boundary))
            {
                throw new InvalidDataException("Missing content-type boundary.");
            }

            if (boundary.Length > lengthLimit)
            {
                throw new InvalidDataException(
                    $"Multipart boundary length limit {lengthLimit} exceeded.");
            }

            return boundary;
        }

        public static bool IsMultipartContentType(string contentType)
        {
            return !string.IsNullOrEmpty(contentType)
                   && contentType.IndexOf("multipart/", StringComparison.OrdinalIgnoreCase) >= 0;
        }

        public static bool HasFormDataContentDisposition(ContentDispositionHeaderValue contentDisposition)
        {
            // Content-Disposition: form-data; name="key";
            return contentDisposition != null
                && contentDisposition.DispositionType.Equals("form-data")
                && string.IsNullOrEmpty(contentDisposition.FileName.Value)
                && string.IsNullOrEmpty(contentDisposition.FileNameStar.Value);
        }

        public static bool HasFileContentDisposition(ContentDispositionHeaderValue contentDisposition)
        {
            // Content-Disposition: form-data; name="myfile1"; filename="Misc 002.jpg"
            return contentDisposition != null
                && contentDisposition.DispositionType.Equals("form-data")
                && (!string.IsNullOrEmpty(contentDisposition.FileName.Value)
                    || !string.IsNullOrEmpty(contentDisposition.FileNameStar.Value));
        }
    }
}
```

The complete `StreamingController.UploadPhysical` method for streaming to a physical location:

```
[HttpPost]
[DisableFormValueModelBinding]
[ValidateAntiForgeryToken]
public async Task<IActionResult> UploadPhysical()
{
    if (!MultipartRequestHelper.IsMultipartContentType(Request.ContentType))
    {
        ModelState.AddModelError("File",
            $"The request couldn't be processed (Error 1).");
```

```
            // Log error

            return BadRequest(ModelState);
        }

        var boundary = MultipartRequestHelper.GetBoundary(
            MediaTypeHeaderValue.Parse(Request.ContentType),
            _defaultFormOptions.MultipartBoundaryLengthLimit);
        var reader = new MultipartReader(boundary, HttpContext.Request.Body);
        var section = await reader.ReadNextSectionAsync();

        while (section != null)
        {
            var hasContentDispositionHeader =
                ContentDispositionHeaderValue.TryParse(
                    section.ContentDisposition, out var contentDisposition);

            if (hasContentDispositionHeader)
            {
                // This check assumes that there's a file
                // present without form data. If form data
                // is present, this method immediately fails
                // and returns the model error.
                if (!MultipartRequestHelper
                    .HasFileContentDisposition(contentDisposition))
                {
                    ModelState.AddModelError("File",
                        $"The request couldn't be processed (Error 2).");
                    // Log error

                    return BadRequest(ModelState);
                }
                else
                {
                    // Don't trust the file name sent by the client. To display
                    // the file name, HTML-encode the value.
                    var trustedFileNameForDisplay = WebUtility.HtmlEncode(
                            contentDisposition.FileName.Value);
                    var trustedFileNameForFileStorage = Path.GetRandomFileName();

                    // **WARNING!**
                    // In the following example, the file is saved without
                    // scanning the file's contents. In most production
                    // scenarios, an anti-virus/anti-malware scanner API
                    // is used on the file before making the file available
                    // for download or for use by other systems.
                    // For more information, see the topic that accompanies
                    // this sample.

                    var streamedFileContent = await FileHelpers.ProcessStreamedFile(
                        section, contentDisposition, ModelState,
                        _permittedExtensions, _fileSizeLimit);

                    if (!ModelState.IsValid)
                    {
                        return BadRequest(ModelState);
                    }

                    using (var targetStream = System.IO.File.Create(
                        Path.Combine(_targetFilePath, trustedFileNameForFileStorage)))
                    {
                        await targetStream.WriteAsync(streamedFileContent);

                        _logger.LogInformation(
                            "Uploaded file '{TrustedFileNameForDisplay}' saved to " +
                            "'{TargetFilePath}' as {TrustedFileNameForFileStorage}",
                            trustedFileNameForDisplay, _targetFilePath,
                            trustedFileNameForFileStorage);
                    }
```

```
            }
        }

        // Drain any remaining section body that hasn't been consumed and
        // read the headers for the next section.
        section = await reader.ReadNextSectionAsync();
    }

    return Created(nameof(StreamingController), null);
}
```

In the sample app, validation checks are handled by `FileHelpers.ProcessStreamedFile`.

Validation

The sample app's `FileHelpers` class demonstrates a several checks for buffered IFormFile and streamed file uploads. For processing IFormFile buffered file uploads in the sample app, see the `ProcessFormFile` method in the *Utilities/FileHelpers.cs* file. For processing streamed files, see the `ProcessStreamedFile` method in the same file.

> **WARNING**
>
> The validation processing methods demonstrated in the sample app don't scan the content of uploaded files. In most production scenarios, a virus/malware scanner API is used on the file before making the file available to users or other systems.
>
> Although the topic sample provides a working example of validation techniques, don't implement the `FileHelpers` class in a production app unless you:
>
> - Fully understand the implementation.
> - Modify the implementation as appropriate for the app's environment and specifications.
>
> **Never indiscriminately implement security code in an app without addressing these requirements.**

Content validation

Use a third party virus/malware scanning API on uploaded content.

Scanning files is demanding on server resources in high volume scenarios. If request processing performance is diminished due to file scanning, consider offloading the scanning work to a background service, possibly a service running on a server different from the app's server. Typically, uploaded files are held in a quarantined area until the background virus scanner checks them. When a file passes, the file is moved to the normal file storage location. These steps are usually performed in conjunction with a database record that indicates the scanning status of a file. By using such an approach, the app and app server remain focused on responding to requests.

File extension validation

The uploaded file's extension should be checked against a list of permitted extensions. For example:

```
private string[] permittedExtensions = { ".txt", ".pdf" };

var ext = Path.GetExtension(uploadedFileName).ToLowerInvariant();

if (string.IsNullOrEmpty(ext) || !permittedExtensions.Contains(ext))
{
    // The extension is invalid ... discontinue processing the file
}
```

File signature validation

A file's signature is determined by the first few bytes at the start of a file. These bytes can be used to indicate if the

extension matches the content of the file. The sample app checks file signatures for a few common file types. In the following example, the file signature for a JPEG image is checked against the file:

```
private static readonly Dictionary<string, List<byte[]>> _fileSignature =
    new Dictionary<string, List<byte[]>>
{
    { ".jpeg", new List<byte[]>
        {
            new byte[] { 0xFF, 0xD8, 0xFF, 0xE0 },
            new byte[] { 0xFF, 0xD8, 0xFF, 0xE2 },
            new byte[] { 0xFF, 0xD8, 0xFF, 0xE3 },
        }
    },
};

using (var reader = new BinaryReader(uploadedFileData))
{
    var signatures = _fileSignature[ext];
    var headerBytes = reader.ReadBytes(signatures.Max(m => m.Length));

    return signatures.Any(signature =>
        headerBytes.Take(signature.Length).SequenceEqual(signature));
}
```

To obtain additional file signatures, see the File Signatures Database and official file specifications.

File name security

Never use a client-supplied file name for saving a file to physical storage. Create a safe file name for the file using Path.GetRandomFileName or Path.GetTempFileName to create a full path (including the file name) for temporary storage.

Razor automatically HTML encodes property values for display. The following code is safe to use:

```
@foreach (var file in Model.DatabaseFiles) {
    <tr>
        <td>
            @file.UntrustedName
        </td>
    </tr>
}
```

Outside of Razor, always HtmlEncode file name content from a user's request.

Many implementations must include a check that the file exists; otherwise, the file is overwritten by a file of the same name. Supply additional logic to meet your app's specifications.

Size validation

Limit the size of uploaded files.

In the sample app, the size of the file is limited to 2 MB (indicated in bytes). The limit is supplied via Configuration from the *appsettings.json* file:

```
{
  "FileSizeLimit": 2097152
}
```

The `FileSizeLimit` is injected into `PageModel` classes:

```
public class BufferedSingleFileUploadPhysicalModel : PageModel
{
    private readonly long _fileSizeLimit;

    public BufferedSingleFileUploadPhysicalModel(IConfiguration config)
    {
        _fileSizeLimit = config.GetValue<long>("FileSizeLimit");
    }

    ...
}
```

When a file size exceeds the limit, the file is rejected:

```
if (formFile.Length > _fileSizeLimit)
{
    // The file is too large ... discontinue processing the file
}
```

Match name attribute value to parameter name of POST method

In non-Razor forms that POST form data or use JavaScript's `FormData` directly, the name specified in the form's element or `FormData` must match the name of the parameter in the controller's action.

In the following example:

- When using an `<input>` element, the `name` attribute is set to the value `battlePlans`:

  ```
  <input type="file" name="battlePlans" multiple>
  ```

- When using `FormData` in JavaScript, the name is set to the value `battlePlans`:

  ```
  var formData = new FormData();

  for (var file in files) {
    formData.append("battlePlans", file, file.name);
  }
  ```

Use a matching name for the parameter of the C# method (`battlePlans`):

- For a Razor Pages page handler method named `Upload`:

  ```
  public async Task<IActionResult> OnPostUploadAsync(List<IFormFile> battlePlans)
  ```

- For an MVC POST controller action method:

  ```
  public async Task<IActionResult> Post(List<IFormFile> battlePlans)
  ```

Server and app configuration

Multipart body length limit

MultipartBodyLengthLimit sets the limit for the length of each multipart body. Form sections that exceed this limit throw an InvalidDataException when parsed. The default is 134,217,728 (128 MB). Customize the limit using the MultipartBodyLengthLimit setting in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<FormOptions>(options =>
    {
        // Set the limit to 256 MB
        options.MultipartBodyLengthLimit = 268435456;
    });
}
```

RequestFormLimitsAttribute is used to set the MultipartBodyLengthLimit for a single page or action.

In a Razor Pages app, apply the filter with a convention in `Startup.ConfigureServices`:

```
services.AddRazorPages(options =>
{
    options.Conventions
        .AddPageApplicationModelConvention("/FileUploadPage",
            model.Filters.Add(
                new RequestFormLimitsAttribute()
                {
                    // Set the limit to 256 MB
                    MultipartBodyLengthLimit = 268435456
                });
});
```

In a Razor Pages app or an MVC app, apply the filter to the page model or action method:

```
// Set the limit to 256 MB
[RequestFormLimits(MultipartBodyLengthLimit = 268435456)]
public class BufferedSingleFileUploadPhysicalModel : PageModel
{
    ...
}
```

Kestrel maximum request body size

For apps hosted by Kestrel, the default maximum request body size is 30,000,000 bytes, which is approximately 28.6 MB. Customize the limit using the MaxRequestBodySize Kestrel server option:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.ConfigureKestrel((context, options) =>
            {
                // Handle requests up to 50 MB
                options.Limits.MaxRequestBodySize = 52428800;
            })
            .UseStartup<Startup>();
        });
```

RequestSizeLimitAttribute is used to set the MaxRequestBodySize for a single page or action.

In a Razor Pages app, apply the filter with a convention in `Startup.ConfigureServices`:

```
services.AddRazorPages(options =>
{
    options.Conventions
        .AddPageApplicationModelConvention("/FileUploadPage",
            model =>
            {
                // Handle requests up to 50 MB
                model.Filters.Add(
                    new RequestSizeLimitAttribute(52428800));
            });
});
```

In a Razor pages app or an MVC app, apply the filter to the page handler class or action method:

```
// Handle requests up to 50 MB
[RequestSizeLimit(52428800)]
public class BufferedSingleFileUploadPhysicalModel : PageModel
{
    ...
}
```

The `RequestSizeLimitAttribute` can also be applied using the `@attribute` Razor directive:

```
@attribute [RequestSizeLimitAttribute(52428800)]
```

Other Kestrel limits

Other Kestrel limits may apply for apps hosted by Kestrel:

- Maximum client connections
- Request and response data rates

IIS

The default request limit (`maxAllowedContentLength`) is 30,000,000 bytes, which is approximately 28.6 MB.
Customize the limit in the `web.config` file. In the following example, the limit is set to 50 MB (52,428,800 bytes):

```
<system.webServer>
  <security>
    <requestFiltering>
      <requestLimits maxAllowedContentLength="52428800" />
    </requestFiltering>
  </security>
</system.webServer>
```

The `maxAllowedContentLength` setting only applies to IIS. For more information, see Request Limits `<requestLimits>`.

Increase the maximum request body size for the HTTP request by setting IISServerOptions.MaxRequestBodySize in `Startup.ConfigureServices`. In the following example, the limit is set to 50 MB (52,428,800 bytes):

```
services.Configure<IISServerOptions>(options =>
{
    options.MaxRequestBodySize = 52428800;
});
```

For more information, see Host ASP.NET Core on Windows with IIS.

Troubleshoot

Below are some common problems encountered when working with uploading files and their possible solutions.

Not Found error when deployed to an IIS server

The following error indicates that the uploaded file exceeds the server's configured content length:

```
HTTP 404.13 - Not Found
The request filtering module is configured to deny a request that exceeds the request content length.
```

For more information, see the IIS section.

Connection failure

A connection error and a reset server connection probably indicates that the uploaded file exceeds Kestrel's maximum request body size. For more information, see the Kestrel maximum request body size section. Kestrel client connection limits may also require adjustment.

Null Reference Exception with IFormFile

If the controller is accepting uploaded files using IFormFile but the value is `null`, confirm that the HTML form is specifying an `enctype` value of `multipart/form-data`. If this attribute isn't set on the `<form>` element, the file upload doesn't occur and any bound IFormFile arguments are `null`. Also confirm that the upload naming in form data matches the app's naming.

Stream was too long

The examples in this topic rely upon MemoryStream to hold the uploaded file's content. The size limit of a `MemoryStream` is `int.MaxValue`. If the app's file upload scenario requires holding file content larger than 50 MB, use an alternative approach that doesn't rely upon a single `MemoryStream` for holding an uploaded file's content.

ASP.NET Core supports uploading one or more files using buffered model binding for smaller files and unbuffered streaming for larger files.

View or download sample code (how to download)

Security considerations

Use caution when providing users with the ability to upload files to a server. Attackers may attempt to:

- Execute denial of service attacks.
- Upload viruses or malware.
- Compromise networks and servers in other ways.

Security steps that reduce the likelihood of a successful attack are:

- Upload files to a dedicated file upload area, preferably to a non-system drive. A dedicated location makes it easier to impose security restrictions on uploaded files. Disable execute permissions on the file upload location.†
- Do **not** persist uploaded files in the same directory tree as the app.†
- Use a safe file name determined by the app. Don't use a file name provided by the user or the untrusted file name of the uploaded file.† HTML encode the untrusted file name when displaying it. For example, logging the file name or displaying in UI (Razor automatically HTML encodes output).
- Allow only approved file extensions for the app's design specification.†
- Verify that client-side checks are performed on the server.† Client-side checks are easy to circumvent.
- Check the size of an uploaded file. Set a maximum size limit to prevent large uploads.†
- When files shouldn't be overwritten by an uploaded file with the same name, check the file name against the database or physical storage before uploading the file.

- **Run a virus/malware scanner on uploaded content before the file is stored.**

†The sample app demonstrates an approach that meets the criteria.

> **WARNING**
> Uploading malicious code to a system is frequently the first step to executing code that can:
>
> - Completely gain control of a system.
> - Overload a system with the result that the system crashes.
> - Compromise user or system data.
> - Apply graffiti to a public UI.
>
> For information on reducing the attack surface area when accepting files from users, see the following resources:
>
> - Unrestricted File Upload
> - Azure Security: Ensure appropriate controls are in place when accepting files from users

For more information on implementing security measures, including examples from the sample app, see the Validation section.

Storage scenarios

Common storage options for files include:

- Database
  - For small file uploads, a database is often faster than physical storage (file system or network share) options.
  - A database is often more convenient than physical storage options because retrieval of a database record for user data can concurrently supply the file content (for example, an avatar image).
  - A database is potentially less expensive than using a data storage service.
- Physical storage (file system or network share)
  - For large file uploads:
    - Database limits may restrict the size of the upload.
    - Physical storage is often less economical than storage in a database.
  - Physical storage is potentially less expensive than using a data storage service.
  - The app's process must have read and write permissions to the storage location. **Never grant execute permission.**
- Data storage service (for example, Azure Blob Storage)
  - Services usually offer improved scalability and resiliency over on-premises solutions that are usually subject to single points of failure.
  - Services are potentially lower cost in large storage infrastructure scenarios.

  For more information, see Quickstart: Use .NET to create a blob in object storage. The topic demonstrates UploadFromFileAsync, but UploadFromStreamAsync can be used to save a FileStream to blob storage when working with a Stream.

File upload scenarios

Two general approaches for uploading files are buffering and streaming.

Buffering

The entire file is read into an IFormFile, which is a C# representation of the file used to process or save the file.

The resources (disk, memory) used by file uploads depend on the number and size of concurrent file uploads. If an app attempts to buffer too many uploads, the site crashes when it runs out of memory or disk space. If the size or frequency of file uploads is exhausting app resources, use streaming.

> **NOTE**
> Any single buffered file exceeding 64 KB is moved from memory to a temp file on disk.

Buffering small files is covered in the following sections of this topic:

- Physical storage
- Database

Streaming

The file is received from a multipart request and directly processed or saved by the app. Streaming doesn't improve performance significantly. Streaming reduces the demands for memory or disk space when uploading files.

Streaming large files is covered in the Upload large files with streaming section.

Upload small files with buffered model binding to physical storage

To upload small files, use a multipart form or construct a POST request using JavaScript.

The following example demonstrates the use of a Razor Pages form to upload a single file (*Pages/BufferedSingleFileUploadPhysical.cshtml* in the sample app):

```
<form enctype="multipart/form-data" method="post">
    <dl>
        <dt>
            <label asp-for="FileUpload.FormFile"></label>
        </dt>
        <dd>
            <input asp-for="FileUpload.FormFile" type="file">
            <span asp-validation-for="FileUpload.FormFile"></span>
        </dd>
    </dl>
    <input asp-page-handler="Upload" class="btn" type="submit" value="Upload" />
</form>
```

The following example is analogous to the prior example except that:

- JavaScript's (Fetch API) is used to submit the form's data.
- There's no validation.

```
<form action="BufferedSingleFileUploadPhysical/?handler=Upload"
      enctype="multipart/form-data" onsubmit="AJAXSubmit(this);return false;"
      method="post">
    <dl>
        <dt>
            <label for="FileUpload_FormFile">File</label>
        </dt>
        <dd>
            <input id="FileUpload_FormFile" type="file"
                name="FileUpload.FormFile" />
        </dd>
    </dl>

    <input class="btn" type="submit" value="Upload" />

    <div style="margin-top:15px">
        <output name="result"></output>
    </div>
</form>

<script>
  async function AJAXSubmit (oFormElement) {
    var resultElement = oFormElement.elements.namedItem("result");
    const formData = new FormData(oFormElement);

    try {
    const response = await fetch(oFormElement.action, {
      method: 'POST',
      body: formData
    });

    if (response.ok) {
      window.location.href = '/';
    }

    resultElement.value = 'Result: ' + response.status + ' ' +
      response.statusText;
    } catch (error) {
      console.error('Error:', error);
    }
  }
</script>
```

To perform the form POST in JavaScript for clients that don't support the Fetch API, use one of the following approaches:

- Use a Fetch Polyfill (for example, window.fetch polyfill (github/fetch)).
- Use `XMLHttpRequest`. For example:

```
  <script>
    "use strict";

    function AJAXSubmit (oFormElement) {
      var oReq = new XMLHttpRequest();
      oReq.onload = function(e) {
      oFormElement.elements.namedItem("result").value =
        'Result: ' + this.status + ' ' + this.statusText;
      };
      oReq.open("post", oFormElement.action);
      oReq.send(new FormData(oFormElement));
    }
  </script>
```

In order to support file uploads, HTML forms must specify an encoding type (`enctype`) of `multipart/form-data` .

For a `files` input element to support uploading multiple files provide the `multiple` attribute on the `<input>` element:

```
<input asp-for="FileUpload.FormFiles" type="file" multiple>
```

The individual files uploaded to the server can be accessed through Model Binding using IFormFile. The sample app demonstrates multiple buffered file uploads for database and physical storage scenarios.

WARNING

Do **not** use the `FileName` property of IFormFile other than for display and logging. When displaying or logging, HTML encode the file name. An attacker can provide a malicious filename, including full paths or relative paths. Applications should:

- Remove the path from the user-supplied filename.
- Save the HTML-encoded, path-removed filename for UI or logging.
- Generate a new random filename for storage.

The following code removes the path from the file name:

```
string untrustedFileName = Path.GetFileName(pathName);
```

The examples provided thus far don't take into account security considerations. Additional information is provided by the following sections and the sample app:

- Security considerations
- Validation

When uploading files using model binding and IFormFile, the action method can accept:

- A single IFormFile.
- Any of the following collections that represent several files:
  - IFormFileCollection
  - IEnumerable<IFormFile>
  - List<IFormFile>

NOTE

Binding matches form files by name. For example, the HTML `name` value in `<input type="file" name="formFile">` must match the C# parameter/property bound (`FormFile`). For more information, see the Match name attribute value to parameter name of POST method section.

The following example:

- Loops through one or more uploaded files.
- Uses Path.GetTempFileName to return a full path for a file, including the file name.
- Saves the files to the local file system using a file name generated by the app.
- Returns the total number and size of files uploaded.

```
public async Task<IActionResult> OnPostUploadAsync(List<IFormFile> files)
{
    long size = files.Sum(f => f.Length);

    foreach (var formFile in files)
    {
        if (formFile.Length > 0)
        {
            var filePath = Path.GetTempFileName();

            using (var stream = System.IO.File.Create(filePath))
            {
                await formFile.CopyToAsync(stream);
            }
        }
    }

    // Process uploaded files
    // Don't rely on or trust the FileName property without validation.

    return Ok(new { count = files.Count, size });
}
```

Use `Path.GetRandomFileName` to generate a file name without a path. In the following example, the path is obtained from configuration:

```
foreach (var formFile in files)
{
    if (formFile.Length > 0)
    {
        var filePath = Path.Combine(_config["StoredFilesPath"],
            Path.GetRandomFileName());

        using (var stream = System.IO.File.Create(filePath))
        {
            await formFile.CopyToAsync(stream);
        }
    }
}
```

The path passed to the FileStream *must* include the file name. If the file name isn't provided, an UnauthorizedAccessException is thrown at runtime.

Files uploaded using the IFormFile technique are buffered in memory or on disk on the server before processing. Inside the action method, the IFormFile contents are accessible as a Stream. In addition to the local file system, files can be saved to a network share or to a file storage service, such as Azure Blob storage.

For another example that loops over multiple files for upload and uses safe file names, see *Pages/BufferedMultipleFileUploadPhysical.cshtml.cs* in the sample app.

> **WARNING**
>
> Path.GetTempFileName throws an IOException if more than 65,535 files are created without deleting previous temporary files. The limit of 65,535 files is a per-server limit. For more information on this limit on Windows OS, see the remarks in the following topics:
>
> - GetTempFileNameA function
> - GetTempFileName

Upload small files with buffered model binding to a database

To store binary file data in a database using Entity Framework, define a Byte array property on the entity:

```
public class AppFile
{
    public int Id { get; set; }
    public byte[] Content { get; set; }
}
```

Specify a page model property for the class that includes an IFormFile:

```
public class BufferedSingleFileUploadDbModel : PageModel
{
    ...

    [BindProperty]
    public BufferedSingleFileUploadDb FileUpload { get; set; }

    ...
}

public class BufferedSingleFileUploadDb
{
    [Required]
    [Display(Name="File")]
    public IFormFile FormFile { get; set; }
}
```

> **NOTE**
>
> IFormFile can be used directly as an action method parameter or as a bound model property. The prior example uses a bound model property.

The `FileUpload` is used in the Razor Pages form:

```
<form enctype="multipart/form-data" method="post">
    <dl>
        <dt>
            <label asp-for="FileUpload.FormFile"></label>
        </dt>
        <dd>
            <input asp-for="FileUpload.FormFile" type="file">
        </dd>
    </dl>
    <input asp-page-handler="Upload" class="btn" type="submit" value="Upload">
</form>
```

When the form is POSTed to the server, copy the IFormFile to a stream and save it as a byte array in the database. In the following example, `_dbContext` stores the app's database context:

```
public async Task<IActionResult> OnPostUploadAsync()
{
    using (var memoryStream = new MemoryStream())
    {
        await FileUpload.FormFile.CopyToAsync(memoryStream);

        // Upload the file if less than 2 MB
        if (memoryStream.Length < 2097152)
        {
            var file = new AppFile()
            {
                Content = memoryStream.ToArray()
            };

            _dbContext.File.Add(file);

            await _dbContext.SaveChangesAsync();
        }
        else
        {
            ModelState.AddModelError("File", "The file is too large.");
        }
    }

    return Page();
}
```

The preceding example is similar to a scenario demonstrated in the sample app:

- *Pages/BufferedSingleFileUploadDb.cshtml*
- *Pages/BufferedSingleFileUploadDb.cshtml.cs*

> **WARNING**
>
> Use caution when storing binary data in relational databases, as it can adversely impact performance.
>
> Don't rely on or trust the `FileName` property of IFormFile without validation. The `FileName` property should only be used for display purposes and only after HTML encoding.
>
> The examples provided don't take into account security considerations. Additional information is provided by the following sections and the sample app:
>
> - Security considerations
> - Validation

Upload large files with streaming

The following example demonstrates how to use JavaScript to stream a file to a controller action. The file's antiforgery token is generated using a custom filter attribute and passed to the client HTTP headers instead of in the request body. Because the action method processes the uploaded data directly, form model binding is disabled by another custom filter. Within the action, the form's contents are read using a `MultipartReader`, which reads each individual `MultipartSection`, processing the file or storing the contents as appropriate. After the multipart sections are read, the action performs its own model binding.

The initial page response loads the form and saves an antiforgery token in a cookie (via the `GenerateAntiforgeryTokenCookieAttribute` attribute). The attribute uses ASP.NET Core's built-in antiforgery support to set a cookie with a request token:

```
public class GenerateAntiforgeryTokenCookieAttribute : ResultFilterAttribute
{
    public override void OnResultExecuting(ResultExecutingContext context)
    {
        var antiforgery = context.HttpContext.RequestServices.GetService<IAntiforgery>();

        // Send the request token as a JavaScript-readable cookie
        var tokens = antiforgery.GetAndStoreTokens(context.HttpContext);

        context.HttpContext.Response.Cookies.Append(
            "RequestVerificationToken",
            tokens.RequestToken,
            new CookieOptions() { HttpOnly = false });
    }

    public override void OnResultExecuted(ResultExecutedContext context)
    {
    }
}
```

The `DisableFormValueModelBindingAttribute` is used to disable model binding:

```
[AttributeUsage(AttributeTargets.Class | AttributeTargets.Method)]
public class DisableFormValueModelBindingAttribute : Attribute, IResourceFilter
{
    public void OnResourceExecuting(ResourceExecutingContext context)
    {
        var factories = context.ValueProviderFactories;
        factories.RemoveType<FormValueProviderFactory>();
        factories.RemoveType<JQueryFormValueProviderFactory>();
    }

    public void OnResourceExecuted(ResourceExecutedContext context)
    {
    }
}
```

In the sample app, `GenerateAntiforgeryTokenCookieAttribute` and `DisableFormValueModelBindingAttribute` are applied as filters to the page application models of `/StreamedSingleFileUploadDb` and `/StreamedSingleFileUploadPhysical` in `Startup.ConfigureServices` using Razor Pages conventions:

```
services.AddMvc()
    .AddRazorPagesOptions(options =>
        {
            options.Conventions
                .AddPageApplicationModelConvention("/StreamedSingleFileUploadDb",
                    model =>
                    {
                        model.Filters.Add(
                            new GenerateAntiforgeryTokenCookieAttribute());
                        model.Filters.Add(
                            new DisableFormValueModelBindingAttribute());
                    });
            options.Conventions
                .AddPageApplicationModelConvention("/StreamedSingleFileUploadPhysical",
                    model =>
                    {
                        model.Filters.Add(
                            new GenerateAntiforgeryTokenCookieAttribute());
                        model.Filters.Add(
                            new DisableFormValueModelBindingAttribute());
                    });
        })
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

Since model binding doesn't read the form, parameters that are bound from the form don't bind (query, route, and header continue to work). The action method works directly with the `Request` property. A `MultipartReader` is used to read each section. Key/value data is stored in a `KeyValueAccumulator`. After the multipart sections are read, the contents of the `KeyValueAccumulator` are used to bind the form data to a model type.

The complete `StreamingController.UploadDatabase` method for streaming to a database with EF Core:

```
[HttpPost]
[DisableFormValueModelBinding]
[ValidateAntiForgeryToken]
public async Task<IActionResult> UploadDatabase()
{
    if (!MultipartRequestHelper.IsMultipartContentType(Request.ContentType))
    {
        ModelState.AddModelError("File",
            $"The request couldn't be processed (Error 1).");
        // Log error

        return BadRequest(ModelState);
    }

    // Accumulate the form data key-value pairs in the request (formAccumulator).
    var formAccumulator = new KeyValueAccumulator();
    var trustedFileNameForDisplay = string.Empty;
    var untrustedFileNameForStorage = string.Empty;
    var streamedFileContent = new byte[0];

    var boundary = MultipartRequestHelper.GetBoundary(
        MediaTypeHeaderValue.Parse(Request.ContentType),
        _defaultFormOptions.MultipartBoundaryLengthLimit);
    var reader = new MultipartReader(boundary, HttpContext.Request.Body);

    var section = await reader.ReadNextSectionAsync();

    while (section != null)
    {
        var hasContentDispositionHeader =
            ContentDispositionHeaderValue.TryParse(
                section.ContentDisposition, out var contentDisposition);

        if (hasContentDispositionHeader)
```

```
        {
            if (MultipartRequestHelper
                .HasFileContentDisposition(contentDisposition))
            {
                untrustedFileNameForStorage = contentDisposition.FileName.Value;
                // Don't trust the file name sent by the client. To display
                // the file name, HTML-encode the value.
                trustedFileNameForDisplay = WebUtility.HtmlEncode(
                        contentDisposition.FileName.Value);

                streamedFileContent =
                    await FileHelpers.ProcessStreamedFile(section, contentDisposition,
                        ModelState, _permittedExtensions, _fileSizeLimit);

                if (!ModelState.IsValid)
                {
                    return BadRequest(ModelState);
                }
            }
            else if (MultipartRequestHelper
                .HasFormDataContentDisposition(contentDisposition))
            {
                // Don't limit the key name length because the
                // multipart headers length limit is already in effect.
                var key = HeaderUtilities
                    .RemoveQuotes(contentDisposition.Name).Value;
                var encoding = GetEncoding(section);

                if (encoding == null)
                {
                    ModelState.AddModelError("File",
                        $"The request couldn't be processed (Error 2).");
                    // Log error

                    return BadRequest(ModelState);
                }

                using (var streamReader = new StreamReader(
                    section.Body,
                    encoding,
                    detectEncodingFromByteOrderMarks: true,
                    bufferSize: 1024,
                    leaveOpen: true))
                {
                    // The value length limit is enforced by
                    // MultipartBodyLengthLimit
                    var value = await streamReader.ReadToEndAsync();

                    if (string.Equals(value, "undefined",
                        StringComparison.OrdinalIgnoreCase))
                    {
                        value = string.Empty;
                    }

                    formAccumulator.Append(key, value);

                    if (formAccumulator.ValueCount >
                        _defaultFormOptions.ValueCountLimit)
                    {
                        // Form key count limit of
                        // _defaultFormOptions.ValueCountLimit
                        // is exceeded.
                        ModelState.AddModelError("File",
                            $"The request couldn't be processed (Error 3).");
                        // Log error

                        return BadRequest(ModelState);
                    }
                }
```

```
                }
            }

            // Drain any remaining section body that hasn't been consumed and
            // read the headers for the next section.
            section = await reader.ReadNextSectionAsync();
        }

        // Bind form data to the model
        var formData = new FormData();
        var formValueProvider = new FormValueProvider(
            BindingSource.Form,
            new FormCollection(formAccumulator.GetResults()),
            CultureInfo.CurrentCulture);
        var bindingSuccessful = await TryUpdateModelAsync(formData, prefix: "",
            valueProvider: formValueProvider);

        if (!bindingSuccessful)
        {
            ModelState.AddModelError("File",
                "The request couldn't be processed (Error 5).");
            // Log error

            return BadRequest(ModelState);
        }

        // **WARNING!**
        // In the following example, the file is saved without
        // scanning the file's contents. In most production
        // scenarios, an anti-virus/anti-malware scanner API
        // is used on the file before making the file available
        // for download or for use by other systems.
        // For more information, see the topic that accompanies
        // this sample app.

        var file = new AppFile()
        {
            Content = streamedFileContent,
            UntrustedName = untrustedFileNameForStorage,
            Note = formData.Note,
            Size = streamedFileContent.Length,
            UploadDT = DateTime.UtcNow
        };

        _context.File.Add(file);
        await _context.SaveChangesAsync();

        return Created(nameof(StreamingController), null);
    }
```

`MultipartRequestHelper` (*Utilities/MultipartRequestHelper.cs*):

```
using System;
using System.IO;
using Microsoft.Net.Http.Headers;

namespace SampleApp.Utilities
{
    public static class MultipartRequestHelper
    {
        // Content-Type: multipart/form-data; boundary="----WebKitFormBoundarymx2fSWqWSd0OxQqq"
        // The spec at https://tools.ietf.org/html/rfc2046#section-5.1 states that 70 characters is a
reasonable limit.
        public static string GetBoundary(MediaTypeHeaderValue contentType, int lengthLimit)
        {
            var boundary = HeaderUtilities.RemoveQuotes(contentType.Boundary).Value;

            if (string.IsNullOrWhiteSpace(boundary))
            {
                throw new InvalidDataException("Missing content-type boundary.");
            }

            if (boundary.Length > lengthLimit)
            {
                throw new InvalidDataException(
                    $"Multipart boundary length limit {lengthLimit} exceeded.");
            }

            return boundary;
        }

        public static bool IsMultipartContentType(string contentType)
        {
            return !string.IsNullOrEmpty(contentType)
                   && contentType.IndexOf("multipart/", StringComparison.OrdinalIgnoreCase) >= 0;
        }

        public static bool HasFormDataContentDisposition(ContentDispositionHeaderValue contentDisposition)
        {
            // Content-Disposition: form-data; name="key";
            return contentDisposition != null
                && contentDisposition.DispositionType.Equals("form-data")
                && string.IsNullOrEmpty(contentDisposition.FileName.Value)
                && string.IsNullOrEmpty(contentDisposition.FileNameStar.Value);
        }

        public static bool HasFileContentDisposition(ContentDispositionHeaderValue contentDisposition)
        {
            // Content-Disposition: form-data; name="myfile1"; filename="Misc 002.jpg"
            return contentDisposition != null
                && contentDisposition.DispositionType.Equals("form-data")
                && (!string.IsNullOrEmpty(contentDisposition.FileName.Value)
                    || !string.IsNullOrEmpty(contentDisposition.FileNameStar.Value));
        }
    }
}
```

The complete `StreamingController.UploadPhysical` method for streaming to a physical location:

```
[HttpPost]
[DisableFormValueModelBinding]
[ValidateAntiForgeryToken]
public async Task<IActionResult> UploadPhysical()
{
    if (!MultipartRequestHelper.IsMultipartContentType(Request.ContentType))
    {
        ModelState.AddModelError("File",
            $"The request couldn't be processed (Error 1).");
```

```
            // Log error

            return BadRequest(ModelState);
        }

        var boundary = MultipartRequestHelper.GetBoundary(
            MediaTypeHeaderValue.Parse(Request.ContentType),
            _defaultFormOptions.MultipartBoundaryLengthLimit);
        var reader = new MultipartReader(boundary, HttpContext.Request.Body);
        var section = await reader.ReadNextSectionAsync();

        while (section != null)
        {
            var hasContentDispositionHeader =
                ContentDispositionHeaderValue.TryParse(
                    section.ContentDisposition, out var contentDisposition);

            if (hasContentDispositionHeader)
            {
                // This check assumes that there's a file
                // present without form data. If form data
                // is present, this method immediately fails
                // and returns the model error.
                if (!MultipartRequestHelper
                    .HasFileContentDisposition(contentDisposition))
                {
                    ModelState.AddModelError("File",
                        $"The request couldn't be processed (Error 2).");
                    // Log error

                    return BadRequest(ModelState);
                }
                else
                {
                    // Don't trust the file name sent by the client. To display
                    // the file name, HTML-encode the value.
                    var trustedFileNameForDisplay = WebUtility.HtmlEncode(
                            contentDisposition.FileName.Value);
                    var trustedFileNameForFileStorage = Path.GetRandomFileName();

                    // **WARNING!**
                    // In the following example, the file is saved without
                    // scanning the file's contents. In most production
                    // scenarios, an anti-virus/anti-malware scanner API
                    // is used on the file before making the file available
                    // for download or for use by other systems.
                    // For more information, see the topic that accompanies
                    // this sample.

                    var streamedFileContent = await FileHelpers.ProcessStreamedFile(
                        section, contentDisposition, ModelState,
                        _permittedExtensions, _fileSizeLimit);

                    if (!ModelState.IsValid)
                    {
                        return BadRequest(ModelState);
                    }

                    using (var targetStream = System.IO.File.Create(
                        Path.Combine(_targetFilePath, trustedFileNameForFileStorage)))
                    {
                        await targetStream.WriteAsync(streamedFileContent);

                        _logger.LogInformation(
                            "Uploaded file '{TrustedFileNameForDisplay}' saved to " +
                            "'{TargetFilePath}' as {TrustedFileNameForFileStorage}",
                            trustedFileNameForDisplay, _targetFilePath,
                            trustedFileNameForFileStorage);
                    }
```

```
            }
        }

        // Drain any remaining section body that hasn't been consumed and
        // read the headers for the next section.
        section = await reader.ReadNextSectionAsync();
    }

    return Created(nameof(StreamingController), null);
}
```

In the sample app, validation checks are handled by `FileHelpers.ProcessStreamedFile`.

Validation

The sample app's `FileHelpers` class demonstrates a several checks for buffered IFormFile and streamed file uploads. For processing IFormFile buffered file uploads in the sample app, see the `ProcessFormFile` method in the *Utilities/FileHelpers.cs* file. For processing streamed files, see the `ProcessStreamedFile` method in the same file.

> **WARNING**
>
> The validation processing methods demonstrated in the sample app don't scan the content of uploaded files. In most production scenarios, a virus/malware scanner API is used on the file before making the file available to users or other systems.
>
> Although the topic sample provides a working example of validation techniques, don't implement the `FileHelpers` class in a production app unless you:
>
> - Fully understand the implementation.
> - Modify the implementation as appropriate for the app's environment and specifications.
>
> **Never indiscriminately implement security code in an app without addressing these requirements.**

Content validation

Use a third party virus/malware scanning API on uploaded content.

Scanning files is demanding on server resources in high volume scenarios. If request processing performance is diminished due to file scanning, consider offloading the scanning work to a background service, possibly a service running on a server different from the app's server. Typically, uploaded files are held in a quarantined area until the background virus scanner checks them. When a file passes, the file is moved to the normal file storage location. These steps are usually performed in conjunction with a database record that indicates the scanning status of a file. By using such an approach, the app and app server remain focused on responding to requests.

File extension validation

The uploaded file's extension should be checked against a list of permitted extensions. For example:

```
private string[] permittedExtensions = { ".txt", ".pdf" };

var ext = Path.GetExtension(uploadedFileName).ToLowerInvariant();

if (string.IsNullOrEmpty(ext) || !permittedExtensions.Contains(ext))
{
    // The extension is invalid ... discontinue processing the file
}
```

File signature validation

A file's signature is determined by the first few bytes at the start of a file. These bytes can be used to indicate if the

extension matches the content of the file. The sample app checks file signatures for a few common file types. In the following example, the file signature for a JPEG image is checked against the file:

```
private static readonly Dictionary<string, List<byte[]>> _fileSignature =
    new Dictionary<string, List<byte[]>>
{
    { ".jpeg", new List<byte[]>
        {
            new byte[] { 0xFF, 0xD8, 0xFF, 0xE0 },
            new byte[] { 0xFF, 0xD8, 0xFF, 0xE2 },
            new byte[] { 0xFF, 0xD8, 0xFF, 0xE3 },
        }
    },
};

using (var reader = new BinaryReader(uploadedFileData))
{
    var signatures = _fileSignature[ext];
    var headerBytes = reader.ReadBytes(signatures.Max(m => m.Length));

    return signatures.Any(signature =>
        headerBytes.Take(signature.Length).SequenceEqual(signature));
}
```

To obtain additional file signatures, see the File Signatures Database and official file specifications.

File name security

Never use a client-supplied file name for saving a file to physical storage. Create a safe file name for the file using Path.GetRandomFileName or Path.GetTempFileName to create a full path (including the file name) for temporary storage.

Razor automatically HTML encodes property values for display. The following code is safe to use:

```
@foreach (var file in Model.DatabaseFiles) {
    <tr>
        <td>
            @file.UntrustedName
        </td>
    </tr>
}
```

Outside of Razor, always HtmlEncode file name content from a user's request.

Many implementations must include a check that the file exists; otherwise, the file is overwritten by a file of the same name. Supply additional logic to meet your app's specifications.

Size validation

Limit the size of uploaded files.

In the sample app, the size of the file is limited to 2 MB (indicated in bytes). The limit is supplied via Configuration from the *appsettings.json* file:

```
{
  "FileSizeLimit": 2097152
}
```

The `FileSizeLimit` is injected into `PageModel` classes:

```
public class BufferedSingleFileUploadPhysicalModel : PageModel
{
    private readonly long _fileSizeLimit;

    public BufferedSingleFileUploadPhysicalModel(IConfiguration config)
    {
        _fileSizeLimit = config.GetValue<long>("FileSizeLimit");
    }

    ...
}
```

When a file size exceeds the limit, the file is rejected:

```
if (formFile.Length > _fileSizeLimit)
{
    // The file is too large ... discontinue processing the file
}
```

Match name attribute value to parameter name of POST method

In non-Razor forms that POST form data or use JavaScript's `FormData` directly, the name specified in the form's element or `FormData` must match the name of the parameter in the controller's action.

In the following example:

- When using an `<input>` element, the `name` attribute is set to the value `battlePlans`:

  ```
  <input type="file" name="battlePlans" multiple>
  ```

- When using `FormData` in JavaScript, the name is set to the value `battlePlans`:

  ```
  var formData = new FormData();

  for (var file in files) {
    formData.append("battlePlans", file, file.name);
  }
  ```

Use a matching name for the parameter of the C# method (`battlePlans`):

- For a Razor Pages page handler method named `Upload`:

  ```
  public async Task<IActionResult> OnPostUploadAsync(List<IFormFile> battlePlans)
  ```

- For an MVC POST controller action method:

  ```
  public async Task<IActionResult> Post(List<IFormFile> battlePlans)
  ```

Server and app configuration

Multipart body length limit

MultipartBodyLengthLimit sets the limit for the length of each multipart body. Form sections that exceed this limit throw an InvalidDataException when parsed. The default is 134,217,728 (128 MB). Customize the limit using the MultipartBodyLengthLimit setting in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<FormOptions>(options =>
    {
        // Set the limit to 256 MB
        options.MultipartBodyLengthLimit = 268435456;
    });
}
```

RequestFormLimitsAttribute is used to set the MultipartBodyLengthLimit for a single page or action.

In a Razor Pages app, apply the filter with a convention in `Startup.ConfigureServices`:

```
services.AddMvc()
    .AddRazorPagesOptions(options =>
    {
        options.Conventions
            .AddPageApplicationModelConvention("/FileUploadPage",
                model.Filters.Add(
                    new RequestFormLimitsAttribute()
                    {
                        // Set the limit to 256 MB
                        MultipartBodyLengthLimit = 268435456
                    });
    })
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

In a Razor Pages app or an MVC app, apply the filter to the page model or action method:

```
// Set the limit to 256 MB
[RequestFormLimits(MultipartBodyLengthLimit = 268435456)]
public class BufferedSingleFileUploadPhysicalModel : PageModel
{
    ...
}
```

Kestrel maximum request body size

For apps hosted by Kestrel, the default maximum request body size is 30,000,000 bytes, which is approximately 28.6 MB. Customize the limit using the MaxRequestBodySize Kestrel server option:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, options) =>
        {
            // Handle requests up to 50 MB
            options.Limits.MaxRequestBodySize = 52428800;
        });
```

RequestSizeLimitAttribute is used to set the MaxRequestBodySize for a single page or action.

In a Razor Pages app, apply the filter with a convention in `Startup.ConfigureServices`:

```
services.AddMvc()
    .AddRazorPagesOptions(options =>
    {
        options.Conventions
            .AddPageApplicationModelConvention("/FileUploadPage",
                model =>
                {
                    // Handle requests up to 50 MB
                    model.Filters.Add(
                        new RequestSizeLimitAttribute(52428800));
                });
    })
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

In a Razor pages app or an MVC app, apply the filter to the page handler class or action method:

```
// Handle requests up to 50 MB
[RequestSizeLimit(52428800)]
public class BufferedSingleFileUploadPhysicalModel : PageModel
{
    ...
}
```

Other Kestrel limits

Other Kestrel limits may apply for apps hosted by Kestrel:

- Maximum client connections
- Request and response data rates

IIS

The default request limit (`maxAllowedContentLength`) is 30,000,000 bytes, which is approximately 28.6 MB. Customize the limit in the `web.config` file. In the following example, the limit is set to 50 MB (52,428,800 bytes):

```
<system.webServer>
  <security>
    <requestFiltering>
      <requestLimits maxAllowedContentLength="52428800" />
    </requestFiltering>
  </security>
</system.webServer>
```

The `maxAllowedContentLength` setting only applies to IIS. For more information, see Request Limits `<requestLimits>`.

Increase the maximum request body size for the HTTP request by setting IISServerOptions.MaxRequestBodySize in `Startup.ConfigureServices`. In the following example, the limit is set to 50 MB (52,428,800 bytes):

```
services.Configure<IISServerOptions>(options =>
{
    options.MaxRequestBodySize = 52428800;
});
```

For more information, see Host ASP.NET Core on Windows with IIS.

Troubleshoot

Below are some common problems encountered when working with uploading files and their possible solutions.

Not Found error when deployed to an IIS server

The following error indicates that the uploaded file exceeds the server's configured content length:

```
HTTP 404.13 - Not Found
The request filtering module is configured to deny a request that exceeds the request content length.
```

For more information, see the IIS section.

Connection failure

A connection error and a reset server connection probably indicates that the uploaded file exceeds Kestrel's maximum request body size. For more information, see the Kestrel maximum request body size section. Kestrel client connection limits may also require adjustment.

Null Reference Exception with IFormFile

If the controller is accepting uploaded files using IFormFile but the value is `null`, confirm that the HTML form is specifying an `enctype` value of `multipart/form-data`. If this attribute isn't set on the `<form>` element, the file upload doesn't occur and any bound IFormFile arguments are `null`. Also confirm that the upload naming in form data matches the app's naming.

Stream was too long

The examples in this topic rely upon MemoryStream to hold the uploaded file's content. The size limit of a `MemoryStream` is `int.MaxValue`. If the app's file upload scenario requires holding file content larger than 50 MB, use an alternative approach that doesn't rely upon a single `MemoryStream` for holding an uploaded file's content.

ASP.NET Core Web SDK

9/22/2020 • 2 minutes to read • Edit Online

Overview

`Microsoft.NET.Sdk.Web` is an MSBuild project SDK for building ASP.NET Core apps. It's possible to build an ASP.NET Core app without this SDK, however, the Web SDK is:

- Tailored towards providing a first-class experience.
- The recommended target for most users.

Use the Web.SDK in a project:

```
<Project Sdk="Microsoft.NET.Sdk.Web">
  <!-- omitted for brevity -->
</Project>
```

Features enabled by using the Web SDK:

- Projects targeting .NET Core 3.0 or later implicitly reference:
  - The ASP.NET Core shared framework.
  - Analyzers designed for building ASP.NET Core apps.
- The Web SDK imports MSBuild targets that enable the use of publish profiles and publishing using WebDeploy.

Properties

PROPERTY	DESCRIPTION
`DisableImplicitFrameworkReferences`	Disables implicit reference to the `Microsoft.AspNetCore.App` shared framework.
`DisableImplicitAspNetCoreAnalyzers`	Disables implicit reference to ASP.NET Core analyzers.
`DisableImplicitComponentsAnalyzers`	Disables implicit reference to Razor Components analyzers when building Blazor (server) applications.

dotnet aspnet-codegenerator

9/22/2020 • 4 minutes to read • Edit Online

By Rick Anderson

`dotnet aspnet-codegenerator` - Runs the ASP.NET Core scaffolding engine. `dotnet aspnet-codegenerator` is only required to scaffold from the command line, it's not needed to use scaffolding with Visual Studio.

This article applies to .NET Core 2.1 SDK and later.

Installing aspnet-codegenerator

`dotnet-aspnet-codegenerator` is a global tool that must be installed. The following command installs the latest stable version of the `dotnet-aspnet-codegenerator` tool:

```
dotnet tool install -g dotnet-aspnet-codegenerator
```

The following command updates `dotnet-aspnet-codegenerator` to the latest stable version available from the installed .NET Core SDKs:

```
dotnet tool update -g dotnet-aspnet-codegenerator
```

Synopsis

```
dotnet aspnet-codegenerator [arguments] [-p|--project] [-n|--nuget-package-dir] [-c|--configuration] [-
tfm|--target-framework] [-b|--build-base-path] [--no-build]
dotnet aspnet-codegenerator [-h|--help]
```

Description

The `dotnet aspnet-codegenerator` global command runs the ASP.NET Core code generator and scaffolding engine.

Arguments

`generator`

The code generator to run. The following generators are available:

GENERATOR	OPERATION
area	Scaffolds an Area
controller	Scaffolds a controller
identity	Scaffolds Identity
razorpage	Scaffolds Razor Pages

GENERATOR	OPERATION
view	Scaffolds a view

Options

`-n|--nuget-package-dir`

Specifies the NuGet package directory.

`-c|--configuration {Debug|Release}`

Defines the build configuration. The default value is `Debug`.

`-tfm|--target-framework`

Target Framework to use. For example, `net46`.

`-b|--build-base-path`

The build base path.

`-h|--help`

Prints out a short help for the command.

`--no-build`

Doesn't build the project before running. It also implicitly sets the `--no-restore` flag.

`-p|--project <PATH>`

Specifies the path of the project file to run (folder name or full path). If not specified, it defaults to the current directory.

Generator options

The following sections detail the options available for the supported generators:

- Area
- Controller
- Identity
- Razorpage
- View

Area options

This tool is intended for ASP.NET Core web projects with controllers and views. It's not intended for Razor Pages apps.

Usage: `dotnet aspnet-codegenerator area AreaNameToGenerate`

The preceding command generates the following folders:

- *Areas*
  - *AreaNameToGenerate*
    - *Controllers*
    - *Data*
    - *Models*

- *Views*

Controller options

The following table lists options for `aspnet-codegenerator` `controller` and `razorpage`:

OPTION	DESCRIPTION
--model or -m	Model class to use.
--dataContext or -dc	The `DbContext` class to use.
--bootstrapVersion or -b	Specifies the bootstrap version. Valid values are `3` or `4`. Default is `4`. If needed and not present, a *wwwroot* directory is created that includes the bootstrap files of the specified version.
--referenceScriptLibraries or -scripts	Reference script libraries in the generated views. Adds `_ValidationScriptsPartial` to Edit and Create pages.
--layout or -l	Custom Layout page to use.
--useDefaultLayout or -udl	Use the default layout for the views.
--force or -f	Overwrite existing files.
--relativeFolderPath or -outDir	The relative output folder path from project where the file are generated. If not specified, files are generated in the project folder.

The following table lists options unique to `aspnet-codegenerator controller`:

OPTION	DESCRIPTION
--controllerName or -name	Name of the controller.
--useAsyncActions or -async	Generate async controller actions.
--noViews or -nv	Generate **no** views.
--restWithNoViews or -api	Generate a Controller with REST style API. `noViews` is assumed and any view related options are ignored.
--readWriteActions or -actions	Generate controller with read/write actions without a model.

Use the `-h` switch for help on the `aspnet-codegenerator controller` command:

```
dotnet aspnet-codegenerator controller -h
```

See Scaffold the movie model for an example of `dotnet aspnet-codegenerator controller`.

Razorpage

Razor Pages can be individually scaffolded by specifying the name of the new page and the template to use. The supported templates are:

- `Empty`
- `Create`
- `Edit`
- `Delete`
- `Details`
- `List`

For example, the following command uses the Edit template to generate *MyEdit.cshtml* and *MyEdit.cshtml.cs*:

```
dotnet aspnet-codegenerator razorpage MyEdit Edit -m Movie -dc RazorPagesMovieContext -outDir
Pages/Movies
```

Typically, the template and generated file name is not specified, and the following templates are created:

- `Create`
- `Edit`
- `Delete`
- `Details`
- `List`

The following table lists options for `aspnet-codegenerator` `razorpage` and `controller`:

OPTION	DESCRIPTION
--model or -m	Model class to use.
--dataContext or -dc	The `DbContext` class to use.
--bootstrapVersion or -b	Specifies the bootstrap version. Valid values are `3` or `4`. Default is `4`. If needed and not present, a *wwwroot* directory is created that includes the bootstrap files of the specified version.
--referenceScriptLibraries or -scripts	Reference script libraries in the generated views. Adds `_ValidationScriptsPartial` to Edit and Create pages.
--layout or -l	Custom Layout page to use.
--useDefaultLayout or -udl	Use the default layout for the views.
--force or -f	Overwrite existing files.
--relativeFolderPath or -outDir	The relative output folder path from project where the file are generated. If not specified, files are generated in the project folder.

The following table lists options unique to `aspnet-codegenerator razorpage`:

OPTION	DESCRIPTION
--namespaceName or -namespace	The name of the namespace to use for the generated PageModel

OPTION	DESCRIPTION
--partialView or -partial	Generate a partial view. Layout options -l and -udl are ignored if this is specified.
--noPageModel or -npm	Switch to not generate a PageModel class for Empty template

Use the `-h` switch for help on the `aspnet-codegenerator razorpage` command:

```
dotnet aspnet-codegenerator razorpage -h
```

See Scaffold the movie model for an example of `dotnet aspnet-codegenerator razorpage`.

Identity

See Scaffold Identity

Create web APIs with ASP.NET Core

9/22/2020 • 10 minutes to read • Edit Online

By Scott Addie and Tom Dykstra

ASP.NET Core supports creating RESTful services, also known as web APIs, using C#. To handle requests, a web API uses controllers. *Controllers* in a web API are classes that derive from `ControllerBase`. This article shows how to use controllers for handling web API requests.

View or download sample code. (How to download).

ControllerBase class

A web API consists of one or more controller classes that derive from ControllerBase. The web API project template provides a starter controller:

```
[ApiController]
[Route("[controller]")]
public class WeatherForecastController : ControllerBase
```

```
[Route("api/[controller]")]
[ApiController]
public class ValuesController : ControllerBase
```

Don't create a web API controller by deriving from the Controller class. `Controller` derives from `ControllerBase` and adds support for views, so it's for handling web pages, not web API requests. There's an exception to this rule: if you plan to use the same controller for both views and web APIs, derive it from `Controller`.

The `ControllerBase` class provides many properties and methods that are useful for handling HTTP requests. For example, `ControllerBase.CreatedAtAction` returns a 201 status code:

```
[HttpPost]
[ProducesResponseType(StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public ActionResult<Pet> Create(Pet pet)
{
    pet.Id = _petsInMemoryStore.Any() ?
             _petsInMemoryStore.Max(p => p.Id) + 1 : 1;
    _petsInMemoryStore.Add(pet);

    return CreatedAtAction(nameof(GetById), new { id = pet.Id }, pet);
}
```

Here are some more examples of methods that `ControllerBase` provides.

METHOD	NOTES
BadRequest	Returns 400 status code.
NotFound	Returns 404 status code.

METHOD	NOTES
PhysicalFile	Returns a file.
TryUpdateModelAsync	Invokes model binding.
TryValidateModel	Invokes model validation.

For a list of all available methods and properties, see ControllerBase.

Attributes

The Microsoft.AspNetCore.Mvc namespace provides attributes that can be used to configure the behavior of web API controllers and action methods. The following example uses attributes to specify the supported HTTP action verb and any known HTTP status codes that could be returned:

```
[HttpPost]
[ProducesResponseType(StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public ActionResult<Pet> Create(Pet pet)
{
    pet.Id = _petsInMemoryStore.Any() ?
             _petsInMemoryStore.Max(p => p.Id) + 1 : 1;
    _petsInMemoryStore.Add(pet);

    return CreatedAtAction(nameof(GetById), new { id = pet.Id }, pet);
}
```

Here are some more examples of attributes that are available.

ATTRIBUTE	NOTES
`[Route]`	Specifies URL pattern for a controller or action.
`[Bind]`	Specifies prefix and properties to include for model binding.
`[HttpGet]`	Identifies an action that supports the HTTP GET action verb.
`[Consumes]`	Specifies data types that an action accepts.
`[Produces]`	Specifies data types that an action returns.

For a list that includes the available attributes, see the Microsoft.AspNetCore.Mvc namespace.

ApiController attribute

The `[ApiController]` attribute can be applied to a controller class to enable the following opinionated, API-specific behaviors:

- Attribute routing requirement
- Automatic HTTP 400 responses
- Binding source parameter inference
- Multipart/form-data request inference

- Problem details for error status codes

The *Problem details for error status codes* feature requires a compatibility version of 2.2 or later. The other features require a compatibility version of 2.1 or later.

- Attribute routing requirement
- Automatic HTTP 400 responses
- Binding source parameter inference
- Multipart/form-data request inference

These features require a compatibility version of 2.1 or later.

Attribute on specific controllers

The `[ApiController]` attribute can be applied to specific controllers, as in the following example from the project template:

```
[ApiController]
[Route("[controller]")]
public class WeatherForecastController : ControllerBase
```

```
[Route("api/[controller]")]
[ApiController]
public class ValuesController : ControllerBase
```

Attribute on multiple controllers

One approach to using the attribute on more than one controller is to create a custom base controller class annotated with the `[ApiController]` attribute. The following example shows a custom base class and a controller that derives from it:

```
[ApiController]
public class MyControllerBase : ControllerBase
{
}
```

```
[Produces(MediaTypeNames.Application.Json)]
[Route("[controller]")]
public class PetsController : MyControllerBase
```

```
[Produces(MediaTypeNames.Application.Json)]
[Route("api/[controller]")]
public class PetsController : MyControllerBase
```

Attribute on an assembly

If compatibility version is set to 2.2 or later, the `[ApiController]` attribute can be applied to an assembly. Annotation in this manner applies web API behavior to all controllers in the assembly. There's no way to opt out for individual controllers. Apply the assembly-level attribute to the namespace declaration surrounding the `Startup` class:

```
[assembly: ApiController]
namespace WebApiSample
{
    public class Startup
    {
        ...
    }
}
```

Attribute routing requirement

The `[ApiController]` attribute makes attribute routing a requirement. For example:

```
[ApiController]
[Route("[controller]")]
public class WeatherForecastController : ControllerBase
```

Actions are inaccessible via conventional routes defined by `UseEndpoints`, UseMvc, or UseMvcWithDefaultRoute in `Startup.Configure`.

```
[Route("api/[controller]")]
[ApiController]
public class ValuesController : ControllerBase
```

Actions are inaccessible via conventional routes defined by UseMvc or UseMvcWithDefaultRoute in `Startup.Configure`.

Automatic HTTP 400 responses

The `[ApiController]` attribute makes model validation errors automatically trigger an HTTP 400 response. Consequently, the following code is unnecessary in an action method:

```
if (!ModelState.IsValid)
{
    return BadRequest(ModelState);
}
```

ASP.NET Core MVC uses the ModelStateInvalidFilter action filter to do the preceding check.

Default BadRequest response

With a compatibility version of 2.1, the default response type for an HTTP 400 response is SerializableError. The following request body is an example of the serialized type:

```
{
  "": [
    "A non-empty request body is required."
  ]
}
```

With a compatibility version of 2.2 or later, the default response type for an HTTP 400 response is ValidationProblemDetails. The following request body is an example of the serialized type:

```
{
  "type": "https://tools.ietf.org/html/rfc7231#section-6.5.1",
  "title": "One or more validation errors occurred.",
  "status": 400,
  "traceId": "|7fb5e16a-4c8f23bbfc974667.",
  "errors": {
    "": [
      "A non-empty request body is required."
    ]
  }
}
```

The `ValidationProblemDetails` type:

- Provides a machine-readable format for specifying errors in web API responses.
- Complies with the RFC 7807 specification.

To make automatic and custom responses consistent, call the ValidationProblem method instead of BadRequest. `ValidationProblem` returns a ValidationProblemDetails object as well as the automatic response.

Log automatic 400 responses

See How to log automatic 400 responses on model validation errors (dotnet/AspNetCore.Docs#12157).

Disable automatic 400 response

To disable the automatic 400 behavior, set the SuppressModelStateInvalidFilter property to `true`. Add the following highlighted code in `Startup.ConfigureServices`:

```
services.AddControllers()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressConsumesConstraintForFormFileParameters = true;
        options.SuppressInferBindingSourcesForParameters = true;
        options.SuppressModelStateInvalidFilter = true;
        options.SuppressMapClientErrors = true;
        options.ClientErrorMapping[StatusCodes.Status404NotFound].Link =
            "https://httpstatuses.com/404";
    });
```

```
services.AddMvc()
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2)
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressConsumesConstraintForFormFileParameters = true;
        options.SuppressInferBindingSourcesForParameters = true;
        options.SuppressModelStateInvalidFilter = true;
        options.SuppressMapClientErrors = true;
        options.ClientErrorMapping[404].Link =
            "https://httpstatuses.com/404";
    });
```

```
services.Configure<ApiBehaviorOptions>(options =>
{
    options.SuppressConsumesConstraintForFormFileParameters = true;
    options.SuppressInferBindingSourcesForParameters = true;
    options.SuppressModelStateInvalidFilter = true;
});
```

Binding source parameter inference

A binding source attribute defines the location at which an action parameter's value is found. The following binding source attributes exist:

ATTRIBUTE	BINDING SOURCE
`[FromBody]`	Request body
`[FromForm]`	Form data in the request body
`[FromHeader]`	Request header
`[FromQuery]`	Request query string parameter
`[FromRoute]`	Route data from the current request
`[FromServices]`	The request service injected as an action parameter

WARNING

Don't use `[FromRoute]` when values might contain `%2f` (that is `/`). `%2f` won't be unescaped to `/`. Use `[FromQuery]` if the value might contain `%2f`.

Without the `[ApiController]` attribute or binding source attributes like `[FromQuery]`, the ASP.NET Core runtime attempts to use the complex object model binder. The complex object model binder pulls data from value providers in a defined order.

In the following example, the `[FromQuery]` attribute indicates that the `discontinuedOnly` parameter value is provided in the request URL's query string:

```
[HttpGet]
public ActionResult<List<Product>> Get(
    [FromQuery] bool discontinuedOnly = false)
{
    List<Product> products = null;

    if (discontinuedOnly)
    {
        products = _productsInMemoryStore.Where(p => p.IsDiscontinued).ToList();
    }
    else
    {
        products = _productsInMemoryStore;
    }

    return products;
}
```

The `[ApiController]` attribute applies inference rules for the default data sources of action parameters. These rules save you from having to identify binding sources manually by applying attributes to the action parameters. The binding source inference rules behave as follows:

- `[FromBody]` is inferred for complex type parameters. An exception to the `[FromBody]` inference rule is any complex, built-in type with a special meaning, such as IFormCollection and CancellationToken. The binding source inference code ignores those special types.

- `[FromForm]` is inferred for action parameters of type IFormFile and IFormFileCollection. It's not inferred for any simple or user-defined types.
- `[FromRoute]` is inferred for any action parameter name matching a parameter in the route template. When more than one route matches an action parameter, any route value is considered `[FromRoute]`.
- `[FromQuery]` is inferred for any other action parameters.

FromBody inference notes

`[FromBody]` isn't inferred for simple types such as `string` or `int`. Therefore, the `[FromBody]` attribute should be used for simple types when that functionality is needed.

When an action has more than one parameter bound from the request body, an exception is thrown. For example, all of the following action method signatures cause an exception:

- `[FromBody]` inferred on both because they're complex types.

```
[HttpPost]
public IActionResult Action1(Product product, Order order)
```

- `[FromBody]` attribute on one, inferred on the other because it's a complex type.

```
[HttpPost]
public IActionResult Action2(Product product, [FromBody] Order order)
```

- `[FromBody]` attribute on both.

```
[HttpPost]
public IActionResult Action3([FromBody] Product product, [FromBody] Order order)
```

> **NOTE**
> In ASP.NET Core 2.1, collection type parameters such as lists and arrays are incorrectly inferred as `[FromQuery]`. The `[FromBody]` attribute should be used for these parameters if they are to be bound from the request body. This behavior is corrected in ASP.NET Core 2.2 or later, where collection type parameters are inferred to be bound from the body by default.

Disable inference rules

To disable binding source inference, set SuppressInferBindingSourcesForParameters to `true`. Add the following code in `Startup.ConfigureServices`:

```
services.AddControllers()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressConsumesConstraintForFormFileParameters = true;
        options.SuppressInferBindingSourcesForParameters = true;
        options.SuppressModelStateInvalidFilter = true;
        options.SuppressMapClientErrors = true;
        options.ClientErrorMapping[StatusCodes.Status404NotFound].Link =
            "https://httpstatuses.com/404";
    });
```

```
services.AddMvc()
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2)
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressConsumesConstraintForFormFileParameters = true;
        options.SuppressInferBindingSourcesForParameters = true;
        options.SuppressModelStateInvalidFilter = true;
        options.SuppressMapClientErrors = true;
        options.ClientErrorMapping[404].Link =
            "https://httpstatuses.com/404";
    });
```

```
services.Configure<ApiBehaviorOptions>(options =>
{
    options.SuppressConsumesConstraintForFormFileParameters = true;
    options.SuppressInferBindingSourcesForParameters = true;
    options.SuppressModelStateInvalidFilter = true;
});
```

Multipart/form-data request inference

The `[ApiController]` attribute applies an inference rule when an action parameter is annotated with the `[FromForm]` attribute. The `multipart/form-data` request content type is inferred.

To disable the default behavior, set the SuppressConsumesConstraintForFormFileParameters property to `true` in `Startup.ConfigureServices`:

```
services.AddControllers()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressConsumesConstraintForFormFileParameters = true;
        options.SuppressInferBindingSourcesForParameters = true;
        options.SuppressModelStateInvalidFilter = true;
        options.SuppressMapClientErrors = true;
        options.ClientErrorMapping[StatusCodes.Status404NotFound].Link =
            "https://httpstatuses.com/404";
    });
```

```
services.AddMvc()
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2)
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressConsumesConstraintForFormFileParameters = true;
        options.SuppressInferBindingSourcesForParameters = true;
        options.SuppressModelStateInvalidFilter = true;
        options.SuppressMapClientErrors = true;
        options.ClientErrorMapping[404].Link =
            "https://httpstatuses.com/404";
    });
```

```
services.Configure<ApiBehaviorOptions>(options =>
{
    options.SuppressConsumesConstraintForFormFileParameters = true;
    options.SuppressInferBindingSourcesForParameters = true;
    options.SuppressModelStateInvalidFilter = true;
});
```

Problem details for error status codes

When the compatibility version is 2.2 or later, MVC transforms an error result (a result with status code 400 or higher) to a result with ProblemDetails. The `ProblemDetails` type is based on the RFC 7807 specification for providing machine-readable error details in an HTTP response.

Consider the following code in a controller action:

```
if (pet == null)
{
    return NotFound();
}
```

The `NotFound` method produces an HTTP 404 status code with a `ProblemDetails` body. For example:

```
{
  type: "https://tools.ietf.org/html/rfc7231#section-6.5.4",
  title: "Not Found",
  status: 404,
  traceId: "0HLHLV31KRN83:00000001"
}
```

Disable ProblemDetails response

The automatic creation of a `ProblemDetails` for error status codes is disabled when the SuppressMapClientErrors property is set to `true`. Add the following code in `Startup.ConfigureServices`:

```
services.AddControllers()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressConsumesConstraintForFormFileParameters = true;
        options.SuppressInferBindingSourcesForParameters = true;
        options.SuppressModelStateInvalidFilter = true;
        options.SuppressMapClientErrors = true;
        options.ClientErrorMapping[StatusCodes.Status404NotFound].Link =
            "https://httpstatuses.com/404";
    });
```

```
services.AddMvc()
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2)
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressConsumesConstraintForFormFileParameters = true;
        options.SuppressInferBindingSourcesForParameters = true;
        options.SuppressModelStateInvalidFilter = true;
        options.SuppressMapClientErrors = true;
        options.ClientErrorMapping[404].Link =
            "https://httpstatuses.com/404";
    });
```

Define supported request content types with the [Consumes] attribute

By default, an action supports all available request content types. For example, if an app is configured to support both JSON and XML input formatters, an action supports multiple content types, including `application/json` and `application/xml`.

The [Consumes] attribute allows an action to limit the supported request content types. Apply the `[Consumes]` attribute to an action or controller, specifying one or more content types:

```
[HttpPost]
[Consumes("application/xml")]
public IActionResult CreateProduct(Product product)
```

In the preceding code, the `CreateProduct` action specifies the content type `application/xml`. Requests routed to this action must specify a `Content-Type` header of `application/xml`. Requests that don't specify a `Content-Type` header of `application/xml` result in a 415 Unsupported Media Type response.

The `[Consumes]` attribute also allows an action to influence its selection based on an incoming request's content type by applying a type constraint. Consider the following example:

```
[ApiController]
[Route("api/[controller]")]
public class ConsumesController : ControllerBase
{
    [HttpPost]
    [Consumes("application/json")]
    public IActionResult PostJson(IEnumerable<int> values) =>
        Ok(new { Consumes = "application/json", Values = values });

    [HttpPost]
    [Consumes("application/x-www-form-urlencoded")]
    public IActionResult PostForm([FromForm] IEnumerable<int> values) =>
        Ok(new { Consumes = "application/x-www-form-urlencoded", Values = values });
}
```

In the preceding code, `ConsumesController` is configured to handle requests sent to the `https://localhost:5001/api/Consumes` URL. Both of the controller's actions, `PostJson` and `PostForm`, handle POST requests with the same URL. Without the `[Consumes]` attribute applying a type constraint, an ambiguous match exception is thrown.

The `[Consumes]` attribute is applied to both actions. The `PostJson` action handles requests sent with a `Content-Type` header of `application/json`. The `PostForm` action handles requests sent with a `Content-Type` header of `application/x-www-form-urlencoded`.

Tutorial: Create a web API with ASP.NET Core

9/22/2020 • 47 minutes to read • Edit Online

By Rick Anderson, Kirk Larkin, and Mike Wasson

This tutorial teaches the basics of building a web API with ASP.NET Core.

In this tutorial, you learn how to:

- Create a web API project.
- Add a model class and a database context.
- Scaffold a controller with CRUD methods.
- Configure routing, URL paths, and return values.
- Call the web API with Postman.

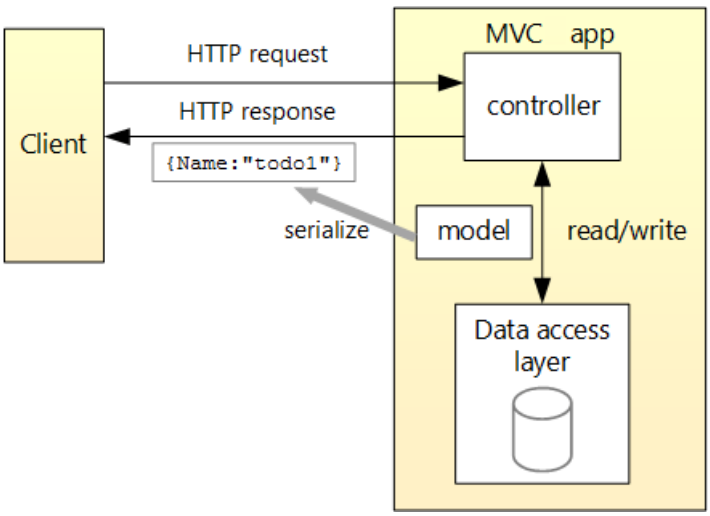
At the end, you have a web API that can manage "to-do" items stored in a database.

Overview

This tutorial creates the following API:

API	DESCRIPTION	REQUEST BODY	RESPONSE BODY
`GET /api/TodoItems`	Get all to-do items	None	Array of to-do items
`GET /api/TodoItems/{id}`	Get an item by ID	None	To-do item
`POST /api/TodoItems`	Add a new item	To-do item	To-do item
`PUT /api/TodoItems/{id}`	Update an existing item	To-do item	None
`DELETE /api/TodoItems/{id}`	Delete an item	None	None

The following diagram shows the design of the app.



Prerequisites

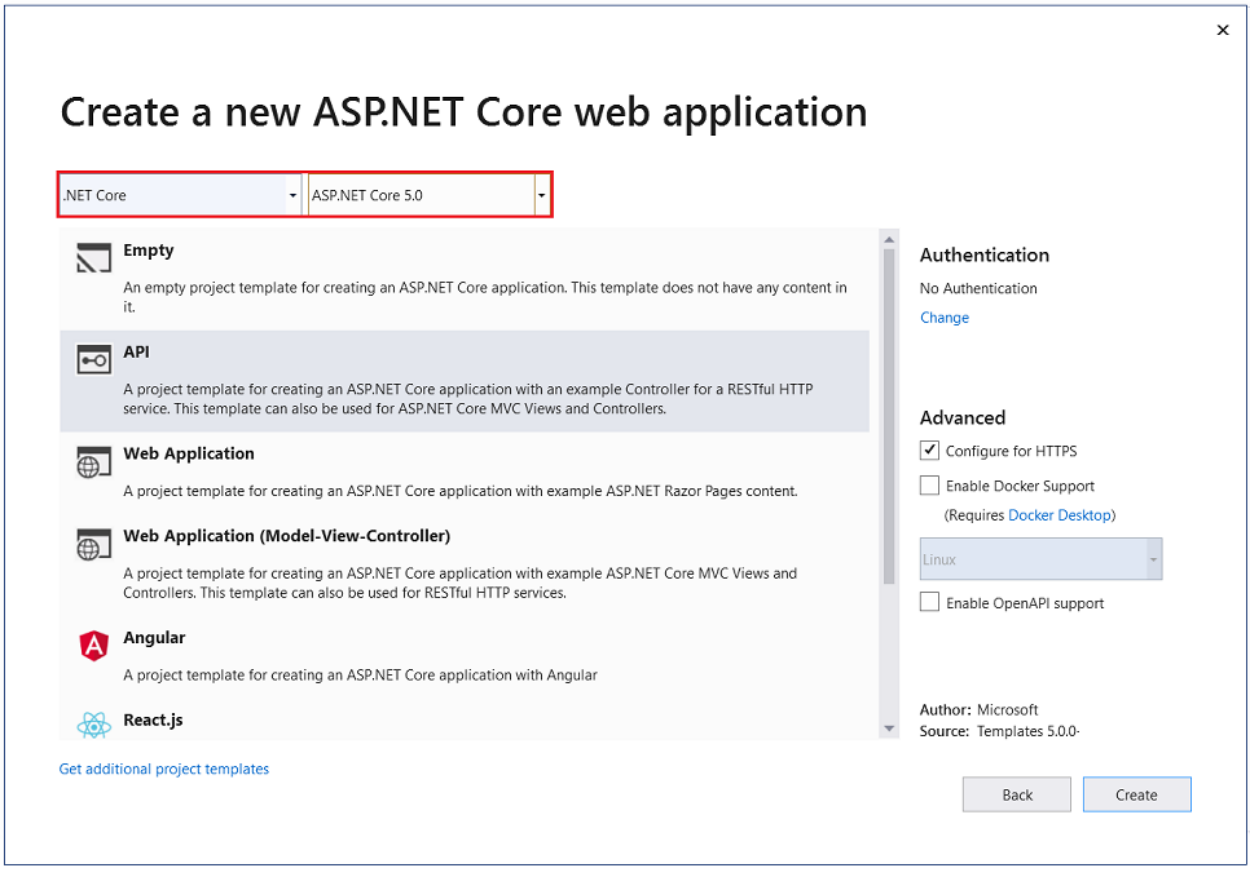
- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 16.8 or later with the **ASP.NET and web development** workload
- .NET 5.0 SDK or later

Create a web project

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- From the **File** menu, select **New** > **Project**.
- Select the **ASP.NET Core Web Application** template and click **Next**.
- Name the project *TodoApi* and click **Create**.
- In the **Create a new ASP.NET Core Web Application** dialog, confirm that **.NET Core** and **ASP.NET Core 5.0** are selected. Select the **API** template and click **Create**.



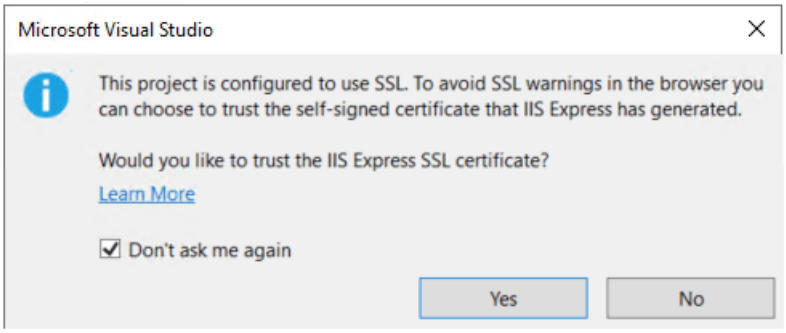
Test the project

The project template creates a `WeatherForecast` API with support for Swagger.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

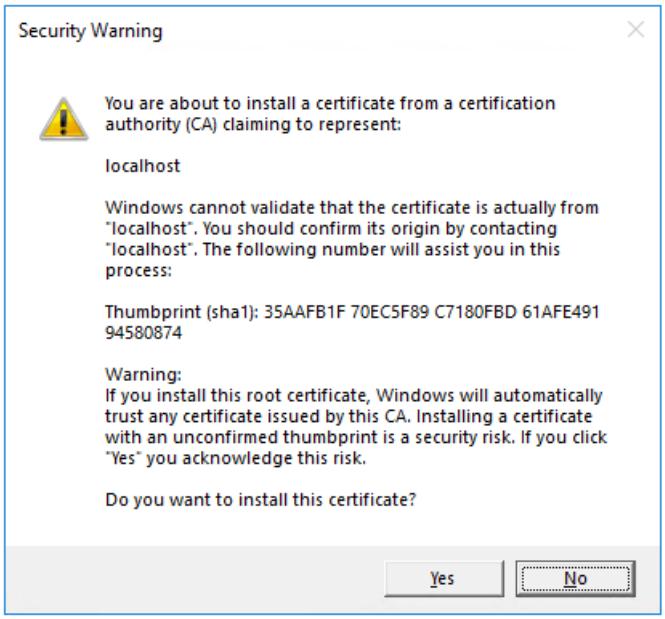
Press Ctrl+F5 to run without the debugger.

Visual Studio displays the following dialog:



Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:



Select **Yes** if you agree to trust the development certificate.

Visual Studio launches:

- The IIS Express web server.
- The default browser and navigates to `https://localhost:<port>/https://localhost:5001/swagger/index.html`, where `<port>` is a randomly chosen port number.

The Swagger page `/swagger/index.html` is displayed. Select **GET** > **Try it out** > **Execute**. The page displays:

- The Curl command to test the WeatherForecast API.
- The URL to test the WeatherForecast API.
- The response code, body, and headers.
- A drop down list box with media types and the example value and schema.

Swagger is used to generate useful documentation and help pages for web APIs. This tutorial focuses on creating a web API. For more information on Swagger, see ASP.NET Core Web API help pages with Swagger / OpenAPI.

Copy and past the **Request URL** in the browser: `https://localhost:<port>/WeatherForecast`

JSON similar to the following is returned:

```
[
    {
        "date": "2019-07-16T19:04:05.7257911-06:00",
        "temperatureC": 52,
        "temperatureF": 125,
        "summary": "Mild"
    },
    {
        "date": "2019-07-17T19:04:05.7258461-06:00",
        "temperatureC": 36,
        "temperatureF": 96,
        "summary": "Warm"
    },
    {
        "date": "2019-07-18T19:04:05.7258467-06:00",
        "temperatureC": 39,
        "temperatureF": 102,
        "summary": "Cool"
    },
    {
        "date": "2019-07-19T19:04:05.7258471-06:00",
        "temperatureC": 10,
        "temperatureF": 49,
        "summary": "Bracing"
    },
    {
        "date": "2019-07-20T19:04:05.7258474-06:00",
        "temperatureC": -1,
        "temperatureF": 31,
        "summary": "Chilly"
    }
]
```

Update the launchUrl

In *Properties\launchSettings.json*, update `launchUrl` from `"swagger"` to `"api/TodoItems"`:

```
"launchUrl": "api/TodoItems",
```

Because Swagger has been removed, the preceding markup changes the URL that is launched to the GET method of the controller added in the following sections.

Add a model class

A *model* is a set of classes that represent the data that the app manages. The model for this app is a single `TodoItem` class.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- In **Solution Explorer**, right-click the project. Select **Add** > **New Folder**. Name the folder *Models*.
- Right-click the *Models* folder and select **Add** > **Class**. Name the class *TodoItem* and select **Add**.
- Replace the template code with the following:

```
namespace TodoApi.Models
{
    public class TodoItem
    {
        public long Id { get; set; }
        public string Name { get; set; }
        public bool IsComplete { get; set; }
    }
}
```

The `Id` property functions as the unique key in a relational database.

Model classes can go anywhere in the project, but the *Models* folder is used by convention.

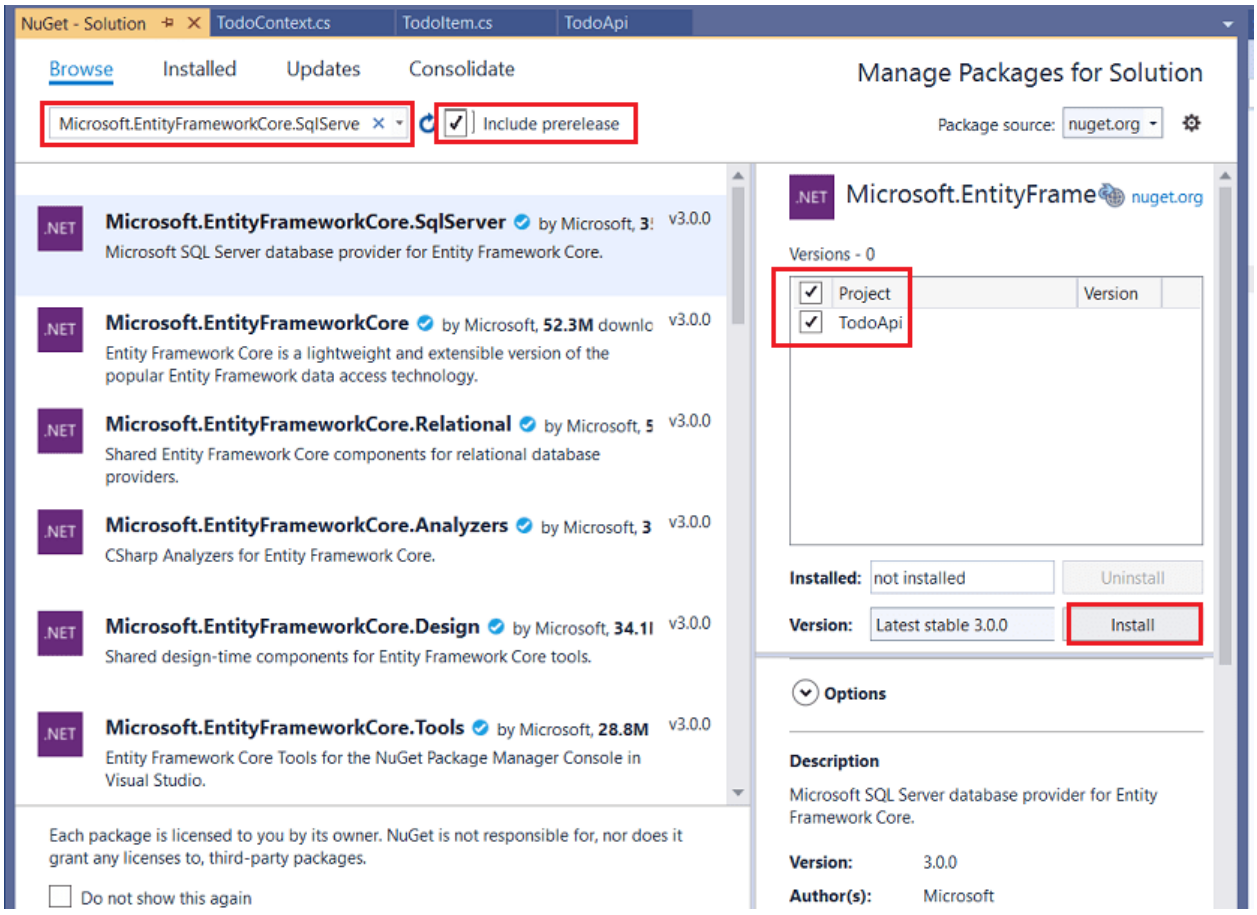
Add a database context

The *database context* is the main class that coordinates Entity Framework functionality for a data model. This class is created by deriving from the Microsoft.EntityFrameworkCore.DbContext class.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

Add NuGet packages

- From the **Tools** menu, select **NuGet Package Manager > Manage NuGet Packages for Solution**.
- Select the **Browse** tab, and then enter **Microsoft. **EntityFrameworkCore.SqlServer** in the search box.
- Select the **Include prerelease** checkbox so the 5.0 RC version is available.
- Select **Microsoft.EntityFrameworkCore.SqlServer** in the left pane.
- Select the **Project** check box in the right pane and then select **Install**.
- Use the preceding instructions to add the **Microsoft.EntityFrameworkCore.InMemory** NuGet package.



Add the TodoContext database context

- Right-click the *Models* folder and select **Add** > **Class**. Name the class *TodoContext* and click **Add**.
- Enter the following code:

```
using Microsoft.EntityFrameworkCore;

namespace TodoApi.Models
{
    public class TodoContext : DbContext
    {
        public TodoContext(DbContextOptions<TodoContext> options)
            : base(options)
        {
        }

        public DbSet<TodoItem> TodoItems { get; set; }
    }
}
```

Register the database context

In ASP.NET Core, services such as the DB context must be registered with the dependency injection (DI) container. The container provides the service to controllers.

Update *Startup.cs* with the following code:

```
// Unused usings removed
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.EntityFrameworkCore;
using TodoApi.Models;

namespace TodoApi
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        public void ConfigureServices(IServiceCollection services)
        {
            services.AddDbContext<TodoContext>(opt =>
                                               opt.UseInMemoryDatabase("TodoList"));
            services.AddControllers();
        }

        public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
        {
            if (env.IsDevelopment())
            {
                app.UseDeveloperExceptionPage();
            }

            app.UseHttpsRedirection();
            app.UseRouting();

            app.UseAuthorization();

            app.UseEndpoints(endpoints =>
            {
                endpoints.MapControllers();
            });
        }
    }
}
```

The preceding code:

- Removes the Swagger calls.
- Removes unused `using` declarations.
- Adds the database context to the DI container.
- Specifies that the database context will use an in-memory database.

Scaffold a controller

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Right-click the *Controllers* folder.
- Select **Add** > **New Scaffolded Item**.

- Select **API Controller with actions, using Entity Framework**, and then select **Add**.
- In the **Add API Controller with actions, using Entity Framework** dialog:
  - Select **TodoItem (TodoApi.Models)** in the **Model class**.
  - Select **TodoContext (TodoApi.Models)** in the **Data context class**.
  - Select **Add**.

The generated code:

- Marks the class with the `[ApiController]` attribute. This attribute indicates that the controller responds to web API requests. For information about specific behaviors that the attribute enables, see Create web APIs with ASP.NET Core.
- Uses DI to inject the database context (`TodoContext`) into the controller. The database context is used in each of the CRUD methods in the controller.

The ASP.NET Core templates for:

- Controllers with views include `[action]` in the route template.
- API controllers don't include `[action]` in the route template.

When the `[action]` token isn't in the route template, the action name is excluded from the route. That is, the action's associated method name isn't used in the matching route.

Update the PostTodoItem create method

Replace the return statement in the `PostTodoItem` to use the nameof operator:

```
// POST: api/TodoItems
[HttpPost]
public async Task<ActionResult<TodoItem>> PostTodoItem(TodoItem todoItem)
{
    _context.TodoItems.Add(todoItem);
    await _context.SaveChangesAsync();

    //return CreatedAtAction("GetTodoItem", new { id = todoItem.Id }, todoItem);
    return CreatedAtAction(nameof(GetTodoItem), new { id = todoItem.Id }, todoItem);
}
```

The preceding code is an HTTP POST method, as indicated by the `[HttpPost]` attribute. The method gets the value of the to-do item from the body of the HTTP request.

For more information, see Attribute routing with Http[Verb] attributes.

The CreatedAtAction method:

- Returns an HTTP 201 status code if successful. HTTP 201 is the standard response for an HTTP POST method that creates a new resource on the server.
- Adds a Location header to the response. The `Location` header specifies the URI of the newly created to-do item. For more information, see 10.2.2 201 Created.
- References the `GetTodoItem` action to create the `Location` header's URI. The C# `nameof` keyword is used to avoid hard-coding the action name in the `CreatedAtAction` call.

Install Postman

This tutorial uses Postman to test the web API.

- Install Postman

- Start the web app.
- Start Postman.
- Disable **SSL certificate verification**
  - From **File** > **Settings** (**General** tab), disable **SSL certificate verification**.

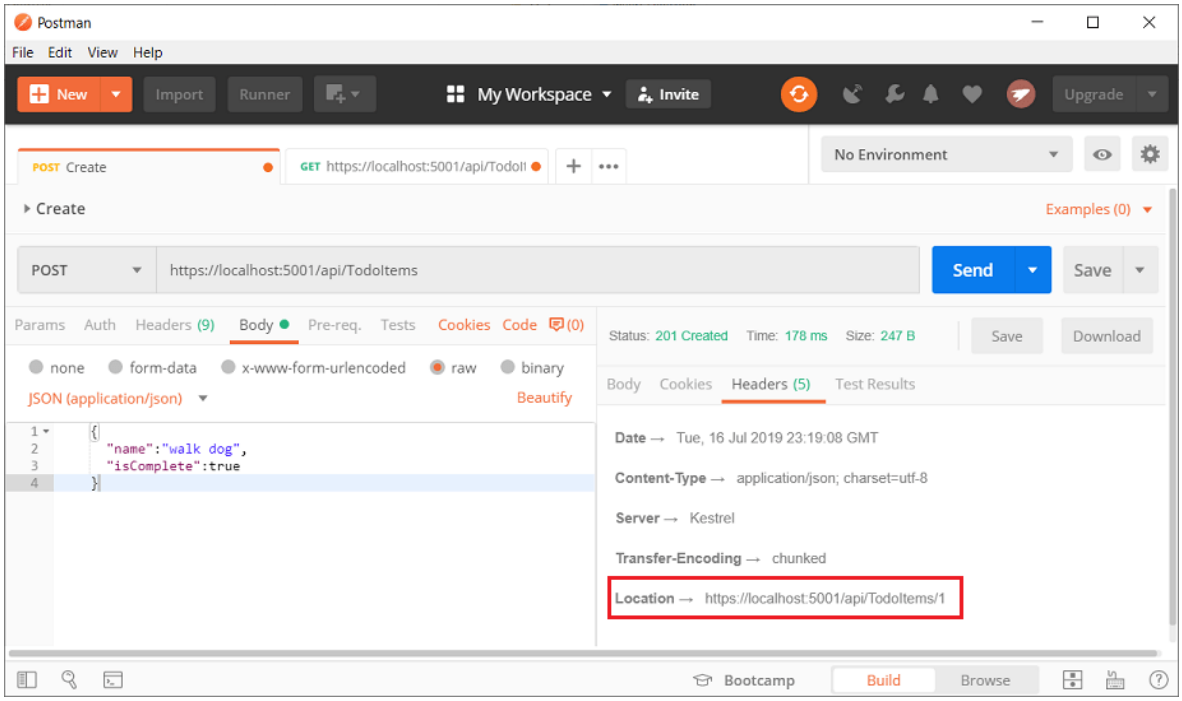
> **WARNING**
>
> Re-enable SSL certificate verification after testing the controller.

Test PostTodoItem with Postman

- Create a new request.
- Set the HTTP method to `POST`.
- Set the URI to `https://localhost:<port>/api/TodoItems`. For example, `https://localhost:5001/api/TodoItems`.
- Select the **Body** tab.
- Select the **raw** radio button.
- Set the type to **JSON (application/json)**.
- In the request body enter JSON for a to-do item:

```
{
  "name":"walk dog",
  "isComplete":true
}
```

- Select **Send**.

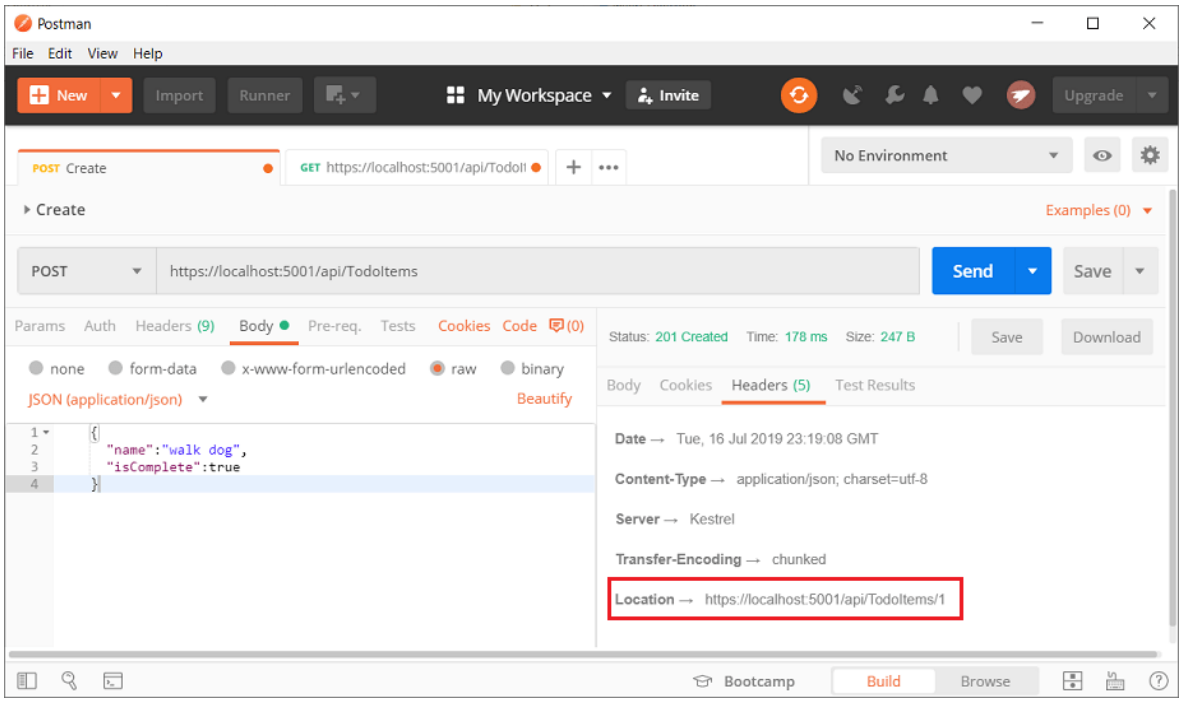


Test the location header URI

The location header URI can be tested in the browser. Copy and paste the location header URI into the browser.

To test in Postman:

- Select the **Headers** tab in the **Response** pane.
- Copy the **Location** header value:



- Set the HTTP method to `GET`.
- Set the URI to `https://localhost:<port>/api/TodoItems/1`. For example, `https://localhost:5001/api/TodoItems/1`.
- Select **Send**.

Examine the GET methods

Two GET endpoints are implemented:

- `GET /api/TodoItems`
- `GET /api/TodoItems/{id}`

Test the app by calling the two endpoints from a browser or Postman. For example:

- `https://localhost:5001/api/TodoItems`
- `https://localhost:5001/api/TodoItems/1`

A response similar to the following is produced by the call to `GetTodoItems`:

```
[
  {
    "id": 1,
    "name": "Item1",
    "isComplete": false
  }
]
```

Test Get with Postman

- Create a new request.
- Set the HTTP method to **GET**.
- Set the request URI to `https://localhost:<port>/api/TodoItems`. For example,

`https://localhost:5001/api/TodoItems`.

- Set **Two pane view** in Postman.
- Select **Send**.

This app uses an in-memory database. If the app is stopped and started, the preceding GET request will not return any data. If no data is returned, POST data to the app.

Routing and URL paths

The `[HttpGet]` attribute denotes a method that responds to an HTTP GET request. The URL path for each method is constructed as follows:

- Start with the template string in the controller's `Route` attribute:

```
[Route("api/[controller]")]
[ApiController]
public class TodoItemsController : ControllerBase
{
    private readonly TodoContext _context;

    public TodoItemsController(TodoContext context)
    {
        _context = context;
    }
```

- Replace `[controller]` with the name of the controller, which by convention is the controller class name minus the "Controller" suffix. For this sample, the controller class name is **TodoItems**Controller, so the controller name is "TodoItems". ASP.NET Core routing is case insensitive.
- If the `[HttpGet]` attribute has a route template (for example, `[HttpGet("products")]`), append that to the path. This sample doesn't use a template. For more information, see Attribute routing with Http[Verb] attributes.

In the following `GetTodoItem` method, `"{id}"` is a placeholder variable for the unique identifier of the to-do item. When `GetTodoItem` is invoked, the value of `"{id}"` in the URL is provided to the method in its `id` parameter.

```
// GET: api/TodoItems/5
[HttpGet("{id}")]
public async Task<ActionResult<TodoItem>> GetTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    return todoItem;
}
```

Return values

The return type of the `GetTodoItems` and `GetTodoItem` methods is ActionResult<T> type. ASP.NET Core automatically serializes the object to JSON and writes the JSON into the body of the response message. The response code for this return type is 200 OK, assuming there are no unhandled exceptions. Unhandled exceptions are translated into 5xx errors.

`ActionResult` return types can represent a wide range of HTTP status codes. For example, `GetTodoItem` can return two different status values:

- If no item matches the requested ID, the method returns a 404 status NotFound error code.
- Otherwise, the method returns 200 with a JSON response body. Returning `item` results in an HTTP 200 response.

The PutTodoItem method

Examine the `PutTodoItem` method:

```
// PUT: api/TodoItems/5
[HttpPut("{id}")]
public async Task<IActionResult> PutTodoItem(long id, TodoItem todoItem)
{
    if (id != todoItem.Id)
    {
        return BadRequest();
    }

    _context.Entry(todoItem).State = EntityState.Modified;

    try
    {
        await _context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!TodoItemExists(id))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }

    return NoContent();
}
```

`PutTodoItem` is similar to `PostTodoItem`, except it uses HTTP PUT. The response is 204 (No Content). According to the HTTP specification, a PUT request requires the client to send the entire updated entity, not just the changes. To support partial updates, use HTTP PATCH.

If you get an error calling `PutTodoItem`, call `GET` to ensure there's an item in the database.

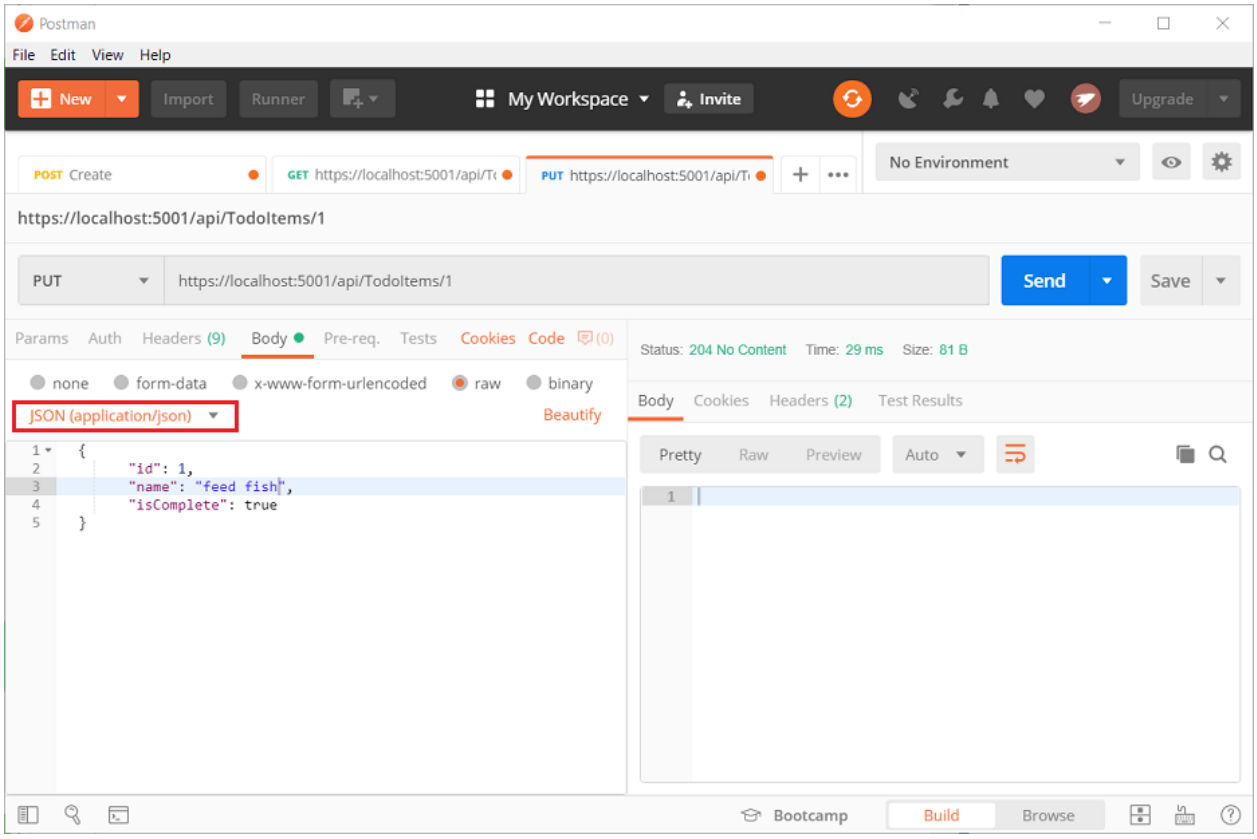
Test the PutTodoItem method

This sample uses an in-memory database that must be initialized each time the app is started. There must be an item in the database before you make a PUT call. Call GET to ensure there's an item in the database before making a PUT call.

Update the to-do item that has Id = 1 and set its name to `"feed fish"`:

```
{
  "Id":1,
  "name":"feed fish",
  "isComplete":true
}
```

The following image shows the Postman update:



The DeleteTodoItem method

Examine the `DeleteTodoItem` method:

```
// DELETE: api/TodoItems/5
[HttpDelete("{id}")]
public async Task<IActionResult> DeleteTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);
    if (todoItem == null)
    {
        return NotFound();
    }

    _context.TodoItems.Remove(todoItem);
    await _context.SaveChangesAsync();

    return NoContent();
}
```

Test the DeleteTodoItem method

Use Postman to delete a to-do item:

- Set the method to `DELETE`.
- Set the URI of the object to delete (for example `https://localhost:5001/api/TodoItems/1`).
- Select **Send**.

Prevent over-posting

Currently the sample app exposes the entire `TodoItem` object. Production apps typically limit the data that's input and returned using a subset of the model. There are multiple reasons behind this and security is a major one. The subset of a model is usually referred to as a Data Transfer Object (DTO), input model, or view model. **DTO** is used

in this article.

A DTO may be used to:

- Prevent over-posting.
- Hide properties that clients are not supposed to view.
- Omit some properties in order to reduce payload size.
- Flatten object graphs that contain nested objects. Flattened object graphs can be more convenient for clients.

To demonstrate the DTO approach, update the `TodoItem` class to include a secret field:

```
namespace TodoApi.Models
{
    public class TodoItem
    {
        public long Id { get; set; }
        public string Name { get; set; }
        public bool IsComplete { get; set; }
        public string Secret { get; set; }
    }
}
```

The secret field needs to be hidden from this app, but an administrative app could choose to expose it.

Verify you can post and get the secret field.

Create a DTO model:

```
public class TodoItemDTO
{
    public long Id { get; set; }
    public string Name { get; set; }
    public bool IsComplete { get; set; }
}
```

Update the `TodoItemsController` to use `TodoItemDTO`:

```
// GET: api/TodoItems
[HttpGet]
public async Task<ActionResult<IEnumerable<TodoItemDTO>>> GetTodoItems()
{
    return await _context.TodoItems
        .Select(x => ItemToDTO(x))
        .ToListAsync();
}

[HttpGet("{id}")]
public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    return ItemToDTO(todoItem);
}

[HttpPut("{id}")]
public async Task<IActionResult> UpdateTodoItem(long id, TodoItemDTO todoItemDTO)
{
```

```
    if (id != todoItemDTO.Id)
    {
        return BadRequest();
    }

    var todoItem = await _context.TodoItems.FindAsync(id);
    if (todoItem == null)
    {
        return NotFound();
    }

    todoItem.Name = todoItemDTO.Name;
    todoItem.IsComplete = todoItemDTO.IsComplete;

    try
    {
        await _context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException) when (!TodoItemExists(id))
    {
        return NotFound();
    }

    return NoContent();
}

[HttpPost]
public async Task<ActionResult<TodoItemDTO>> CreateTodoItem(TodoItemDTO todoItemDTO)
{
    var todoItem = new TodoItem
    {
        IsComplete = todoItemDTO.IsComplete,
        Name = todoItemDTO.Name
    };

    _context.TodoItems.Add(todoItem);
    await _context.SaveChangesAsync();

    return CreatedAtAction(
        nameof(GetTodoItem),
        new { id = todoItem.Id },
        ItemToDTO(todoItem));
}

[HttpDelete("{id}")]
public async Task<IActionResult> DeleteTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    _context.TodoItems.Remove(todoItem);
    await _context.SaveChangesAsync();

    return NoContent();
}

private bool TodoItemExists(long id) =>
     _context.TodoItems.Any(e => e.Id == id);

private static TodoItemDTO ItemToDTO(TodoItem todoItem) =>
    new TodoItemDTO
    {
        Id = todoItem.Id,
        Name = todoItem.Name,
        IsComplete = todoItem.IsComplete
```

```
    };
```

Verify you can't post or get the secret field.

Call the web API with JavaScript

See Tutorial: Call an ASP.NET Core web API with JavaScript.

In this tutorial, you learn how to:

- Create a web API project.
- Add a model class and a database context.
- Scaffold a controller with CRUD methods.
- Configure routing, URL paths, and return values.
- Call the web API with Postman.

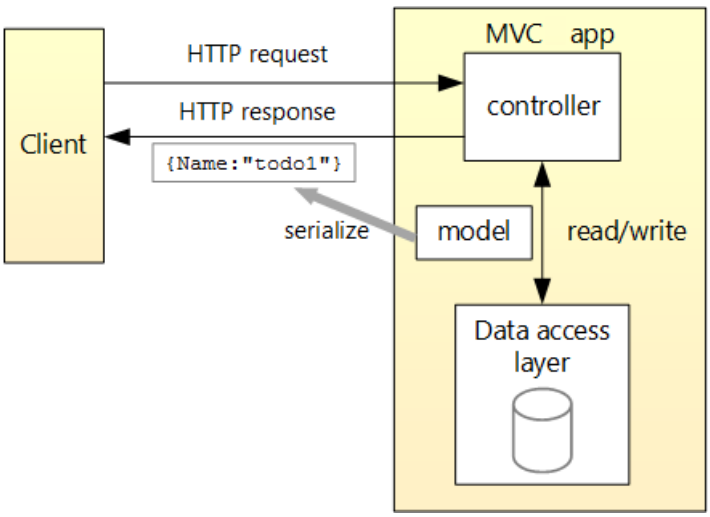
At the end, you have a web API that can manage "to-do" items stored in a database.

Overview

This tutorial creates the following API:

API	DESCRIPTION	REQUEST BODY	RESPONSE BODY
`GET /api/TodoItems`	Get all to-do items	None	Array of to-do items
`GET /api/TodoItems/{id}`	Get an item by ID	None	To-do item
`POST /api/TodoItems`	Add a new item	To-do item	To-do item
`PUT /api/TodoItems/{id}`	Update an existing item	To-do item	None
`DELETE /api/TodoItems/{id}`	Delete an item	None	None

The following diagram shows the design of the app.



Prerequisites

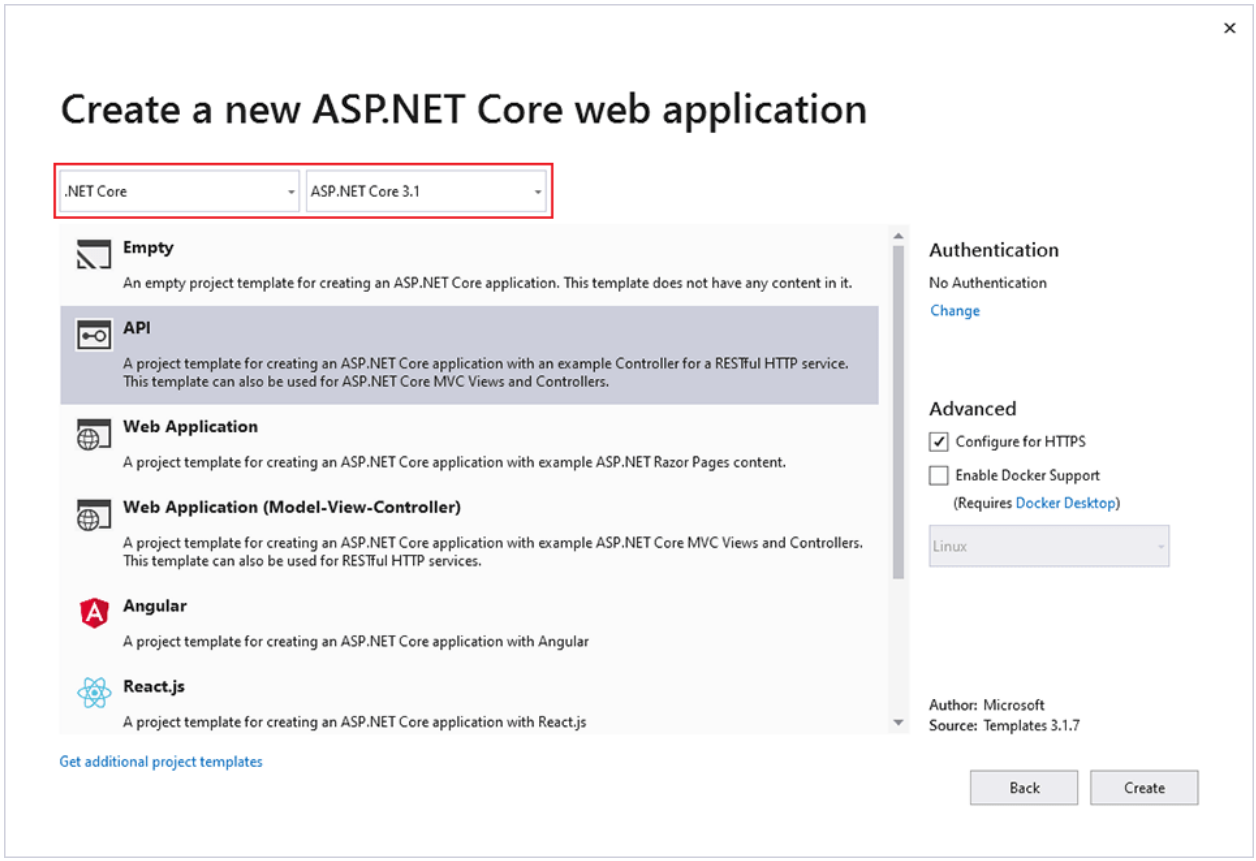
- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 16.4 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

Create a web project

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- From the **File** menu, select **New** > **Project**.
- Select the **ASP.NET Core Web Application** template and click **Next**.
- Name the project *TodoApi* and click **Create**.
- In the **Create a new ASP.NET Core Web Application** dialog, confirm that **.NET Core** and **ASP.NET Core 3.1** are selected. Select the **API** template and click **Create**.



Test the API

The project template creates a `WeatherForecast` API. Call the `Get` method from a browser to test the app.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Press Ctrl+F5 to run the app. Visual Studio launches a browser and navigates to `https://localhost:<port>/WeatherForecast`, where `<port>` is a randomly chosen port number.

If you get a dialog box that asks if you should trust the IIS Express certificate, select **Yes**. In the **Security Warning** dialog that appears next, select **Yes**.

JSON similar to the following is returned:

```
[
    {
        "date": "2019-07-16T19:04:05.7257911-06:00",
        "temperatureC": 52,
        "temperatureF": 125,
        "summary": "Mild"
    },
    {
        "date": "2019-07-17T19:04:05.7258461-06:00",
        "temperatureC": 36,
        "temperatureF": 96,
        "summary": "Warm"
    },
    {
        "date": "2019-07-18T19:04:05.7258467-06:00",
        "temperatureC": 39,
        "temperatureF": 102,
        "summary": "Cool"
    },
    {
        "date": "2019-07-19T19:04:05.7258471-06:00",
        "temperatureC": 10,
        "temperatureF": 49,
        "summary": "Bracing"
    },
    {
        "date": "2019-07-20T19:04:05.7258474-06:00",
        "temperatureC": -1,
        "temperatureF": 31,
        "summary": "Chilly"
    }
]
```

Add a model class

A *model* is a set of classes that represent the data that the app manages. The model for this app is a single `TodoItem` class.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- In **Solution Explorer**, right-click the project. Select **Add** > **New Folder**. Name the folder *Models*.
- Right-click the *Models* folder and select **Add** > **Class**. Name the class *TodoItem* and select **Add**.
- Replace the template code with the following code:

```
public class TodoItem
{
    public long Id { get; set; }
    public string Name { get; set; }
    public bool IsComplete { get; set; }
}
```

The `Id` property functions as the unique key in a relational database.

Model classes can go anywhere in the project, but the *Models* folder is used by convention.

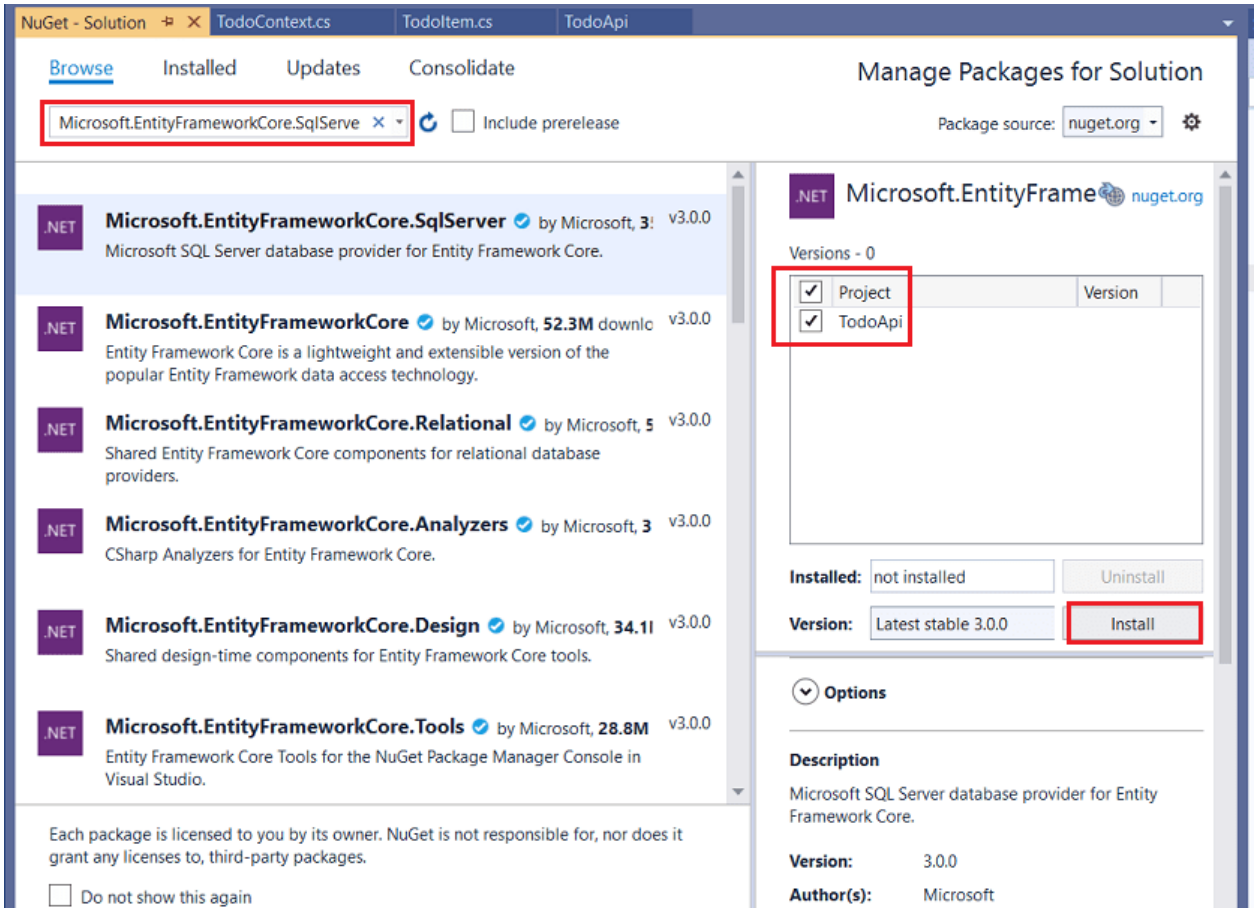
Add a database context

The *database context* is the main class that coordinates Entity Framework functionality for a data model. This class is created by deriving from the `Microsoft.EntityFrameworkCore.DbContext` class.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

Add NuGet packages

- From the **Tools** menu, select **NuGet Package Manager** > **Manage NuGet Packages for Solution**.
- Select the **Browse** tab, and then enter **Microsoft.EntityFrameworkCore.SqlServer** in the search box.
- Select **Microsoft.EntityFrameworkCore.SqlServer** in the left pane.
- Select the **Project** check box in the right pane and then select **Install**.
- Use the preceding instructions to add the **Microsoft.EntityFrameworkCore.InMemory** NuGet package.



Add the TodoContext database context

- Right-click the *Models* folder and select **Add** > **Class**. Name the class *TodoContext* and click **Add**.
- Enter the following code:

```
using Microsoft.EntityFrameworkCore;

namespace TodoApi.Models
{
    public class TodoContext : DbContext
    {
        public TodoContext(DbContextOptions<TodoContext> options)
            : base(options)
        {
        }

        public DbSet<TodoItem> TodoItems { get; set; }
    }
}
```

Register the database context

In ASP.NET Core, services such as the DB context must be registered with the dependency injection (DI) container. The container provides the service to controllers.

Update *Startup.cs* with the following highlighted code:

```
// Unused usings removed
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.EntityFrameworkCore;
using TodoApi.Models;

namespace TodoApi
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        public void ConfigureServices(IServiceCollection services)
        {
            services.AddDbContext<TodoContext>(opt =>
               opt.UseInMemoryDatabase("TodoList"));
            services.AddControllers();
        }

        public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
        {
            if (env.IsDevelopment())
            {
                app.UseDeveloperExceptionPage();
            }

            app.UseHttpsRedirection();

            app.UseRouting();

            app.UseAuthorization();

            app.UseEndpoints(endpoints =>
            {
                endpoints.MapControllers();
            });
        }
    }
}
```

The preceding code:

- Removes unused `using` declarations.
- Adds the database context to the DI container.
- Specifies that the database context will use an in-memory database.

Scaffold a controller

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Right-click the *Controllers* folder.
- Select **Add** > **New Scaffolded Item**.
- Select **API Controller with actions, using Entity Framework**, and then select **Add**.

- In the **Add API Controller with actions, using Entity Framework** dialog:
  - Select **TodoItem (TodoApi.Models)** in the **Model class**.
  - Select **TodoContext (TodoApi.Models)** in the **Data context class**.
  - Select **Add**.

The generated code:

- Marks the class with the `[ApiController]` attribute. This attribute indicates that the controller responds to web API requests. For information about specific behaviors that the attribute enables, see Create web APIs with ASP.NET Core.
- Uses DI to inject the database context (`TodoContext`) into the controller. The database context is used in each of the CRUD methods in the controller.

The ASP.NET Core templates for:

- Controllers with views include `[action]` in the route template.
- API controllers don't include `[action]` in the route template.

When the `[action]` token isn't in the route template, the action name is excluded from the route. That is, the action's associated method name isn't used in the matching route.

Examine the PostTodoItem create method

Replace the return statement in the `PostTodoItem` to use the nameof operator:

```
// POST: api/TodoItems
[HttpPost]
public async Task<ActionResult<TodoItem>> PostTodoItem(TodoItem todoItem)
{
    _context.TodoItems.Add(todoItem);
    await _context.SaveChangesAsync();

    //return CreatedAtAction("GetTodoItem", new { id = todoItem.Id }, todoItem);
    return CreatedAtAction(nameof(GetTodoItem), new { id = todoItem.Id }, todoItem);
}
```

The preceding code is an HTTP POST method, as indicated by the `[HttpPost]` attribute. The method gets the value of the to-do item from the body of the HTTP request.

For more information, see Attribute routing with Http[Verb] attributes.

The CreatedAtAction method:

- Returns an HTTP 201 status code if successful. HTTP 201 is the standard response for an HTTP POST method that creates a new resource on the server.
- Adds a Location header to the response. The `Location` header specifies the URI of the newly created to-do item. For more information, see 10.2.2 201 Created.
- References the `GetTodoItem` action to create the `Location` header's URI. The C# `nameof` keyword is used to avoid hard-coding the action name in the `CreatedAtAction` call.

Install Postman

This tutorial uses Postman to test the web API.

- Install Postman
- Start the web app.
- Start Postman.

- Disable **SSL certificate verification**
  - From **File** > **Settings** (**General** tab), disable **SSL certificate verification**.

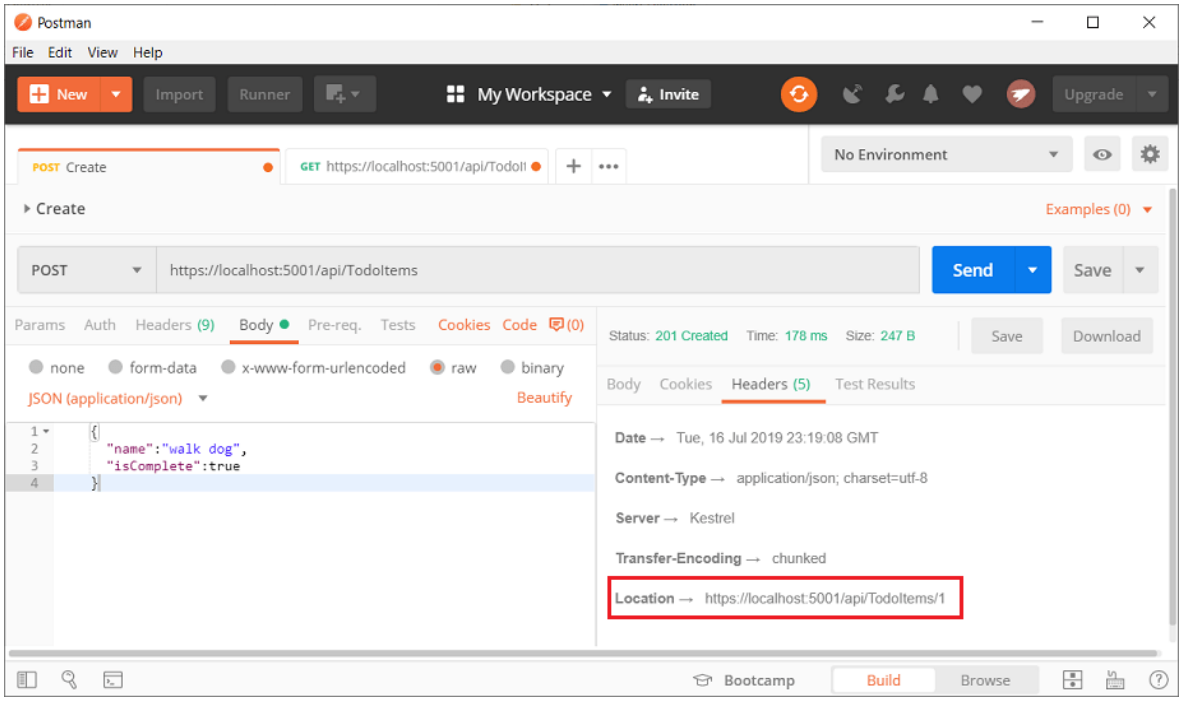
> **WARNING**
> Re-enable SSL certificate verification after testing the controller.

Test PostTodoItem with Postman

- Create a new request.
- Set the HTTP method to `POST`.
- Set the URI to `https://localhost:<port>/api/TodoItems`. For example, `https://localhost:5001/api/TodoItems`.
- Select the **Body** tab.
- Select the **raw** radio button.
- Set the type to **JSON (application/json)**.
- In the request body enter JSON for a to-do item:

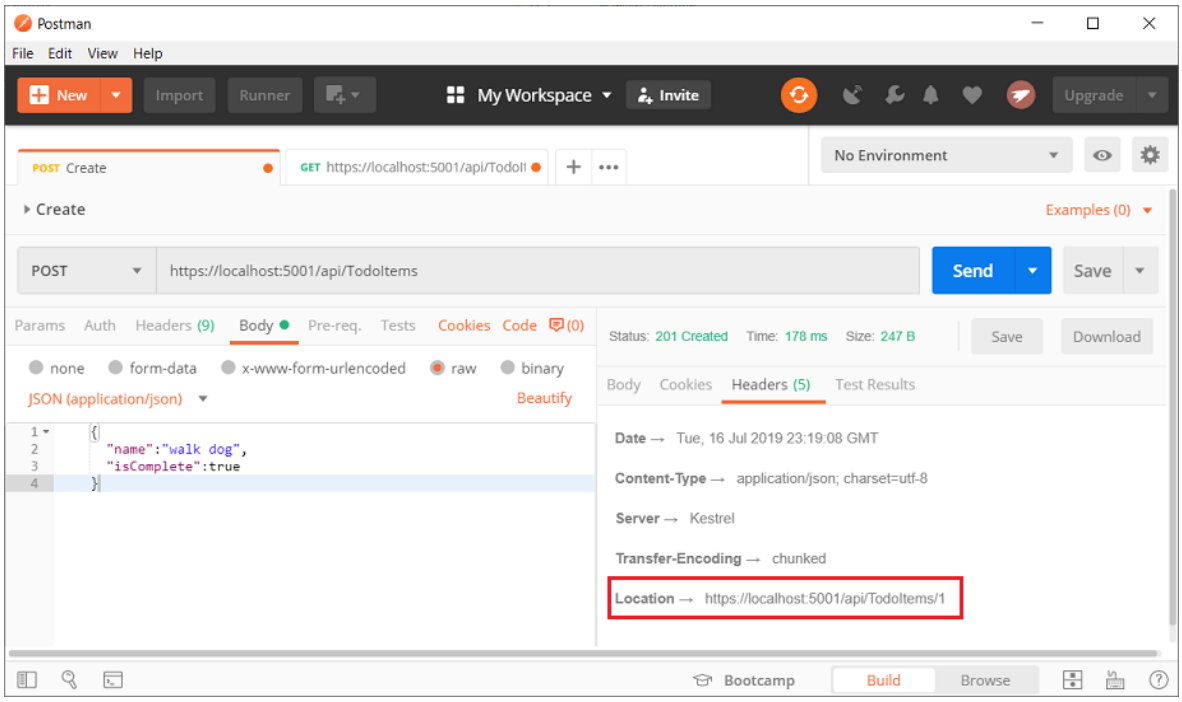
```
{
  "name":"walk dog",
  "isComplete":true
}
```

- Select **Send**.



Test the location header URI with Postman

- Select the **Headers** tab in the **Response** pane.
- Copy the **Location** header value:



- Set the HTTP method to `GET`.
- Set the URI to `https://localhost:<port>/api/TodoItems/1`. For example, `https://localhost:5001/api/TodoItems/1`.
- Select **Send**.

Examine the GET methods

These methods implement two GET endpoints:

- `GET /api/TodoItems`
- `GET /api/TodoItems/{id}`

Test the app by calling the two endpoints from a browser or Postman. For example:

- `https://localhost:5001/api/TodoItems`
- `https://localhost:5001/api/TodoItems/1`

A response similar to the following is produced by the call to `GetTodoItems`:

```
[
  {
    "id": 1,
    "name": "Item1",
    "isComplete": false
  }
]
```

Test Get with Postman

- Create a new request.
- Set the HTTP method to **GET**.
- Set the request URI to `https://localhost:<port>/api/TodoItems`. For example, `https://localhost:5001/api/TodoItems`.
- Set **Two pane view** in Postman.
- Select **Send**.

This app uses an in-memory database. If the app is stopped and started, the preceding GET request will not return any data. If no data is returned, POST data to the app.

Routing and URL paths

The `[HttpGet]` attribute denotes a method that responds to an HTTP GET request. The URL path for each method is constructed as follows:

- Start with the template string in the controller's `Route` attribute:

```
[Route("api/[controller]")]
[ApiController]
public class TodoItemsController : ControllerBase
{
    private readonly TodoContext _context;

    public TodoItemsController(TodoContext context)
    {
        _context = context;
    }
```

- Replace `[controller]` with the name of the controller, which by convention is the controller class name minus the "Controller" suffix. For this sample, the controller class name is **TodoItems**Controller, so the controller name is "TodoItems". ASP.NET Core routing is case insensitive.
- If the `[HttpGet]` attribute has a route template (for example, `[HttpGet("products")]`), append that to the path. This sample doesn't use a template. For more information, see Attribute routing with Http[Verb] attributes.

In the following `GetTodoItem` method, `"{id}"` is a placeholder variable for the unique identifier of the to-do item. When `GetTodoItem` is invoked, the value of `"{id}"` in the URL is provided to the method in its `id` parameter.

```
// GET: api/TodoItems/5
[HttpGet("{id}")]
public async Task<ActionResult<TodoItem>> GetTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    return todoItem;
}
```

Return values

The return type of the `GetTodoItems` and `GetTodoItem` methods is ActionResult<T> type. ASP.NET Core automatically serializes the object to JSON and writes the JSON into the body of the response message. The response code for this return type is 200, assuming there are no unhandled exceptions. Unhandled exceptions are translated into 5xx errors.

`ActionResult` return types can represent a wide range of HTTP status codes. For example, `GetTodoItem` can return two different status values:

- If no item matches the requested ID, the method returns a 404 NotFound error code.

- Otherwise, the method returns 200 with a JSON response body. Returning `item` results in an HTTP 200 response.

The PutTodoItem method

Examine the `PutTodoItem` method:

```
// PUT: api/TodoItems/5
[HttpPut("{id}")]
public async Task<IActionResult> PutTodoItem(long id, TodoItem todoItem)
{
    if (id != todoItem.Id)
    {
        return BadRequest();
    }

    _context.Entry(todoItem).State = EntityState.Modified;

    try
    {
        await _context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!TodoItemExists(id))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }

    return NoContent();
}
```

`PutTodoItem` is similar to `PostTodoItem`, except it uses HTTP PUT. The response is 204 (No Content). According to the HTTP specification, a PUT request requires the client to send the entire updated entity, not just the changes. To support partial updates, use HTTP PATCH.

If you get an error calling `PutTodoItem`, call `GET` to ensure there's an item in the database.

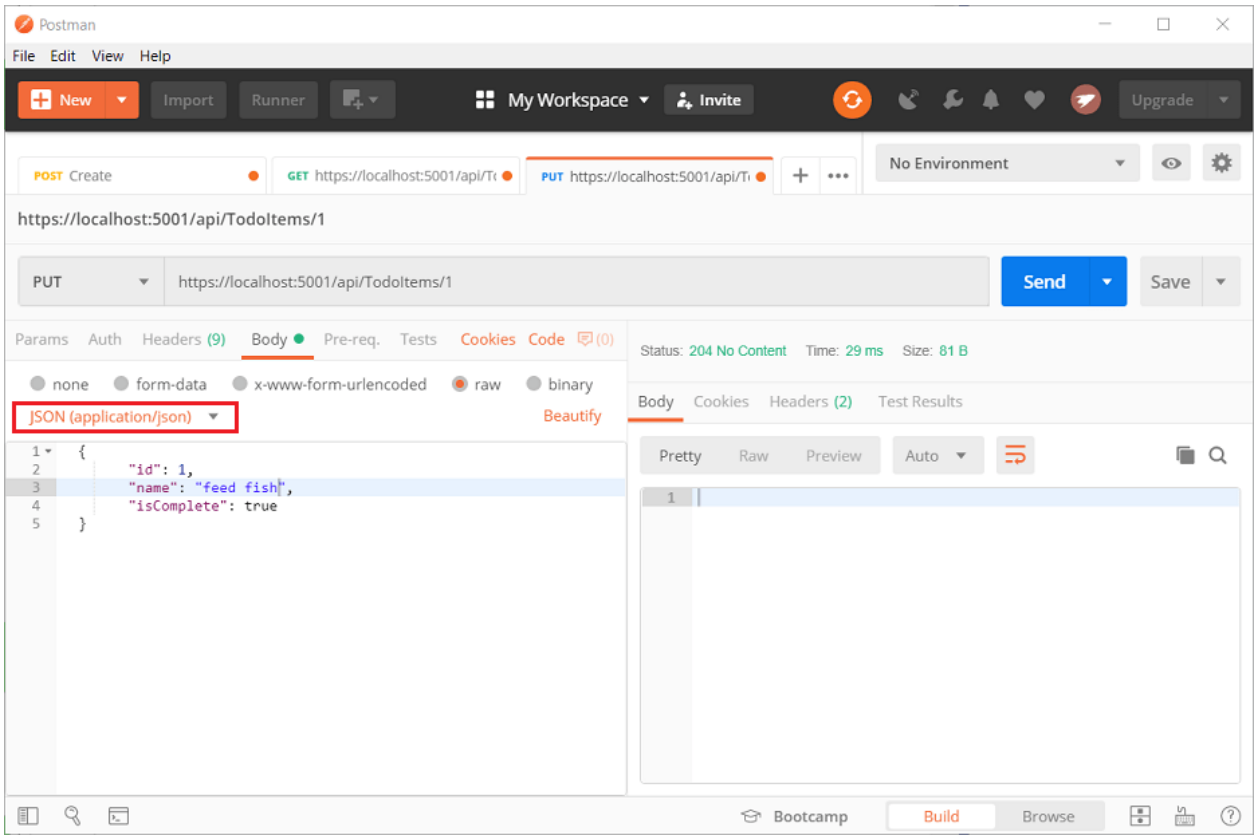
Test the PutTodoItem method

This sample uses an in-memory database that must be initialized each time the app is started. There must be an item in the database before you make a PUT call. Call GET to ensure there's an item in the database before making a PUT call.

Update the to-do item that has Id = 1 and set its name to "feed fish":

```
{
  "Id":1,
  "name":"feed fish",
  "isComplete":true
}
```

The following image shows the Postman update:



The DeleteTodoItem method

Examine the `DeleteTodoItem` method:

```
// DELETE: api/TodoItems/5
[HttpDelete("{id}")]
public async Task<ActionResult<TodoItem>> DeleteTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);
    if (todoItem == null)
    {
        return NotFound();
    }

    _context.TodoItems.Remove(todoItem);
    await _context.SaveChangesAsync();

    return todoItem;
}
```

Test the DeleteTodoItem method

Use Postman to delete a to-do item:

- Set the method to `DELETE`.
- Set the URI of the object to delete (for example `https://localhost:5001/api/TodoItems/1`).
- Select **Send**.

Prevent over-posting

Currently the sample app exposes the entire `TodoItem` object. Production apps typically limit the data that's input and returned using a subset of the model. There are multiple reasons behind this and security is a major one. The subset of a model is usually referred to as a Data Transfer Object (DTO), input model, or view model. **DTO** is used in this article.

A DTO may be used to:

- Prevent over-posting.
- Hide properties that clients are not supposed to view.
- Omit some properties in order to reduce payload size.
- Flatten object graphs that contain nested objects. Flattened object graphs can be more convenient for clients.

To demonstrate the DTO approach, update the `TodoItem` class to include a secret field:

```
public class TodoItem
{
    public long Id { get; set; }
    public string Name { get; set; }
    public bool IsComplete { get; set; }
    public string Secret { get; set; }
}
```

The secret field needs to be hidden from this app, but an administrative app could choose to expose it.

Verify you can post and get the secret field.

Create a DTO model:

```
public class TodoItemDTO
{
    public long Id { get; set; }
    public string Name { get; set; }
    public bool IsComplete { get; set; }
}
```

Update the `TodoItemsController` to use `TodoItemDTO`:

```
    [HttpGet]
    public async Task<ActionResult<IEnumerable<TodoItemDTO>>> GetTodoItems()
    {
        return await _context.TodoItems
            .Select(x => ItemToDTO(x))
            .ToListAsync();
    }

    [HttpGet("{id}")]
    public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
    {
        var todoItem = await _context.TodoItems.FindAsync(id);

        if (todoItem == null)
        {
            return NotFound();
        }

        return ItemToDTO(todoItem);
    }

    [HttpPut("{id}")]
    public async Task<IActionResult> UpdateTodoItem(long id, TodoItemDTO todoItemDTO)
    {
        if (id != todoItemDTO.Id)
        {
            return BadRequest();
        }

        var todoItem = await _context.TodoItems.FindAsync(id);
```

```
        if (todoItem == null)
        {
            return NotFound();
        }

        todoItem.Name = todoItemDTO.Name;
        todoItem.IsComplete = todoItemDTO.IsComplete;

        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException) when (!TodoItemExists(id))
        {
            return NotFound();
        }

        return NoContent();
    }

    [HttpPost]
    public async Task<ActionResult<TodoItemDTO>> CreateTodoItem(TodoItemDTO todoItemDTO)
    {
        var todoItem = new TodoItem
        {
            IsComplete = todoItemDTO.IsComplete,
            Name = todoItemDTO.Name
        };

        _context.TodoItems.Add(todoItem);
        await _context.SaveChangesAsync();

        return CreatedAtAction(
            nameof(GetTodoItem),
            new { id = todoItem.Id },
            ItemToDTO(todoItem));
    }

    [HttpDelete("{id}")]
    public async Task<IActionResult> DeleteTodoItem(long id)
    {
        var todoItem = await _context.TodoItems.FindAsync(id);

        if (todoItem == null)
        {
            return NotFound();
        }

        _context.TodoItems.Remove(todoItem);
        await _context.SaveChangesAsync();

        return NoContent();
    }

    private bool TodoItemExists(long id) =>
         _context.TodoItems.Any(e => e.Id == id);

    private static TodoItemDTO ItemToDTO(TodoItem todoItem) =>
        new TodoItemDTO
        {
            Id = todoItem.Id,
            Name = todoItem.Name,
            IsComplete = todoItem.IsComplete
        };
}
```

Verify you can't post or get the secret field.

Call the web API with JavaScript

See Tutorial: Call an ASP.NET Core web API with JavaScript.

In this tutorial, you learn how to:

- Create a web API project.
- Add a model class and a database context.
- Add a controller.
- Add CRUD methods.
- Configure routing and URL paths.
- Specify return values.
- Call the web API with Postman.
- Call the web API with JavaScript.

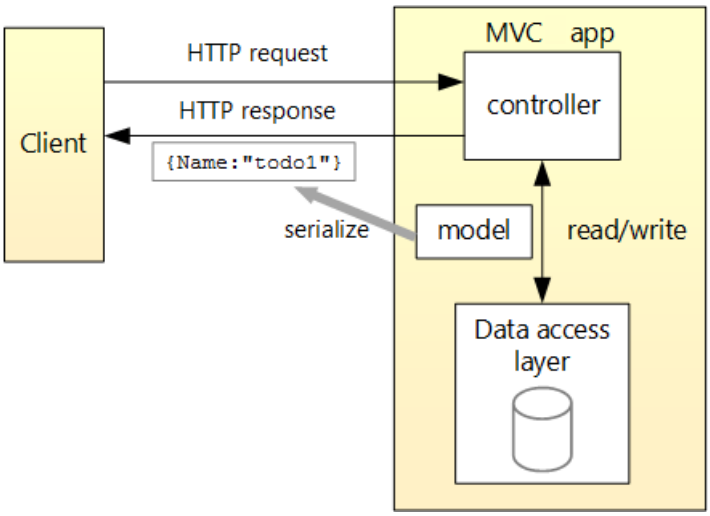
At the end, you have a web API that can manage "to-do" items stored in a relational database.

Overview 2.1

This tutorial creates the following API:

API	DESCRIPTION	REQUEST BODY	RESPONSE BODY
GET /api/TodoItems	Get all to-do items	None	Array of to-do items
GET /api/TodoItems/{id}	Get an item by ID	None	To-do item
POST /api/TodoItems	Add a new item	To-do item	To-do item
PUT /api/TodoItems/{id}	Update an existing item	To-do item	None
DELETE /api/TodoItems/{id}	Delete an item	None	None

The following diagram shows the design of the app.



Prerequisites 2.1

- Visual Studio
- Visual Studio Code

- Visual Studio for Mac

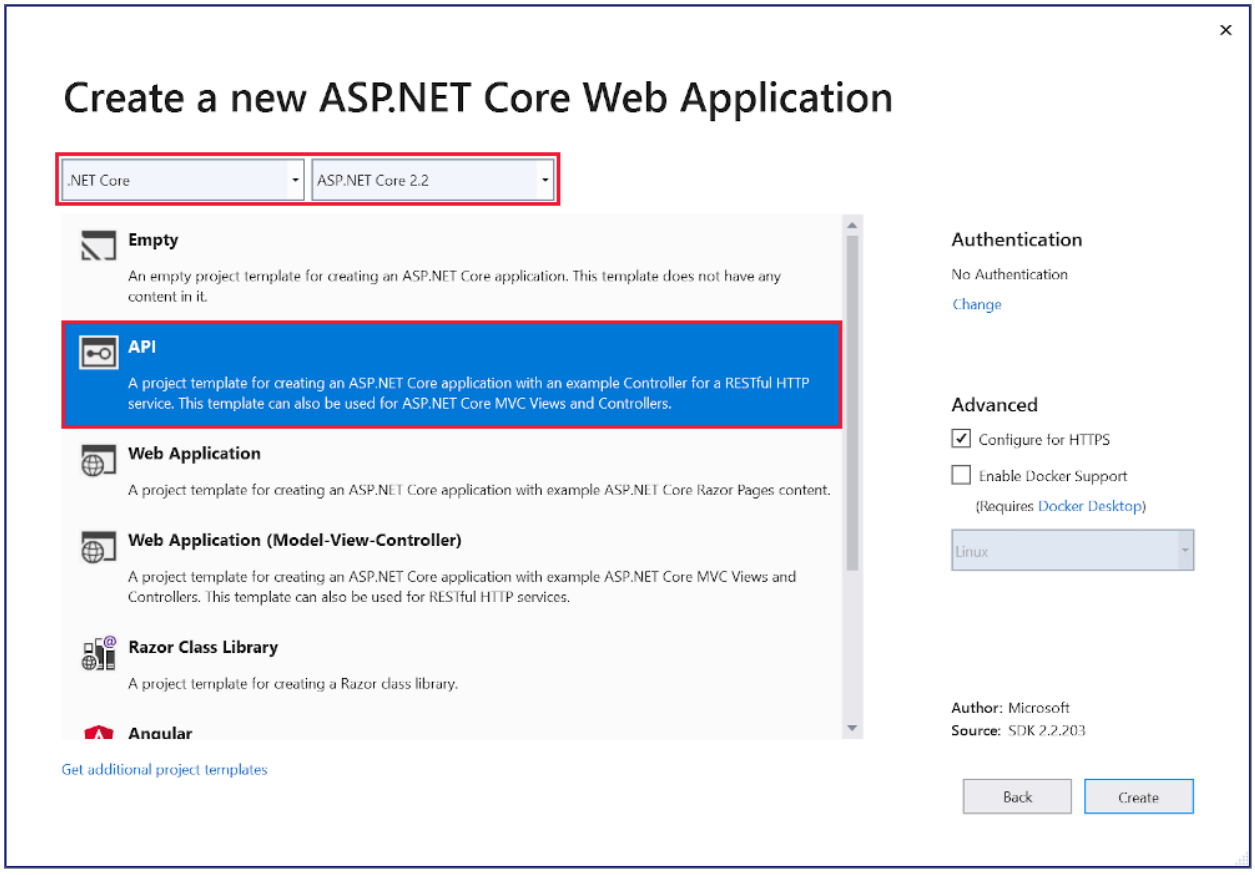
- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core SDK 2.2 or later

> **WARNING**
> If you use Visual Studio 2017, see dotnet/sdk issue #3124 for information about .NET Core SDK versions that don't work with Visual Studio.

Create a web project 2.1

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- From the **File** menu, select **New** > **Project**.
- Select the **ASP.NET Core Web Application** template and click **Next**.
- Name the project *TodoApi* and click **Create**.
- In the **Create a new ASP.NET Core Web Application** dialog, confirm that **.NET Core** and **ASP.NET Core 2.2** are selected. Select the **API** template and click **Create**. **Don't** select **Enable Docker Support**.



Test the API 2.1

The project template creates a `values` API. Call the `Get` method from a browser to test the app.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Press Ctrl+F5 to run the app. Visual Studio launches a browser and navigates to

`https://localhost:<port>/api/values`, where `<port>` is a randomly chosen port number.

If you get a dialog box that asks if you should trust the IIS Express certificate, select **Yes**. In the **Security Warning** dialog that appears next, select **Yes**.

The following JSON is returned:

```
["value1","value2"]
```

Add a model class 2.1

A *model* is a set of classes that represent the data that the app manages. The model for this app is a single `TodoItem` class.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- In **Solution Explorer**, right-click the project. Select **Add** > **New Folder**. Name the folder *Models*.
- Right-click the *Models* folder and select **Add** > **Class**. Name the class *TodoItem* and select **Add**.
- Replace the template code with the following code:

```
namespace TodoApi.Models
{
    public class TodoItem
    {
        public long Id { get; set; }
        public string Name { get; set; }
        public bool IsComplete { get; set; }
    }
}
```

The `Id` property functions as the unique key in a relational database.

Model classes can go anywhere in the project, but the *Models* folder is used by convention.

Add a database context 2.1

The *database context* is the main class that coordinates Entity Framework functionality for a data model. This class is created by deriving from the `Microsoft.EntityFrameworkCore.DbContext` class.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Right-click the *Models* folder and select **Add** > **Class**. Name the class *TodoContext* and click **Add**.
- Replace the template code with the following code:

```
using Microsoft.EntityFrameworkCore;

namespace TodoApi.Models
{
    public class TodoContext : DbContext
    {
        public TodoContext(DbContextOptions<TodoContext> options)
            : base(options)
        {
        }

        public DbSet<TodoItem> TodoItems { get; set; }
    }
}
```

Register the database context 2.1

In ASP.NET Core, services such as the DB context must be registered with the dependency injection (DI) container. The container provides the service to controllers.

Update *Startup.cs* with the following highlighted code:

```
// Unused usings removed
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using TodoApi.Models;

namespace TodoApi
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        // This method gets called by the runtime. Use this method to add services to the
        //container.
        public void ConfigureServices(IServiceCollection services)
        {
            services.AddDbContext<TodoContext>(opt =>
                opt.UseInMemoryDatabase("TodoList"));
            services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
        }

        // This method gets called by the runtime. Use this method to configure the HTTP
        //request pipeline.
        public void Configure(IApplicationBuilder app, IHostingEnvironment env)
        {
            if (env.IsDevelopment())
            {
                app.UseDeveloperExceptionPage();
            }
            else
            {
                // The default HSTS value is 30 days. You may want to change this for
                // production scenarios, see https://aka.ms/aspnetcore-hsts.
                app.UseHsts();
            }

            app.UseHttpsRedirection();
            app.UseMvc();
        }
    }
}
```

The preceding code:

- Removes unused `using` declarations.
- Adds the database context to the DI container.
- Specifies that the database context will use an in-memory database.

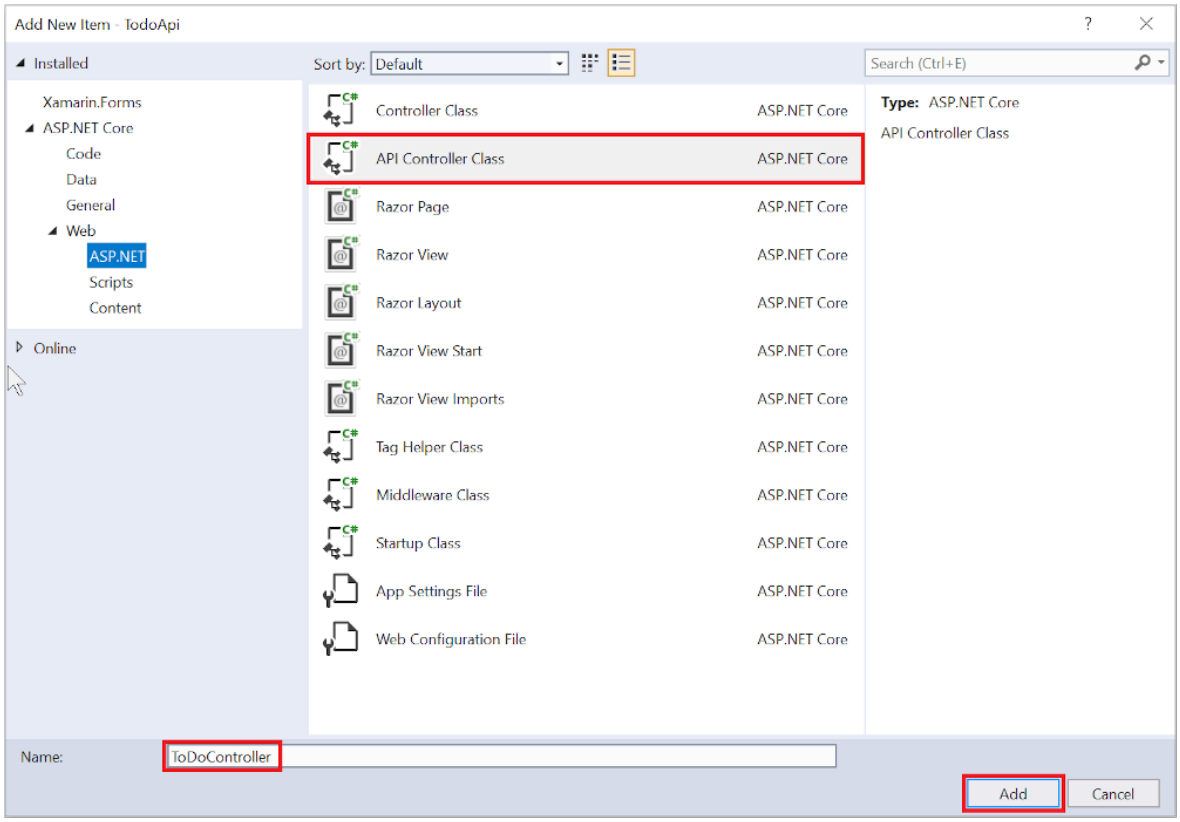
Add a controller 2.1

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Right-click the *Controllers* folder.

- Select **Add** > **New Item**.

- In the **Add New Item** dialog, select the **API Controller Class** template.
- Name the class *TodoController*, and select **Add**.



- Replace the template code with the following code:

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using TodoApi.Models;

namespace TodoApi.Controllers
{
    [Route("api/[controller]")]
    [ApiController]
    public class TodoController : ControllerBase
    {
        private readonly TodoContext _context;

        public TodoController(TodoContext context)
        {
            _context = context;

            if (_context.TodoItems.Count() == 0)
            {
                // Create a new TodoItem if collection is empty,
                // which means you can't delete all TodoItems.
                _context.TodoItems.Add(new TodoItem { Name = "Item1" });
                _context.SaveChanges();
            }
        }
    }
}
```

The preceding code:

- Defines an API controller class without methods.
- Marks the class with the `[ApiController]` attribute. This attribute indicates that the controller responds to web API requests. For information about specific behaviors that the attribute enables, see Create web APIs with ASP.NET Core.
- Uses DI to inject the database context (`TodoContext`) into the controller. The database context is used in each of the CRUD methods in the controller.
- Adds an item named `Item1` to the database if the database is empty. This code is in the constructor, so it runs every time there's a new HTTP request. If you delete all items, the constructor creates `Item1` again the next time an API method is called. So it may look like the deletion didn't work when it actually did work.

Add Get methods 2.1

To provide an API that retrieves to-do items, add the following methods to the `TodoController` class:

```
// GET: api/Todo
[HttpGet]
public async Task<ActionResult<IEnumerable<TodoItem>>> GetTodoItems()
{
    return await _context.TodoItems.ToListAsync();
}

// GET: api/Todo/5
[HttpGet("{id}")]
public async Task<ActionResult<TodoItem>> GetTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    return todoItem;
}
```

These methods implement two GET endpoints:

- `GET /api/todo`
- `GET /api/todo/{id}`

Stop the app if it's still running. Then run it again to include the latest changes.

Test the app by calling the two endpoints from a browser. For example:

- `https://localhost:<port>/api/todo`
- `https://localhost:<port>/api/todo/1`

The following HTTP response is produced by the call to `GetTodoItems` :

```
[
  {
    "id": 1,
    "name": "Item1",
    "isComplete": false
  }
]
```

Routing and URL paths 2.1

The `[HttpGet]` attribute denotes a method that responds to an HTTP GET request. The URL path for each method is constructed as follows:

- Start with the template string in the controller's `Route` attribute:

```
namespace TodoApi.Controllers
{
    [Route("api/[controller]")]
    [ApiController]
    public class TodoController : ControllerBase
    {
        private readonly TodoContext _context;
```

- Replace `[controller]` with the name of the controller, which by convention is the controller class name minus the "Controller" suffix. For this sample, the controller class name is **Todo**Controller, so the controller name is "todo". ASP.NET Core routing is case insensitive.
- If the `[HttpGet]` attribute has a route template (for example, `[HttpGet("products")]`), append that to the path. This sample doesn't use a template. For more information, see Attribute routing with Http[Verb] attributes.

In the following `GetTodoItem` method, `"{id}"` is a placeholder variable for the unique identifier of the to-do item. When `GetTodoItem` is invoked, the value of `"{id}"` in the URL is provided to the method in its `id` parameter.

```
// GET: api/Todo/5
[HttpGet("{id}")]
public async Task<ActionResult<TodoItem>> GetTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    return todoItem;
}
```

Return values 2.1

The return type of the `GetTodoItems` and `GetTodoItem` methods is ActionResult<T> type. ASP.NET Core automatically serializes the object to JSON and writes the JSON into the body of the response message. The response code for this return type is 200, assuming there are no unhandled exceptions. Unhandled exceptions are translated into 5xx errors.

`ActionResult` return types can represent a wide range of HTTP status codes. For example, `GetTodoItem` can return two different status values:

- If no item matches the requested ID, the method returns a 404 NotFound error code.
- Otherwise, the method returns 200 with a JSON response body. Returning `item` results in an HTTP 200 response.

Test the GetTodoItems method 2.1

This tutorial uses Postman to test the web API.

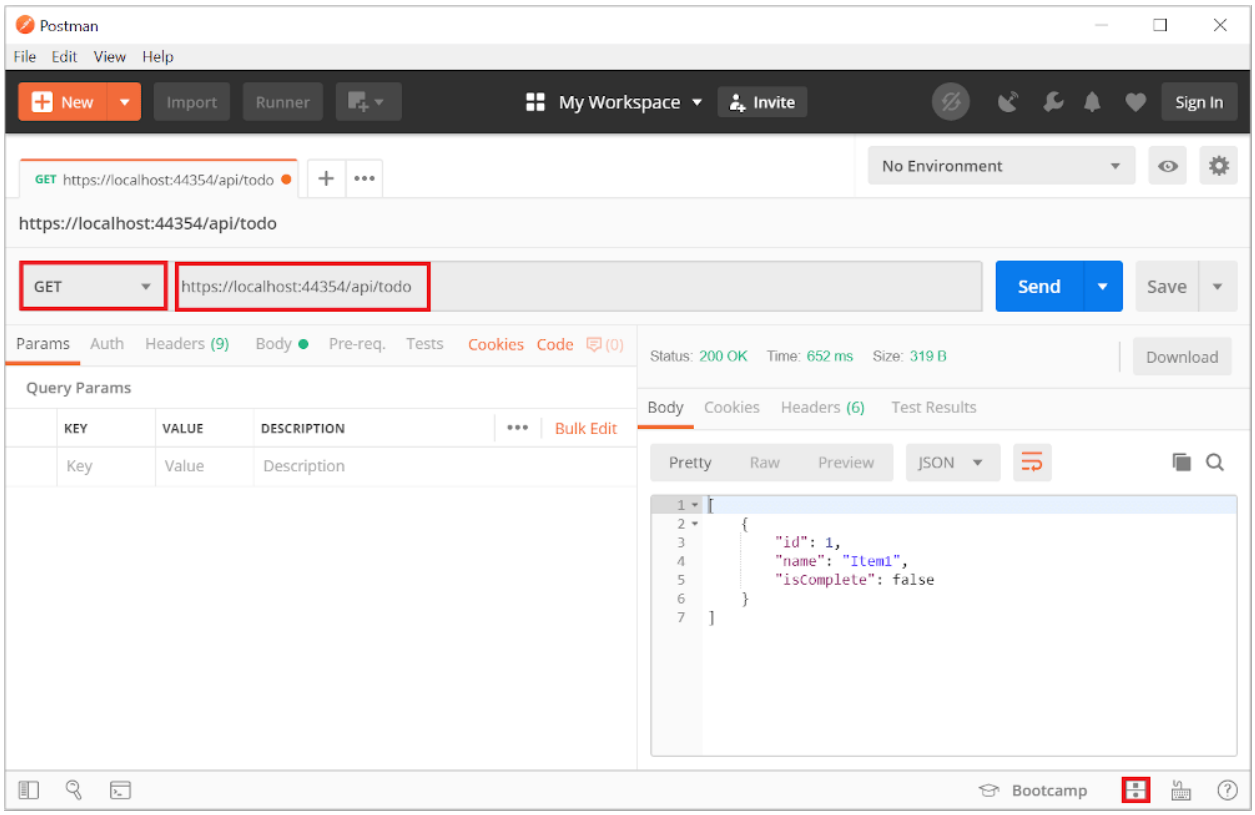
- Install Postman.
- Start the web app.
- Start Postman.
- Disable **SSL certificate verification**.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- From **File** > **Settings** (**General** tab), disable **SSL certificate verification**.

> **WARNING**
> Re-enable SSL certificate verification after testing the controller.

- Create a new request.
  - Set the HTTP method to **GET**.
  - Set the request URI to `https://localhost:<port>/api/todo`. For example, `https://localhost:5001/api/todo`.
- Set **Two pane view** in Postman.
- Select **Send**.



Add a Create method 2.1

Add the following `PostTodoItem` method inside of *Controllers/TodoController.cs*:

```
// POST: api/Todo
[HttpPost]
public async Task<ActionResult<TodoItem>> PostTodoItem(TodoItem item)
{
    _context.TodoItems.Add(item);
    await _context.SaveChangesAsync();

    return CreatedAtAction(nameof(GetTodoItem), new { id = item.Id }, item);
}
```

The preceding code is an HTTP POST method, as indicated by the `[HttpPost]` attribute. The method gets the value of the to-do item from the body of the HTTP request.

The `CreatedAtAction` method:

- Returns an HTTP 201 status code, if successful. HTTP 201 is the standard response for an HTTP POST method that creates a new resource on the server.
- Adds a `Location` header to the response. The `Location` header specifies the URI of the newly created to-do item. For more information, see 10.2.2 201 Created.
- References the `GetTodoItem` action to create the `Location` header's URI. The C# `nameof` keyword is used to avoid hard-coding the action name in the `CreatedAtAction` call.

```
// GET: api/Todo/5
[HttpGet("{id}")]
public async Task<ActionResult<TodoItem>> GetTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

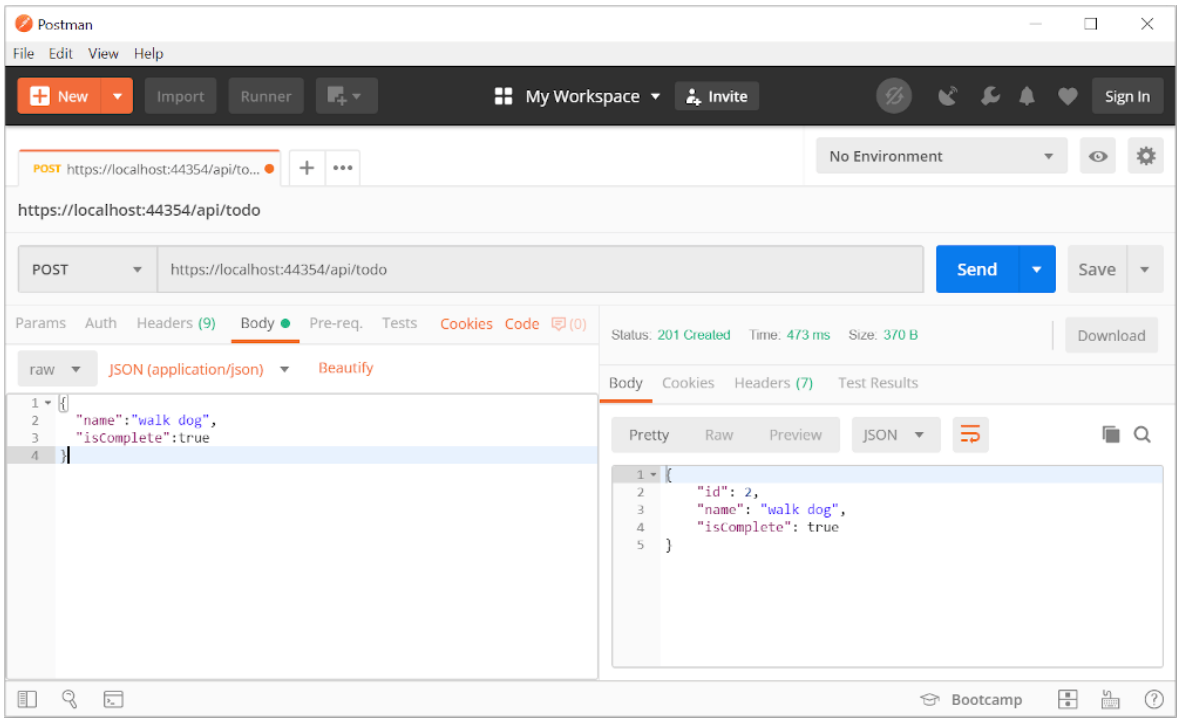
    return todoItem;
}
```

Test the PostTodoItem method 2.1

- Build the project.
- In Postman, set the HTTP method to `POST`.
- Set the URI to `https://localhost:<port>/api/TodoItem`. For example, `https://localhost:5001/api/TodoItem`.
- Select the **Body** tab.
- Select the **raw** radio button.
- Set the type to **JSON (application/json)**.
- In the request body enter JSON for a to-do item:

```
{
  "name":"walk dog",
  "isComplete":true
}
```

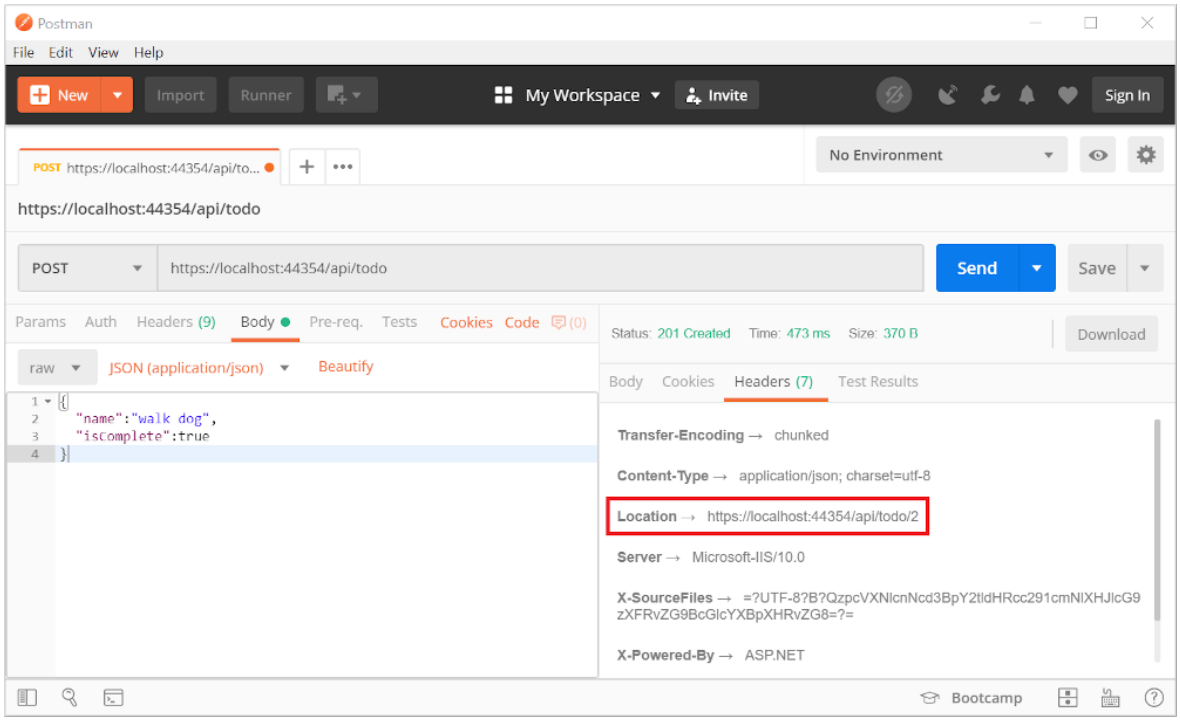
- Select **Send**.



If you get a 405 Method Not Allowed error, it's probably the result of not compiling the project after adding the `PostTodoItem` method.

Test the location header URI 2.1

- Select the **Headers** tab in the **Response** pane.
- Copy the **Location** header value:



- Set the method to GET. * Set the URI to `https://localhost:<port>/api/TodoItems/2`. For example, `https://localhost:5001/api/TodoItems/2`.
- Select **Send**.

Add a PutTodoItem method 2.1

Add the following `PutTodoItem` method:

```
// PUT: api/Todo/5
[HttpPut("{id}")]
public async Task<IActionResult> PutTodoItem(long id, TodoItem item)
{
    if (id != item.Id)
    {
        return BadRequest();
    }

    _context.Entry(item).State = EntityState.Modified;
    await _context.SaveChangesAsync();

    return NoContent();
}
```

`PutTodoItem` is similar to `PostTodoItem`, except it uses HTTP PUT. The response is 204 (No Content). According to the HTTP specification, a PUT request requires the client to send the entire updated entity, not just the changes. To support partial updates, use HTTP PATCH.

If you get an error calling `PutTodoItem`, call `GET` to ensure there's an item in the database.

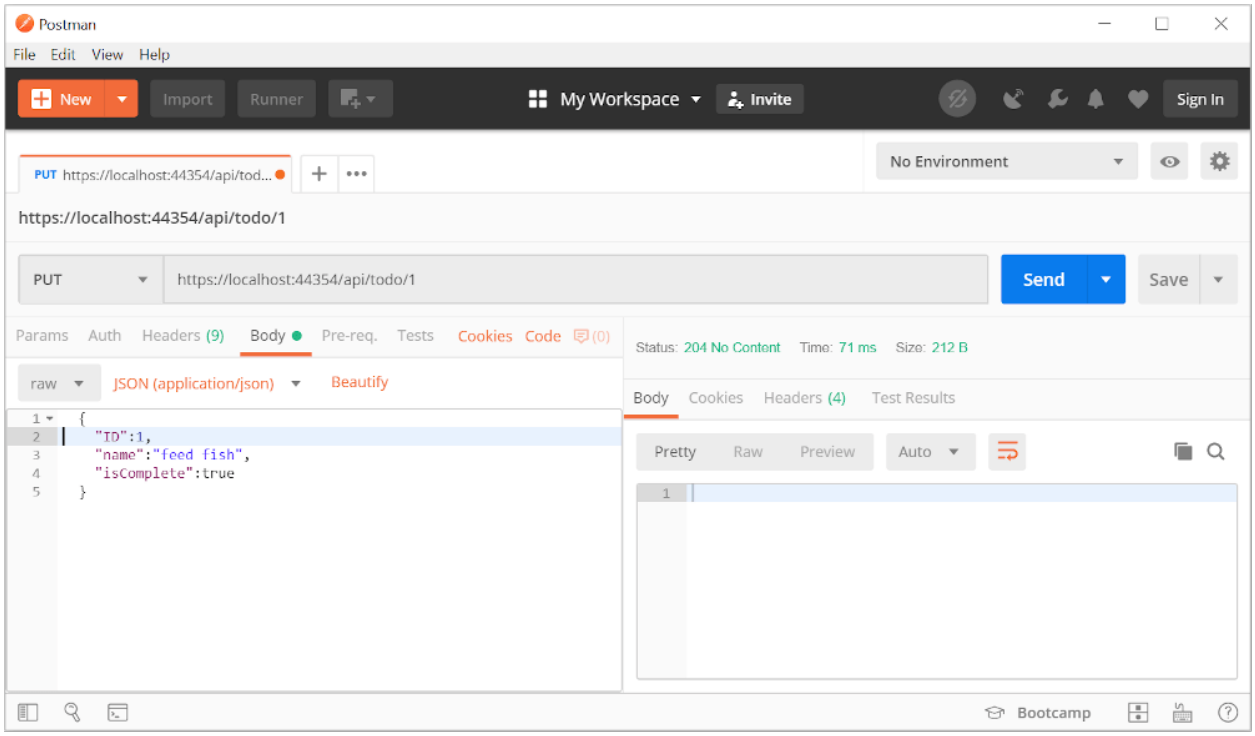
Test the PutTodoItem method 2.1

This sample uses an in-memory database that must be initialized each time the app is started. There must be an item in the database before you make a PUT call. Call GET to ensure there's an item in the database before making a PUT call.

Update the to-do item that has Id = 1 and set its name to "feed fish":

```
{
  "Id":1,
  "name":"feed fish",
  "isComplete":true
}
```

The following image shows the Postman update:



Add a DeleteTodoItem method 2.1

Add the following `DeleteTodoItem` method:

```
// DELETE: api/Todo/5
[HttpDelete("{id}")]
public async Task<IActionResult> DeleteTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    _context.TodoItems.Remove(todoItem);
    await _context.SaveChangesAsync();

    return NoContent();
}
```

The `DeleteTodoItem` response is 204 (No Content).

Test the DeleteTodoItem method 2.1

Use Postman to delete a to-do item:

- Set the method to `DELETE`.
- Set the URI of the object to delete (for example, `https://localhost:5001/api/todo/1`).
- Select **Send**.

The sample app allows you to delete all the items. However, when the last item is deleted, a new one is created by the model class constructor the next time the API is called.

Call the web API with JavaScript 2.1

In this section, an HTML page is added that uses JavaScript to call the web API. jQuery initiates the request. JavaScript updates the page with the details from the web API's response.

Configure the app to serve static files and enable default file mapping by updating *Startup.cs* with the following highlighted code:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        // The default HSTS value is 30 days. You may want to change this for
        // production scenarios, see https://aka.ms/aspnetcore-hsts.
        app.UseHsts();
    }

    app.UseDefaultFiles();
    app.UseStaticFiles();
    app.UseHttpsRedirection();
    app.UseMvc();
}
```

Create a *wwwroot* folder in the project directory.

Add an HTML file named *index.html* to the *wwwroot* directory. Replace its contents with the following markup:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="UTF-8">
    <title>To-do CRUD</title>
    <style>
        input[type='submit'], button, [aria-label] {
            cursor: pointer;
        }

        #spoiler {
            display: none;
        }

        table {
            font-family: Arial, sans-serif;
            border: 1px solid;
            border-collapse: collapse;
        }

        th {
            background-color: #0066CC;
            color: white;
        }

        td {
            border: 1px solid;
            padding: 5px;
        }
    </style>
</head>
<body>
    <h1>To-do CRUD</h1>
    <h3>Add</h3>
    <form action="javascript:void(0);" method="POST" onsubmit="addItem()">
        <input type="text" id="add-name" placeholder="New to-do">
        <input type="submit" value="Add">
    </form>

    <div id="spoiler">
        <h3>Edit</h3>
        <form class="my-form">
            <input type="hidden" id="edit-id">
            <input type="checkbox" id="edit-isComplete">
            <input type="text" id="edit-name">
            <input type="submit" value="Save">
            <a onclick="closeInput()" aria-label="Close">&#10006;</a>
        </form>
    </div>

    <p id="counter"></p>

    <table>
        <tr>
            <th>Is Complete</th>
            <th>Name</th>
            <th></th>
            <th></th>
        </tr>
        <tbody id="todos"></tbody>
    </table>

    <script src="https://code.jquery.com/jquery-3.3.1.min.js"
            integrity="sha256-FgpCb/KJQlLNfOu91ta32o/NMZxltwRo8QtmkMRdAu8="
```

```
            integrity="sha256-[illegible]"
            crossorigin="anonymous"></script>
    <script src="site.js"></script>
</body>
</html>
```

Add a JavaScript file named *site.js* to the *wwwroot* directory. Replace its contents with the following code:

```
const uri = "api/todo";
let todos = null;
function getCount(data) {
  const el = $("#counter");
  let name = "to-do";
  if (data) {
    if (data > 1) {
      name = "to-dos";
    }
    el.text(data + " " + name);
  } else {
    el.text("No " + name);
  }
}

$(document).ready(function() {
  getData();
});

function getData() {
  $.ajax({
    type: "GET",
    url: uri,
    cache: false,
    success: function(data) {
      const tBody = $("#todos");

      $(tBody).empty();

      getCount(data.length);

      $.each(data, function(key, item) {
        const tr = $("<tr></tr>")
          .append(
            $("<td></td>").append(
              $("<input/>", {
                type: "checkbox",
                disabled: true,
                checked: item.isComplete
              })
            )
          )
          .append($("<td></td>").text(item.name))
          .append(
            $("<td></td>").append(
              $("<button>Edit</button>").on("click", function() {
                editItem(item.id);
              })
            )
          )
          .append(
            $("<td></td>").append(
              $("<button>Delete</button>").on("click", function() {
                deleteItem(item.id);
              })
            )
          );

        tr.appendTo(tBody);
      });
```

```
      todos = data;
    }
  });
}

function addItem() {
  const item = {
    name: $("#add-name").val(),
    isComplete: false
  };

  $.ajax({
    type: "POST",
    accepts: "application/json",
    url: uri,
    contentType: "application/json",
    data: JSON.stringify(item),
    error: function(jqXHR, textStatus, errorThrown) {
      alert("Something went wrong!");
    },
    success: function(result) {
      getData();
      $("#add-name").val("");
    }
  });
}

function deleteItem(id) {
  $.ajax({
    url: uri + "/" + id,
    type: "DELETE",
    success: function(result) {
      getData();
    }
  });
}

function editItem(id) {
  $.each(todos, function(key, item) {
    if (item.id === id) {
      $("#edit-name").val(item.name);
      $("#edit-id").val(item.id);
      $("#edit-isComplete")[0].checked = item.isComplete;
    }
  });
  $("#spoiler").css({ display: "block" });
}

$(".my-form").on("submit", function() {
  const item = {
    name: $("#edit-name").val(),
    isComplete: $("#edit-isComplete").is(":checked"),
    id: $("#edit-id").val()
  };

  $.ajax({
    url: uri + "/" + $("#edit-id").val(),
    type: "PUT",
    accepts: "application/json",
    contentType: "application/json",
    data: JSON.stringify(item),
    success: function(result) {
      getData();
    }
  });

  closeInput();
  return false;
```

```
  return false;
});

function closeInput() {
  $("#spoiler").css({ display: "none" });
}
```

A change to the ASP.NET Core project's launch settings may be required to test the HTML page locally:

- Open *Properties\launchSettings.json*.
- Remove the `launchUrl` property to force the app to open at *index.html*—the project's default file.

This sample calls all of the CRUD methods of the web API. Following are explanations of the calls to the API.

Get a list of to-do items 2.1

jQuery sends an HTTP GET request to the web API, which returns JSON representing an array of to-do items. The `success` callback function is invoked if the request succeeds. In the callback, the DOM is updated with the to-do information.

```
$(document).ready(function() {
  getData();
});

function getData() {
  $.ajax({
    type: "GET",
    url: uri,
    cache: false,
    success: function(data) {
      const tBody = $("#todos");

      $(tBody).empty();

      getCount(data.length);

      $.each(data, function(key, item) {
        const tr = $("<tr></tr>")
          .append(
            $("<td></td>").append(
              $("<input/>", {
                type: "checkbox",
                disabled: true,
                checked: item.isComplete
              })
            )
          )
          .append($("<td></td>").text(item.name))
          .append(
            $("<td></td>").append(
              $("<button>Edit</button>").on("click", function() {
                editItem(item.id);
              })
            )
          )
          .append(
            $("<td></td>").append(
              $("<button>Delete</button>").on("click", function() {
                deleteItem(item.id);
              })
            )
          );

        tr.appendTo(tBody);
      });

      todos = data;
    }
  });
}
```

Add a to-do item 2.1

jQuery sends an HTTP POST request with the to-do item in the request body. The `accepts` and `contentType` options are set to `application/json` to specify the media type being received and sent. The to-do item is converted to JSON by using JSON.stringify. When the API returns a successful status code, the `getData` function is invoked to update the HTML table.

```
function addItem() {
  const item = {
    name: $("#add-name").val(),
    isComplete: false
  };

  $.ajax({
    type: "POST",
    accepts: "application/json",
    url: uri,
    contentType: "application/json",
    data: JSON.stringify(item),
    error: function(jqXHR, textStatus, errorThrown) {
      alert("Something went wrong!");
    },
    success: function(result) {
      getData();
      $("#add-name").val("");
    }
  });
}
```

Update a to-do item 2.1

Updating a to-do item is similar to adding one. The `url` changes to add the unique identifier of the item, and the `type` is `PUT`.

```
$.ajax({
  url: uri + "/" + $("#edit-id").val(),
  type: "PUT",
  accepts: "application/json",
  contentType: "application/json",
  data: JSON.stringify(item),
  success: function(result) {
    getData();
  }
});
```

Delete a to-do item 2.1

Deleting a to-do item is accomplished by setting the `type` on the AJAX call to `DELETE` and specifying the item's unique identifier in the URL.

```
$.ajax({
  url: uri + "/" + id,
  type: "DELETE",
  success: function(result) {
    getData();
  }
});
```

Add authentication support to a web API 2.1

ASP.NET Core Identity adds user interface (UI) login functionality to ASP.NET Core web apps. To secure web APIs and SPAs, use one of the following:

- Azure Active Directory
- Azure Active Directory B2C (Azure AD B2C)
- IdentityServer4

IdentityServer4 is an OpenID Connect and OAuth 2.0 framework for ASP.NET Core. IdentityServer4 enables the following security features:

- Authentication as a Service (AaaS)
- Single sign-on/off (SSO) over multiple application types
- Access control for APIs
- Federation Gateway

For more information, see Welcome to IdentityServer4.

Additional resources 2.1

View or download sample code for this tutorial. See how to download.

Create a web API with ASP.NET Core and MongoDB

9/22/2020 • 21 minutes to read • Edit Online

By Pratik Khandelwal and Scott Addie

This tutorial creates a web API that performs Create, Read, Update, and Delete (CRUD) operations on a MongoDB NoSQL database.

In this tutorial, you learn how to:

- Configure MongoDB
- Create a MongoDB database
- Define a MongoDB collection and schema
- Perform MongoDB CRUD operations from a web API
- Customize JSON serialization

View or download sample code (how to download)

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- .NET Core SDK 3.0 or later
- Visual Studio 2019 with the **ASP.NET and web development** workload
- MongoDB

Configure MongoDB

If using Windows, MongoDB is installed at *C:\Program Files\MongoDB* by default. Add *C:\Program Files\MongoDB\Server\<version_number>\bin* to the `Path` environment variable. This change enables MongoDB access from anywhere on your development machine.

Use the mongo Shell in the following steps to create a database, make collections, and store documents. For more information on mongo Shell commands, see Working with the mongo Shell.

1. Choose a directory on your development machine for storing the data. For example, *C:\BooksData* on Windows. Create the directory if it doesn't exist. The mongo Shell doesn't create new directories.

2. Open a command shell. Run the following command to connect to MongoDB on default port 27017. Remember to replace `<data_directory_path>` with the directory you chose in the previous step.

   ```
   mongod --dbpath <data_directory_path>
   ```

3. Open another command shell instance. Connect to the default test database by running the following command:

   ```
   mongo
   ```

4. Run the following in a command shell:

```
use BookstoreDb
```

   If it doesn't already exist, a database named *BookstoreDb* is created. If the database does exist, its connection is opened for transactions.

5. Create a `Books` collection using following command:

```
db.createCollection('Books')
```

   The following result is displayed:

```
{ "ok" : 1 }
```

6. Define a schema for the `Books` collection and insert two documents using the following command:

```
db.Books.insertMany([{'Name':'Design Patterns','Price':54.93,'Category':'Computers','Author':'Ralph
Johnson'}, {'Name':'Clean Code','Price':43.15,'Category':'Computers','Author':'Robert C. Martin'}])
```

   The following result is displayed:

```
{
  "acknowledged" : true,
  "insertedIds" : [
    ObjectId("5bfd996f7b8e48dc15ff215d"),
    ObjectId("5bfd996f7b8e48dc15ff215e")
  ]
}
```

   NOTE

   The ID's shown in this article will not match the IDs when you run this sample.

7. View the documents in the database using the following command:

```
db.Books.find({}).pretty()
```

   The following result is displayed:

```
{
  "_id" : ObjectId("5bfd996f7b8e48dc15ff215d"),
  "Name" : "Design Patterns",
  "Price" : 54.93,
  "Category" : "Computers",
  "Author" : "Ralph Johnson"
}
{
  "_id" : ObjectId("5bfd996f7b8e48dc15ff215e"),
  "Name" : "Clean Code",
  "Price" : 43.15,
  "Category" : "Computers",
  "Author" : "Robert C. Martin"
}
```

The schema adds an autogenerated `_id` property of type `ObjectId` for each document.

The database is ready. You can start creating the ASP.NET Core web API.

Create the ASP.NET Core web API project

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

1. Go to **File** > **New** > **Project**.
2. Select the **ASP.NET Core Web Application** project type, and select **Next**.
3. Name the project *BooksApi*, and select **Create**.
4. Select the **.NET Core** target framework and **ASP.NET Core 3.0**. Select the **API** project template, and select **Create**.
5. Visit the NuGet Gallery: MongoDB.Driver to determine the latest stable version of the .NET driver for MongoDB. In the **Package Manager Console** window, navigate to the project root. Run the following command to install the .NET driver for MongoDB:

```
Install-Package MongoDB.Driver -Version {VERSION}
```

Add an entity model

1. Add a *Models* directory to the project root.
2. Add a `Book` class to the *Models* directory with the following code:

```
using MongoDB.Bson;
using MongoDB.Bson.Serialization.Attributes;

namespace BooksApi.Models
{
    public class Book
    {
        [BsonId]
        [BsonRepresentation(BsonType.ObjectId)]
        public string Id { get; set; }

        [BsonElement("Name")]
        public string BookName { get; set; }

        public decimal Price { get; set; }

        public string Category { get; set; }

        public string Author { get; set; }
    }
}
```

In the preceding class, the `Id` property:

- Is required for mapping the Common Language Runtime (CLR) object to the MongoDB collection.
- Is annotated with `[BsonId]` to designate this property as the document's primary key.
- Is annotated with `[BsonRepresentation(BsonType.ObjectId)]` to allow passing the parameter as type `string` instead of an ObjectId structure. Mongo handles the conversion from `string` to `ObjectId`.

The `BookName` property is annotated with the `[BsonElement]` attribute. The attribute's value of `Name` represents the property name in the MongoDB collection.

Add a configuration model

1. Add the following database configuration values to *appsettings.json*:

```
{
  "BookstoreDatabaseSettings": {
    "BooksCollectionName": "Books",
    "ConnectionString": "mongodb://localhost:27017",
    "DatabaseName": "BookstoreDb"
  },
  "Logging": {
    "IncludeScopes": false,
    "Debug": {
      "LogLevel": {
        "Default": "Warning"
      }
    },
    "Console": {
      "LogLevel": {
        "Default": "Warning"
      }
    }
  }
}
```

2. Add a *BookstoreDatabaseSettings.cs* file to the *Models* directory with the following code:

```
namespace BooksApi.Models
{
    public class BookstoreDatabaseSettings : IBookstoreDatabaseSettings
    {
        public string BooksCollectionName { get; set; }
        public string ConnectionString { get; set; }
        public string DatabaseName { get; set; }
    }

    public interface IBookstoreDatabaseSettings
    {
        string BooksCollectionName { get; set; }
        string ConnectionString { get; set; }
        string DatabaseName { get; set; }
    }
}
```

The preceding `BookstoreDatabaseSettings` class is used to store the *appsettings.json* file's `BookstoreDatabaseSettings` property values. The JSON and C# property names are named identically to ease the mapping process.

3. Add the following highlighted code to `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    // requires using Microsoft.Extensions.Options
    services.Configure<BookstoreDatabaseSettings>(
        Configuration.GetSection(nameof(BookstoreDatabaseSettings)));

    services.AddSingleton<IBookstoreDatabaseSettings>(sp =>
        sp.GetRequiredService<IOptions<BookstoreDatabaseSettings>>().Value);

    services.AddControllers();
}
```

In the preceding code:

- The configuration instance to which the *appsettings.json* file's `BookstoreDatabaseSettings` section binds is registered in the Dependency Injection (DI) container. For example, a `BookstoreDatabaseSettings` object's `ConnectionString` property is populated with the `BookstoreDatabaseSettings:ConnectionString` property in *appsettings.json*.
- The `IBookstoreDatabaseSettings` interface is registered in DI with a singleton service lifetime. When injected, the interface instance resolves to a `BookstoreDatabaseSettings` object.

4. Add the following code to the top of *Startup.cs* to resolve the `BookstoreDatabaseSettings` and `IBookstoreDatabaseSettings` references:

```
using BooksApi.Models;
```

Add a CRUD operations service

1. Add a *Services* directory to the project root.
2. Add a `BookService` class to the *Services* directory with the following code:

```
using BooksApi.Models;
using MongoDB.Driver;
using System.Collections.Generic;
using System.Linq;

namespace BooksApi.Services
{
    public class BookService
    {
        private readonly IMongoCollection<Book> _books;

        public BookService(IBookstoreDatabaseSettings settings)
        {
            var client = new MongoClient(settings.ConnectionString);
            var database = client.GetDatabase(settings.DatabaseName);

            _books = database.GetCollection<Book>(settings.BooksCollectionName);
        }

        public List<Book> Get() =>
            _books.Find(book => true).ToList();

        public Book Get(string id) =>
            _books.Find<Book>(book => book.Id == id).FirstOrDefault();

        public Book Create(Book book)
        {
            _books.InsertOne(book);
            return book;
        }

        public void Update(string id, Book bookIn) =>
            _books.ReplaceOne(book => book.Id == id, bookIn);

        public void Remove(Book bookIn) =>
            _books.DeleteOne(book => book.Id == bookIn.Id);

        public void Remove(string id) =>
            _books.DeleteOne(book => book.Id == id);
    }
}
```

In the preceding code, an `IBookstoreDatabaseSettings` instance is retrieved from DI via constructor injection. This technique provides access to the *appsettings.json* configuration values that were added in the Add a configuration model section.

3. Add the following highlighted code to `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<BookstoreDatabaseSettings>(
        Configuration.GetSection(nameof(BookstoreDatabaseSettings)));

    services.AddSingleton<IBookstoreDatabaseSettings>(sp =>
        sp.GetRequiredService<IOptions<BookstoreDatabaseSettings>>().Value);

    services.AddSingleton<BookService>();

    services.AddControllers();
}
```

In the preceding code, the `BookService` class is registered with DI to support constructor injection in consuming classes. The singleton service lifetime is most appropriate because `BookService` takes a direct

dependency on `MongoClient`. Per the official Mongo Client reuse guidelines, `MongoClient` should be registered in DI with a singleton service lifetime.

4. Add the following code to the top of *Startup.cs* to resolve the `BookService` reference:

```
using BooksApi.Services;
```

The `BookService` class uses the following `MongoDB.Driver` members to perform CRUD operations against the database:

- MongoClient: Reads the server instance for performing database operations. The constructor of this class is provided the MongoDB connection string:

```
public BookService(IBookstoreDatabaseSettings settings)
{
    var client = new MongoClient(settings.ConnectionString);
    var database = client.GetDatabase(settings.DatabaseName);

    _books = database.GetCollection<Book>(settings.BooksCollectionName);
}
```

- IMongoDatabase: Represents the Mongo database for performing operations. This tutorial uses the generic GetCollection<TDocument>(collection) method on the interface to gain access to data in a specific collection. Perform CRUD operations against the collection after this method is called. In the `GetCollection<TDocument>(collection)` method call:
  - `collection` represents the collection name.
  - `TDocument` represents the CLR object type stored in the collection.

`GetCollection<TDocument>(collection)` returns a MongoCollection object representing the collection. In this tutorial, the following methods are invoked on the collection:

- DeleteOne: Deletes a single document matching the provided search criteria.
- Find<TDocument>: Returns all documents in the collection matching the provided search criteria.
- InsertOne: Inserts the provided object as a new document in the collection.
- ReplaceOne: Replaces the single document matching the provided search criteria with the provided object.

Add a controller

Add a `BooksController` class to the *Controllers* directory with the following code:

```
using BooksApi.Models;
using BooksApi.Services;
using Microsoft.AspNetCore.Mvc;
using System.Collections.Generic;

namespace BooksApi.Controllers
{
    [Route("api/[controller]")]
    [ApiController]
    public class BooksController : ControllerBase
    {
        private readonly BookService _bookService;

        public BooksController(BookService bookService)
        {
            _bookService = bookService;
        }
```

```
        [HttpGet]
        public ActionResult<List<Book>> Get() =>
            _bookService.Get();

        [HttpGet("{id:length(24)}", Name = "GetBook")]
        public ActionResult<Book> Get(string id)
        {
            var book = _bookService.Get(id);

            if (book == null)
            {
                return NotFound();
            }

            return book;
        }

        [HttpPost]
        public ActionResult<Book> Create(Book book)
        {
            _bookService.Create(book);

            return CreatedAtRoute("GetBook", new { id = book.Id.ToString() }, book);
        }

        [HttpPut("{id:length(24)}")]
        public IActionResult Update(string id, Book bookIn)
        {
            var book = _bookService.Get(id);

            if (book == null)
            {
                return NotFound();
            }

            _bookService.Update(id, bookIn);

            return NoContent();
        }

        [HttpDelete("{id:length(24)}")]
        public IActionResult Delete(string id)
        {
            var book = _bookService.Get(id);

            if (book == null)
            {
                return NotFound();
            }

            _bookService.Remove(book.Id);

            return NoContent();
        }
    }
}
```

The preceding web API controller:

- Uses the `BookService` class to perform CRUD operations.
- Contains action methods to support GET, POST, PUT, and DELETE HTTP requests.
- Calls CreatedAtRoute in the `Create` action method to return an HTTP 201 response. Status code 201 is the standard response for an HTTP POST method that creates a new resource on the server. `CreatedAtRoute` also adds a `Location` header to the response. The `Location` header specifies the URI of the newly created book.

Test the web API

1. Build and run the app.
2. Navigate to `http://localhost:<port>/api/books` to test the controller's parameterless `Get` action method. The following JSON response is displayed:

```
[
  {
    "id":"5bfd996f7b8e48dc15ff215d",
    "bookName":"Design Patterns",
    "price":54.93,
    "category":"Computers",
    "author":"Ralph Johnson"
  },
  {
    "id":"5bfd996f7b8e48dc15ff215e",
    "bookName":"Clean Code",
    "price":43.15,
    "category":"Computers",
    "author":"Robert C. Martin"
  }
]
```

3. Navigate to `http://localhost:<port>/api/books/{id here}` to test the controller's overloaded `Get` action method. The following JSON response is displayed:

```
{
  "id":"{ID}",
  "bookName":"Clean Code",
  "price":43.15,
  "category":"Computers",
  "author":"Robert C. Martin"
}
```

Configure JSON serialization options

There are two details to change about the JSON responses returned in the Test the web API section:

- The property names' default camel casing should be changed to match the Pascal casing of the CLR object's property names.
- The `bookName` property should be returned as `Name`.

To satisfy the preceding requirements, make the following changes:

1. JSON.NET has been removed from ASP.NET shared framework. Add a package reference to `Microsoft.AspNetCore.Mvc.NewtonsoftJson`.
2. In `Startup.ConfigureServices`, chain the following highlighted code on to the `AddControllers` method call:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<BookstoreDatabaseSettings>(
        Configuration.GetSection(nameof(BookstoreDatabaseSettings)));

    services.AddSingleton<IBookstoreDatabaseSettings>(sp =>
        sp.GetRequiredService<IOptions<BookstoreDatabaseSettings>>().Value);

    services.AddSingleton<BookService>();

    services.AddControllers()
        .AddNewtonsoftJson(options => options.UseMemberCasing());
}
```

With the preceding change, property names in the web API's serialized JSON response match their corresponding property names in the CLR object type. For example, the `Book` class's `Author` property serializes as `Author`.

3. In *Models/Book.cs*, annotate the `BookName` property with the following `[JsonProperty]` attribute:

```
[BsonElement("Name")]
[JsonProperty("Name")]
public string BookName { get; set; }
```

The `[JsonProperty]` attribute's value of `Name` represents the property name in the web API's serialized JSON response.

4. Add the following code to the top of *Models/Book.cs* to resolve the `[JsonProperty]` attribute reference:

```
using Newtonsoft.Json;
```

5. Repeat the steps defined in the Test the web API section. Notice the difference in JSON property names.

This tutorial creates a web API that performs Create, Read, Update, and Delete (CRUD) operations on a MongoDB NoSQL database.

In this tutorial, you learn how to:

- Configure MongoDB
- Create a MongoDB database
- Define a MongoDB collection and schema
- Perform MongoDB CRUD operations from a web API
- Customize JSON serialization

View or download sample code (how to download)

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- .NET Core SDK 2.2
- Visual Studio 2019 with the **ASP.NET and web development** workload
- MongoDB

Configure MongoDB

If using Windows, MongoDB is installed at *C:\Program Files\MongoDB* by default. Add *C:\Program Files\MongoDB\Server\<version_number>\bin* to the `Path` environment variable. This change enables MongoDB access from anywhere on your development machine.

Use the mongo Shell in the following steps to create a database, make collections, and store documents. For more information on mongo Shell commands, see Working with the mongo Shell.

1. Choose a directory on your development machine for storing the data. For example, *C:\BooksData* on Windows. Create the directory if it doesn't exist. The mongo Shell doesn't create new directories.

2. Open a command shell. Run the following command to connect to MongoDB on default port 27017. Remember to replace `<data_directory_path>` with the directory you chose in the previous step.

   ```
   mongod --dbpath <data_directory_path>
   ```

3. Open another command shell instance. Connect to the default test database by running the following command:

   ```
   mongo
   ```

4. Run the following in a command shell:

   ```
   use BookstoreDb
   ```

   If it doesn't already exist, a database named *BookstoreDb* is created. If the database does exist, its connection is opened for transactions.

5. Create a `Books` collection using following command:

   ```
   db.createCollection('Books')
   ```

   The following result is displayed:

   ```
   { "ok" : 1 }
   ```

6. Define a schema for the `Books` collection and insert two documents using the following command:

   ```
   db.Books.insertMany([{'Name':'Design Patterns','Price':54.93,'Category':'Computers','Author':'Ralph
   Johnson'}, {'Name':'Clean Code','Price':43.15,'Category':'Computers','Author':'Robert C. Martin'}])
   ```

   The following result is displayed:

   ```
   {
     "acknowledged" : true,
     "insertedIds" : [
       ObjectId("5bfd996f7b8e48dc15ff215d"),
       ObjectId("5bfd996f7b8e48dc15ff215e")
     ]
   }
   ```

> **NOTE**
> The ID's shown in this article will not match the IDs when you run this sample.

7. View the documents in the database using the following command:

```
db.Books.find({}).pretty()
```

   The following result is displayed:

```
{
  "_id" : ObjectId("5bfd996f7b8e48dc15ff215d"),
  "Name" : "Design Patterns",
  "Price" : 54.93,
  "Category" : "Computers",
  "Author" : "Ralph Johnson"
}
{
  "_id" : ObjectId("5bfd996f7b8e48dc15ff215e"),
  "Name" : "Clean Code",
  "Price" : 43.15,
  "Category" : "Computers",
  "Author" : "Robert C. Martin"
}
```

   The schema adds an autogenerated `_id` property of type `ObjectId` for each document.

The database is ready. You can start creating the ASP.NET Core web API.

Create the ASP.NET Core web API project

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

1. Go to **File** > **New** > **Project**.
2. Select the **ASP.NET Core Web Application** project type, and select **Next**.
3. Name the project *BooksApi*, and select **Create**.
4. Select the **.NET Core** target framework and **ASP.NET Core 2.2**. Select the **API** project template, and select **Create**.
5. Visit the NuGet Gallery: MongoDB.Driver to determine the latest stable version of the .NET driver for MongoDB. In the **Package Manager Console** window, navigate to the project root. Run the following command to install the .NET driver for MongoDB:

```
Install-Package MongoDB.Driver -Version {VERSION}
```

Add an entity model

1. Add a *Models* directory to the project root.
2. Add a `Book` class to the *Models* directory with the following code:

```
using MongoDB.Bson;
using MongoDB.Bson.Serialization.Attributes;

namespace BooksApi.Models
{
    public class Book
    {
        [BsonId]
        [BsonRepresentation(BsonType.ObjectId)]
        public string Id { get; set; }

        [BsonElement("Name")]
        public string BookName { get; set; }

        public decimal Price { get; set; }

        public string Category { get; set; }

        public string Author { get; set; }
    }
}
```

In the preceding class, the `Id` property:

- Is required for mapping the Common Language Runtime (CLR) object to the MongoDB collection.
- Is annotated with `[BsonId]` to designate this property as the document's primary key.
- Is annotated with `[BsonRepresentation(BsonType.ObjectId)]` to allow passing the parameter as type `string` instead of an ObjectId structure. Mongo handles the conversion from `string` to `ObjectId`.

The `BookName` property is annotated with the `[BsonElement]` attribute. The attribute's value of `Name` represents the property name in the MongoDB collection.

Add a configuration model

1. Add the following database configuration values to *appsettings.json*:

```
{
  "BookstoreDatabaseSettings": {
    "BooksCollectionName": "Books",
    "ConnectionString": "mongodb://localhost:27017",
    "DatabaseName": "BookstoreDb"
  },
  "Logging": {
    "IncludeScopes": false,
    "Debug": {
      "LogLevel": {
        "Default": "Warning"
      }
    },
    "Console": {
      "LogLevel": {
        "Default": "Warning"
      }
    }
  }
}
```

2. Add a *BookstoreDatabaseSettings.cs* file to the *Models* directory with the following code:

```
namespace BooksApi.Models
{
    public class BookstoreDatabaseSettings : IBookstoreDatabaseSettings
    {
        public string BooksCollectionName { get; set; }
        public string ConnectionString { get; set; }
        public string DatabaseName { get; set; }
    }

    public interface IBookstoreDatabaseSettings
    {
        string BooksCollectionName { get; set; }
        string ConnectionString { get; set; }
        string DatabaseName { get; set; }
    }
}
```

The preceding `BookstoreDatabaseSettings` class is used to store the *appsettings.json* file's `BookstoreDatabaseSettings` property values. The JSON and C# property names are named identically to ease the mapping process.

3. Add the following highlighted code to `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<BookstoreDatabaseSettings>(
        Configuration.GetSection(nameof(BookstoreDatabaseSettings)));

    services.AddSingleton<IBookstoreDatabaseSettings>(sp =>
        sp.GetRequiredService<IOptions<BookstoreDatabaseSettings>>().Value);

    services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

In the preceding code:

- The configuration instance to which the *appsettings.json* file's `BookstoreDatabaseSettings` section binds is registered in the Dependency Injection (DI) container. For example, a `BookstoreDatabaseSettings` object's `ConnectionString` property is populated with the `BookstoreDatabaseSettings:ConnectionString` property in *appsettings.json*.
- The `IBookstoreDatabaseSettings` interface is registered in DI with a singleton service lifetime. When injected, the interface instance resolves to a `BookstoreDatabaseSettings` object.

4. Add the following code to the top of *Startup.cs* to resolve the `BookstoreDatabaseSettings` and `IBookstoreDatabaseSettings` references:

```
using BooksApi.Models;
```

Add a CRUD operations service

1. Add a *Services* directory to the project root.
2. Add a `BookService` class to the *Services* directory with the following code:

```
using BooksApi.Models;
using MongoDB.Driver;
using System.Collections.Generic;
using System.Linq;

namespace BooksApi.Services
{
    public class BookService
    {
        private readonly IMongoCollection<Book> _books;

        public BookService(IBookstoreDatabaseSettings settings)
        {
            var client = new MongoClient(settings.ConnectionString);
            var database = client.GetDatabase(settings.DatabaseName);

            _books = database.GetCollection<Book>(settings.BooksCollectionName);
        }

        public List<Book> Get() =>
            _books.Find(book => true).ToList();

        public Book Get(string id) =>
            _books.Find<Book>(book => book.Id == id).FirstOrDefault();

        public Book Create(Book book)
        {
            _books.InsertOne(book);
            return book;
        }

        public void Update(string id, Book bookIn) =>
            _books.ReplaceOne(book => book.Id == id, bookIn);

        public void Remove(Book bookIn) =>
            _books.DeleteOne(book => book.Id == bookIn.Id);

        public void Remove(string id) =>
            _books.DeleteOne(book => book.Id == id);
    }
}
```

In the preceding code, an `IBookstoreDatabaseSettings` instance is retrieved from DI via constructor injection. This technique provides access to the *appsettings.json* configuration values that were added in the Add a configuration model section.

3. Add the following highlighted code to `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<BookstoreDatabaseSettings>(
        Configuration.GetSection(nameof(BookstoreDatabaseSettings)));

    services.AddSingleton<IBookstoreDatabaseSettings>(sp =>
        sp.GetRequiredService<IOptions<BookstoreDatabaseSettings>>().Value);

    services.AddSingleton<BookService>();

    services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

In the preceding code, the `BookService` class is registered with DI to support constructor injection in

consuming classes. The singleton service lifetime is most appropriate because `BookService` takes a direct dependency on `MongoClient`. Per the official Mongo Client reuse guidelines, `MongoClient` should be registered in DI with a singleton service lifetime.

4. Add the following code to the top of *Startup.cs* to resolve the `BookService` reference:

```
using BooksApi.Services;
```

The `BookService` class uses the following `MongoDB.Driver` members to perform CRUD operations against the database:

- MongoClient: Reads the server instance for performing database operations. The constructor of this class is provided the MongoDB connection string:

```
public BookService(IBookstoreDatabaseSettings settings)
{
    var client = new MongoClient(settings.ConnectionString);
    var database = client.GetDatabase(settings.DatabaseName);

    _books = database.GetCollection<Book>(settings.BooksCollectionName);
}
```

- IMongoDatabase: Represents the Mongo database for performing operations. This tutorial uses the generic GetCollection<TDocument>(collection) method on the interface to gain access to data in a specific collection. Perform CRUD operations against the collection after this method is called. In the `GetCollection<TDocument>(collection)` method call:
  - `collection` represents the collection name.
  - `TDocument` represents the CLR object type stored in the collection.

`GetCollection<TDocument>(collection)` returns a MongoCollection object representing the collection. In this tutorial, the following methods are invoked on the collection:

- DeleteOne: Deletes a single document matching the provided search criteria.
- Find<TDocument>: Returns all documents in the collection matching the provided search criteria.
- InsertOne: Inserts the provided object as a new document in the collection.
- ReplaceOne: Replaces the single document matching the provided search criteria with the provided object.

Add a controller

Add a `BooksController` class to the *Controllers* directory with the following code:

```
using BooksApi.Models;
using BooksApi.Services;
using Microsoft.AspNetCore.Mvc;
using System.Collections.Generic;

namespace BooksApi.Controllers
{
    [Route("api/[controller]")]
    [ApiController]
    public class BooksController : ControllerBase
    {
        private readonly BookService _bookService;

        public BooksController(BookService bookService)
        {
            _bookService = bookService;
```

```
        }

        [HttpGet]
        public ActionResult<List<Book>> Get() =>
            _bookService.Get();

        [HttpGet("{id:length(24)}", Name = "GetBook")]
        public ActionResult<Book> Get(string id)
        {
            var book = _bookService.Get(id);

            if (book == null)
            {
                return NotFound();
            }

            return book;
        }

        [HttpPost]
        public ActionResult<Book> Create(Book book)
        {
            _bookService.Create(book);

            return CreatedAtRoute("GetBook", new { id = book.Id.ToString() }, book);
        }

        [HttpPut("{id:length(24)}")]
        public IActionResult Update(string id, Book bookIn)
        {
            var book = _bookService.Get(id);

            if (book == null)
            {
                return NotFound();
            }

            _bookService.Update(id, bookIn);

            return NoContent();
        }

        [HttpDelete("{id:length(24)}")]
        public IActionResult Delete(string id)
        {
            var book = _bookService.Get(id);

            if (book == null)
            {
                return NotFound();
            }

            _bookService.Remove(book.Id);

            return NoContent();
        }
    }
}
```

The preceding web API controller:

- Uses the `BookService` class to perform CRUD operations.
- Contains action methods to support GET, POST, PUT, and DELETE HTTP requests.
- Calls CreatedAtRoute in the `Create` action method to return an HTTP 201 response. Status code 201 is the standard response for an HTTP POST method that creates a new resource on the server. `CreatedAtRoute` also

adds a `Location` header to the response. The `Location` header specifies the URI of the newly created book.

Test the web API

1. Build and run the app.
2. Navigate to `http://localhost:<port>/api/books` to test the controller's parameterless `Get` action method. The following JSON response is displayed:

```
[
  {
    "id":"5bfd996f7b8e48dc15ff215d",
    "bookName":"Design Patterns",
    "price":54.93,
    "category":"Computers",
    "author":"Ralph Johnson"
  },
  {
    "id":"5bfd996f7b8e48dc15ff215e",
    "bookName":"Clean Code",
    "price":43.15,
    "category":"Computers",
    "author":"Robert C. Martin"
  }
]
```

3. Navigate to `http://localhost:<port>/api/books/{id here}` to test the controller's overloaded `Get` action method. The following JSON response is displayed:

```
{
  "id":"{ID}",
  "bookName":"Clean Code",
  "price":43.15,
  "category":"Computers",
  "author":"Robert C. Martin"
}
```

Configure JSON serialization options

There are two details to change about the JSON responses returned in the Test the web API section:

- The property names' default camel casing should be changed to match the Pascal casing of the CLR object's property names.
- The `bookName` property should be returned as `Name`.

To satisfy the preceding requirements, make the following changes:

1. In `Startup.ConfigureServices`, chain the following highlighted code on to the `AddMvc` method call:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<BookstoreDatabaseSettings>(
        Configuration.GetSection(nameof(BookstoreDatabaseSettings)));

    services.AddSingleton<IBookstoreDatabaseSettings>(sp =>
        sp.GetRequiredService<IOptions<BookstoreDatabaseSettings>>().Value);

    services.AddSingleton<BookService>();

    services.AddMvc()
            .AddJsonOptions(options => options.UseMemberCasing())
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

With the preceding change, property names in the web API's serialized JSON response match their corresponding property names in the CLR object type. For example, the `Book` class's `Author` property serializes as `Author`.

2. In *Models/Book.cs*, annotate the `BookName` property with the following `[JsonProperty]` attribute:

```
[BsonElement("Name")]
[JsonProperty("Name")]
public string BookName { get; set; }
```

The `[JsonProperty]` attribute's value of `Name` represents the property name in the web API's serialized JSON response.

3. Add the following code to the top of *Models/Book.cs* to resolve the `[JsonProperty]` attribute reference:

```
using Newtonsoft.Json;
```

4. Repeat the steps defined in the Test the web API section. Notice the difference in JSON property names.

Add authentication support to a web API

ASP.NET Core Identity adds user interface (UI) login functionality to ASP.NET Core web apps. To secure web APIs and SPAs, use one of the following:

- Azure Active Directory
- Azure Active Directory B2C (Azure AD B2C)
- IdentityServer4

IdentityServer4 is an OpenID Connect and OAuth 2.0 framework for ASP.NET Core. IdentityServer4 enables the following security features:

- Authentication as a Service (AaaS)
- Single sign-on/off (SSO) over multiple application types
- Access control for APIs
- Federation Gateway

For more information, see Welcome to IdentityServer4.

ASP.NET Core web API help pages with Swagger / OpenAPI

9/22/2020 • 2 minutes to read • Edit Online

By Christoph Nienaber and Rico Suter

When consuming a web API, understanding its various methods can be challenging for a developer. Swagger, also known as OpenAPI, solves the problem of generating useful documentation and help pages for web APIs. It provides benefits such as interactive documentation, client SDK generation, and API discoverability.

In this article, the Swashbuckle.AspNetCore and NSwag .NET Swagger implementations are showcased:

- **Swashbuckle.AspNetCore** is an open source project for generating Swagger documents for ASP.NET Core Web APIs.
- **NSwag** is another open source project for generating Swagger documents and integrating Swagger UI or ReDoc into ASP.NET Core web APIs. Additionally, NSwag offers approaches to generate C# and TypeScript client code for your API.

What is Swagger / OpenAPI?

Swagger is a language-agnostic specification for describing REST APIs. The Swagger project was donated to the OpenAPI Initiative, where it's now referred to as OpenAPI. Both names are used interchangeably; however, OpenAPI is preferred. It allows both computers and humans to understand the capabilities of a service without any direct access to the implementation (source code, network access, documentation). One goal is to minimize the amount of work needed to connect disassociated services. Another goal is to reduce the amount of time needed to accurately document a service.

OpenAPI specification (openapi.json)

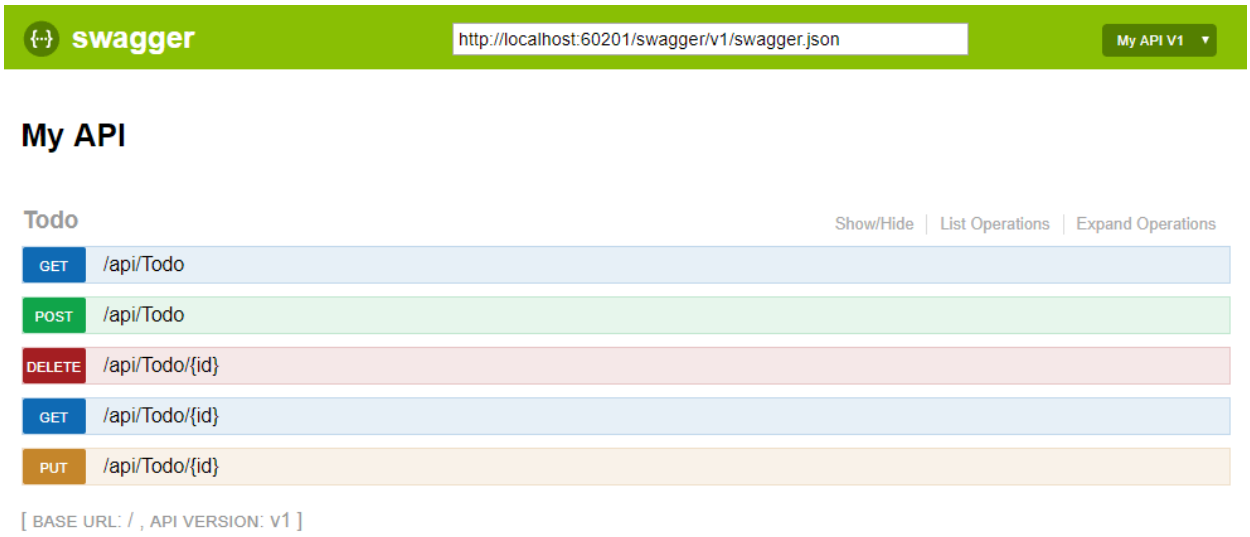
The core to the OpenAPI flow is the specification—by default, a document named *openapi.json*. It's generated by the OpenAPI tool chain (or third-party implementations of it) based on your service. It describes the capabilities of your API and how to access it with HTTP. It drives the Swagger UI and is used by the tool chain to enable discovery and client code generation. Here's an example of an OpenAPI specification, reduced for brevity:

```
{
  "openapi": "3.0.1",
  "info": {
    "title": "API V1",
    "version": "v1"
  },
  "paths": {
    "/api/Todo": {
      "get": {
        "tags": [
          "Todo"
        ],
        "operationId": "ApiTodoGet",
        "responses": {
          "200": {
            "description": "Success",
            "content": {
              "text/plain": {
                "schema": {
                  "type": "array"
```

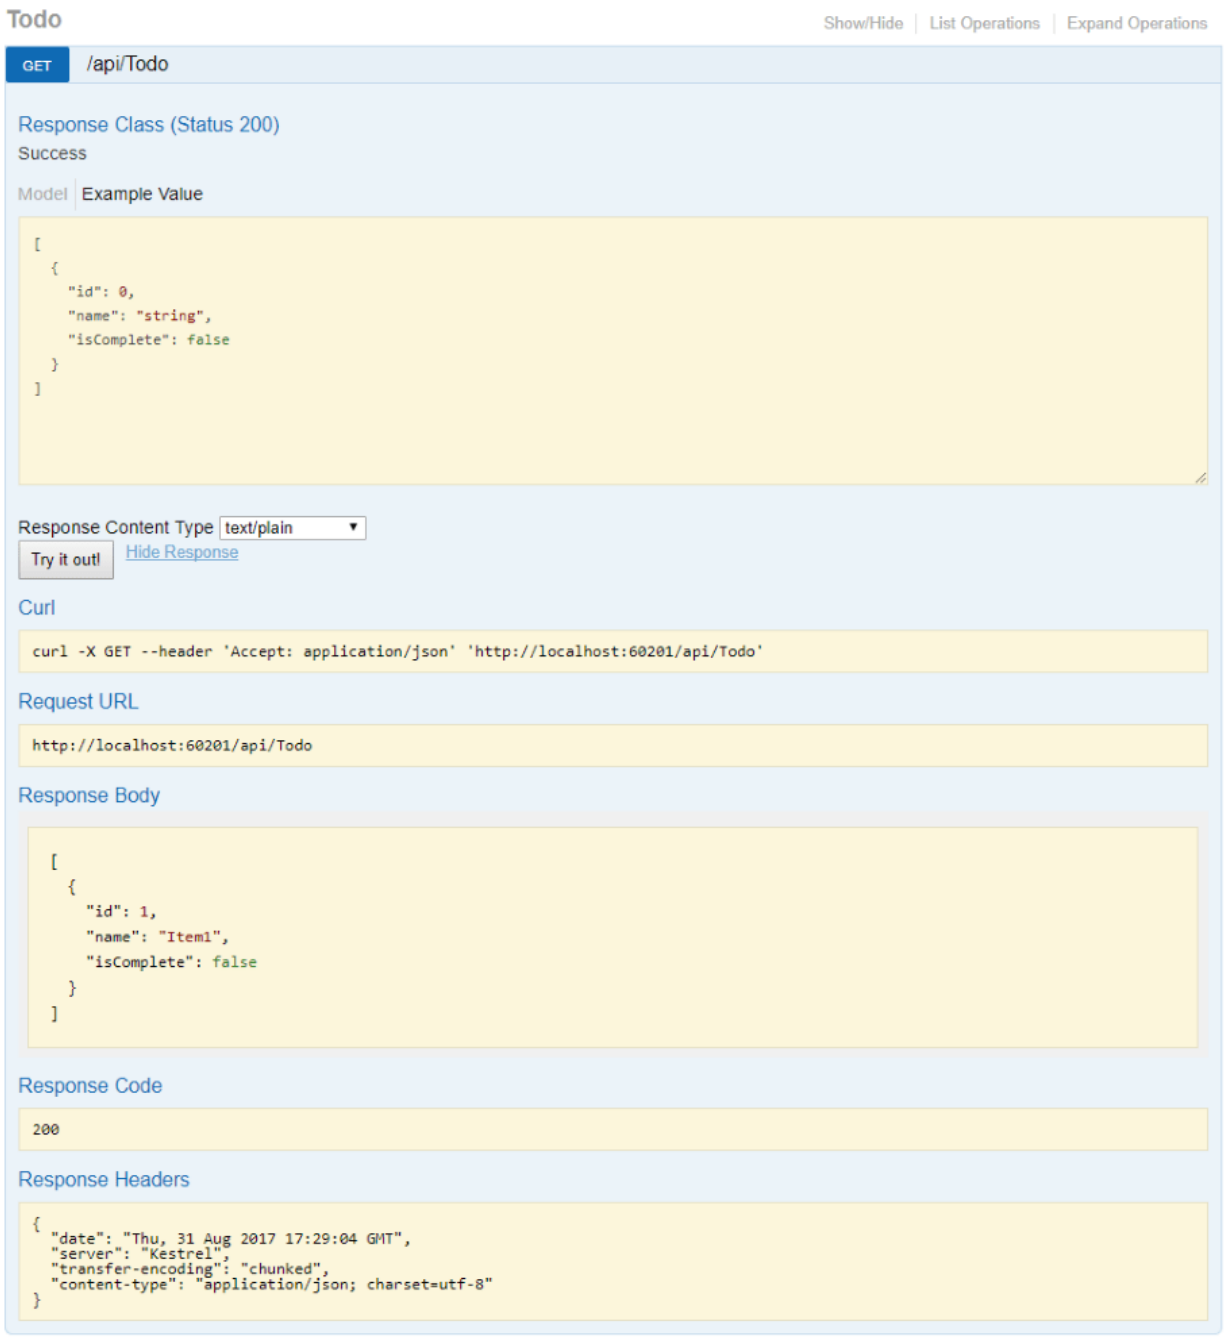
```
                "type": "array",
                "items": {
                  "$ref": "#/components/schemas/ToDoItem"
                }
              }
            },
            "application/json": {
              "schema": {
                "type": "array",
                "items": {
                  "$ref": "#/components/schemas/ToDoItem"
                }
              }
            },
            "text/json": {
              "schema": {
                "type": "array",
                "items": {
                  "$ref": "#/components/schemas/ToDoItem"
                }
              }
            }
          }
        }
      },
      "post": {
        …
      }
    },
    "/api/Todo/{id}": {
      "get": {
        …
      },
      "put": {
        …
      },
      "delete": {
        …
      }
    }
  },
  "components": {
    "schemas": {
      "ToDoItem": {
        "type": "object",
        "properties": {
          "id": {
            "type": "integer",
            "format": "int32"
          },
          "name": {
            "type": "string",
            "nullable": true
          },
          "isCompleted": {
            "type": "boolean"
          }
        },
        "additionalProperties": false
      }
    }
  }
}
```

Swagger UI

Swagger UI offers a web-based UI that provides information about the service, using the generated OpenAPI specification. Both Swashbuckle and NSwag include an embedded version of Swagger UI, so that it can be hosted in your ASP.NET Core app using a middleware registration call. The web UI looks like this:



Each public action method in your controllers can be tested from the UI. Click a method name to expand the section. Add any necessary parameters, and click **Try it out!**.



> **NOTE**
>
> The Swagger UI version used for the screenshots is version 2. For a version 3 example, see Petstore example.

- Get started with Swashbuckle
- Get started with NSwag

Get started with Swashbuckle and ASP.NET Core

9/22/2020 • 14 minutes to read • Edit Online

By Shayne Boyer and Scott Addie

View or download sample code (how to download)

There are three main components to Swashbuckle:

- Swashbuckle.AspNetCore.Swagger: a Swagger object model and middleware to expose `SwaggerDocument` objects as JSON endpoints.
- Swashbuckle.AspNetCore.SwaggerGen: a Swagger generator that builds `SwaggerDocument` objects directly from your routes, controllers, and models. It's typically combined with the Swagger endpoint middleware to automatically expose Swagger JSON.
- Swashbuckle.AspNetCore.SwaggerUI: an embedded version of the Swagger UI tool. It interprets Swagger JSON to build a rich, customizable experience for describing the web API functionality. It includes built-in test harnesses for the public methods.

Package installation

Swashbuckle can be added with the following approaches:

- Visual Studio
- Visual Studio for Mac
- Visual Studio Code
- .NET Core CLI
- From the **Package Manager Console** window:
  - Go to **View** > **Other Windows** > **Package Manager Console**
  - Navigate to the directory in which the *TodoApi.csproj* file exists
  - Execute the following command:

    ```
    Install-Package Swashbuckle.AspNetCore -Version 5.5.0
    ```

- From the **Manage NuGet Packages** dialog:
  - Right-click the project in **Solution Explorer** > **Manage NuGet Packages**
  - Set the **Package source** to "nuget.org"
  - Ensure the "Include prerelease" option is enabled
  - Enter "Swashbuckle.AspNetCore" in the search box
  - Select the latest "Swashbuckle.AspNetCore" package from the **Browse** tab and click **Install**

Add and configure Swagger middleware

Add the Swagger generator to the services collection in the `Startup.ConfigureServices` method:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<TodoContext>(opt =>
        opt.UseInMemoryDatabase("TodoList"));
    services.AddMvc();

    // Register the Swagger generator, defining 1 or more Swagger documents
    services.AddSwaggerGen();
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<TodoContext>(opt =>
        opt.UseInMemoryDatabase("TodoList"));
    services.AddMvc()
        .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);

    // Register the Swagger generator, defining 1 or more Swagger documents
    services.AddSwaggerGen();
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<TodoContext>(opt =>
        opt.UseInMemoryDatabase("TodoList"));
    services.AddControllers();

    // Register the Swagger generator, defining 1 or more Swagger documents
    services.AddSwaggerGen();
}
```

In the `Startup.Configure` method, enable the middleware for serving the generated JSON document and the Swagger UI:

```
public void Configure(IApplicationBuilder app)
{
    // Enable middleware to serve generated Swagger as a JSON endpoint.
    app.UseSwagger();

    // Enable middleware to serve swagger-ui (HTML, JS, CSS, etc.),
    // specifying the Swagger JSON endpoint.
    app.UseSwaggerUI(c =>
    {
        c.SwaggerEndpoint("/swagger/v1/swagger.json", "My API V1");
    });

    app.UseMvc();
}
```

```
public void Configure(IApplicationBuilder app)
{
    // Enable middleware to serve generated Swagger as a JSON endpoint.
    app.UseSwagger();

    // Enable middleware to serve swagger-ui (HTML, JS, CSS, etc.),
    // specifying the Swagger JSON endpoint.
    app.UseSwaggerUI(c =>
    {
        c.SwaggerEndpoint("/swagger/v1/swagger.json", "My API V1");
    });

    app.UseRouting();
    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
    });
}
```

NOTE

Swashbuckle relies on MVC's Microsoft.AspNetCore.Mvc.ApiExplorer to discover the routes and endpoints. If the project calls AddMvc, routes and endpoints are discovered automatically. When calling AddMvcCore, the AddApiExplorer method must be explicitly called. For more information, see Swashbuckle, ApiExplorer, and Routing.

The preceding `UseSwaggerUI` method call enables the Static File Middleware. If targeting .NET Framework or .NET Core 1.x, add the Microsoft.AspNetCore.StaticFiles NuGet package to the project.

Launch the app, and navigate to `http://localhost:<port>/swagger/v1/swagger.json`. The generated document describing the endpoints appears as shown in OpenAPI specification (openapi.json).

The Swagger UI can be found at `http://localhost:<port>/swagger`. Explore the API via Swagger UI and incorporate it in other programs.

TIP

To serve the Swagger UI at the app's root (`http://localhost:<port>/`), set the `RoutePrefix` property to an empty string:

```
app.UseSwaggerUI(c =>
{
    c.SwaggerEndpoint("/swagger/v1/swagger.json", "My API V1");
    c.RoutePrefix = string.Empty;
});
```

If using directories with IIS or a reverse proxy, set the Swagger endpoint to a relative path using the `./` prefix. For example, `./swagger/v1/swagger.json`. Using `/swagger/v1/swagger.json` instructs the app to look for the JSON file at the true root of the URL (plus the route prefix, if used). For example, use `http://localhost:<port>/<route_prefix>/swagger/v1/swagger.json` instead of `http://localhost:<port>/<virtual_directory>/<route_prefix>/swagger/v1/swagger.json`.

NOTE

By default, Swashbuckle generates and exposes Swagger JSON in version 3.0 of the specification—officially called the OpenAPI Specification. To support backwards compatibility, you can opt into exposing JSON in the 2.0 format instead. This 2.0 format is important for integrations such as Microsoft Power Apps and Microsoft Flow that currently support OpenAPI version 2.0. To opt into the 2.0 format, set the `SerializeAsV2` property in `Startup.Configure`:

```
public void Configure(IApplicationBuilder app)
{
    // Enable middleware to serve generated Swagger as a JSON endpoint.
    app.UseSwagger(c =>
    {
        c.SerializeAsV2 = true;
    });

    // Enable middleware to serve swagger-ui (HTML, JS, CSS, etc.),
    // specifying the Swagger JSON endpoint.
    app.UseSwaggerUI(c =>
    {
        c.SwaggerEndpoint("/swagger/v1/swagger.json", "My API V1");
    });

    app.UseRouting();
    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
    });
}
```

Customize and extend

Swagger provides options for documenting the object model and customizing the UI to match your theme.

In the `Startup` class, add the following namespaces:

```
using System;
using System.Reflection;
using System.IO;
```

API info and description

The configuration action passed to the `AddSwaggerGen` method adds information such as the author, license, and description:

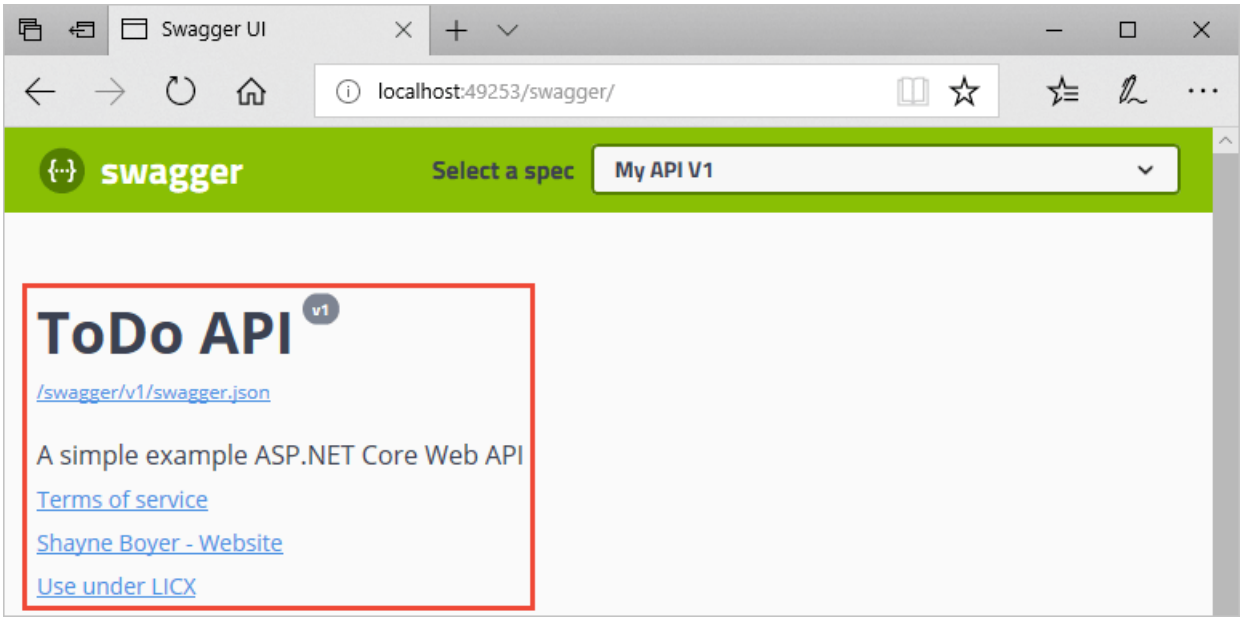
In the `Startup` class, import the following namespace to use the `OpenApiInfo` class:

```
using Microsoft.OpenApi.Models;
```

Using the `OpenApiInfo` class, modify the information displayed in the UI:

```
// Register the Swagger generator, defining 1 or more Swagger documents
services.AddSwaggerGen(c =>
{
    c.SwaggerDoc("v1", new OpenApiInfo
    {
        Version = "v1",
        Title = "ToDo API",
        Description = "A simple example ASP.NET Core Web API",
        TermsOfService = new Uri("https://example.com/terms"),
        Contact = new OpenApiContact
        {
            Name = "Shayne Boyer",
            Email = string.Empty,
            Url = new Uri("https://twitter.com/spboyer"),
        },
        License = new OpenApiLicense
        {
            Name = "Use under LICX",
            Url = new Uri("https://example.com/license"),
        }
    });
});
```

The Swagger UI displays the version's information:



XML comments

XML comments can be enabled with the following approaches:

- Visual Studio
- Visual Studio for Mac
- Visual Studio Code
- .NET Core CLI

- Right-click the project in **Solution Explorer** and select **Edit <project_name>.csproj**.
- Manually add the highlighted lines to the *.csproj* file:

```
<PropertyGroup>
  <GenerateDocumentationFile>true</GenerateDocumentationFile>
  <NoWarn>$(NoWarn);1591</NoWarn>
</PropertyGroup>
```

- Right-click the project in **Solution Explorer** and select **Properties**.
- Check the **XML documentation file** box under the **Output** section of the **Build** tab.

Enabling XML comments provides debug information for undocumented public types and members. Undocumented types and members are indicated by the warning message. For example, the following message indicates a violation of warning code 1591:

```
warning CS1591: Missing XML comment for publicly visible type or member 'TodoController.GetAll()'
```

To suppress warnings project-wide, define a semicolon-delimited list of warning codes to ignore in the project file. Appending the warning codes to `$(NoWarn);` applies the C# default values too.

```
<PropertyGroup>
  <GenerateDocumentationFile>true</GenerateDocumentationFile>
  <NoWarn>$(NoWarn);1591</NoWarn>
</PropertyGroup>
```

```
<PropertyGroup>
  <DocumentationFile>bin\$(Configuration)\$(TargetFramework)\$(AssemblyName).xml</DocumentationFile>
  <NoWarn>$(NoWarn);1591</NoWarn>
</PropertyGroup>
```

To suppress warnings only for specific members, enclose the code in #pragma warning preprocessor directives. This approach is useful for code that shouldn't be exposed via the API docs. In the following example, warning code CS1591 is ignored for the entire `Program` class. Enforcement of the warning code is restored at the close of the class definition. Specify multiple warning codes with a comma-delimited list.

```
namespace TodoApi
{
#pragma warning disable CS1591
    public class Program
    {
        public static void Main(string[] args) =>
            BuildWebHost(args).Run();

        public static IWebHost BuildWebHost(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>()
                .Build();
    }
#pragma warning restore CS1591
}
```

Configure Swagger to use the XML file that's generated with the preceding instructions. For Linux or non-Windows operating systems, file names and paths can be case-sensitive. For example, a *TodoApi.XML* file is valid on Windows but not CentOS.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<TodoContext>(opt =>
        opt.UseInMemoryDatabase("TodoList"));
    services.AddControllers();

    // Register the Swagger generator, defining 1 or more Swagger documents
    services.AddSwaggerGen(c =>
    {
        c.SwaggerDoc("v1", new OpenApiInfo
        {
            Version = "v1",
            Title = "ToDo API",
            Description = "A simple example ASP.NET Core Web API",
            TermsOfService = new Uri("https://example.com/terms"),
            Contact = new OpenApiContact
            {
                Name = "Shayne Boyer",
                Email = string.Empty,
                Url = new Uri("https://twitter.com/spboyer"),
            },
            License = new OpenApiLicense
            {
                Name = "Use under LICX",
                Url = new Uri("https://example.com/license"),
            }
        });

        // Set the comments path for the Swagger JSON and UI.
        var xmlFile = $"{Assembly.GetExecutingAssembly().GetName().Name}.xml";
        var xmlPath = Path.Combine(AppContext.BaseDirectory, xmlFile);
        c.IncludeXmlComments(xmlPath);
    });
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<TodoContext>(opt =>
        opt.UseInMemoryDatabase("TodoList"));
    services.AddMvc()
        .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);

    // Register the Swagger generator, defining 1 or more Swagger documents
    services.AddSwaggerGen(c =>
    {
        c.SwaggerDoc("v1", new OpenApiInfo
        {
            Version = "v1",
            Title = "ToDo API",
            Description = "A simple example ASP.NET Core Web API",
            TermsOfService = new Uri("https://example.com/terms"),
            Contact = new OpenApiContact
            {
                Name = "Shayne Boyer",
                Email = string.Empty,
                Url = new Uri("https://twitter.com/spboyer"),
            },
            License = new OpenApiLicense
            {
                Name = "Use under LICX",
                Url = new Uri("https://example.com/license"),
            }
        });

        // Set the comments path for the Swagger JSON and UI.
        var xmlFile = $"{Assembly.GetExecutingAssembly().GetName().Name}.xml";
        var xmlPath = Path.Combine(AppContext.BaseDirectory, xmlFile);
        c.IncludeXmlComments(xmlPath);
    });
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<TodoContext>(opt =>
        opt.UseInMemoryDatabase("TodoList"));
    services.AddMvc();

    // Register the Swagger generator, defining 1 or more Swagger documents
    services.AddSwaggerGen(c =>
    {
        c.SwaggerDoc("v1", new OpenApiInfo
        {
            Version = "v1",
            Title = "ToDo API",
            Description = "A simple example ASP.NET Core Web API",
            TermsOfService = new Uri("https://example.com/terms"),
            Contact = new OpenApiContact
            {
                Name = "Shayne Boyer",
                Email = string.Empty,
                Url = new Uri("https://twitter.com/spboyer"),
            },
            License = new OpenApiLicense
            {
                Name = "Use under LICX",
                Url = new Uri("https://example.com/license"),
            }
        });

        // Set the comments path for the Swagger JSON and UI.
        var xmlFile = $"{Assembly.GetExecutingAssembly().GetName().Name}.xml";
        var xmlPath = Path.Combine(AppContext.BaseDirectory, xmlFile);
        c.IncludeXmlComments(xmlPath);
    });
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<TodoContext>(opt =>
        opt.UseInMemoryDatabase("TodoList"));
    services.AddMvc();

    // Register the Swagger generator, defining 1 or more Swagger documents
    services.AddSwaggerGen(c =>
    {
        c.SwaggerDoc("v1", new OpenApiInfo
        {
            Version = "v1",
            Title = "ToDo API",
            Description = "A simple example ASP.NET Core Web API",
            TermsOfService = new Uri("https://example.com/terms"),
            Contact = new OpenApiContact
            {
                Name = "Shayne Boyer",
                Email = string.Empty,
                Url = new Uri("https://twitter.com/spboyer"),
            },
            License = new OpenApiLicense
            {
                Name = "Use under LICX",
                Url = new Uri("https://example.com/license"),
            }
        });

        // Set the comments path for the Swagger JSON and UI.
        var xmlFile = $"{Assembly.GetEntryAssembly().GetName().Name}.xml";
        var xmlPath = Path.Combine(AppContext.BaseDirectory, xmlFile);
        c.IncludeXmlComments(xmlPath);
    });
}
```

In the preceding code, Reflection is used to build an XML file name matching that of the web API project. The AppContext.BaseDirectory property is used to construct a path to the XML file. Some Swagger features (for example, schemata of input parameters or HTTP methods and response codes from the respective attributes) work without the use of an XML documentation file. For most features, namely method summaries and the descriptions of parameters and response codes, the use of an XML file is mandatory.

Adding triple-slash comments to an action enhances the Swagger UI by adding the description to the section header. Add a <summary> element above the `Delete` action:

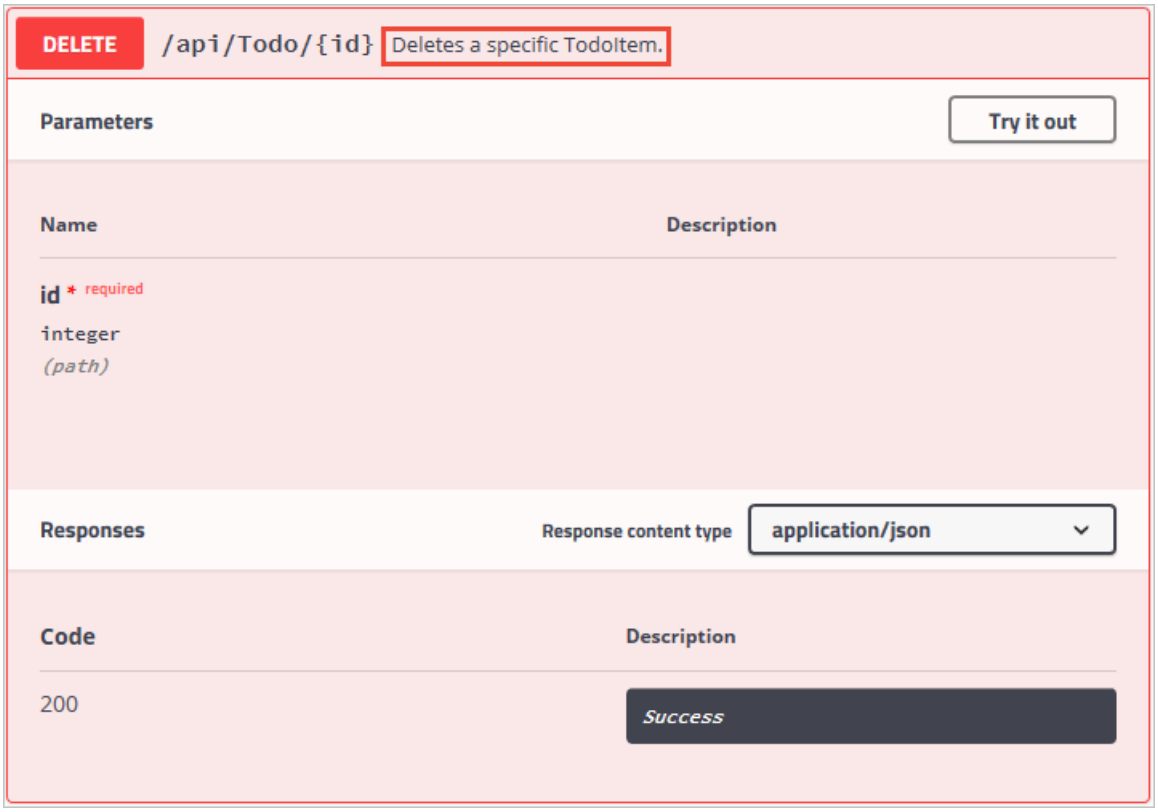
```
/// <summary>
/// Deletes a specific TodoItem.
/// </summary>
/// <param name="id"></param>
[HttpDelete("{id}")]
public IActionResult Delete(long id)
{
    var todo = _context.TodoItems.Find(id);

    if (todo == null)
    {
        return NotFound();
    }

    _context.TodoItems.Remove(todo);
    _context.SaveChanges();

    return NoContent();
}
```

The Swagger UI displays the inner text of the preceding code's `<summary>` element:



The UI is driven by the generated JSON schema:

```
"delete": {
    "tags": [
        "Todo"
    ],
    "summary": "Deletes a specific TodoItem.",
    "operationId": "ApiTodoByIdDelete",
    "consumes": [],
    "produces": [],
    "parameters": [
        {
            "name": "id",
            "in": "path",
            "description": "",
            "required": true,
            "type": "integer",
            "format": "int64"
        }
    ],
    "responses": {
        "200": {
            "description": "Success"
        }
    }
}
```

Add a <remarks> element to the `Create` action method documentation. It supplements information specified in the `<summary>` element and provides a more robust Swagger UI. The `<remarks>` element content can consist of text, JSON, or XML.

```
/// <summary>
/// Creates a TodoItem.
/// </summary>
/// <remarks>
/// Sample request:
///
///     POST /Todo
///     {
///        "id": 1,
///        "name": "Item1",
///        "isComplete": true
///     }
///
/// </remarks>
/// <param name="item"></param>
/// <returns>A newly created TodoItem</returns>
/// <response code="201">Returns the newly created item</response>
/// <response code="400">If the item is null</response>
[HttpPost]
[ProducesResponseType(typeof(TodoItem), StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public IActionResult Create([FromBody] TodoItem item)
{
    if (item == null)
    {
        return BadRequest();
    }

    _context.TodoItems.Add(item);
    _context.SaveChanges();

    return CreatedAtRoute("GetTodo", new { id = item.Id }, item);
}
```

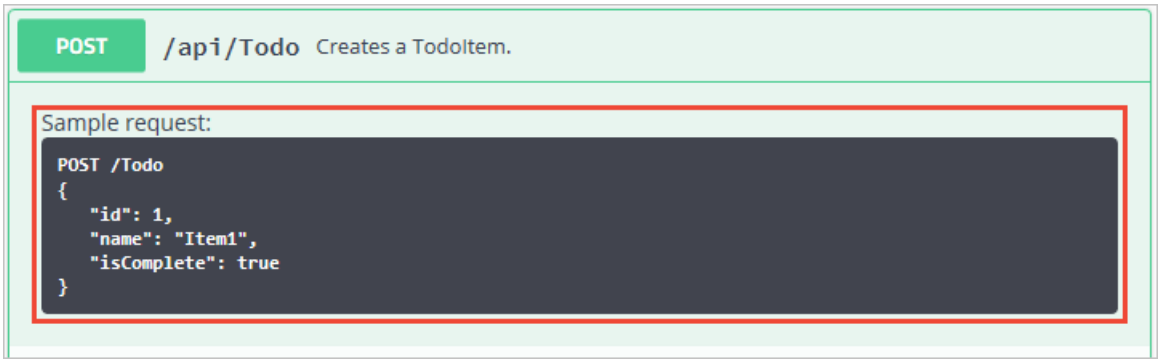
```
/// <summary>
/// Creates a TodoItem.
/// </summary>
/// <remarks>
/// Sample request:
///
///     POST /Todo
///     {
///        "id": 1,
///        "name": "Item1",
///        "isComplete": true
///     }
///
/// </remarks>
/// <param name="item"></param>
/// <returns>A newly created TodoItem</returns>
/// <response code="201">Returns the newly created item</response>
/// <response code="400">If the item is null</response>
[HttpPost]
[ProducesResponseType(StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public ActionResult<TodoItem> Create(TodoItem item)
{
    _context.TodoItems.Add(item);
    _context.SaveChanges();

    return CreatedAtRoute("GetTodo", new { id = item.Id }, item);
}
```

```
/// <summary>
/// Creates a TodoItem.
/// </summary>
/// <remarks>
/// Sample request:
///
///     POST /Todo
///     {
///        "id": 1,
///        "name": "Item1",
///        "isComplete": true
///     }
///
/// </remarks>
/// <param name="item"></param>
/// <returns>A newly created TodoItem</returns>
/// <response code="201">Returns the newly created item</response>
/// <response code="400">If the item is null</response>
[HttpPost]
[ProducesResponseType(StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public ActionResult<TodoItem> Create(TodoItem item)
{
    _context.TodoItems.Add(item);
    _context.SaveChanges();

    return CreatedAtRoute("GetTodo", new { id = item.Id }, item);
}
```

Notice the UI enhancements with these additional comments:



Data annotations

Mark the model with attributes, found in the System.ComponentModel.DataAnnotations namespace, to help drive the Swagger UI components.

Add the `[Required]` attribute to the `Name` property of the `TodoItem` class:

```
using System.ComponentModel;
using System.ComponentModel.DataAnnotations;

namespace TodoApi.Models
{
    public class TodoItem
    {
        public long Id { get; set; }

        [Required]
        public string Name { get; set; }

        [DefaultValue(false)]
        public bool IsComplete { get; set; }
    }
}
```

The presence of this attribute changes the UI behavior and alters the underlying JSON schema:

```
"definitions": {
    "TodoItem": {
        "required": [
            "name"
        ],
        "type": "object",
        "properties": {
            "id": {
                "format": "int64",
                "type": "integer"
            },
            "name": {
                "type": "string"
            },
            "isComplete": {
                "default": false,
                "type": "boolean"
            }
        }
    }
},
```

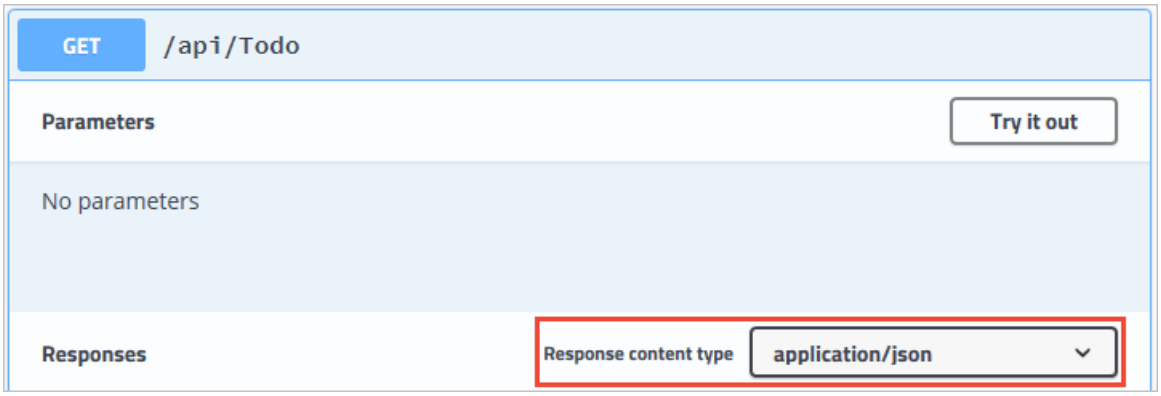
Add the `[Produces("application/json")]` attribute to the API controller. Its purpose is to declare that the controller's actions support a response content type of *application/json*:

```
[Produces("application/json")]
[Route("api/[controller]")]
public class TodoController : ControllerBase
{
    private readonly TodoContext _context;
```

```
[Produces("application/json")]
[Route("api/[controller]")]
[ApiController]
public class TodoController : ControllerBase
{
    private readonly TodoContext _context;
```

```
[Produces("application/json")]
[Route("api/[controller]")]
[ApiController]
public class TodoController : ControllerBase
{
    private readonly TodoContext _context;
```

The **Response Content Type** drop-down selects this content type as the default for the controller's GET actions:



As the usage of data annotations in the web API increases, the UI and API help pages become more descriptive and useful.

Describe response types

Developers consuming a web API are most concerned with what's returned—specifically response types and error codes (if not standard). The response types and error codes are denoted in the XML comments and data annotations.

The `Create` action returns an HTTP 201 status code on success. An HTTP 400 status code is returned when the posted request body is null. Without proper documentation in the Swagger UI, the consumer lacks knowledge of these expected outcomes. Fix that problem by adding the highlighted lines in the following example:

```
/// <summary>
/// Creates a TodoItem.
/// </summary>
/// <remarks>
/// Sample request:
///
///     POST /Todo
///     {
///        "id": 1,
///        "name": "Item1",
///        "isComplete": true
///     }
///
/// </remarks>
/// <param name="item"></param>
/// <returns>A newly created TodoItem</returns>
/// <response code="201">Returns the newly created item</response>
/// <response code="400">If the item is null</response>
[HttpPost]
[ProducesResponseType(typeof(TodoItem), StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public IActionResult Create([FromBody] TodoItem item)
{
    if (item == null)
    {
        return BadRequest();
    }

    _context.TodoItems.Add(item);
    _context.SaveChanges();

    return CreatedAtRoute("GetTodo", new { id = item.Id }, item);
}
```

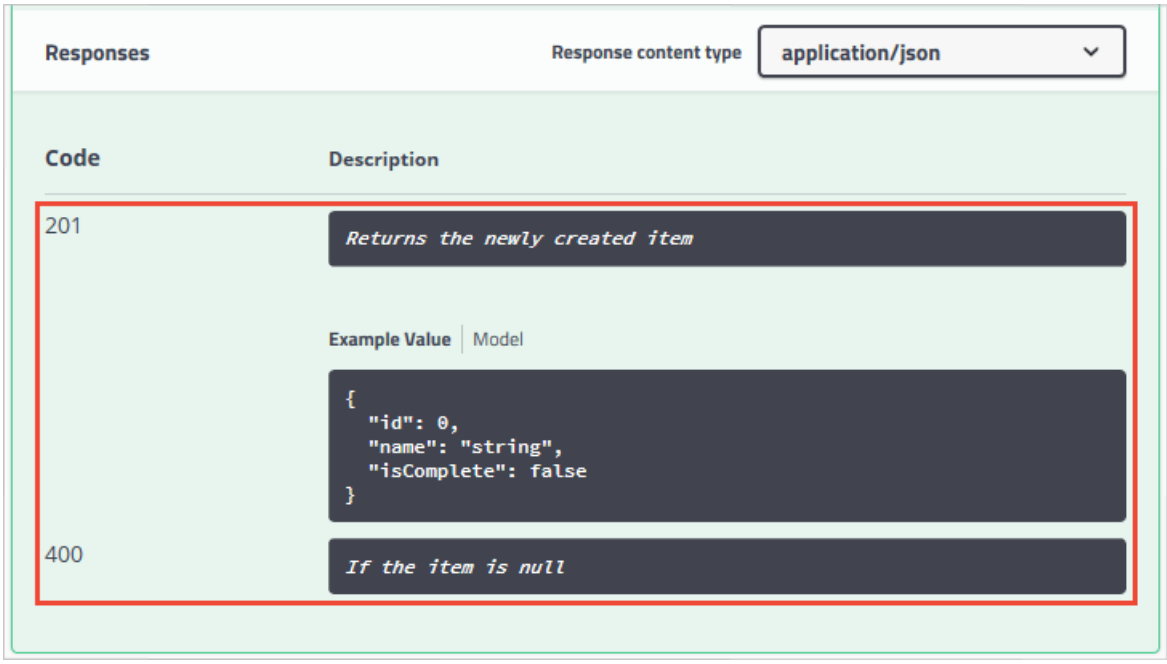
```
/// <summary>
/// Creates a TodoItem.
/// </summary>
/// <remarks>
/// Sample request:
///
///     POST /Todo
///     {
///        "id": 1,
///        "name": "Item1",
///        "isComplete": true
///     }
///
/// </remarks>
/// <param name="item"></param>
/// <returns>A newly created TodoItem</returns>
/// <response code="201">Returns the newly created item</response>
/// <response code="400">If the item is null</response>
[HttpPost]
[ProducesResponseType(StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public ActionResult<TodoItem> Create(TodoItem item)
{
    _context.TodoItems.Add(item);
    _context.SaveChanges();

    return CreatedAtRoute("GetTodo", new { id = item.Id }, item);
}
```

```
/// <summary>
/// Creates a TodoItem.
/// </summary>
/// <remarks>
/// Sample request:
///
///     POST /Todo
///     {
///        "id": 1,
///        "name": "Item1",
///        "isComplete": true
///     }
///
/// </remarks>
/// <param name="item"></param>
/// <returns>A newly created TodoItem</returns>
/// <response code="201">Returns the newly created item</response>
/// <response code="400">If the item is null</response>
[HttpPost]
[ProducesResponseType(StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public ActionResult<TodoItem> Create(TodoItem item)
{
    _context.TodoItems.Add(item);
    _context.SaveChanges();

    return CreatedAtRoute("GetTodo", new { id = item.Id }, item);
}
```

The Swagger UI now clearly documents the expected HTTP response codes:



In ASP.NET Core 2.2 or later, conventions can be used as an alternative to explicitly decorating individual actions with `[ProducesResponseType]`. For more information, see Use web API conventions.

To support the `[ProducesResponseType]` decoration, the Swashbuckle.AspNetCore.Annotations package offers extensions to enable and enrich the response, schema, and parameter metadata.

Customize the UI

The default UI is both functional and presentable. However, API documentation pages should represent your brand or theme. Branding the Swashbuckle components requires adding the resources to serve static files and building the folder structure to host those files.

If targeting .NET Framework or .NET Core 1.x, add the Microsoft.AspNetCore.StaticFiles NuGet package to the project:

```
<PackageReference Include="Microsoft.AspNetCore.StaticFiles" Version="2.0.0" />
```

The preceding NuGet package is already installed if targeting .NET Core 2.x and using the metapackage.

Enable Static File Middleware:

```
public void Configure(IApplicationBuilder app)
{
    app.UseStaticFiles();

    // Enable middleware to serve generated Swagger as a JSON endpoint.
    app.UseSwagger();

    // Enable middleware to serve swagger-ui (HTML, JS, CSS, etc.),
    // specifying the Swagger JSON endpoint.
    app.UseSwaggerUI(c =>
    {
        c.SwaggerEndpoint("/swagger/v1/swagger.json", "My API V1");
    });

    app.UseMvc();
}
```

```
public void Configure(IApplicationBuilder app)
{
    app.UseStaticFiles();

    // Enable middleware to serve generated Swagger as a JSON endpoint.
    app.UseSwagger();

    // Enable middleware to serve swagger-ui (HTML, JS, CSS, etc.),
    // specifying the Swagger JSON endpoint.
    app.UseSwaggerUI(c =>
    {
        c.SwaggerEndpoint("/swagger/v1/swagger.json", "My API V1");
    });

    app.UseRouting();
    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
    });
}
```

To inject additional CSS stylesheets, add them to the project's *wwwroot* folder and specify the relative path in the middleware options:

```
app.UseSwaggerUI(c =>
{
     c.InjectStylesheet("/swagger-ui/custom.css");
}
```

Get started with NSwag and ASP.NET Core

View or download sample code (how to download)

View or download sample code (how to download)

NSwag offers the following capabilities:

- The ability to utilize the Swagger UI and Swagger generator.
- Flexible code generation capabilities.

With NSwag, you don't need an existing API—you can use third-party APIs that incorporate Swagger and generate a client implementation. NSwag allows you to expedite the development cycle and easily adapt to API changes.

Register the NSwag middleware

Register the NSwag middleware to:

- Generate the Swagger specification for the implemented web API.
- Serve the Swagger UI to browse and test the web API.

To use the NSwag ASP.NET Core middleware, install the NSwag.AspNetCore NuGet package. This package contains the middleware to generate and serve the Swagger specification, Swagger UI (v2 and v3), and ReDoc UI.

Use one of the following approaches to install the NSwag NuGet package:

- Visual Studio
- Visual Studio for Mac
- .NET Core CLI

- From the **Package Manager Console** window:
  - Go to **View** > **Other Windows** > **Package Manager Console**
  - Navigate to the directory in which the *TodoApi.csproj* file exists
  - Execute the following command:

    ```
    Install-Package NSwag.AspNetCore
    ```

- From the **Manage NuGet Packages** dialog:
  - Right-click the project in **Solution Explorer** > **Manage NuGet Packages**
  - Set the **Package source** to "nuget.org"
  - Enter "NSwag.AspNetCore" in the search box
  - Select the "NSwag.AspNetCore" package from the **Browse** tab and click **Install**

Add and configure Swagger middleware

Add and configure Swagger in your ASP.NET Core app by performing the following steps:

- In the `Startup.ConfigureServices` method, register the required Swagger services:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<TodoContext>(opt =>
        opt.UseInMemoryDatabase("TodoList"));
    services.AddMvc();

    // Register the Swagger services
    services.AddSwaggerDocument();
}
```

- In the `Startup.Configure` method, enable the middleware for serving the generated Swagger specification and the Swagger UI:

```
public void Configure(IApplicationBuilder app)
{
    app.UseStaticFiles();

    // Register the Swagger generator and the Swagger UI middlewares
    app.UseOpenApi();
    app.UseSwaggerUi3();

    app.UseMvc();
}
```

- Launch the app. Navigate to:
  - `http://localhost:<port>/swagger` to view the Swagger UI.
  - `http://localhost:<port>/swagger/v1/swagger.json` to view the Swagger specification.

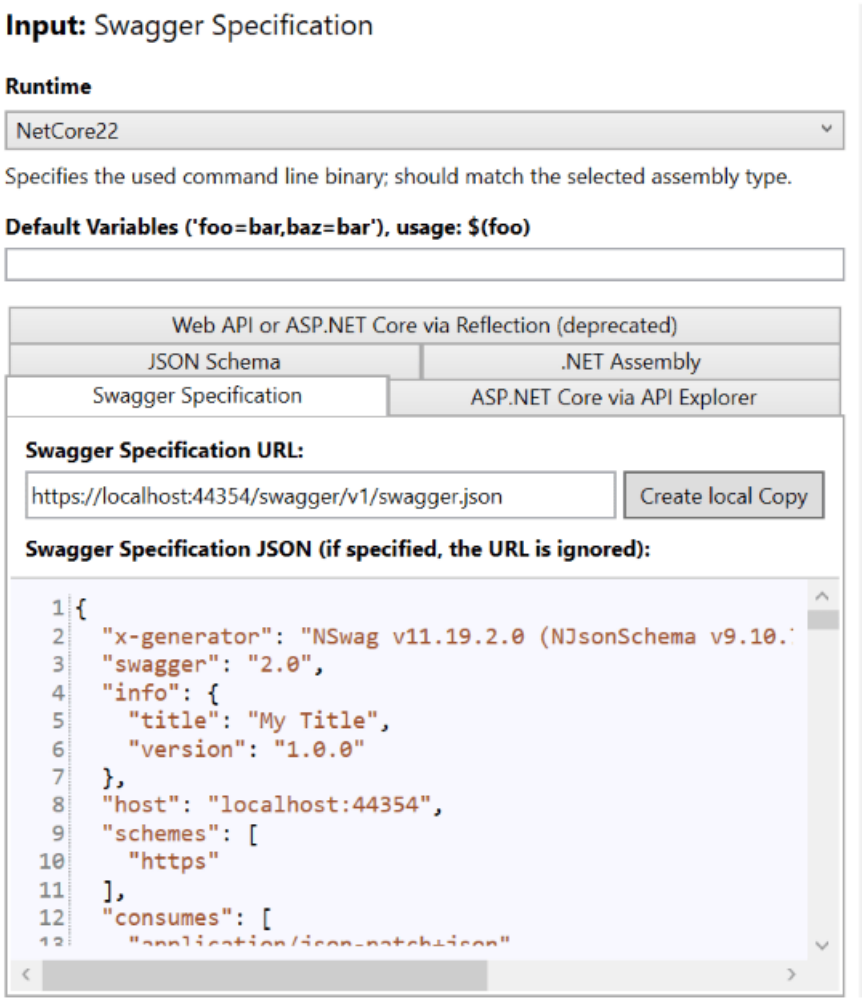
Code generation

You can take advantage of NSwag's code generation capabilities by choosing one of the following options:

- NSwagStudio: A Windows desktop app for generating API client code in C# or TypeScript.
- The NSwag.CodeGeneration.CSharp or NSwag.CodeGeneration.TypeScript NuGet packages for code generation inside your project.
- NSwag from the command line.
- The NSwag.MSBuild NuGet package.
- The Unchase OpenAPI (Swagger) Connected Service: A Visual Studio Connected Service for generating API client code in C# or TypeScript. Also generates C# controllers for OpenAPI services with NSwag.

Generate code with NSwagStudio

- Install NSwagStudio by following the instructions at the NSwagStudio GitHub repository. On the NSwag release page you can download an xcopy version which can be started without installation and admin privileges.
- Launch NSwagStudio and enter the *swagger.json* file URL in the **Swagger Specification URL** text box. For example, *http://localhost:44354/swagger/v1/swagger.json*.
- Click the **Create local Copy** button to generate a JSON representation of your Swagger specification.



- In the **Outputs** area, click the **CSharp Client** check box. Depending on your project, you can also choose **TypeScript Client** or **CSharp Web API Controller**. If you select **CSharp Web API Controller**, a service specification rebuilds the service, serving as a reverse generation.
- Click **Generate Outputs** to produce a complete C# client implementation of the *TodoApi.NSwag* project. To see the generated client code, click the **CSharp Client** tab:

```
//----------------------
// <auto-generated>
//     Generated using the NSwag toolchain v12.0.9.0 (NJsonSchema v9.13.10.0 (Newtonsoft.Json v11.0.0.0))
(http://NSwag.org)
// </auto-generated>
//----------------------

namespace MyNamespace
{
    #pragma warning disable

    [System.CodeDom.Compiler.GeneratedCode("NSwag", "12.0.9.0 (NJsonSchema v9.13.10.0 (Newtonsoft.Json
v11.0.0.0))")]
    public partial class TodoClient
    {
        private string _baseUrl = "https://localhost:44354";
        private System.Net.Http.HttpClient _httpClient;
        private System.Lazy<Newtonsoft.Json.JsonSerializerSettings> _settings;

        public TodoClient(System.Net.Http.HttpClient httpClient)
        {
            _httpClient = httpClient;
            _settings = new System.Lazy<Newtonsoft.Json.JsonSerializerSettings>(() =>
            {
                var settings = new Newtonsoft.Json.JsonSerializerSettings();
                UpdateJsonSerializerSettings(settings);
                return settings;
            });
        }

        public string BaseUrl
        {
            get { return _baseUrl; }
            set { _baseUrl = value; }
        }

        // code omitted for brevity
```

TIP

The C# client code is generated based on selections in the **Settings** tab. Modify the settings to perform tasks such as default namespace renaming and synchronous method generation.

- Copy the generated C# code into a file in the client project that will consume the API.
- Start consuming the web API:

```
 var todoClient = new TodoClient();

// Gets all to-dos from the API
 var allTodos = await todoClient.GetAllAsync();

 // Create a new TodoItem, and save it via the API.
var createdTodo = await todoClient.CreateAsync(new TodoItem());

// Get a single to-do by ID
var foundTodo = await todoClient.GetByIdAsync(1);
```

Customize API documentation

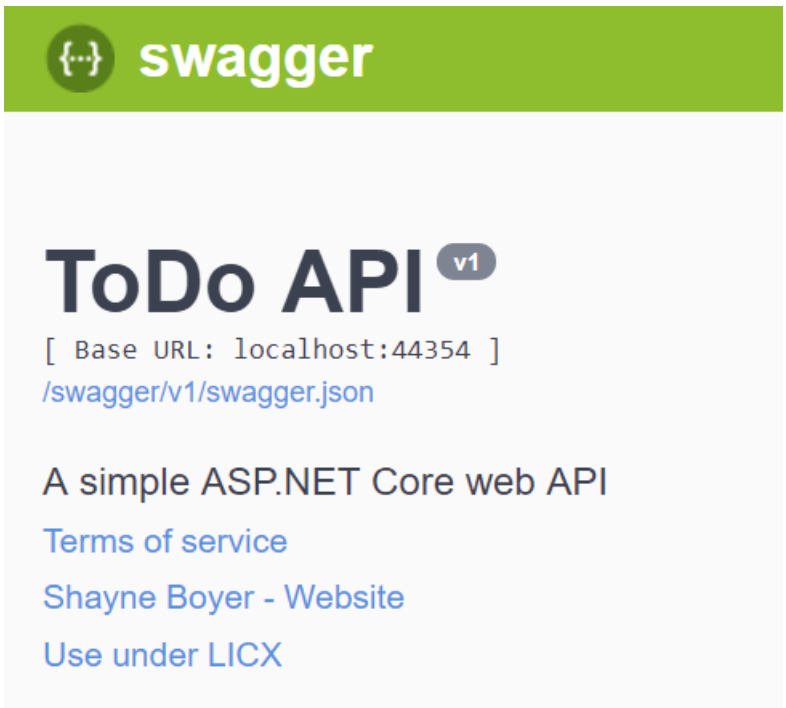
Swagger provides options for documenting the object model to ease consumption of the web API.

API info and description

In the `Startup.ConfigureServices` method, a configuration action passed to the `AddSwaggerDocument` method adds information such as the author, license, and description:

```
services.AddSwaggerDocument(config =>
{
    config.PostProcess = document =>
    {
        document.Info.Version = "v1";
        document.Info.Title = "ToDo API";
        document.Info.Description = "A simple ASP.NET Core web API";
        document.Info.TermsOfService = "None";
        document.Info.Contact = new NSwag.OpenApiContact
        {
            Name = "Shayne Boyer",
            Email = string.Empty,
            Url = "https://twitter.com/spboyer"
        };
        document.Info.License = new NSwag.OpenApiLicense
        {
            Name = "Use under LICX",
            Url = "https://example.com/license"
        };
    };
});
```

The Swagger UI displays the version's information:



XML comments

To enable XML comments, perform the following steps:

- Visual Studio
- Visual Studio for Mac
- .NET Core CLI

- Right-click the project in **Solution Explorer** and select **Edit <project_name>.csproj**.
- Manually add the highlighted lines to the *.csproj* file:

```
<PropertyGroup>
  <GenerateDocumentationFile>true</GenerateDocumentationFile>
  <NoWarn>$(NoWarn);1591</NoWarn>
</PropertyGroup>
```

- Right-click the project in **Solution Explorer** and select **Properties**
- Check the **XML documentation file** box under the **Output** section of the **Build** tab

Data annotations

Because NSwag uses Reflection, and the recommended return type for web API actions is IActionResult, it can't infer what your action is doing and what it returns.

Consider the following example:

```
[HttpPost]
public IActionResult Create([FromBody] TodoItem item)
{
    if (item == null)
    {
        return BadRequest();
    }

    _context.TodoItems.Add(item);
    _context.SaveChanges();

    return CreatedAtRoute("GetTodo", new { id = item.Id }, item);
}
```

The preceding action returns `IActionResult`, but inside the action it's returning either CreatedAtRoute or BadRequest. Use data annotations to tell clients which HTTP status codes this action is known to return. Mark the action with the following attributes:

```
[ProducesResponseType(typeof(TodoItem), StatusCodes.Status201Created)]  // Created
[ProducesResponseType(StatusCodes.Status400BadRequest)]                 // BadRequest
```

Because NSwag uses Reflection, and the recommended return type for web API actions is ActionResult<T>, it can only infer the return type defined by `T`. You can't automatically infer other possible return types.

Consider the following example:

```
[HttpPost]
public ActionResult<TodoItem> Create(TodoItem item)
{
    _context.TodoItems.Add(item);
    _context.SaveChanges();

    return CreatedAtRoute("GetTodo", new { id = item.Id }, item);
}
```

The preceding action returns `ActionResult<T>`. Inside the action, it's returning CreatedAtRoute. Since the controller has the `[ApiController]` attribute, a BadRequest response is possible, too. For more information, see Automatic HTTP 400 responses. Use data annotations to tell clients which HTTP status codes this action is known to return. Mark the action with the following attributes:

```
[ProducesResponseType(StatusCodes.Status201Created)]     // Created
[ProducesResponseType(StatusCodes.Status400BadRequest)]  // BadRequest
```

In ASP.NET Core 2.2 or later, you can use conventions instead of explicitly decorating individual actions with `[ProducesResponseType]`. For more information, see Use web API conventions.

The Swagger generator can now accurately describe this action, and generated clients know what they receive when calling the endpoint. As a recommendation, mark all actions with these attributes.

For guidelines on what HTTP responses your API actions should return, see the RFC 7231 specification.

Develop ASP.NET Core apps using OpenAPI tools

9/22/2020 • 2 minutes to read • Edit Online

By Ryan Brandenburg

Microsoft.dotnet-openapi is a .NET Core Global Tool for managing OpenAPI references within a project.

Installation

To install `Microsoft.dotnet-openapi`, run the following command:

```
dotnet tool install -g Microsoft.dotnet-openapi
```

Add

Adding an OpenAPI reference using any of the commands on this page adds an `<OpenApiReference />` element similar to the following to the *.csproj* file:

```
<OpenApiReference Include="openapi.json" />
```

The preceding reference is required for the app to call the generated client code.

Add File

Options

SHORT OPTION	LONG OPTION	DESCRIPTION	EXAMPLE
-p	--updateProject	The project to operate on.	dotnet openapi add file --*updateProject* .*Ref.csproj* .\OpenAPI.json
-c	--code-generator	The code generator to apply to the reference. Options are `NSwagCSharp` and `NSwagTypeScript`. If `--code-generator` is not specified the tooling defaults to `NSwagCSharp`.	dotnet openapi add file .\OpenApi.json --code-generator
-h	--help	Show help information	dotnet openapi add file --help

Arguments

ARGUMENT	DESCRIPTION	EXAMPLE
source-file	The source to create a reference from. Must be an OpenAPI file.	dotnet openapi add file .*OpenAPI.json*

Add URL

Options

SHORT OPTION	LONG OPTION	DESCRIPTION	EXAMPLE
-p	--updateProject	The project to operate on.	dotnet openapi add url --*updateProject .\Ref.csproj* `https://contoso.com/openapi.json`
-o	--output-file	Where to place the local copy of the OpenAPI file.	dotnet openapi add url `https://contoso.com/openapi.json` *--output-file myclient.json*
-c	--code-generator	The code generator to apply to the reference. Options are `NSwagCSharp` and `NSwagTypeScript`.	dotnet openapi add file .\OpenApi.json --code-generator
-h	--help	Show help information	dotnet openapi add url --help

Arguments

ARGUMENT	DESCRIPTION	EXAMPLE
source-URL	The source to create a reference from. Must be a URL.	dotnet openapi add url `https://contoso.com/openapi.json`

Remove

Removes the OpenAPI reference matching the given filename from the *.csproj* file. When the OpenAPI reference is removed, clients won't be generated. Local *.json* and *.yaml* files are deleted.

Options

SHORT OPTION	LONG OPTION	DESCRIPTION	EXAMPLE
-p	--updateProject	The project to operate on.	dotnet openapi remove --*updateProject .\Ref.csproj* .\OpenAPI.json
-h	--help	Show help information	dotnet openapi remove --help

Arguments

ARGUMENT	DESCRIPTION	EXAMPLE
source-file	The source to remove the reference to.	dotnet openapi remove *.\OpenAPI.json*

Refresh

Refreshes the local version of a file that was downloaded using the latest content from the download URL.

Options

SHORT OPTION	LONG OPTION	DESCRIPTION	EXAMPLE

SHORT OPTION	LONG OPTION	DESCRIPTION	EXAMPLE
-p	--updateProject	The project to operate on.	dotnet openapi refresh --*updateProject .\Ref.csproj* `https://contoso.com/openapi.json`
-h	--help	Show help information	dotnet openapi refresh --help

Arguments

ARGUMENT	DESCRIPTION	EXAMPLE
source-URL	The URL to refresh the reference from.	dotnet openapi refresh `https://contoso.com/openapi.json`

Controller action return types in ASP.NET Core web API

9/22/2020 • 6 minutes to read • Edit Online

By Scott Addie

View or download sample code (how to download)

ASP.NET Core offers the following options for web API controller action return types:

- Specific type
- IActionResult
- ActionResult<T>

- Specific type
- IActionResult

This document explains when it's most appropriate to use each return type.

Specific type

The simplest action returns a primitive or complex data type (for example, `string` or a custom object type). Consider the following action, which returns a collection of custom `Product` objects:

```
[HttpGet]
public List<Product> Get() =>
    _repository.GetProducts();
```

Without known conditions to safeguard against during action execution, returning a specific type could suffice. The preceding action accepts no parameters, so parameter constraints validation isn't needed.

When multiple return types are possible, it's common to mix an ActionResult return type with the primitive or complex return type. Either IActionResult or ActionResult<T> are necessary to accommodate this type of action. Several samples of multiple return types are provided in this document.

Return IEnumerable<T> or IAsyncEnumerable<T>

In ASP.NET Core 2.2 and earlier, returning IEnumerable<T> from an action results in synchronous collection iteration by the serializer. The result is the blocking of calls and a potential for thread pool starvation. To illustrate, imagine that Entity Framework (EF) Core is being used for the web API's data access needs. The following action's return type is synchronously enumerated during serialization:

```
public IEnumerable<Product> GetOnSaleProducts() =>
    _context.Products.Where(p => p.IsOnSale);
```

To avoid synchronous enumeration and blocking waits on the database in ASP.NET Core 2.2 and earlier, invoke `ToListAsync`:

```
public async Task<IEnumerable<Product>> GetOnSaleProducts() =>
    await _context.Products.Where(p => p.IsOnSale).ToListAsync();
```

In ASP.NET Core 3.0 and later, returning `IAsyncEnumerable<T>` from an action:

- No longer results in synchronous iteration.
- Becomes as efficient as returning IEnumerable<T>.

ASP.NET Core 3.0 and later buffers the result of the following action before providing it to the serializer:

```
public IEnumerable<Product> GetOnSaleProducts() =>
    _context.Products.Where(p => p.IsOnSale);
```

Consider declaring the action signature's return type as `IAsyncEnumerable<T>` to guarantee the asynchronous iteration. Ultimately, the iteration mode is based on the underlying concrete type being returned. MVC automatically buffers any concrete type that implements `IAsyncEnumerable<T>`.

Consider the following action, which returns sale-priced product records as `IEnumerable<Product>`:

```
[HttpGet("syncsale")]
public IEnumerable<Product> GetOnSaleProducts()
{
    var products = _repository.GetProducts();

    foreach (var product in products)
    {
        if (product.IsOnSale)
        {
            yield return product;
        }
    }
}
```

The `IAsyncEnumerable<Product>` equivalent of the preceding action is:

```
[HttpGet("asyncsale")]
public async IAsyncEnumerable<Product> GetOnSaleProductsAsync()
{
    var products = _repository.GetProductsAsync();

    await foreach (var product in products)
    {
        if (product.IsOnSale)
        {
            yield return product;
        }
    }
}
```

Both of the preceding actions are non-blocking as of ASP.NET Core 3.0.

IActionResult type

The IActionResult return type is appropriate when multiple `ActionResult` return types are possible in an action. The `ActionResult` types represent various HTTP status codes. Any non-abstract class deriving from `ActionResult` qualifies as a valid return type. Some common return types in this category are BadRequestResult (400), NotFoundResult (404), and OkObjectResult (200). Alternatively, convenience methods in the ControllerBase class can be used to return `ActionResult` types from an action. For example, `return BadRequest();` is a shorthand form of `return new BadRequestResult();`.

Because there are multiple return types and paths in this type of action, liberal use of the `[ProducesResponseType]`

attribute is necessary. This attribute produces more descriptive response details for web API help pages generated by tools like Swagger. `[ProducesResponseType]` indicates the known types and HTTP status codes to be returned by the action.

Synchronous action

Consider the following synchronous action in which there are two possible return types:

```
[HttpGet("{id}")]
[ProducesResponseType(StatusCodes.Status200OK)]
[ProducesResponseType(StatusCodes.Status404NotFound)]
public IActionResult GetById(int id)
{
    if (!_repository.TryGetProduct(id, out var product))
    {
        return NotFound();
    }

    return Ok(product);
}
```

```
[HttpGet("{id}")]
[ProducesResponseType(typeof(Product), StatusCodes.Status200OK)]
[ProducesResponseType(StatusCodes.Status404NotFound)]
public IActionResult GetById(int id)
{
    if (!_repository.TryGetProduct(id, out var product))
    {
        return NotFound();
    }

    return Ok(product);
}
```

In the preceding action:

- A 404 status code is returned when the product represented by `id` doesn't exist in the underlying data store. The NotFound convenience method is invoked as shorthand for `return new NotFoundResult();`.
- A 200 status code is returned with the `Product` object when the product does exist. The Ok convenience method is invoked as shorthand for `return new OkObjectResult(product);`.

Asynchronous action

Consider the following asynchronous action in which there are two possible return types:

```
[HttpPost]
[Consumes(MediaTypeNames.Application.Json)]
[ProducesResponseType(StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public async Task<IActionResult> CreateAsync(Product product)
{
    if (product.Description.Contains("XYZ Widget"))
    {
        return BadRequest();
    }

    await _repository.AddProductAsync(product);

    return CreatedAtAction(nameof(GetById), new { id = product.Id }, product);
}
```

```
[HttpPost]
[Consumes("application/json")]
[ProducesResponseType(typeof(Product), StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public async Task<IActionResult> CreateAsync([FromBody] Product product)
{
    if (product.Description.Contains("XYZ Widget"))
    {
        return BadRequest();
    }

    await _repository.AddProductAsync(product);

    return CreatedAtAction(nameof(GetById), new { id = product.Id }, product);
}
```

In the preceding action:

- A 400 status code is returned when the product description contains "XYZ Widget". The BadRequest convenience method is invoked as shorthand for `return new BadRequestResult();`.
- A 201 status code is generated by the CreatedAtAction convenience method when a product is created. An alternative to calling `CreatedAtAction` is `return new CreatedAtActionResult(nameof(GetById), "Products", new { id = product.Id }, product);`. In this code path, the `Product` object is provided in the response body. A `Location` response header containing the newly created product's URL is provided.

For example, the following model indicates that requests must include the `Name` and `Description` properties. Failure to provide `Name` and `Description` in the request causes model validation to fail.

```
public class Product
{
    public int Id { get; set; }

    [Required]
    public string Name { get; set; }

    [Required]
    public string Description { get; set; }
}
```

If the `[ApiController]` attribute in ASP.NET Core 2.1 or later is applied, model validation errors result in a 400 status code. For more information, see Automatic HTTP 400 responses.

ActionResult<T> type

ASP.NET Core 2.1 introduced the ActionResult<T> return type for web API controller actions. It enables you to return a type deriving from ActionResult or return a specific type. `ActionResult<T>` offers the following benefits over the IActionResult type:

- The `[ProducesResponseType]` attribute's `Type` property can be excluded. For example, `[ProducesResponseType(200, Type = typeof(Product))]` is simplified to `[ProducesResponseType(200)]`. The action's expected return type is instead inferred from the `T` in `ActionResult<T>`.
- Implicit cast operators support the conversion of both `T` and `ActionResult` to `ActionResult<T>`. `T` converts to ObjectResult, which means `return new ObjectResult(T);` is simplified to `return T;`.

C# doesn't support implicit cast operators on interfaces. Consequently, conversion of the interface to a concrete type is necessary to use `ActionResult<T>`. For example, use of `IEnumerable` in the following example doesn't

work:

```
[HttpGet]
public ActionResult<IEnumerable<Product>> Get() =>
    _repository.GetProducts();
```

One option to fix the preceding code is to return `_repository.GetProducts().ToList();`.

Most actions have a specific return type. Unexpected conditions can occur during action execution, in which case the specific type isn't returned. For example, an action's input parameter may fail model validation. In such a case, it's common to return the appropriate `ActionResult` type instead of the specific type.

Synchronous action

Consider a synchronous action in which there are two possible return types:

```
[HttpGet("{id}")]
[ProducesResponseType(StatusCodes.Status200OK)]
[ProducesResponseType(StatusCodes.Status404NotFound)]
public ActionResult<Product> GetById(int id)
{
    if (!_repository.TryGetProduct(id, out var product))
    {
        return NotFound();
    }

    return product;
}
```

In the preceding action:

- A 404 status code is returned when the product doesn't exist in the database.
- A 200 status code is returned with the corresponding `Product` object when the product does exist. Before ASP.NET Core 2.1, the `return product;` line had to be `return Ok(product);`.

Asynchronous action

Consider an asynchronous action in which there are two possible return types:

```
[HttpPost]
[Consumes(MediaTypeNames.Application.Json)]
[ProducesResponseType(StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public async Task<ActionResult<Product>> CreateAsync(Product product)
{
    if (product.Description.Contains("XYZ Widget"))
    {
        return BadRequest();
    }

    await _repository.AddProductAsync(product);

    return CreatedAtAction(nameof(GetById), new { id = product.Id }, product);
}
```

In the preceding action:

- A 400 status code (BadRequest) is returned by the ASP.NET Core runtime when:
  - The `[ApiController]` attribute has been applied and model validation fails.
  - The product description contains "XYZ Widget".

- A 201 status code is generated by the CreatedAtAction method when a product is created. In this code path, the `Product` object is provided in the response body. A `Location` response header containing the newly created product's URL is provided.

JsonPatch in ASP.NET Core web API

9/22/2020 • 13 minutes to read • Edit Online

By Tom Dykstra and Kirk Larkin

This article explains how to handle JSON Patch requests in an ASP.NET Core web API.

Package installation

To enable JSON Patch support in your app, complete the following steps:

1. Install the `Microsoft.AspNetCore.Mvc.NewtonsoftJson` NuGet package.
2. Update the project's `Startup.ConfigureServices` method to call AddNewtonsoftJson. For example:

```
services
    .AddControllersWithViews()
    .AddNewtonsoftJson();
```

`AddNewtonsoftJson` is compatible with the MVC service registration methods:

- AddRazorPages
- AddControllersWithViews
- AddControllers

JSON Patch, AddNewtonsoftJson, and System.Text.Json

`AddNewtonsoftJson` replaces the `System.Text.Json`-based input and output formatters used for formatting **all** JSON content. To add support for JSON Patch using `Newtonsoft.Json`, while leaving the other formatters unchanged, update the project's `Startup.ConfigureServices` method as follows:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews(options =>
    {
        options.InputFormatters.Insert(0, GetJsonPatchInputFormatter());
    });
}

private static NewtonsoftJsonPatchInputFormatter GetJsonPatchInputFormatter()
{
    var builder = new ServiceCollection()
        .AddLogging()
        .AddMvc()
        .AddNewtonsoftJson()
        .Services.BuildServiceProvider();

    return builder
        .GetRequiredService<IOptions<MvcOptions>>()
        .Value
        .InputFormatters
        .OfType<NewtonsoftJsonPatchInputFormatter>()
        .First();
}
```

The preceding code requires the `Microsoft.AspNetCore.Mvc.NewtonsoftJson` package and the following `using` statements:

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.Formatters;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Options;
using System.Linq;
```

PATCH HTTP request method

The PUT and PATCH methods are used to update an existing resource. The difference between them is that PUT replaces the entire resource, while PATCH specifies only the changes.

JSON Patch

JSON Patch is a format for specifying updates to be applied to a resource. A JSON Patch document has an array of *operations*. Each operation identifies a particular type of change. Examples of such changes include adding an array element or replacing a property value.

For example, the following JSON documents represent a resource, a JSON Patch document for the resource, and the result of applying the Patch operations.

Resource example

```
{
  "customerName": "John",
  "orders": [
    {
      "orderName": "Order0",
      "orderType": null
    },
    {
      "orderName": "Order1",
      "orderType": null
    }
  ]
}
```

JSON patch example

```
[
  {
    "op": "add",
    "path": "/customerName",
    "value": "Barry"
  },
  {
    "op": "add",
    "path": "/orders/-",
    "value": {
      "orderName": "Order2",
      "orderType": null
    }
  }
]
```

In the preceding JSON:

- The `op` property indicates the type of operation.
- The `path` property indicates the element to update.
- The `value` property provides the new value.

Resource after patch

Here's the resource after applying the preceding JSON Patch document:

```
{
  "customerName": "Barry",
  "orders": [
    {
      "orderName": "Order0",
      "orderType": null
    },
    {
      "orderName": "Order1",
      "orderType": null
    },
    {
      "orderName": "Order2",
      "orderType": null
    }
  ]
}
```

The changes made by applying a JSON Patch document to a resource are atomic. If any operation in the list fails, no operation in the list is applied.

Path syntax

The path property of an operation object has slashes between levels. For example, `"/address/zipCode"`.

Zero-based indexes are used to specify array elements. The first element of the `addresses` array would be at `/addresses/0`. To `add` to the end of an array, use a hyphen (`-`) rather than an index number: `/addresses/-`.

Operations

The following table shows supported operations as defined in the JSON Patch specification:

OPERATION	NOTES

OPERATION	NOTES
`add`	Add a property or array element. For existing property: set value.
`remove`	Remove a property or array element.
`replace`	Same as `remove` followed by `add` at same location.
`move`	Same as `remove` from source followed by `add` to destination using value from source.
`copy`	Same as `add` to destination using value from source.
`test`	Return success status code if value at `path` = provided `value`.

JSON Patch in ASP.NET Core

The ASP.NET Core implementation of JSON Patch is provided in the Microsoft.AspNetCore.JsonPatch NuGet package.

Action method code

In an API controller, an action method for JSON Patch:

- Is annotated with the `HttpPatch` attribute.
- Accepts a `JsonPatchDocument<T>`, typically with `[FromBody]`.
- Calls `ApplyTo` on the patch document to apply the changes.

Here's an example:

```
[HttpPatch]
public IActionResult JsonPatchWithModelState(
    [FromBody] JsonPatchDocument<Customer> patchDoc)
{
    if (patchDoc != null)
    {
        var customer = CreateCustomer();

        patchDoc.ApplyTo(customer, ModelState);

        if (!ModelState.IsValid)
        {
            return BadRequest(ModelState);
        }

        return new ObjectResult(customer);
    }
    else
    {
        return BadRequest(ModelState);
    }
}
```

This code from the sample app works with the following `Customer` model:

```
public class Customer
{
    public string CustomerName { get; set; }
    public List<Order> Orders { get; set; }
}
```

```
public class Order
{
    public string OrderName { get; set; }
    public string OrderType { get; set; }
}
```

The sample action method:

- Constructs a `Customer`.
- Applies the patch.
- Returns the result in the body of the response.

In a real app, the code would retrieve the data from a store such as a database and update the database after applying the patch.

Model state

The preceding action method example calls an overload of `ApplyTo` that takes model state as one of its parameters. With this option, you can get error messages in responses. The following example shows the body of a 400 Bad Request response for a `test` operation:

```
{
    "Customer": [
        "The current value 'John' at path 'customerName' is not equal to the test value 'Nancy'."
    ]
}
```

Dynamic objects

The following action method example shows how to apply a patch to a dynamic object:

```
[HttpPatch]
public IActionResult JsonPatchForDynamic([FromBody]JsonPatchDocument patch)
{
    dynamic obj = new ExpandoObject();
    patch.ApplyTo(obj);

    return Ok(obj);
}
```

The add operation

- If `path` points to an array element: inserts new element before the one specified by `path`.
- If `path` points to a property: sets the property value.
- If `path` points to a nonexistent location:
  - If the resource to patch is a dynamic object: adds a property.
  - If the resource to patch is a static object: the request fails.

The following sample patch document sets the value of `CustomerName` and adds an `Order` object to the end of the `Orders` array.

```
[
  {
    "op": "add",
    "path": "/customerName",
    "value": "Barry"
  },
  {
    "op": "add",
    "path": "/orders/-",
    "value": {
      "orderName": "Order2",
      "orderType": null
    }
  }
]
```

The remove operation

- If `path` points to an array element: removes the element.
- If `path` points to a property:
  - If resource to patch is a dynamic object: removes the property.
  - If resource to patch is a static object:
    - If the property is nullable: sets it to null.
    - If the property is non-nullable, sets it to `default<T>`.

The following sample patch document sets `CustomerName` to null and deletes `Orders[0]`:

```
[
  {
    "op": "remove",
    "path": "/customerName"
  },
  {
    "op": "remove",
    "path": "/orders/0"
  }
]
```

The replace operation

This operation is functionally the same as a `remove` followed by an `add`.

The following sample patch document sets the value of `CustomerName` and replaces `Orders[0]` with a new `Order` object:

```
[
  {
    "op": "replace",
    "path": "/customerName",
    "value": "Barry"
  },
  {
    "op": "replace",
    "path": "/orders/0",
    "value": {
      "orderName": "Order2",
      "orderType": null
    }
  }
]
```

The move operation

- If `path` points to an array element: copies `from` element to location of `path` element, then runs a `remove` operation on the `from` element.
- If `path` points to a property: copies value of `from` property to `path` property, then runs a `remove` operation on the `from` property.
- If `path` points to a nonexistent property:
  - If the resource to patch is a static object: the request fails.
  - If the resource to patch is a dynamic object: copies `from` property to location indicated by `path`, then runs a `remove` operation on the `from` property.

The following sample patch document:

- Copies the value of `Orders[0].OrderName` to `CustomerName`.
- Sets `Orders[0].OrderName` to null.
- Moves `Orders[1]` to before `Orders[0]`.

```
[
  {
    "op": "move",
    "from": "/orders/0/orderName",
    "path": "/customerName"
  },
  {
    "op": "move",
    "from": "/orders/1",
    "path": "/orders/0"
  }
]
```

The copy operation

This operation is functionally the same as a `move` operation without the final `remove` step.

The following sample patch document:

- Copies the value of `Orders[0].OrderName` to `CustomerName`.
- Inserts a copy of `Orders[1]` before `Orders[0]`.

```
[
  {
    "op": "copy",
    "from": "/orders/0/orderName",
    "path": "/customerName"
  },
  {
    "op": "copy",
    "from": "/orders/1",
    "path": "/orders/0"
  }
]
```

The test operation

If the value at the location indicated by `path` is different from the value provided in `value`, the request fails. In that case, the whole PATCH request fails even if all other operations in the patch document would otherwise succeed.

The `test` operation is commonly used to prevent an update when there's a concurrency conflict.

The following sample patch document has no effect if the initial value of `CustomerName` is "John", because the test fails:

```
[
  {
    "op": "test",
    "path": "/customerName",
    "value": "Nancy"
  },
  {
    "op": "add",
    "path": "/customerName",
    "value": "Barry"
  }
]
```

Get the code

View or download sample code. (How to download).

To test the sample, run the app and send HTTP requests with the following settings:

- URL: `http://localhost:{port}/jsonpatch/jsonpatchwithmodelstate`
- HTTP method: `PATCH`
- Header: `Content-Type: application/json-patch+json`
- Body: Copy and paste one of the JSON patch document samples from the *JSON* project folder.

This article explains how to handle JSON Patch requests in an ASP.NET Core web API.

PATCH HTTP request method

The PUT and PATCH methods are used to update an existing resource. The difference between them is that PUT replaces the entire resource, while PATCH specifies only the changes.

JSON Patch

JSON Patch is a format for specifying updates to be applied to a resource. A JSON Patch document has an array of *operations*. Each operation identifies a particular type of change, such as add an array element or replace a property value.

For example, the following JSON documents represent a resource, a JSON patch document for the resource, and the result of applying the patch operations.

Resource example

```
{
  "customerName": "John",
  "orders": [
    {
      "orderName": "Order0",
      "orderType": null
    },
    {
      "orderName": "Order1",
      "orderType": null
    }
  ]
}
```

JSON patch example

```
[
  {
    "op": "add",
    "path": "/customerName",
    "value": "Barry"
  },
  {
    "op": "add",
    "path": "/orders/-",
    "value": {
      "orderName": "Order2",
      "orderType": null
    }
  }
]
```

In the preceding JSON:

- The `op` property indicates the type of operation.
- The `path` property indicates the element to update.
- The `value` property provides the new value.

Resource after patch

Here's the resource after applying the preceding JSON Patch document:

```
{
  "customerName": "Barry",
  "orders": [
    {
      "orderName": "Order0",
      "orderType": null
    },
    {
      "orderName": "Order1",
      "orderType": null
    },
    {
      "orderName": "Order2",
      "orderType": null
    }
  ]
}
```

The changes made by applying a JSON Patch document to a resource are atomic: if any operation in the list fails, no operation in the list is applied.

Path syntax

The path property of an operation object has slashes between levels. For example, `"/address/zipCode"`.

Zero-based indexes are used to specify array elements. The first element of the `addresses` array would be at `/addresses/0`. To `add` to the end of an array, use a hyphen (-) rather than an index number: `/addresses/-`.

Operations

The following table shows supported operations as defined in the JSON Patch specification:

OPERATION	NOTES
`add`	Add a property or array element. For existing property: set value.
`remove`	Remove a property or array element.
`replace`	Same as `remove` followed by `add` at same location.
`move`	Same as `remove` from source followed by `add` to destination using value from source.
`copy`	Same as `add` to destination using value from source.
`test`	Return success status code if value at `path` = provided `value`.

JsonPatch in ASP.NET Core

The ASP.NET Core implementation of JSON Patch is provided in the Microsoft.AspNetCore.JsonPatch NuGet package. The package is included in the Microsoft.AspnetCore.App metapackage.

Action method code

In an API controller, an action method for JSON Patch:

- Is annotated with the `HttpPatch` attribute.
- Accepts a `JsonPatchDocument<T>`, typically with `[FromBody]`.
- Calls `ApplyTo` on the patch document to apply the changes.

Here's an example:

```
[HttpPatch]
public IActionResult JsonPatchWithModelState(
    [FromBody] JsonPatchDocument<Customer> patchDoc)
{
    if (patchDoc != null)
    {
        var customer = CreateCustomer();

        patchDoc.ApplyTo(customer, ModelState);

        if (!ModelState.IsValid)
        {
            return BadRequest(ModelState);
        }

        return new ObjectResult(customer);
    }
    else
    {
        return BadRequest(ModelState);
    }
}
```

This code from the sample app works with the following `Customer` model.

```
public class Customer
{
    public string CustomerName { get; set; }
    public List<Order> Orders { get; set; }
}
```

```
public class Order
{
    public string OrderName { get; set; }
    public string OrderType { get; set; }
}
```

The sample action method:

- Constructs a `Customer`.
- Applies the patch.
- Returns the result in the body of the response.

In a real app, the code would retrieve the data from a store such as a database and update the database after applying the patch.

Model state

The preceding action method example calls an overload of `ApplyTo` that takes model state as one of its parameters. With this option, you can get error messages in responses. The following example shows the body of a 400 Bad Request response for a `test` operation:

```
{
    "Customer": [
        "The current value 'John' at path 'customerName' is not equal to the test value 'Nancy'."
    ]
}
```

Dynamic objects

The following action method example shows how to apply a patch to a dynamic object.

```
[HttpPatch]
public IActionResult JsonPatchForDynamic([FromBody]JsonPatchDocument patch)
{
    dynamic obj = new ExpandoObject();
    patch.ApplyTo(obj);

    return Ok(obj);
}
```

The add operation

- If `path` points to an array element: inserts new element before the one specified by `path`.
- If `path` points to a property: sets the property value.
- If `path` points to a nonexistent location:
  - If the resource to patch is a dynamic object: adds a property.
  - If the resource to patch is a static object: the request fails.

The following sample patch document sets the value of `CustomerName` and adds an `Order` object to the end of the `Orders` array.

```
[
  {
    "op": "add",
    "path": "/customerName",
    "value": "Barry"
  },
  {
    "op": "add",
    "path": "/orders/-",
    "value": {
      "orderName": "Order2",
      "orderType": null
    }
  }
]
```

The remove operation

- If `path` points to an array element: removes the element.
- If `path` points to a property:
  - If resource to patch is a dynamic object: removes the property.
  - If resource to patch is a static object:
    - If the property is nullable: sets it to null.
    - If the property is non-nullable, sets it to `default<T>`.

The following sample patch document sets `CustomerName` to null and deletes `Orders[0]`.

```
[
  {
    "op": "remove",
    "path": "/customerName"
  },
  {
    "op": "remove",
    "path": "/orders/0"
  }
]
```

The replace operation

This operation is functionally the same as a `remove` followed by an `add`.

The following sample patch document sets the value of `CustomerName` and replaces `Orders[0]` with a new `Order` object.

```
[
  {
    "op": "replace",
    "path": "/customerName",
    "value": "Barry"
  },
  {
    "op": "replace",
    "path": "/orders/0",
    "value": {
      "orderName": "Order2",
      "orderType": null
    }
  }
]
```

The move operation

- If `path` points to an array element: copies `from` element to location of `path` element, then runs a `remove` operation on the `from` element.
- If `path` points to a property: copies value of `from` property to `path` property, then runs a `remove` operation on the `from` property.
- If `path` points to a nonexistent property:
  - If the resource to patch is a static object: the request fails.
  - If the resource to patch is a dynamic object: copies `from` property to location indicated by `path`, then runs a `remove` operation on the `from` property.

The following sample patch document:

- Copies the value of `Orders[0].OrderName` to `CustomerName`.
- Sets `Orders[0].OrderName` to null.
- Moves `Orders[1]` to before `Orders[0]`.

```
[
  {
    "op": "move",
    "from": "/orders/0/orderName",
    "path": "/customerName"
  },
  {
    "op": "move",
    "from": "/orders/1",
    "path": "/orders/0"
  }
]
```

The copy operation

This operation is functionally the same as a `move` operation without the final `remove` step.

The following sample patch document:

- Copies the value of `Orders[0].OrderName` to `CustomerName`.
- Inserts a copy of `Orders[1]` before `Orders[0]`.

```
[
  {
    "op": "copy",
    "from": "/orders/0/orderName",
    "path": "/customerName"
  },
  {
    "op": "copy",
    "from": "/orders/1",
    "path": "/orders/0"
  }
]
```

The test operation

If the value at the location indicated by `path` is different from the value provided in `value`, the request fails. In that case, the whole PATCH request fails even if all other operations in the patch document would otherwise succeed.

The `test` operation is commonly used to prevent an update when there's a concurrency conflict.

The following sample patch document has no effect if the initial value of `CustomerName` is "John", because the test fails:

```
[
  {
    "op": "test",
    "path": "/customerName",
    "value": "Nancy"
  },
  {
    "op": "add",
    "path": "/customerName",
    "value": "Barry"
  }
]
```

Format response data in ASP.NET Core Web API

9/22/2020 • 7 minutes to read • Edit Online

By Rick Anderson and Steve Smith

ASP.NET Core MVC has support for formatting response data. Response data can be formatted using specific formats or in response to client requested format.

View or download sample code (how to download)

Format-specific Action Results

Some action result types are specific to a particular format, such as JsonResult and ContentResult. Actions can return results that are formatted in a particular format, regardless of client preferences. For example, returning `JsonResult` returns JSON-formatted data. Returning `ContentResult` or a string returns plain-text-formatted string data.

An action isn't required to return any specific type. ASP.NET Core supports any object return value. Results from actions that return objects that are not IActionResult types are serialized using the appropriate IOutputFormatter implementation. For more information, see Controller action return types in ASP.NET Core web API.

The built-in helper method Ok returns JSON-formatted data:

```
// GET: api/authors
[HttpGet]
public ActionResult Get()
{
    return Ok(_authors.List());
}
```

The sample download returns the list of authors. Using the F12 browser developer tools or Postman with the previous code:

- The response header containing **content-type:** `application/json; charset=utf-8` is displayed.
- The request headers are displayed. For example, the `Accept` header. The `Accept` header is ignored by the preceding code.

To return plain text formatted data, use ContentResult and the Content helper:

```
// GET api/authors/about
[HttpGet("About")]
public ContentResult About()
{
    return Content("An API listing authors of docs.asp.net.");
}
```

In the preceding code, the `Content-Type` returned is `text/plain`. Returning a string delivers `Content-Type` of `text/plain`:

```
// GET api/authors/version
[HttpGet("version")]
public string Version()
{
    return "Version 1.0.0";
}
```

For actions with multiple return types, return `IActionResult`. For example, returning different HTTP status codes based on the result of operations performed.

Content negotiation

Content negotiation occurs when the client specifies an Accept header. The default format used by ASP.NET Core is JSON. Content negotiation is:

- Implemented by ObjectResult.
- Built into the status code-specific action results returned from the helper methods. The action results helper methods are based on `ObjectResult`.

When a model type is returned, the return type is `ObjectResult`.

The following action method uses the `Ok` and `NotFound` helper methods:

```
// GET: api/authors/search?namelike=th
[HttpGet("Search")]
public IActionResult Search(string namelike)
{
    var result = _authors.GetByNameSubstring(namelike);
    if (!result.Any())
    {
        return NotFound(namelike);
    }
    return Ok(result);
}
```

By default, ASP.NET Core supports `application/json`, `text/json`, and `text/plain` media types. Tools such as Fiddler or Postman can set the `Accept` request header to specify the return format. When the `Accept` header contains a type the server supports, that type is returned. The next section shows how to add additional formatters.

Controller actions can return POCOs (Plain Old CLR Objects). When a POCO is returned, the runtime automatically creates an `ObjectResult` that wraps the object. The client gets the formatted serialized object. If the object being returned is `null`, a `204 No Content` response is returned.

Returning an object type:

```
// GET api/authors/RickAndMSFT
[HttpGet("{alias}")]
public Author Get(string alias)
{
    return _authors.GetByAlias(alias);
}
```

In the preceding code, a request for a valid author alias returns a `200 OK` response with the author's data. A request for an invalid alias returns a `204 No Content` response.

The Accept header

Content *negotiation* takes place when an `Accept` header appears in the request. When a request contains an accept header, ASP.NET Core:

- Enumerates the media types in the accept header in preference order.
- Tries to find a formatter that can produce a response in one of the formats specified.

If no formatter is found that can satisfy the client's request, ASP.NET Core:

- Returns `406 Not Acceptable` if MvcOptions has been set, or -
- Tries to find the first formatter that can produce a response.

If no formatter is configured for the requested format, the first formatter that can format the object is used. If no `Accept` header appears in the request:

- The first formatter that can handle the object is used to serialize the response.
- There isn't any negotiation taking place. The server is determining what format to return.

If the Accept header contains `*/*`, the Header is ignored unless `RespectBrowserAcceptHeader` is set to true on MvcOptions.

Browsers and content negotiation

Unlike typical API clients, web browsers supply `Accept` headers. Web browser specify many formats, including wildcards. By default, when the framework detects that the request is coming from a browser:

- The `Accept` header is ignored.
- The content is returned in JSON, unless otherwise configured.

This provides a more consistent experience across browsers when consuming APIs.

To configure an app to honor browser accept headers, set RespectBrowserAcceptHeader to `true`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllers(options =>
    {
        options.RespectBrowserAcceptHeader = true; // false by default
    });
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc(options =>
    {
        options.RespectBrowserAcceptHeader = true; // false by default
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
}
```

Configure formatters

Apps that need to support additional formats can add the appropriate NuGet packages and configure support. There are separate formatters for input and output. Input formatters are used by Model Binding. Output formatters are used to format responses. For information on creating a custom formatter, see Custom Formatters.

Add XML format support

XML formatters implemented using XmlSerializer are configured by calling AddXmlSerializerFormatters:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllers()
        .AddXmlSerializerFormatters();
}
```

The preceding code serializes results using `XmlSerializer`.

When using the preceding code, controller methods return the appropriate format based on the request's `Accept` header.

Configure System.Text.Json-based formatters

Features for the `System.Text.Json`-based formatters can be configured using `Microsoft.AspNetCore.Mvc.JsonOptions.SerializerOptions`.

```
services.AddControllers().AddJsonOptions(options =>
{
    // Use the default property (Pascal) casing.
    options.JsonSerializerOptions.PropertyNamingPolicy = null;

    // Configure a custom converter.
    options.JsonSerializerOptions.Converters.Add(new MyCustomJsonConverter());
});
```

Output serialization options, on a per-action basis, can be configured using `JsonResult`. For example:

```
public IActionResult Get()
{
    return Json(model, new JsonSerializerOptions
    {
        WriteIndented = true,
    });
}
```

Add Newtonsoft.Json-based JSON format support

Prior to ASP.NET Core 3.0, the default used JSON formatters implemented using the `Newtonsoft.Json` package. In ASP.NET Core 3.0 or later, the default JSON formatters are based on `System.Text.Json`. Support for `Newtonsoft.Json` based formatters and features is available by installing the `Microsoft.AspNetCore.Mvc.NewtonsoftJson` NuGet package and configuring it in `Startup.ConfigureServices`.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllers()
        .AddNewtonsoftJson();
}
```

Some features may not work well with `System.Text.Json`-based formatters and require a reference to the `Newtonsoft.Json`-based formatters. Continue using the `Newtonsoft.Json`-based formatters if the app:

- Uses `Newtonsoft.Json` attributes. For example, `[JsonProperty]` or `[JsonIgnore]`.
- Customizes the serialization settings.
- Relies on features that `Newtonsoft.Json` provides.
- Configures `Microsoft.AspNetCore.Mvc.JsonResult.SerializerSettings`. Prior to ASP.NET Core 3.0, `JsonResult.SerializerSettings` accepts an instance of `JsonSerializerSettings` that is specific to `Newtonsoft.Json`.

- Generates OpenAPI documentation.

Features for the `Newtonsoft.Json`-based formatters can be configured using `Microsoft.AspNetCore.Mvc.MvcNewtonsoftJsonOptions.SerializerSettings`:

```
services.AddControllers().AddNewtonsoftJson(options =>
{
    // Use the default property (Pascal) casing
    options.SerializerSettings.ContractResolver = new DefaultContractResolver();

    // Configure a custom converter
    options.SerializerSettings.Converters.Add(new MyCustomJsonConverter());
});
```

Output serialization options, on a per-action basis, can be configured using `JsonResult`. For example:

```
public IActionResult Get()
{
    return Json(model, new JsonSerializerSettings
    {
        Formatting = Formatting.Indented,
    });
}
```

Add XML format support

XML formatting requires the Microsoft.AspNetCore.Mvc.Formatters.Xml NuGet package.

XML formatters implemented using XmlSerializer are configured by calling AddXmlSerializerFormatters:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc()
        .SetCompatibilityVersion(CompatibilityVersion.Version_2_1)
        .AddXmlSerializerFormatters();
}
```

The preceding code serializes results using `XmlSerializer`.

When using the preceding code, controller methods should return the appropriate format based on the request's `Accept` header.

Specify a format

To restrict the response formats, apply the `[Produces]` filter. Like most Filters, `[Produces]` can be applied at the action, controller, or global scope:

```
[ApiController]
[Route("[controller]")]
[Produces("application/json")]
public class WeatherForecastController : ControllerBase
{
```

The preceding `[Produces]` filter:

- Forces all actions within the controller to return JSON-formatted responses.
- If other formatters are configured and the client specifies a different format, JSON is returned.

For more information, see Filters.

Special case formatters

Some special cases are implemented using built-in formatters. By default, `string` return types are formatted as *text/plain* (*text/html* if requested via the `Accept` header). This behavior can be deleted by removing the StringOutputFormatter. Formatters are removed in the `ConfigureServices` method. Actions that have a model object return type return `204 No Content` when returning `null`. This behavior can be deleted by removing the HttpNoContentOutputFormatter. The following code removes the `StringOutputFormatter` and `HttpNoContentOutputFormatter`.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllers(options =>
    {
        // requires using Microsoft.AspNetCore.Mvc.Formatters;
        options.OutputFormatters.RemoveType<StringOutputFormatter>();
        options.OutputFormatters.RemoveType<HttpNoContentOutputFormatter>();
    });
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc(options =>
    {
        // requires using Microsoft.AspNetCore.Mvc.Formatters;
        options.OutputFormatters.RemoveType<StringOutputFormatter>();
        options.OutputFormatters.RemoveType<HttpNoContentOutputFormatter>();
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
}
```

Without the `StringOutputFormatter`, the built-in JSON formatter formats `string` return types. If the built-in JSON formatter is removed and an XML formatter is available, the XML formatter formats `string` return types. Otherwise, `string` return types return `406 Not Acceptable`.

Without the `HttpNoContentOutputFormatter`, null objects are formatted using the configured formatter. For example:

- The JSON formatter returns a response with a body of `null`.
- The XML formatter returns an empty XML element with the attribute `xsi:nil="true"` set.

Response format URL mappings

Clients can request a particular format as part of the URL, for example:

- In the query string or part of the path.
- By using a format-specific file extension such as .xml or .json.

The mapping from request path should be specified in the route the API is using. For example:

```
[Route("api/[controller]")]
[ApiController]
[FormatFilter]
public class ProductsController : ControllerBase
{
    [HttpGet("{id}.{format?}")]
    public Product Get(int id)
    {
```

The preceding route allows the requested format to be specified as an optional file extension. The `[FormatFilter]` attribute checks for the existence of the format value in the `RouteData` and maps the response format to the appropriate formatter when the response is created.

ROUTE	FORMATTER
`/api/products/5`	The default output formatter
`/api/products/5.json`	The JSON formatter (if configured)
`/api/products/5.xml`	The XML formatter (if configured)

Custom formatters in ASP.NET Core Web API

9/22/2020 • 5 minutes to read • Edit Online

By Kirk Larkin and Tom Dykstra.

ASP.NET Core MVC supports data exchange in Web APIs using input and output formatters. Input formatters are used by Model Binding. Output formatters are used to format responses.

The framework provides built-in input and output formatters for JSON and XML. It provides a built-in output formatter for plain text, but doesn't provide an input formatter for plain text.

This article shows how to add support for additional formats by creating custom formatters. For an example of a custom plain text input formatter, see TextPlainInputFormatter on GitHub.

View or download sample code (how to download)

When to use custom formatters

Use a custom formatter to add support for a content type that isn't handled by the built-in formatters.

Overview of how to use a custom formatter

To create a custom formatter:

- For serializing data sent to the client, create an output formatter class.
- For deserializing data received from the client, create an input formatter class.
- Add instances of formatter classes to the `InputFormatters` and `OutputFormatters` collections in MvcOptions.

How to create a custom formatter class

To create a formatter:

- Derive the class from the appropriate base class. The sample app derives from TextOutputFormatter and TextInputFormatter.
- Specify valid media types and encodings in the constructor.
- Override the CanReadType and CanWriteType methods.
- Override the ReadRequestBodyAsync and `WriteResponseBodyAsync` methods.

The following code shows the `VcardOutputFormatter` class from the sample:

```
public class VcardOutputFormatter : TextOutputFormatter
{
    public VcardOutputFormatter()
    {
        SupportedMediaTypes.Add(MediaTypeHeaderValue.Parse("text/vcard"));

        SupportedEncodings.Add(Encoding.UTF8);
        SupportedEncodings.Add(Encoding.Unicode);
    }

    protected override bool CanWriteType(Type type)
    {
        return typeof(Contact).IsAssignableFrom(type) ||
            typeof(IEnumerable<Contact>).IsAssignableFrom(type);
    }

    public override async Task WriteResponseBodyAsync(
        OutputFormatterWriteContext context, Encoding selectedEncoding)
    {
        var httpContext = context.HttpContext;
        var serviceProvider = httpContext.RequestServices;

        var logger = serviceProvider.GetRequiredService<ILogger<VcardOutputFormatter>>();
        var buffer = new StringBuilder();

        if (context.Object is IEnumerable<Contact> contacts)
        {
            foreach (var contact in contacts)
            {
                FormatVcard(buffer, contact, logger);
            }
        }
        else
        {
            FormatVcard(buffer, (Contact)context.Object, logger);
        }

        await httpContext.Response.WriteAsync(buffer.ToString());
    }

    private static void FormatVcard(
        StringBuilder buffer, Contact contact, ILogger logger)
    {
        buffer.AppendLine("BEGIN:VCARD");
        buffer.AppendLine("VERSION:2.1");
        buffer.AppendLine($"N:{contact.LastName};{contact.FirstName}");
        buffer.AppendLine($"FN:{contact.FirstName} {contact.LastName}");
        buffer.AppendLine($"UID:{contact.Id}");
        buffer.AppendLine("END:VCARD");

        logger.LogInformation("Writing {FirstName} {LastName}",
            contact.FirstName, contact.LastName);
    }
}
```

Derive from the appropriate base class

For text media types (for example, vCard), derive from the TextInputFormatter or TextOutputFormatter base class.

```
public class VcardOutputFormatter : TextOutputFormatter
```

For binary types, derive from the InputFormatter or OutputFormatter base class.

Specify valid media types and encodings

In the constructor, specify valid media types and encodings by adding to the `SupportedMediaTypes` and `SupportedEncodings` collections.

```
public VcardOutputFormatter()
{
    SupportedMediaTypes.Add(MediaTypeHeaderValue.Parse("text/vcard"));

    SupportedEncodings.Add(Encoding.UTF8);
    SupportedEncodings.Add(Encoding.Unicode);
}
```

A formatter class can **not** use constructor injection for its dependencies. For example, `ILogger<VcardOutputFormatter>` cannot be added as a parameter to the constructor. To access services, use the context object that gets passed in to the methods. A code example in this article and the sample show how to do this.

Override CanReadType and CanWriteType

Specify the type to deserialize into or serialize from by overriding the `CanReadType` or `CanWriteType` methods. For example, creating vCard text from a `Contact` type and vice versa.

```
protected override bool CanWriteType(Type type)
{
    return typeof(Contact).IsAssignableFrom(type) ||
        typeof(IEnumerable<Contact>).IsAssignableFrom(type);
}
```

The CanWriteResult method

In some scenarios, `CanWriteResult` must be overridden rather than `CanWriteType`. Use `CanWriteResult` if the following conditions are true:

- The action method returns a model class.
- There are derived classes which might be returned at runtime.
- The derived class returned by the action must be known at runtime.

For example, suppose the action method:

- Signature returns a `Person` type.
- Can return a `Student` or `Instructor` type that derives from `Person`.

For the formatter to handle only `Student` objects, check the type of Object in the context object provided to the `CanWriteResult` method. When the action method returns `IActionResult`:

- It's not necessary to use `CanWriteResult`.
- The `CanWriteType` method receives the runtime type.

Override ReadRequestBodyAsync and WriteResponseBodyAsync

Deserialization or serialization is performed in `ReadRequestBodyAsync` or `WriteResponseBodyAsync`. The following example shows how to get services from the dependency injection container. Services can't be obtained from constructor parameters.

```
public override async Task WriteResponseBodyAsync(
    OutputFormatterWriteContext context, Encoding selectedEncoding)
{
    var httpContext = context.HttpContext;
    var serviceProvider = httpContext.RequestServices;

    var logger = serviceProvider.GetRequiredService<ILogger<VcardOutputFormatter>>();
    var buffer = new StringBuilder();

    if (context.Object is IEnumerable<Contact> contacts)
    {
        foreach (var contact in contacts)
        {
            FormatVcard(buffer, contact, logger);
        }
    }
    else
    {
        FormatVcard(buffer, (Contact)context.Object, logger);
    }

    await httpContext.Response.WriteAsync(buffer.ToString());
}

private static void FormatVcard(
    StringBuilder buffer, Contact contact, ILogger logger)
{
    buffer.AppendLine("BEGIN:VCARD");
    buffer.AppendLine("VERSION:2.1");
    buffer.AppendLine($"N:{contact.LastName};{contact.FirstName}");
    buffer.AppendLine($"FN:{contact.FirstName} {contact.LastName}");
    buffer.AppendLine($"UID:{contact.Id}");
    buffer.AppendLine("END:VCARD");

    logger.LogInformation("Writing {FirstName} {LastName}",
        contact.FirstName, contact.LastName);
}
```

How to configure MVC to use a custom formatter

To use a custom formatter, add an instance of the formatter class to the `InputFormatters` or `OutputFormatters` collection.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllers(options =>
    {
        options.InputFormatters.Insert(0, new VcardInputFormatter());
        options.OutputFormatters.Insert(0, new VcardOutputFormatter());
    });
}
```

```
services.AddMvc(options =>
{
    options.InputFormatters.Insert(0, new VcardInputFormatter());
    options.OutputFormatters.Insert(0, new VcardOutputFormatter());
})
.SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

Formatters are evaluated in the order you insert them. The first one takes precedence.

The complete `VcardInputFormatter` class

The following code shows the `VcardInputFormatter` class from the sample:

```
public class VcardInputFormatter : TextInputFormatter
{
    public VcardInputFormatter()
    {
        SupportedMediaTypes.Add(MediaTypeHeaderValue.Parse("text/vcard"));

        SupportedEncodings.Add(Encoding.UTF8);
        SupportedEncodings.Add(Encoding.Unicode);
    }

    protected override bool CanReadType(Type type)
    {
        return type == typeof(Contact);
    }

    public override async Task<InputFormatterResult> ReadRequestBodyAsync(
        InputFormatterContext context, Encoding effectiveEncoding)
    {
        var httpContext = context.HttpContext;
        var serviceProvider = httpContext.RequestServices;

        var logger = serviceProvider.GetRequiredService<ILogger<VcardInputFormatter>>();

        using var reader = new StreamReader(httpContext.Request.Body, effectiveEncoding);
        string nameLine = null;

        try
        {
            await ReadLineAsync("BEGIN:VCARD", reader, context, logger);
            await ReadLineAsync("VERSION:", reader, context, logger);

            nameLine = await ReadLineAsync("N:", reader, context, logger);

            var split = nameLine.Split(";".ToCharArray());
            var contact = new Contact
            {
                LastName = split[0].Substring(2),
                FirstName = split[1]
            };

            await ReadLineAsync("FN:", reader, context, logger);
            await ReadLineAsync("END:VCARD", reader, context, logger);

            logger.LogInformation("nameLine = {nameLine}", nameLine);

            return await InputFormatterResult.SuccessAsync(contact);
        }
        catch
        {
            logger.LogError("Read failed: nameLine = {nameLine}", nameLine);
            return await InputFormatterResult.FailureAsync();
        }
    }

    private static async Task<string> ReadLineAsync(
        string expectedText, StreamReader reader, InputFormatterContext context,
        ILogger logger)
    {
        var line = await reader.ReadLineAsync();

        if (!line.StartsWith(expectedText))
        {
            var errorMessage = $"Looked for '{expectedText}' and got '{line}'";
```

```
            context.ModelState.TryAddModelError(context.ModelName, errorMessage);
            logger.LogError(errorMessage);

            throw new Exception(errorMessage);
        }

        return line;
    }
}
```

Test the app

Run the sample app for this article, which implements basic vCard input and output formatters. The app reads and writes vCards similar to the following:

```
BEGIN:VCARD
VERSION:2.1
N:Davolio;Nancy
FN:Nancy Davolio
END:VCARD
```

To see vCard output, run the app and send a Get request with Accept header `text/vcard` to `https://localhost:5001/api/contacts`.

To add a vCard to the in-memory collection of contacts:

- Send a `Post` request to `/api/contacts` with a tool like Postman.
- Set the `Content-Type` header to `text/vcard`.
- Set `vCard` text in the body, formatted like the preceding example.

Use web API analyzers

9/22/2020 • 2 minutes to read • Edit Online

ASP.NET Core 2.2 and later provides an MVC analyzers package intended for use with web API projects. The analyzers work with controllers annotated with ApiControllerAttribute, while building on web API conventions.

The analyzers package notifies you of any controller action that:

- Returns an undeclared status code.
- Returns an undeclared success result.
- Documents a status code that isn't returned.
- Includes an explicit model validation check.

Reference the analyzer package

In ASP.NET Core 3.0 or later, the analyzers are included in the .NET Core SDK. To enable the analyzer in your project, include the `IncludeOpenAPIAnalyzers` property in the project file:

```
<PropertyGroup>
 <IncludeOpenAPIAnalyzers>true</IncludeOpenAPIAnalyzers>
</PropertyGroup>
```

Package installation

Install the Microsoft.AspNetCore.Mvc.Api.Analyzers NuGet package with one of the following approaches:

- Visual Studio
- Visual Studio for Mac
- Visual Studio Code
- .NET Core CLI

From the **Package Manager Console** window:

- Go to **View** > **Other Windows** > **Package Manager Console**.
- Navigate to the directory in which the *ApiConventions.csproj* file exists.
- Execute the following command:

```
Install-Package Microsoft.AspNetCore.Mvc.Api.Analyzers
```

Analyzers for web API conventions

OpenAPI documents contain status codes and response types that an action may return. In ASP.NET Core MVC, attributes such as ProducesResponseTypeAttribute and ProducesAttribute are used to document an action. ASP.NET Core Web API help pages with Swagger / OpenAPI goes into further detail on documenting your web API.

One of the analyzers in the package inspects controllers annotated with ApiControllerAttribute and identifies actions that don't entirely document their responses. Consider the following example:

```
// GET api/contacts/{guid}
[HttpGet("{id}", Name = "GetById")]
[ProducesResponseType(typeof(Contact), StatusCodes.Status200OK)]
public IActionResult Get(string id)
{
    var contact = _contacts.Get(id);

    if (contact == null)
    {
        return NotFound();
    }

    return Ok(contact);
}
```

The preceding action documents the HTTP 200 success return type but doesn't document the HTTP 404 failure status code. The analyzer reports the missing documentation for the HTTP 404 status code as a warning. An option to fix the problem is provided.

Use web API conventions

9/22/2020 • 3 minutes to read • Edit Online

By Pranav Krishnamoorthy and Scott Addie

ASP.NET Core 2.2 and later includes a way to extract common API documentation and apply it to multiple actions, controllers, or all controllers within an assembly. Web API conventions are a substitute for decorating individual actions with `[ProducesResponseType]`.

A convention allows you to:

- Define the most common return types and status codes returned from a specific type of action.
- Identify actions that deviate from the defined standard.

ASP.NET Core MVC 2.2 and later includes a set of default conventions in Microsoft.AspNetCore.Mvc.DefaultApiConventions. The conventions are based on the controller (*ValuesController.cs*) provided in the ASP.NET Core **API** project template. If your actions follow the patterns in the template, you should be successful using the default conventions. If the default conventions don't meet your needs, see Create web API conventions.

At runtime, Microsoft.AspNetCore.Mvc.ApiExplorer understands conventions. `ApiExplorer` is MVC's abstraction to communicate with OpenAPI (also known as Swagger) document generators. Attributes from the applied convention are associated with an action and are included in the action's OpenAPI documentation. API analyzers also understand conventions. If your action is unconventional (for example, it returns a status code that isn't documented by the applied convention), a warning encourages you to document the status code.

View or download sample code (how to download)

Apply web API conventions

Conventions don't compose; each action may be associated with exactly one convention. More specific conventions take precedence over less specific conventions. The selection is non-deterministic when two or more conventions of the same priority apply to an action. The following options exist to apply a convention to an action, from the most specific to the least specific:

1. `Microsoft.AspNetCore.Mvc.ApiConventionMethodAttribute` — Applies to individual actions and specifies the convention type and the convention method that applies.

   In the following example, the default convention type's `Microsoft.AspNetCore.Mvc.DefaultApiConventions.Put` convention method is applied to the `Update` action:

```
// PUT api/contactsconvention/{guid}
[HttpPut("{id}")]
[ApiConventionMethod(typeof(DefaultApiConventions),
                     nameof(DefaultApiConventions.Put))]
public IActionResult Update(string id, Contact contact)
{
    var contactToUpdate = _contacts.Get(id);

    if (contactToUpdate == null)
    {
        return NotFound();
    }

    _contacts.Update(contact);

    return NoContent();
}
```

The `Microsoft.AspNetCore.Mvc.DefaultApiConventions.Put` convention method applies the following attributes to the action:

```
[ProducesDefaultResponseType]
[ProducesResponseType(StatusCodes.Status204NoContent)]
[ProducesResponseType(StatusCodes.Status404NotFound)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
```

For more information on `[ProducesDefaultResponseType]`, see Default Response.

2. `Microsoft.AspNetCore.Mvc.ApiConventionTypeAttribute` applied to a controller — Applies the specified convention type to all actions on the controller. A convention method is marked with hints that determine the actions to which the convention method applies. For more information on hints, see Create web API conventions).

   In the following example, the default set of conventions is applied to all actions in *ContactsConventionController*.

   ```
   [ApiController]
   [ApiConventionType(typeof(DefaultApiConventions))]
   [Route("api/[controller]")]
   public class ContactsConventionController : ControllerBase
   {
   ```

3. `Microsoft.AspNetCore.Mvc.ApiConventionTypeAttribute` applied to an assembly — Applies the specified convention type to all controllers in the current assembly. As a recommendation, apply assembly-level attributes in the *Startup.cs* file.

   In the following example, the default set of conventions is applied to all controllers in the assembly:

   ```
   [assembly: ApiConventionType(typeof(DefaultApiConventions))]
   namespace ApiConventions
   {
       public class Startup
       {
   ```

Create web API conventions

If the default API conventions don't meet your needs, create your own conventions. A convention is:

- A static type with methods.
- Capable of defining response types and naming requirements on actions.

Response types

These methods are annotated with `[ProducesResponseType]` or `[ProducesDefaultResponseType]` attributes. For example:

```
public static class MyAppConventions
{
    [ProducesResponseType(StatusCodes.Status200OK)]
    [ProducesResponseType(StatusCodes.Status404NotFound)]
    public static void Find(int id)
    {
    }
}
```

If more specific metadata attributes are absent, applying this convention to an assembly enforces that:

- The convention method applies to any action named `Find`.
- A parameter named `id` is present on the `Find` action.

Naming requirements

The `[ApiConventionNameMatch]` and `[ApiConventionTypeMatch]` attributes can be applied to the convention method that determines the actions to which they apply. For example:

```
[ProducesResponseType(StatusCodes.Status200OK)]
[ProducesResponseType(StatusCodes.Status404NotFound)]
[ApiConventionNameMatch(ApiConventionNameMatchBehavior.Prefix)]
public static void Find(
    [ApiConventionNameMatch(ApiConventionNameMatchBehavior.Suffix)]
    int id)
{ }
```

In the preceding example:

- The `Microsoft.AspNetCore.Mvc.ApiExplorer.ApiConventionNameMatchBehavior.Prefix` option applied to the method indicates that the convention matches any action prefixed with "Find". Examples of matching actions include `Find`, `FindPet`, and `FindById`.
- The `Microsoft.AspNetCore.Mvc.ApiExplorer.ApiConventionNameMatchBehavior.Suffix` applied to the parameter indicates that the convention matches methods with exactly one parameter ending in the suffix identifier. Examples include parameters such as `id` or `petId`. `ApiConventionTypeMatch` can be similarly applied to types to constrain the parameter type. A `params[]` argument indicates remaining parameters that don't need to be explicitly matched.

Handle errors in ASP.NET Core web APIs

9/22/2020 • 7 minutes to read • Edit Online

This article describes how to handle and customize error handling with ASP.NET Core web APIs.

View or download sample code (How to download)

Developer Exception Page

The Developer Exception Page is a useful tool to get detailed stack traces for server errors. It uses DeveloperExceptionPageMiddleware to capture synchronous and asynchronous exceptions from the HTTP pipeline and to generate error responses. To illustrate, consider the following controller action:

```
[HttpGet("{city}")]
public WeatherForecast Get(string city)
{
    if (!string.Equals(city?.TrimEnd(), "Redmond", StringComparison.OrdinalIgnoreCase))
    {
        throw new ArgumentException(
            $"We don't offer a weather forecast for {city}.", nameof(city));
    }

    return GetWeather().First();
}
```

Run the following `curl` command to test the preceding action:

```
curl -i https://localhost:5001/weatherforecast/chicago
```

In ASP.NET Core 3.0 and later, the Developer Exception Page displays a plain-text response if the client doesn't request HTML-formatted output. The following output appears:

```
HTTP/1.1 500 Internal Server Error
Transfer-Encoding: chunked
Content-Type: text/plain
Server: Microsoft-IIS/10.0
X-Powered-By: ASP.NET
Date: Fri, 27 Sep 2019 16:13:16 GMT

System.ArgumentException: We don't offer a weather forecast for chicago. (Parameter 'city')
   at WebApiSample.Controllers.WeatherForecastController.Get(String city) in

HEADERS
=======
Accept: */*
Host: localhost:44312
User-Agent: curl/7.55.1
```

To display an HTML-formatted response instead, set the `Accept` HTTP request header to the `text/html` media type. For example:

```
curl -i -H "Accept: text/html" https://localhost:5001/weatherforecast/chicago
```

Consider the following excerpt from the HTTP response:

In ASP.NET Core 2.2 and earlier, the Developer Exception Page displays an HTML-formatted response. For example, consider the following excerpt from the HTTP response:

```
HTTP/1.1 500 Internal Server Error
Transfer-Encoding: chunked
Content-Type: text/html; charset=utf-8
Server: Microsoft-IIS/10.0
X-Powered-By: ASP.NET
Date: Fri, 27 Sep 2019 16:55:37 GMT

<!DOCTYPE html>
<html lang="en" xmlns="http://www.w3.org/1999/xhtml">
    <head>
        <meta charset="utf-8" />
        <title>Internal Server Error</title>
        <style>
            body {
    font-family: 'Segoe UI', Tahoma, Arial, Helvetica, sans-serif;
    font-size: .813em;
    color: #222;
    background-color: #fff;
}
```

The HTML-formatted response becomes useful when testing via tools like Postman. The following screen capture shows both the plain-text and the HTML-formatted responses in Postman:

WARNING

Enable the Developer Exception Page **only when the app is running in the Development environment**. You don't want to share detailed exception information publicly when the app runs in production. For more information on configuring environments, see Use multiple environments in ASP.NET Core.

Exception handler

In non-development environments, Exception Handling Middleware can be used to produce an error payload:

1. In `Startup.Configure`, invoke UseExceptionHandler to use the middleware:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/error");
    }

    app.UseHttpsRedirection();
    app.UseRouting();
    app.UseAuthorization();
    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
    });
}
```

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseMvc();
}
```

2. Configure a controller action to respond to the `/error` route:

```
[ApiController]
public class ErrorController : ControllerBase
{
    [Route("/error")]
    public IActionResult Error() => Problem();
}
```

```
[ApiController]
public class ErrorController : ControllerBase
{
    [Route("/error")]
    public ActionResult Error([FromServices] IHostingEnvironment webHostEnvironment)
    {
        var feature = HttpContext.Features.Get<IExceptionHandlerPathFeature>();
        var ex = feature?.Error;
        var isDev = webHostEnvironment.IsDevelopment();
        var problemDetails = new ProblemDetails
        {
            Status = (int)HttpStatusCode.InternalServerError,
            Instance = feature?.Path,
            Title = isDev ? $"{ex.GetType().Name}: {ex.Message}" : "An error occurred.",
            Detail = isDev ? ex.StackTrace : null,
        };

        return StatusCode(problemDetails.Status.Value, problemDetails);
    }
}
```

The preceding `Error` action sends an RFC 7807-compliant payload to the client.

Exception Handling Middleware can also provide more detailed content-negotiated output in the local development environment. Use the following steps to produce a consistent payload format across development and production environments:

1. In `Startup.Configure`, register environment-specific Exception Handling Middleware instances:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseExceptionHandler("/error-local-development");
    }
    else
    {
        app.UseExceptionHandler("/error");
    }
}
```

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseExceptionHandler("/error-local-development");
    }
    else
    {
        app.UseExceptionHandler("/error");
    }
}
```

   In the preceding code, the middleware is registered with:

   - A route of `/error-local-development` in the Development environment.
   - A route of `/error` in environments that aren't Development.

2. Apply attribute routing to controller actions:

```
[ApiController]
public class ErrorController : ControllerBase
{
    [Route("/error-local-development")]
    public IActionResult ErrorLocalDevelopment(
        [FromServices] IWebHostEnvironment webHostEnvironment)
    {
        if (webHostEnvironment.EnvironmentName != "Development")
        {
            throw new InvalidOperationException(
                "This shouldn't be invoked in non-development environments.");
        }

        var context = HttpContext.Features.Get<IExceptionHandlerFeature>();

        return Problem(
            detail: context.Error.StackTrace,
            title: context.Error.Message);
    }

    [Route("/error")]
    public IActionResult Error() => Problem();
}
```

```
[ApiController]
public class ErrorController : ControllerBase
{
    [Route("/error-local-development")]
    public IActionResult ErrorLocalDevelopment(
        [FromServices] IHostingEnvironment webHostEnvironment)
    {
        if (!webHostEnvironment.IsDevelopment())
        {
            throw new InvalidOperationException(
                "This shouldn't be invoked in non-development environments.");
        }

        var feature = HttpContext.Features.Get<IExceptionHandlerPathFeature>();
        var ex = feature?.Error;

        var problemDetails = new ProblemDetails
        {
            Status = (int)HttpStatusCode.InternalServerError,
            Instance = feature?.Path,
            Title = ex.GetType().Name,
            Detail = ex.StackTrace,
        };

        return StatusCode(problemDetails.Status.Value, problemDetails);
    }

    [Route("/error")]
    public ActionResult Error(
        [FromServices] IHostingEnvironment webHostEnvironment)
    {
        var feature = HttpContext.Features.Get<IExceptionHandlerPathFeature>();
        var ex = feature?.Error;
        var isDev = webHostEnvironment.IsDevelopment();
        var problemDetails = new ProblemDetails
        {
            Status = (int)HttpStatusCode.InternalServerError,
            Instance = feature?.Path,
            Title = isDev ? $"{ex.GetType().Name}: {ex.Message}" : "An error occurred.",
            Detail = isDev ? ex.StackTrace : null,
        };

        return StatusCode(problemDetails.Status.Value, problemDetails);
    }
}
```

Use exceptions to modify the response

The contents of the response can be modified from outside of the controller. In ASP.NET 4.x Web API, one way to do this was using the HttpResponseException type. ASP.NET Core doesn't include an equivalent type. Support for `HttpResponseException` can be added with the following steps:

1. Create a well-known exception type named `HttpResponseException`:

```
public class HttpResponseException : Exception
{
    public int Status { get; set; } = 500;

    public object Value { get; set; }
}
```

2. Create an action filter named `HttpResponseExceptionFilter`:

```
public class HttpResponseExceptionFilter : IActionFilter, IOrderedFilter
{
    public int Order { get; set; } = int.MaxValue - 10;

    public void OnActionExecuting(ActionExecutingContext context) { }

    public void OnActionExecuted(ActionExecutedContext context)
    {
        if (context.Exception is HttpResponseException exception)
        {
            context.Result = new ObjectResult(exception.Value)
            {
                StatusCode = exception.Status,
            };
            context.ExceptionHandled = true;
        }
    }
}
```

In the preceding filter, the magic number 10 is subtracted from the maximum integer value. Subtracting this number allows other filters to run at the very end of the pipeline.

3. In `Startup.ConfigureServices`, add the action filter to the filters collection:

```
services.AddControllers(options =>
    options.Filters.Add(new HttpResponseExceptionFilter()));
```

```
services.AddMvc(options =>
        options.Filters.Add(new HttpResponseExceptionFilter()))
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

```
services.AddMvc(options =>
        options.Filters.Add(new HttpResponseExceptionFilter()))
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
```

Validation failure error response

For web API controllers, MVC responds with a ValidationProblemDetails response type when model validation fails. MVC uses the results of InvalidModelStateResponseFactory to construct the error response for a validation failure. The following example uses the factory to change the default response type to SerializableError in `Startup.ConfigureServices`:

```
services.AddControllers()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.InvalidModelStateResponseFactory = context =>
        {
            var result = new BadRequestObjectResult(context.ModelState);

            // TODO: add `using System.Net.Mime;` to resolve MediaTypeNames
            result.ContentTypes.Add(MediaTypeNames.Application.Json);
            result.ContentTypes.Add(MediaTypeNames.Application.Xml);

            return result;
        };
    });
```

```
services.AddMvc()
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2)
    .ConfigureApiBehaviorOptions(options =>
    {
        options.InvalidModelStateResponseFactory = context =>
        {
            var result = new BadRequestObjectResult(context.ModelState);

            // TODO: add `using System.Net.Mime;` to resolve MediaTypeNames
            result.ContentTypes.Add(MediaTypeNames.Application.Json);
            result.ContentTypes.Add(MediaTypeNames.Application.Xml);

            return result;
        };
    });
```

```
services.AddMvc()
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);

services.Configure<ApiBehaviorOptions>(options =>
{
    options.InvalidModelStateResponseFactory = context =>
    {
        var result = new BadRequestObjectResult(context.ModelState);

        // TODO: add `using using System.Net.Mime;` to resolve MediaTypeNames
        result.ContentTypes.Add(MediaTypeNames.Application.Json);
        result.ContentTypes.Add(MediaTypeNames.Application.Xml);

        return result;
    };
});
```

Client error response

An *error result* is defined as a result with an HTTP status code of 400 or higher. For web API controllers, MVC transforms an error result to a result with ProblemDetails.

> **IMPORTANT**
> ASP.NET Core 2.1 generates a problem details response that's nearly RFC 7807-compliant. If 100 percent compliance is important, upgrade the project to ASP.NET Core 2.2 or later.

The error response can be configured in one of the following ways:

1. Implement ProblemDetailsFactory
2. Use ApiBehaviorOptions.ClientErrorMapping

Implement `ProblemDetailsFactory`

MVC uses Microsoft.AspNetCore.Mvc.Infrastructure.ProblemDetailsFactory to produce all instances of ProblemDetails and ValidationProblemDetails. This includes client error responses, validation failure error responses, and the ControllerBase.Problem and ControllerBase.ValidationProblem helper methods.

To customize the problem details response, register a custom implementation of ProblemDetailsFactory in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection serviceCollection)
{
    services.AddControllers();
    services.AddTransient<ProblemDetailsFactory, CustomProblemDetailsFactory>();
}
```

The error response can be configured as outlined in the Use ApiBehaviorOptions.ClientErrorMapping section.

Use ApiBehaviorOptions.ClientErrorMapping

Use the ClientErrorMapping property to configure the contents of the `ProblemDetails` response. For example, the following code in `Startup.ConfigureServices` updates the `type` property for 404 responses:

```
services.AddControllers()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressConsumesConstraintForFormFileParameters = true;
        options.SuppressInferBindingSourcesForParameters = true;
        options.SuppressModelStateInvalidFilter = true;
        options.SuppressMapClientErrors = true;
        options.ClientErrorMapping[StatusCodes.Status404NotFound].Link =
            "https://httpstatuses.com/404";
    });
```

```
services.AddMvc()
    .SetCompatibilityVersion(CompatibilityVersion.Version_2_2)
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressConsumesConstraintForFormFileParameters = true;
        options.SuppressInferBindingSourcesForParameters = true;
        options.SuppressModelStateInvalidFilter = true;
        options.SuppressMapClientErrors = true;
        options.ClientErrorMapping[404].Link =
            "https://httpstatuses.com/404";
    });
```

Test web APIs with the HTTP REPL

9/22/2020 • 19 minutes to read • Edit Online

By Scott Addie

The HTTP Read-Eval-Print Loop (REPL) is:

- A lightweight, cross-platform command-line tool that's supported everywhere .NET Core is supported.
- Used for making HTTP requests to test ASP.NET Core web APIs (and non-ASP.NET Core web APIs) and view their results.
- Capable of testing web APIs hosted in any environment, including localhost and Azure App Service.

The following HTTP verbs are supported:

- DELETE
- GET
- HEAD
- OPTIONS
- PATCH
- POST
- PUT

To follow along, view or download the sample ASP.NET Core web API (how to download).

Prerequisites

- .NET Core 2.1 SDK or later

Installation

To install the HTTP REPL, run the following command:

```
dotnet tool install -g Microsoft.dotnet-httprepl
```

A .NET Core Global Tool is installed from the Microsoft.dotnet-httprepl NuGet package.

Usage

After successful installation of the tool, run the following command to start the HTTP REPL:

```
httprepl
```

To view the available HTTP REPL commands, run one of the following commands:

```
httprepl -h
```

```
httprepl --help
```

The following output is displayed:

```
Usage:
  httprepl [<BASE_ADDRESS>] [options]

Arguments:
  <BASE_ADDRESS> - The initial base address for the REPL.

Options:
  -h|--help - Show help information.

Once the REPL starts, these commands are valid:

Setup Commands:
Use these commands to configure the tool for your API server

connect        Configures the directory structure and base address of the api server
set header     Sets or clears a header for all requests. e.g. `set header content-type application/json`

HTTP Commands:
Use these commands to execute requests against your application.

GET            get - Issues a GET request
POST           post - Issues a POST request
PUT            put - Issues a PUT request
DELETE         delete - Issues a DELETE request
PATCH          patch - Issues a PATCH request
HEAD           head - Issues a HEAD request
OPTIONS        options - Issues a OPTIONS request

Navigation Commands:
The REPL allows you to navigate your URL space and focus on specific APIs that you are working on.

set base       Set the base URI. e.g. `set base http://locahost:5000`
ls             Show all endpoints for the current path
cd             Append the given directory to the currently selected path, or move up a path when using `cd ..`

Shell Commands:
Use these commands to interact with the REPL shell.

clear          Removes all text from the shell
echo [on/off]  Turns request echoing on or off, show the request that was made when using request commands
exit           Exit the shell

REPL Customization Commands:
Use these commands to customize the REPL behavior.

pref [get/set] Allows viewing or changing preferences, e.g. 'pref set editor.command.default 'C:\\Program
Files\\Microsoft VS Code\\Code.exe'`
run            Runs the script at the given path. A script is a set of commands that can be typed with one
command per line
ui             Displays the Swagger UI page, if available, in the default browser

Use `help <COMMAND>` for more detail on an individual command. e.g. `help get`.
For detailed tool info, see https://aka.ms/http-repl-doc.
```

The HTTP REPL offers command completion. Pressing the Tab key iterates through the list of commands that complete the characters or API endpoint that you typed. The following sections outline the available CLI commands.

Connect to the web API

Connect to a web API by running the following command:

```
httprepl <ROOT URI>
```

`<ROOT URI>` is the base URI for the web API. For example:

```
httprepl https://localhost:5001
```

Alternatively, run the following command at any time while the HTTP REPL is running:

```
connect <ROOT URI>
```

For example:

```
(Disconnected)~ connect https://localhost:5001
```

Manually point to the Swagger document for the web API

The connect command above will attempt to find the Swagger document automatically. If for some reason it is unable to do so, you can specify the URI of the Swagger document for the web API by using the `--swagger` option:

```
connect <ROOT URI> --swagger <SWAGGER URI>
```

For example:

```
(Disconnected)~ connect https://localhost:5001 --swagger /swagger/v1/swagger.json
```

Navigate the web API

View available endpoints

To list the different endpoints (controllers) at the current path of the web API address, run the `ls` or `dir` command:

```
https://localhot:5001/~ ls
```

The following output format is displayed:

```
.       []
Fruits  [get|post]
People  [get|post]

https://localhost:5001/~
```

The preceding output indicates that there are two controllers available: `Fruits` and `People`. Both controllers support parameterless HTTP GET and POST operations.

Navigating into a specific controller reveals more detail. For example, the following command's output shows the `Fruits` controller also supports HTTP GET, PUT, and DELETE operations. Each of these operations expects an `id` parameter in the route:

```
https://localhost:5001/fruits~ ls
.      [get|post]
..     []
{id}   [get|put|delete]

https://localhost:5001/fruits~
```

Alternatively, run the `ui` command to open the web API's Swagger UI page in a browser. For example:

```
https://localhost:5001/~ ui
```

Navigate to an endpoint

To navigate to a different endpoint on the web API, run the `cd` command:

```
https://localhost:5001/~ cd people
```

The path following the `cd` command is case insensitive. The following output format is displayed:

```
/people    [get|post]

https://localhost:5001/people~
```

Customize the HTTP REPL

The HTTP REPL's default colors can be customized. Additionally, a default text editor can be defined. The HTTP REPL preferences are persisted across the current session and are honored in future sessions. Once modified, the preferences are stored in the following file:

- Linux
- macOS
- Windows

%HOME%/.httpreplprefs

The *.httpreplprefs* file is loaded on startup and not monitored for changes at runtime. Manual modifications to the file take effect only after restarting the tool.

View the settings

To view the available settings, run the `pref get` command. For example:

```
https://localhost:5001/~ pref get
```

The preceding command displays the available key-value pairs:

```
colors.json=Green
colors.json.arrayBrace=BoldCyan
colors.json.comma=BoldYellow
colors.json.name=BoldMagenta
colors.json.nameSeparator=BoldWhite
colors.json.objectBrace=Cyan
colors.protocol=BoldGreen
colors.status=BoldYellow
```

Set color preferences

Response colorization is currently supported for JSON only. To customize the default HTTP REPL tool coloring, locate the key corresponding to the color to be changed. For instructions on how to find the keys, see the View the settings section. For example, change the `colors.json` key value from `Green` to `White` as follows:

```
https://localhost:5001/people~ pref set colors.json White
```

Only the allowed colors may be used. Subsequent HTTP requests display output with the new coloring.

When specific color keys aren't set, more generic keys are considered. To demonstrate this fallback behavior, consider the following example:

- If `colors.json.name` doesn't have a value, `colors.json.string` is used.
- If `colors.json.string` doesn't have a value, `colors.json.literal` is used.
- If `colors.json.literal` doesn't have a value, `colors.json` is used.
- If `colors.json` doesn't have a value, the command shell's default text color (`AllowedColors.None`) is used.

Set indentation size

Response indentation size customization is currently supported for JSON only. The default size is two spaces. For example:

```
[
  {
    "id": 1,
    "name": "Apple"
  },
  {
    "id": 2,
    "name": "Orange"
  },
  {
    "id": 3,
    "name": "Strawberry"
  }
]
```

To change the default size, set the `formatting.json.indentSize` key. For example, to always use four spaces:

```
pref set formatting.json.indentSize 4
```

Subsequent responses honor the setting of four spaces:

```
[
    {
        "id": 1,
        "name": "Apple"
    },
    {
        "id": 2,
        "name": "Orange"
    },
    {
        "id": 3,
        "name": "Strawberry"
    }
]
```

Set the default text editor

By default, the HTTP REPL has no text editor configured for use. To test web API methods requiring an HTTP request body, a default text editor must be set. The HTTP REPL tool launches the configured text editor for the sole purpose of composing the request body. Run the following command to set your preferred text editor as the default:

```
pref set editor.command.default "<EXECUTABLE>"
```

In the preceding command, `<EXECUTABLE>` is the full path to the text editor's executable file. For example, run the following command to set Visual Studio Code as the default text editor:

- Linux
- macOS
- Windows

```
pref set editor.command.default "/usr/bin/code"
```

To launch the default text editor with specific CLI arguments, set the `editor.command.default.arguments` key. For example, assume Visual Studio Code is the default text editor and that you always want the HTTP REPL to open Visual Studio Code in a new session with extensions disabled. Run the following command:

```
pref set editor.command.default.arguments "--disable-extensions --new-window"
```

Set the Swagger search paths

By default, the HTTP REPL has a set of relative paths that it uses to find the Swagger document when executing the `connect` command without the `--swagger` option. These relative paths are combined with the root and base paths specified in the `connect` command. The default relative paths are:

- *swagger.json*
- *swagger/v1/swagger.json*
- */swagger.json*
- */swagger/v1/swagger.json*

To use a different set of search paths in your environment, set the `swagger.searchPaths` preference. The value must be a pipe-delimited list of relative paths. For example:

```
pref set swagger.searchPaths "swagger/v2/swagger.json|swagger/v3/swagger.json"
```

Test HTTP GET requests

Synopsis

```
get <PARAMETER> [-F|--no-formatting] [-h|--header] [--response] [--response:body] [--response:headers] [-s|--
streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

The following options are available for the `get` command:

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:

  - `{header}={value}`
  - `{header}:{value}`

- `--response`

  Specifies a file to which the entire HTTP response (including headers and body) should be written. For example, `--response "C:\response.txt"`. The file is created if it doesn't exist.

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

Example

To issue an HTTP GET request:

1. Run the `get` command on an endpoint that supports it:

   ```
   https://localhost:5001/people~ get
   ```

   The preceding command displays the following output format:

```
HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Date: Fri, 21 Jun 2019 03:38:45 GMT
Server: Kestrel
Transfer-Encoding: chunked

[
  {
    "id": 1,
    "name": "Scott Hunter"
  },
  {
    "id": 2,
    "name": "Scott Hanselman"
  },
  {
    "id": 3,
    "name": "Scott Guthrie"
  }
]

https://localhost:5001/people~
```

2. Retrieve a specific record by passing a parameter to the `get` command:

```
https://localhost:5001/people~ get 2
```

The preceding command displays the following output format:

```
HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Date: Fri, 21 Jun 2019 06:17:57 GMT
Server: Kestrel
Transfer-Encoding: chunked

[
  {
    "id": 2,
    "name": "Scott Hanselman"
  }
]

https://localhost:5001/people~
```

Test HTTP POST requests

Synopsis

```
post <PARAMETER> [-c|--content] [-f|--file] [-h|--header] [--no-body] [-F|--no-formatting] [--response] [--
response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:

  - `{header}={value}`
  - `{header}:{value}`

- `--response`

  Specifies a file to which the entire HTTP response (including headers and body) should be written. For example, `--response "C:\response.txt"`. The file is created if it doesn't exist.

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

- `-c|--content`

  Provides an inline HTTP request body. For example, `-c "{"id":2,"name":"Cherry"}"`.

- `-f|--file`

  Provides a path to a file containing the HTTP request body. For example, `-f "C:\request.json"`.

- `--no-body`

  Indicates that no HTTP request body is needed.

Example

To issue an HTTP POST request:

1. Run the `post` command on an endpoint that supports it:

   ```
   https://localhost:5001/people~ post -h Content-Type=application/json
   ```

   In the preceding command, the `Content-Type` HTTP request header is set to indicate a request body media type of JSON. The default text editor opens a *.tmp* file with a JSON template representing the HTTP request body. For example:

   ```
   {
     "id": 0,
     "name": ""
   }
   ```

> **TIP**
> To set the default text editor, see the Set the default text editor section.

2. Modify the JSON template to satisfy model validation requirements:

```
{
  "id": 0,
  "name": "Scott Addie"
}
```

3. Save the *.tmp* file, and close the text editor. The following output appears in the command shell:

```
HTTP/1.1 201 Created
Content-Type: application/json; charset=utf-8
Date: Thu, 27 Jun 2019 21:24:18 GMT
Location: https://localhost:5001/people/4
Server: Kestrel
Transfer-Encoding: chunked

{
  "id": 4,
  "name": "Scott Addie"
}

https://localhost:5001/people~
```

Test HTTP PUT requests

Synopsis

```
put <PARAMETER> [-c|--content] [-f|--file] [-h|--header] [--no-body] [-F|--no-formatting] [--response] [--
response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:

  - `{header}={value}`
  - `{header}:{value}`

- `--response`

  Specifies a file to which the entire HTTP response (including headers and body) should be written. For example, `--response "C:\response.txt"`. The file is created if it doesn't exist.

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

- `-c|--content`

  Provides an inline HTTP request body. For example, `-c "{"id":2,"name":"Cherry"}"`.

- `-f|--file`

  Provides a path to a file containing the HTTP request body. For example, `-f "C:\request.json"`.

- `--no-body`

  Indicates that no HTTP request body is needed.

Example

To issue an HTTP PUT request:

1. *Optional*: Run the `get` command to view the data before modifying it:

   ```
   https://localhost:5001/fruits~ get
   HTTP/1.1 200 OK
   Content-Type: application/json; charset=utf-8
   Date: Sat, 22 Jun 2019 00:07:32 GMT
   Server: Kestrel
   Transfer-Encoding: chunked

   [
     {
       "id": 1,
       "data": "Apple"
     },
     {
       "id": 2,
       "data": "Orange"
     },
     {
       "id": 3,
       "data": "Strawberry"
     }
   ]
   ```

2. Run the `put` command on an endpoint that supports it:

   ```
   https://localhost:5001/fruits~ put 2 -h Content-Type=application/json
   ```

   In the preceding command, the `Content-Type` HTTP request header is set to indicate a request body media type of JSON. The default text editor opens a *.tmp* file with a JSON template representing the HTTP request body. For example:

```
{
  "id": 0,
  "name": ""
}
```

> **TIP**
> To set the default text editor, see the Set the default text editor section.

3. Modify the JSON template to satisfy model validation requirements:

```
{
  "id": 2,
  "name": "Cherry"
}
```

4. Save the *.tmp* file, and close the text editor. The following output appears in the command shell:

```
[main 2019-06-28T17:27:01.805Z] update#setState idle
HTTP/1.1 204 No Content
Date: Fri, 28 Jun 2019 17:28:21 GMT
Server: Kestrel
```

5. *Optional*: Issue a `get` command to see the modifications. For example, if you typed "Cherry" in the text editor, a `get` returns the following:

```
https://localhost:5001/fruits~ get
HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Date: Sat, 22 Jun 2019 00:08:20 GMT
Server: Kestrel
Transfer-Encoding: chunked

[
  {
    "id": 1,
    "data": "Apple"
  },
  {
    "id": 2,
    "data": "Cherry"
  },
  {
    "id": 3,
    "data": "Strawberry"
  }
]

https://localhost:5001/fruits~
```

Test HTTP DELETE requests

Synopsis

```
delete <PARAMETER> [-F|--no-formatting] [-h|--header] [--response] [--response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:

  - `{header}={value}`
  - `{header}:{value}`

- `--response`

  Specifies a file to which the entire HTTP response (including headers and body) should be written. For example, `--response "C:\response.txt"`. The file is created if it doesn't exist.

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

Example

To issue an HTTP DELETE request:

1. *Optional*: Run the `get` command to view the data before modifying it:

```
https://localhost:5001/fruits~ get
HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Date: Sat, 22 Jun 2019 00:07:32 GMT
Server: Kestrel
Transfer-Encoding: chunked

[
  {
    "id": 1,
    "data": "Apple"
  },
  {
    "id": 2,
    "data": "Orange"
  },
  {
    "id": 3,
    "data": "Strawberry"
  }
]
```

2. Run the `delete` command on an endpoint that supports it:

   ```
   https://localhost:5001/fruits~ delete 2
   ```

   The preceding command displays the following output format:

   ```
   HTTP/1.1 204 No Content
   Date: Fri, 28 Jun 2019 17:36:42 GMT
   Server: Kestrel
   ```

3. *Optional*: Issue a `get` command to see the modifications. In this example, a `get` returns the following:

   ```
   https://localhost:5001/fruits~ get
   HTTP/1.1 200 OK
   Content-Type: application/json; charset=utf-8
   Date: Sat, 22 Jun 2019 00:16:30 GMT
   Server: Kestrel
   Transfer-Encoding: chunked

   [
     {
       "id": 1,
       "data": "Apple"
     },
     {
       "id": 3,
       "data": "Strawberry"
     }
   ]

   https://localhost:5001/fruits~
   ```

Test HTTP PATCH requests

Synopsis

```
patch <PARAMETER> [-c|--content] [-f|--file] [-h|--header] [--no-body] [-F|--no-formatting] [--response] [--response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:

  - `{header}={value}`
  - `{header}:{value}`

- `--response`

  Specifies a file to which the entire HTTP response (including headers and body) should be written. For example, `--response "C:\response.txt"`. The file is created if it doesn't exist.

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

- `-c|--content`

  Provides an inline HTTP request body. For example, `-c "{"id":2,"name":"Cherry"}"`.

- `-f|--file`

  Provides a path to a file containing the HTTP request body. For example, `-f "C:\request.json"`.

- `--no-body`

  Indicates that no HTTP request body is needed.

Test HTTP HEAD requests

Synopsis

```
head <PARAMETER> [-F|--no-formatting] [-h|--header] [--response] [--response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:

  - `{header}={value}`
  - `{header}:{value}`

- `--response`

  Specifies a file to which the entire HTTP response (including headers and body) should be written. For example, `--response "C:\response.txt"`. The file is created if it doesn't exist.

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

Test HTTP OPTIONS requests

Synopsis

```
options <PARAMETER> [-F|--no-formatting] [-h|--header] [--response] [--response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:

  - `{header}={value}`
  - `{header}:{value}`

- `--response`

Specifies a file to which the entire HTTP response (including headers and body) should be written. For example, `--response "C:\response.txt"`. The file is created if it doesn't exist.

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

Set HTTP request headers

To set an HTTP request header, use one of the following approaches:

- Set inline with the HTTP request. For example:

  ```
  https://localhost:5001/people~ post -h Content-Type=application/json
  ```

  With the preceding approach, each distinct HTTP request header requires its own `-h` option.

- Set before sending the HTTP request. For example:

  ```
  https://localhost:5001/people~ set header Content-Type application/json
  ```

  When setting the header before sending a request, the header remains set for the duration of the command shell session. To clear the header, provide an empty value. For example:

  ```
  https://localhost:5001/people~ set header Content-Type
  ```

Test secured endpoints

The HTTP REPL supports the testing of secured endpoints in two ways: via the default credentials of the logged in user or through the use of HTTP request headers.

Default credentials

Consider a scenario in which the web API you're testing is hosted in IIS and is secured with Windows authentication. You want the credentials of the user running the tool to flow across to the HTTP endpoints being tested. To pass the default credentials of the logged in user:

1. Set the `httpClient.useDefaultCredentials` preference to `true`:

   ```
   pref set httpClient.useDefaultCredentials true
   ```

2. Exit and restart the tool before sending another request to the web API.

HTTP request headers

Examples of supported authentication and authorization schemes include basic authentication, JWT bearer tokens,

and digest authentication. For example, you can send a bearer token to an endpoint with the following command:

```
set header Authorization "bearer <TOKEN VALUE>"
```

To access an Azure-hosted endpoint or to use the Azure REST API, you need a bearer token. Use the following steps to obtain a bearer token for your Azure subscription via the Azure CLI. The HTTP REPL sets the bearer token in an HTTP request header and retrieves a list of Azure App Service Web Apps.

1. Log in to Azure:

   ```
   az login
   ```

2. Get your subscription ID with the following command:

   ```
   az account show --query id
   ```

3. Copy your subscription ID and run the following command:

   ```
   az account set --subscription "<SUBSCRIPTION ID>"
   ```

4. Get your bearer token with the following command:

   ```
   az account get-access-token --query accessToken
   ```

5. Connect to the Azure REST API via the HTTP REPL:

   ```
   httprepl https://management.azure.com
   ```

6. Set the `Authorization` HTTP request header:

   ```
   https://management.azure.com/> set header Authorization "bearer <ACCESS TOKEN>"
   ```

7. Navigate to the subscription:

   ```
   https://management.azure.com/> cd subscriptions/<SUBSCRIPTION ID>
   ```

8. Get a list of your subscription's Azure App Service Web Apps:

   ```
   https://management.azure.com/subscriptions/{SUBSCRIPTION ID}> get providers/Microsoft.Web/sites?api-version=2016-08-01
   ```

   The following response is displayed:

```
HTTP/1.1 200 OK
Cache-Control: no-cache
Content-Length: 35948
Content-Type: application/json; charset=utf-8
Date: Thu, 19 Sep 2019 23:04:03 GMT
Expires: -1
Pragma: no-cache
Strict-Transport-Security: max-age=31536000; includeSubDomains
X-Content-Type-Options: nosniff
x-ms-correlation-request-id: <em>xxxxxxxx-xxxx-xxxx-xxxx-xxxxxxxxxxxx</em>
x-ms-original-request-ids: <em>xxxxxxxx-xxxx-xxxx-xxxx-xxxxxxxxxxxx;xxxxxxxx-xxxx-xxxx-xxxx-
xxxxxxxxxxxx</em>
x-ms-ratelimit-remaining-subscription-reads: 11999
x-ms-request-id: xxxxxxxx-xxxx-xxxx-xxxx-xxxxxxxxxxxx
x-ms-routing-request-id: WESTUS:xxxxxxxxxxxxxxxx:xxxxxxxx-xxxx-xxxx-xxxx-xxxxxxxxxx
{
  "value": [
    <AZURE RESOURCES LIST>
  ]
}
```

Toggle HTTP request display

By default, display of the HTTP request being sent is suppressed. It's possible to change the corresponding setting for the duration of the command shell session.

Enable request display

View the HTTP request being sent by running the `echo on` command. For example:

```
https://localhost:5001/people~ echo on
Request echoing is on
```

Subsequent HTTP requests in the current session display the request headers. For example:

```
https://localhost:5001/people~ post

[main 2019-06-28T18:50:11.930Z] update#setState idle
Request to https://localhost:5001...

POST /people HTTP/1.1
Content-Length: 41
Content-Type: application/json
User-Agent: HTTP-REPL

{
  "id": 0,
  "name": "Scott Addie"
}

Response from https://localhost:5001...

HTTP/1.1 201 Created
Content-Type: application/json; charset=utf-8
Date: Fri, 28 Jun 2019 18:50:21 GMT
Location: https://localhost:5001/people/4
Server: Kestrel
Transfer-Encoding: chunked

{
  "id": 4,
  "name": "Scott Addie"
}

https://localhost:5001/people~
```

Disable request display

Suppress display of the HTTP request being sent by running the `echo off` command. For example:

```
https://localhost:5001/people~ echo off
Request echoing is off
```

Run a script

If you frequently execute the same set of HTTP REPL commands, consider storing them in a text file. Commands in the file take the same form as those executed manually on the command line. The commands can be executed in a batched fashion using the `run` command. For example:

1. Create a text file containing a set of newline-delimited commands. To illustrate, consider a *people-script.txt* file containing the following commands:

   ```
   set base https://localhost:5001
   ls
   cd People
   ls
   get 1
   ```

2. Execute the `run` command, passing in the text file's path. For example:

   ```
   https://localhost:5001/~ run C:\http-repl-scripts\people-script.txt
   ```

   The following output appears:

```
https://localhost:5001/~ set base https://localhost:5001
Using swagger metadata from https://localhost:5001/swagger/v1/swagger.json

https://localhost:5001/~ ls
.        []
Fruits   [get|post]
People   [get|post]

https://localhost:5001/~ cd People
/People    [get|post]

https://localhost:5001/People~ ls
.      [get|post]
..     []
{id}   [get|put|delete]

https://localhost:5001/People~ get 1
HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Date: Fri, 12 Jul 2019 19:20:10 GMT
Server: Kestrel
Transfer-Encoding: chunked

{
  "id": 1,
  "name": "Scott Hunter"
}

https://localhost:5001/People~
```

Clear the output

To remove all output written to the command shell by the HTTP REPL tool, run the `clear` or `cls` command. To illustrate, imagine the command shell contains the following output:

```
httprepl https://localhost:5001
(Disconnected)~ set base "https://localhost:5001"
Using swagger metadata from https://localhost:5001/swagger/v1/swagger.json

https://localhost:5001/~ ls
.        []
Fruits   [get|post]
People   [get|post]

https://localhost:5001/~
```

Run the following command to clear the output:

```
https://localhost:5001/~ clear
```

After running the preceding command, the command shell contains only the following output:

```
https://localhost:5001/~
```

Introduction to ASP.NET Core SignalR

9/22/2020 • 2 minutes to read • Edit Online

What is SignalR?

ASP.NET Core SignalR is an open-source library that simplifies adding real-time web functionality to apps. Real-time web functionality enables server-side code to push content to clients instantly.

Good candidates for SignalR:

- Apps that require high frequency updates from the server. Examples are gaming, social networks, voting, auction, maps, and GPS apps.
- Dashboards and monitoring apps. Examples include company dashboards, instant sales updates, or travel alerts.
- Collaborative apps. Whiteboard apps and team meeting software are examples of collaborative apps.
- Apps that require notifications. Social networks, email, chat, games, travel alerts, and many other apps use notifications.

SignalR provides an API for creating server-to-client remote procedure calls (RPC). The RPCs call JavaScript functions on clients from server-side .NET Core code.

Here are some features of SignalR for ASP.NET Core:

- Handles connection management automatically.
- Sends messages to all connected clients simultaneously. For example, a chat room.
- Sends messages to specific clients or groups of clients.
- Scales to handle increasing traffic.

The source is hosted in a SignalR repository on GitHub.

Transports

SignalR supports the following techniques for handling real-time communication (in order of graceful fallback):

- WebSockets
- Server-Sent Events
- Long Polling

SignalR automatically chooses the best transport method that is within the capabilities of the server and client.

Hubs

SignalR uses *hubs* to communicate between clients and servers.

A hub is a high-level pipeline that allows a client and server to call methods on each other. SignalR handles the dispatching across machine boundaries automatically, allowing clients to call methods on the server and vice versa. You can pass strongly-typed parameters to methods, which enables model binding. SignalR provides two built-in hub protocols: a text protocol based on JSON and a binary protocol based on MessagePack. MessagePack generally creates smaller messages compared to JSON. Older browsers must support XHR level 2 to provide MessagePack protocol support.

Hubs call client-side code by sending messages that contain the name and parameters of the client-side method. Objects sent as method parameters are deserialized using the configured protocol. The client tries to match the name to a method in the client-side code. When the client finds a match, it calls the method and passes to it the deserialized parameter data.

- Hubs
- JavaScript client

ASP.NET Core SignalR supported platforms

9/22/2020 • 2 minutes to read • Edit Online

Server system requirements

SignalR for ASP.NET Core supports any server platform that ASP.NET Core supports.

JavaScript client

The JavaScript client runs on NodeJS 8 and later versions and the following browsers:

BROWSER	VERSION
Microsoft Edge	Current†
Mozilla Firefox	Current†
Google Chrome; includes Android	Current†
Safari; includes iOS	Current†
Microsoft Internet Explorer	11

†*Current* refers to the latest version of the browser.

.NET client

The .NET client runs on any platform supported by ASP.NET Core. For example, Xamarin developers can use SignalR for building Android apps using Xamarin.Android 8.4.0.1 and later and iOS apps using Xamarin.iOS 11.14.0.4 and later.

If the server runs IIS, the WebSockets transport requires IIS 8.0 or later on Windows Server 2012 or later. Other transports are supported on all platforms.

Java client

The Java client supports Java 8 and later versions.

Unsupported clients

The following clients are available but are experimental or unofficial. They aren't currently supported and may never be.

- C++ client
- Swift client

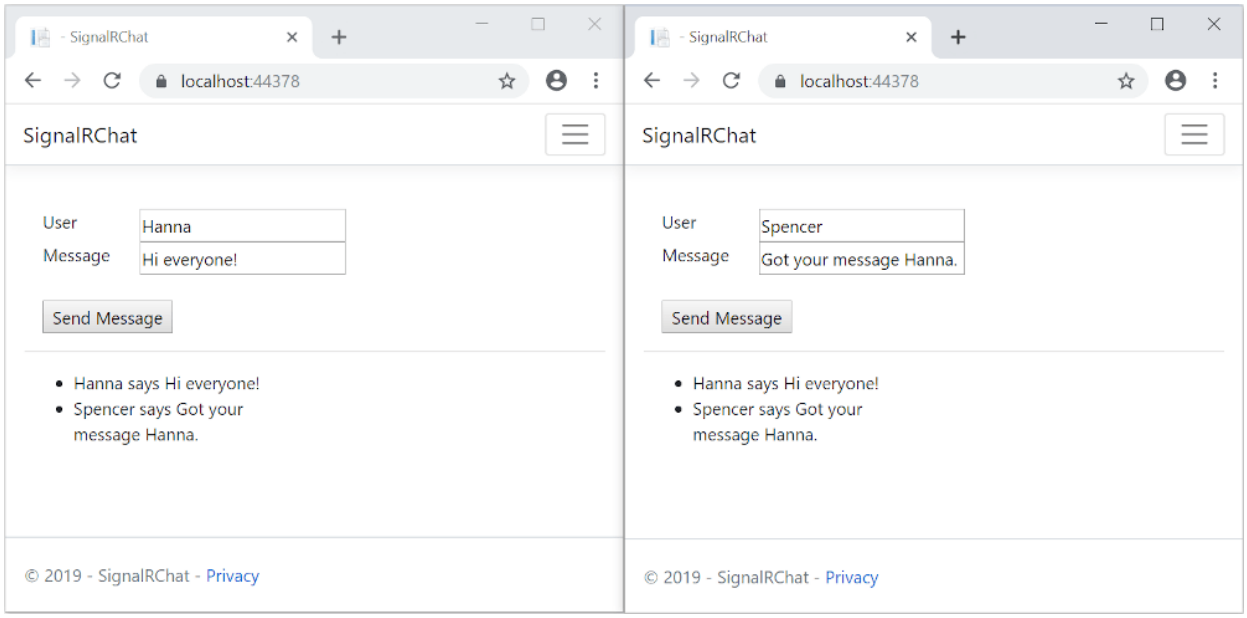
Tutorial: Get started with ASP.NET Core SignalR

9/22/2020 • 13 minutes to read • Edit Online

This tutorial teaches the basics of building a real-time app using SignalR. You learn how to:

- Create a web project.
- Add the SignalR client library.
- Create a SignalR hub.
- Configure the project to use SignalR.
- Add code that sends messages from any client to all connected clients.

At the end, you'll have a working chat app:



Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 16.4 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

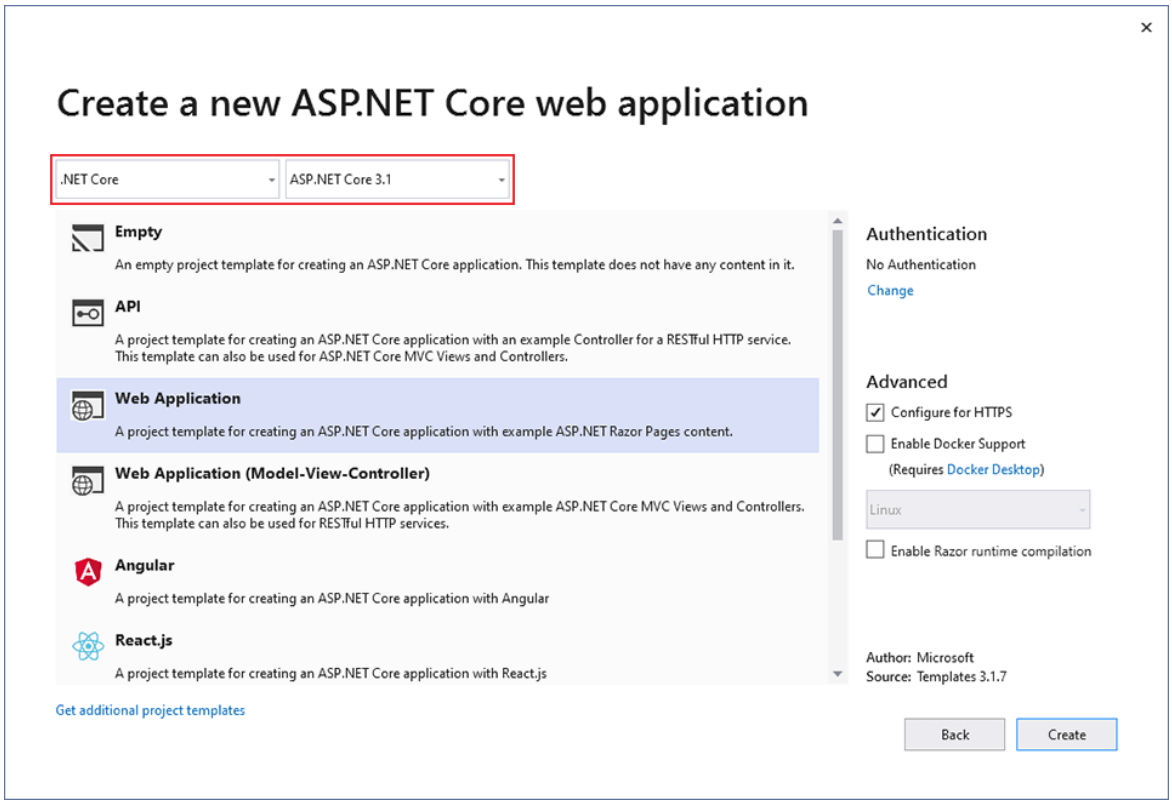
Create a web app project

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- From the menu, select **File > New Project**.
- In the **Create a new project** dialog, select **ASP.NET Core Web Application**, and then select **Next**.
- In the **Configure your new project** dialog, name the project *SignalRChat*, and then select **Create**.
- In the **Create a new ASP.NET Core web Application** dialog, select **.NET Core** and **ASP.NET Core**

3.1.

- Select **Web Application** to create a project that uses Razor Pages, and then select **Create**.

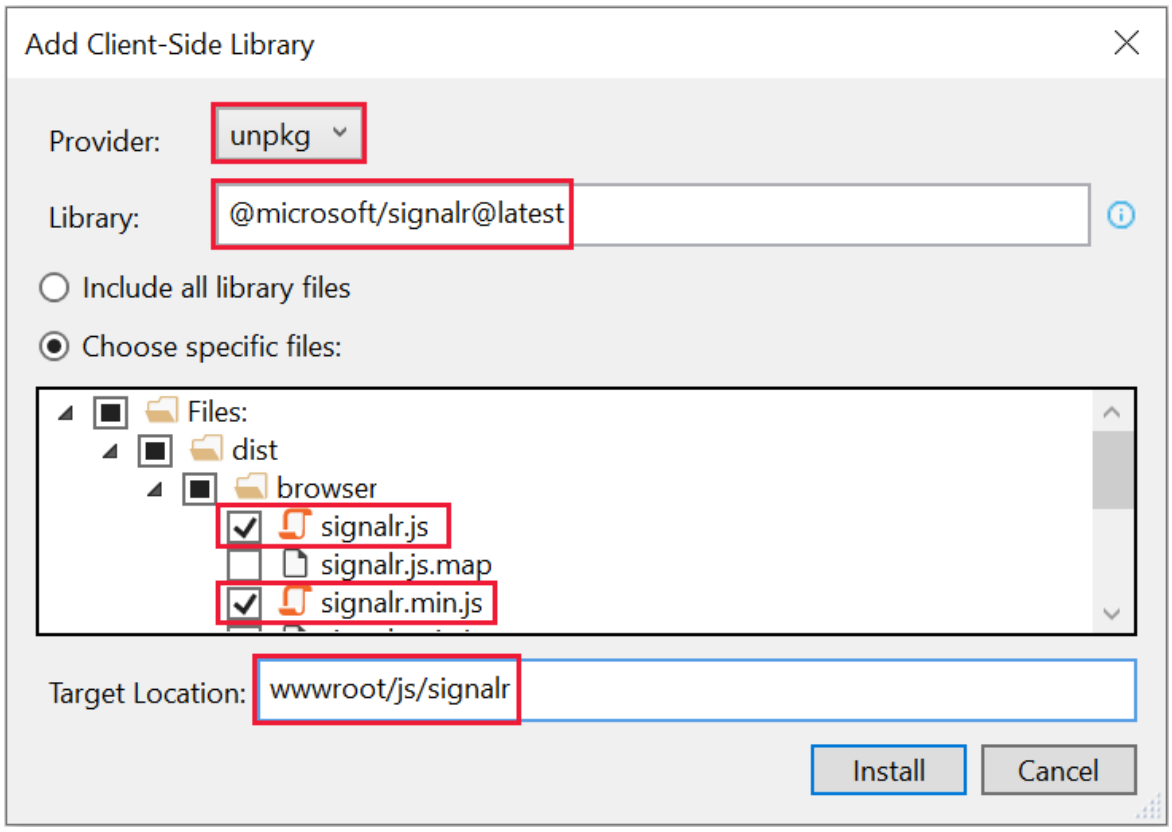


Add the SignalR client library

The SignalR server library is included in the ASP.NET Core 3.1 shared framework. The JavaScript client library isn't automatically included in the project. For this tutorial, you use Library Manager (LibMan) to get the client library from *unpkg*. unpkg is a content delivery network (CDN) that can deliver anything found in npm, the Node.js package manager.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- In **Solution Explorer**, right-click the project, and select **Add** > **Client-Side Library**.
- In the **Add Client-Side Library** dialog, for **Provider** select **unpkg**.
- For **Library**, enter `@microsoft/signalr@latest`.
- Select **Choose specific files**, expand the *dist/browser* folder, and select *signalr.js* and *signalr.min.js*.
- Set **Target Location** to *wwwroot/js/signalr/*, and select **Install**.



LibMan creates a *wwwroot/js/signalr* folder and copies the selected files to it.

Create a SignalR hub

A *hub* is a class that serves as a high-level pipeline that handles client-server communication.

- In the SignalRChat project folder, create a *Hubs* folder.
- In the *Hubs* folder, create a *ChatHub.cs* file with the following code:

```
using Microsoft.AspNetCore.SignalR;
using System.Threading.Tasks;

namespace SignalRChat.Hubs
{
    public class ChatHub : Hub
    {
        public async Task SendMessage(string user, string message)
        {
            await Clients.All.SendAsync("ReceiveMessage", user, message);
        }
    }
}
```

The `ChatHub` class inherits from the SignalR `Hub` class. The `Hub` class manages connections, groups, and messaging.

The `SendMessage` method can be called by a connected client to send a message to all clients. JavaScript client code that calls the method is shown later in the tutorial. SignalR code is asynchronous to provide maximum scalability.

Configure SignalR

The SignalR server must be configured to pass SignalR requests to SignalR.

- Add the following highlighted code to the *Startup.cs* file.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.AspNetCore.HttpsPolicy;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using SignalRChat.Hubs;

namespace SignalRChat
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        // This method gets called by the runtime. Use this method to add services to the container.
        public void ConfigureServices(IServiceCollection services)
        {
            services.AddRazorPages();
            services.AddSignalR();
        }

        // This method gets called by the runtime. Use this method to configure the HTTP request
pipeline.
        public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
        {
            if (env.IsDevelopment())
            {
                app.UseDeveloperExceptionPage();
            }
            else
            {
                app.UseExceptionHandler("/Error");
                // The default HSTS value is 30 days. You may want to change this for production
scenarios, see https://aka.ms/aspnetcore-hsts.
                app.UseHsts();
            }

            app.UseHttpsRedirection();
            app.UseStaticFiles();

            app.UseRouting();

            app.UseAuthorization();

            app.UseEndpoints(endpoints =>
            {
                endpoints.MapRazorPages();
                endpoints.MapHub<ChatHub>("/chathub");
            });
        }
    }
}
```

These changes add SignalR to the ASP.NET Core dependency injection and routing systems.

Add SignalR client code

- Replace the content in *Pages\Index.cshtml* with the following code:

```
@page
    <div class="container">
        <div class="row"> </div>
        <div class="row">
            <div class="col-2">User</div>
            <div class="col-4"><input type="text" id="userInput" /></div>
        </div>
        <div class="row">
            <div class="col-2">Message</div>
            <div class="col-4"><input type="text" id="messageInput" /></div>
        </div>
        <div class="row"> </div>
        <div class="row">
            <div class="col-6">
                <input type="button" id="sendButton" value="Send Message" />
            </div>
        </div>
    </div>
    <div class="row">
        <div class="col-12">
            <hr />
        </div>
    </div>
    <div class="row">
        <div class="col-6">
            <ul id="messagesList"></ul>
        </div>
    </div>
<script src="~/js/signalr/dist/browser/signalr.js"></script>
<script src="~/js/chat.js"></script>
```

  The preceding code:

  - Creates text boxes for name and message text, and a submit button.
  - Creates a list with `id="messagesList"` for displaying messages that are received from the SignalR hub.
  - Includes script references to SignalR and the *chat.js* application code that you create in the next step.
- In the *wwwroot/js* folder, create a *chat.js* file with the following code:

```
"use strict";

var connection = new signalR.HubConnectionBuilder().withUrl("/chatHub").build();

//Disable send button until connection is established
document.getElementById("sendButton").disabled = true;

connection.on("ReceiveMessage", function (user, message) {
    var msg = message.replace(/&/g, "&amp;").replace(/</g, "&lt;").replace(/>/g, "&gt;");
    var encodedMsg = user + " says " + msg;
    var li = document.createElement("li");
    li.textContent = encodedMsg;
    document.getElementById("messagesList").appendChild(li);
});

connection.start().then(function () {
    document.getElementById("sendButton").disabled = false;
}).catch(function (err) {
    return console.error(err.toString());
});

document.getElementById("sendButton").addEventListener("click", function (event) {
    var user = document.getElementById("userInput").value;
    var message = document.getElementById("messageInput").value;
    connection.invoke("SendMessage", user, message).catch(function (err) {
        return console.error(err.toString());
    });
    event.preventDefault();
});
```

The preceding code:

- Creates and starts a connection.
- Adds to the submit button a handler that sends messages to the hub.
- Adds to the connection object a handler that receives messages from the hub and adds them to the list.

Run the app

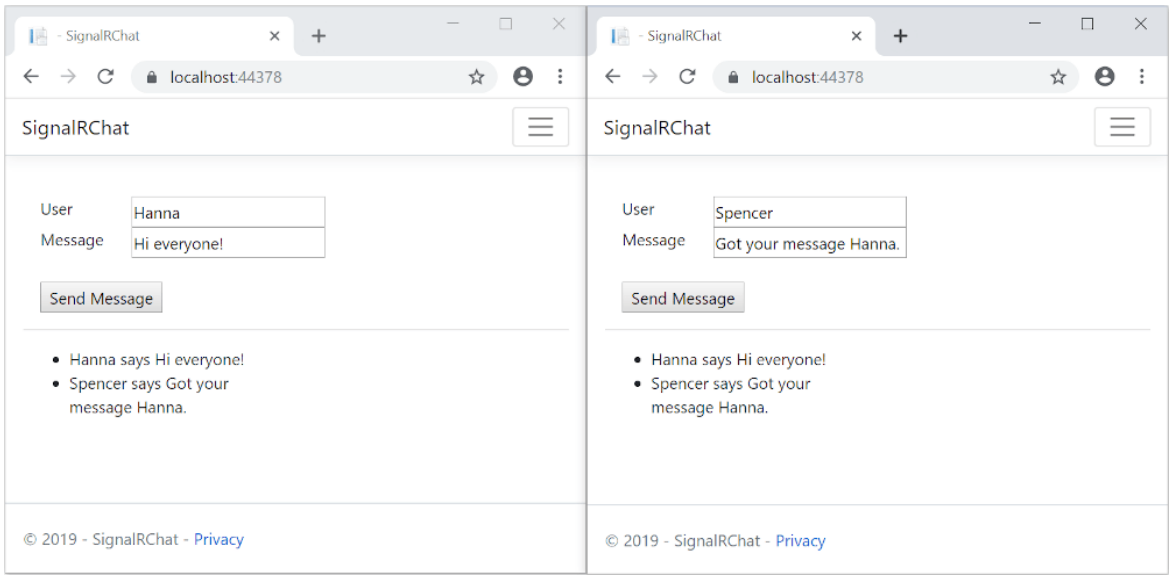
- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Press **CTRL+F5** to run the app without debugging.

- Copy the URL from the address bar, open another browser instance or tab, and paste the URL in the address bar.

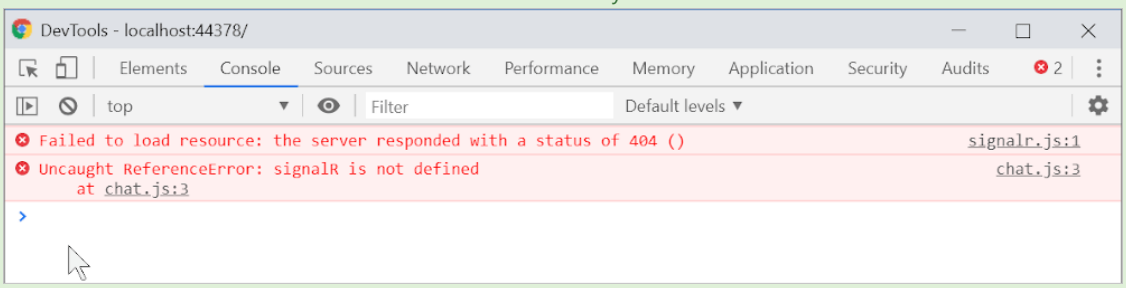
- Choose either browser, enter a name and message, and select the **Send Message** button.

  The name and message are displayed on both pages instantly.



TIP

- If the app doesn't work, open your browser developer tools (F12) and go to the console. You might see errors related to your HTML and JavaScript code. For example, suppose you put *signalr.js* in a different folder than directed. In that case the reference to that file won't work and you'll see a 404 error in the console.

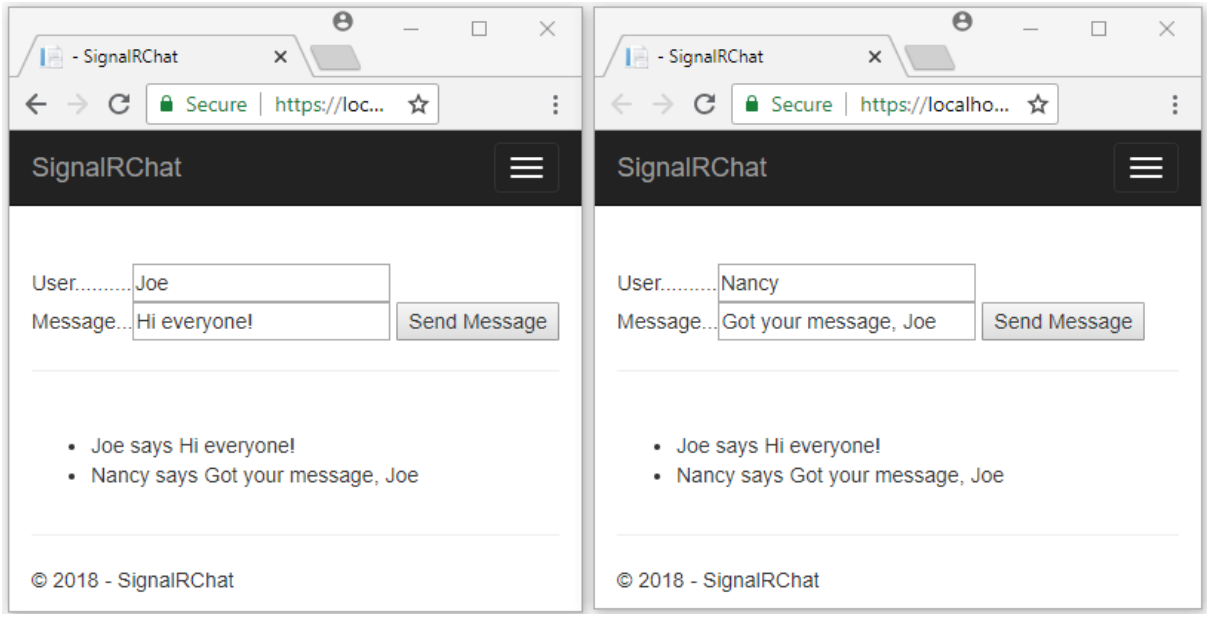


- If you get the error ERR_SPDY_INADEQUATE_TRANSPORT_SECURITY in Chrome, run these commands to update your development certificate:

```
dotnet dev-certs https --clean
dotnet dev-certs https --trust
```

This tutorial teaches the basics of building a real-time app using SignalR. You learn how to:

- Create a web project.
- Add the SignalR client library.
- Create a SignalR hub.
- Configure the project to use SignalR.
- Add code that sends messages from any client to all connected clients. At the end, you'll have a working chat app:



Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

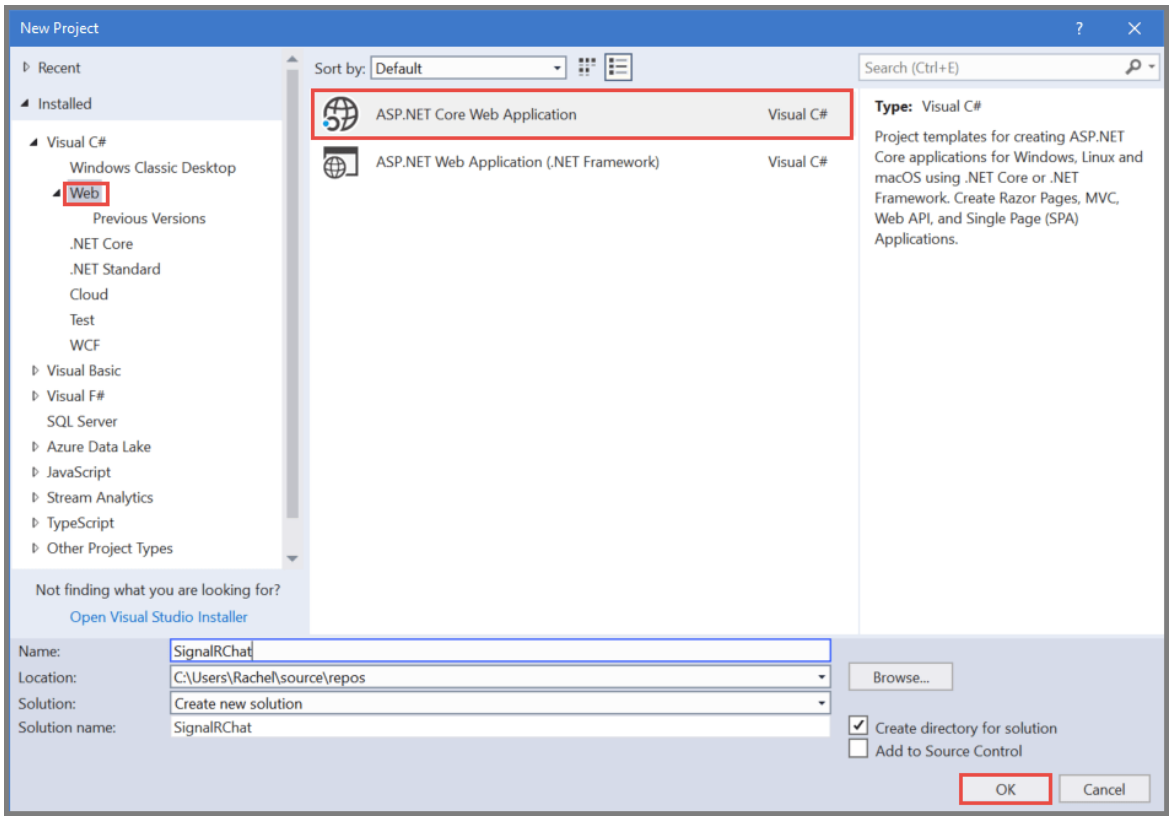
- Visual Studio 2017 version 15.9 or later with the **ASP.NET and web development** workload. You can use Visual Studio 2019, but some project creation steps differ from what's shown in the tutorial.
- .NET Core SDK 2.2 or later

> **WARNING**
> If you use Visual Studio 2017, see dotnet/sdk issue #3124 for information about .NET Core SDK versions that don't work with Visual Studio.

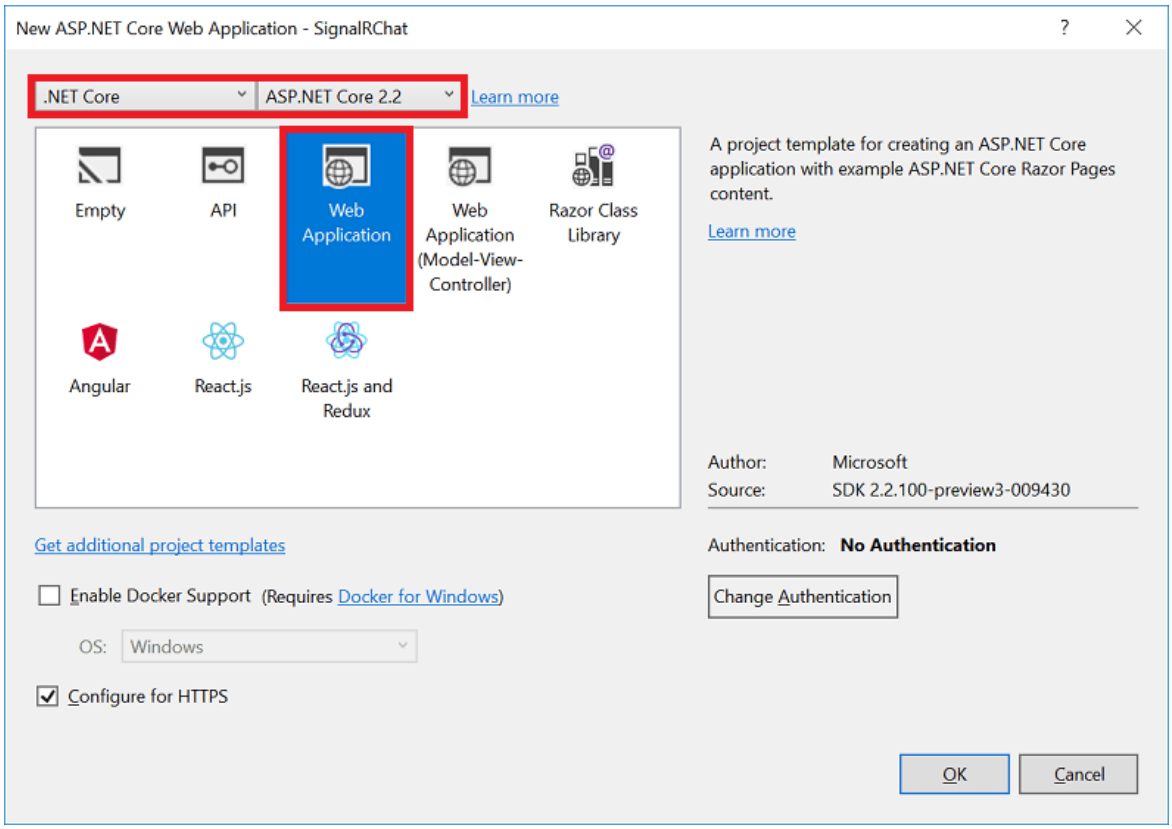
Create a web project

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- From the menu, select **File > New Project**.
- In the **New Project** dialog, select **Installed > Visual C# > Web > ASP.NET Core Web Application**. Name the project *SignalRChat*.



- Select **Web Application** to create a project that uses Razor Pages.
- Select a target framework of **.NET Core**, select **ASP.NET Core 2.2**, and click **OK**.

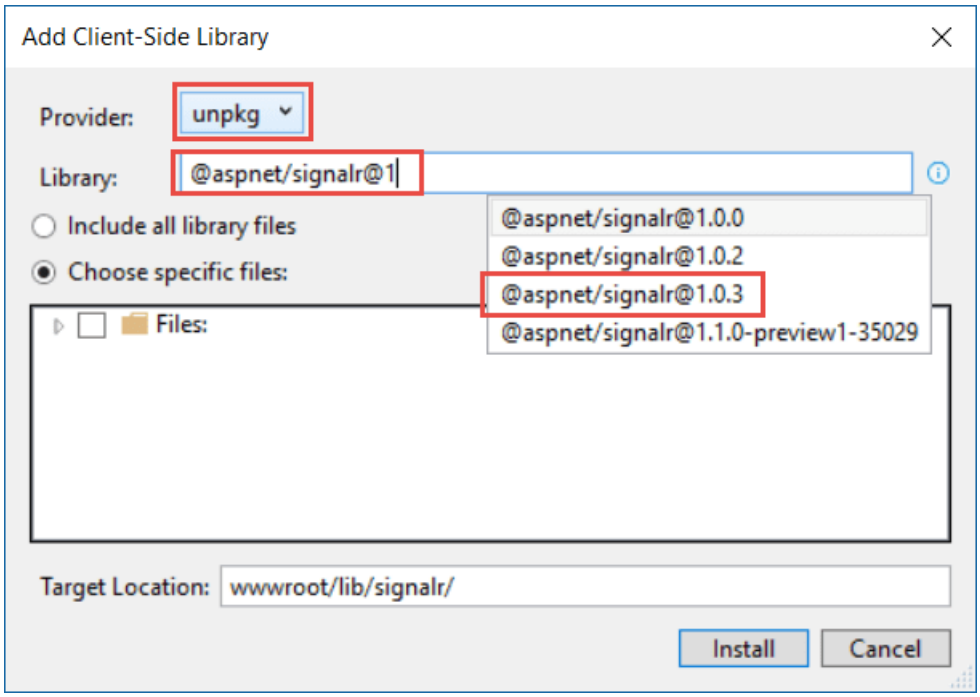


Add the SignalR client library

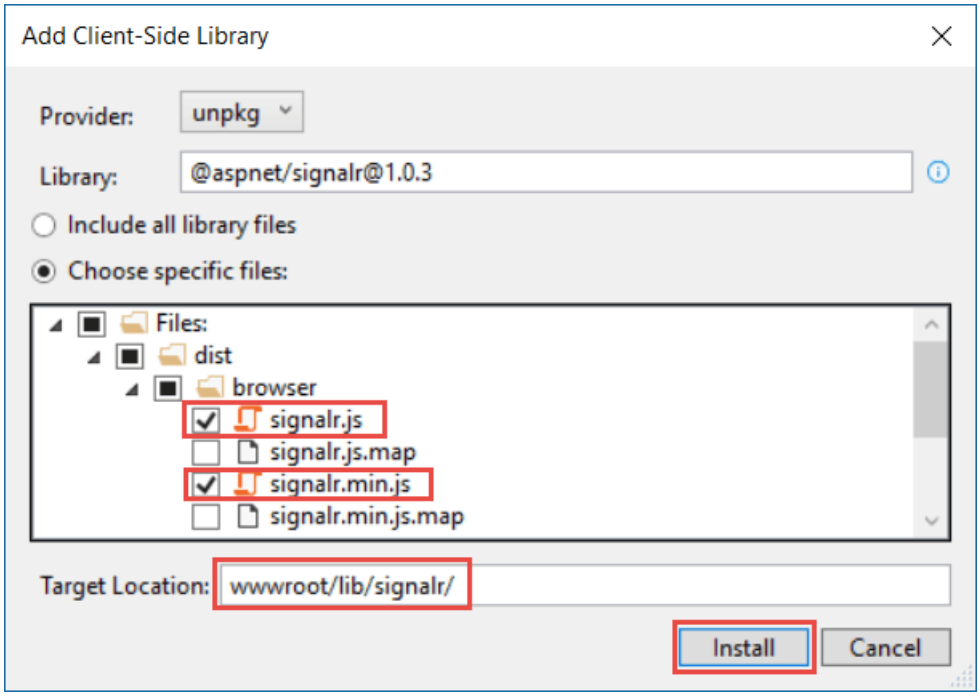
The SignalR server library is included in the `Microsoft.AspNetCore.App` metapackage. The JavaScript client library isn't automatically included in the project. For this tutorial, you use Library Manager (LibMan) to get the client library from *unpkg*. unpkg is a content delivery network (CDN) that can deliver anything found in npm, the Node.js package manager.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- In **Solution Explorer**, right-click the project, and select **Add** > **Client-Side Library**.
- In the **Add Client-Side Library** dialog, for **Provider** select **unpkg**.
- For **Library**, enter `@microsoft/signalr@3`, and select the latest version that isn't preview.



- Select **Choose specific files**, expand the *dist/browser* folder, and select *signalr.js* and *signalr.min.js*.
- Set **Target Location** to *wwwroot/lib/signalr/*, and select **Install**.



LibMan creates a *wwwroot/lib/signalr* folder and copies the selected files to it.

Create a SignalR hub

A *hub* is a class that serves as a high-level pipeline that handles client-server communication.

- In the SignalRChat project folder, create a *Hubs* folder.
- In the *Hubs* folder, create a *ChatHub.cs* file with the following code:

```
using Microsoft.AspNetCore.SignalR;
using System.Threading.Tasks;

namespace SignalRChat.Hubs
{
    public class ChatHub : Hub
    {
        public async Task SendMessage(string user, string message)
        {
            await Clients.All.SendAsync("ReceiveMessage", user, message);
        }
    }
}
```

  The `ChatHub` class inherits from the SignalR `Hub` class. The `Hub` class manages connections, groups, and messaging.

  The `SendMessage` method can be called by a connected client to send a message to all clients. JavaScript client code that calls the method is shown later in the tutorial. SignalR code is asynchronous to provide maximum scalability.

Configure SignalR

The SignalR server must be configured to pass SignalR requests to SignalR.

- Add the following highlighted code to the *Startup.cs* file.

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.AspNetCore.Http;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using SignalRChat.Hubs;

namespace SignalRChat
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        // This method gets called by the runtime. Use this method to add services to the container.
        public void ConfigureServices(IServiceCollection services)
        {
            services.Configure<CookiePolicyOptions>(options =>
            {
                // This lambda determines whether user consent for non-essential cookies is needed
for a given request.
                options.CheckConsentNeeded = context => true;
                options.MinimumSameSitePolicy = SameSiteMode.None;
            });

            services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);

            services.AddSignalR();
        }

        // This method gets called by the runtime. Use this method to configure the HTTP request
pipeline.
        public void Configure(IApplicationBuilder app, IHostingEnvironment env)
        {
            if (env.IsDevelopment())
            {
                app.UseDeveloperExceptionPage();
            }
            else
            {
                app.UseExceptionHandler("/Error");
                app.UseHsts();
            }

            app.UseHttpsRedirection();
            app.UseStaticFiles();
            app.UseCookiePolicy();
            app.UseSignalR(routes =>
            {
                routes.MapHub<ChatHub>("/chathub");
            });
            app.UseMvc();
        }
    }
}
```

These changes add SignalR to the ASP.NET Core dependency injection system and the middleware pipeline.

Add SignalR client code

- Replace the content in *Pages\Index.cshtml* with the following code:

```
@page
<div class="container">
    <div class="row"> </div>
    <div class="row">
        <div class="col-6"> </div>
        <div class="col-6">
            User.....<input type="text" id="userInput" />
            <br />
            Message...<input type="text" id="messageInput" />
            <input type="button" id="sendButton" value="Send Message" />
        </div>
    </div>
    <div class="row">
        <div class="col-12">
            <hr />
        </div>
    </div>
    <div class="row">
        <div class="col-6"> </div>
        <div class="col-6">
            <ul id="messagesList"></ul>
        </div>
    </div>
</div>
<script src="~/lib/signalr/dist/browser/signalr.js"></script>
<script src="~/js/chat.js"></script>
```

  The preceding code:

  - Creates text boxes for name and message text, and a submit button.
  - Creates a list with `id="messagesList"` for displaying messages that are received from the SignalR hub.
  - Includes script references to SignalR and the *chat.js* application code that you create in the next step.

- In the *wwwroot/js* folder, create a *chat.js* file with the following code:

```
"use strict";

var connection = new signalR.HubConnectionBuilder().withUrl("/chatHub").build();

//Disable send button until connection is established
document.getElementById("sendButton").disabled = true;

connection.on("ReceiveMessage", function (user, message) {
    var msg = message.replace(/&/g, "&amp;").replace(/</g, "&lt;").replace(/>/g, "&gt;");
    var encodedMsg = user + " says " + msg;
    var li = document.createElement("li");
    li.textContent = encodedMsg;
    document.getElementById("messagesList").appendChild(li);
});

connection.start().then(function(){
    document.getElementById("sendButton").disabled = false;
}).catch(function (err) {
    return console.error(err.toString());
});

document.getElementById("sendButton").addEventListener("click", function (event) {
    var user = document.getElementById("userInput").value;
    var message = document.getElementById("messageInput").value;
    connection.invoke("SendMessage", user, message).catch(function (err) {
        return console.error(err.toString());
    });
    event.preventDefault();
});
```

The preceding code:

- Creates and starts a connection.
- Adds to the submit button a handler that sends messages to the hub.
- Adds to the connection object a handler that receives messages from the hub and adds them to the list.

Run the app

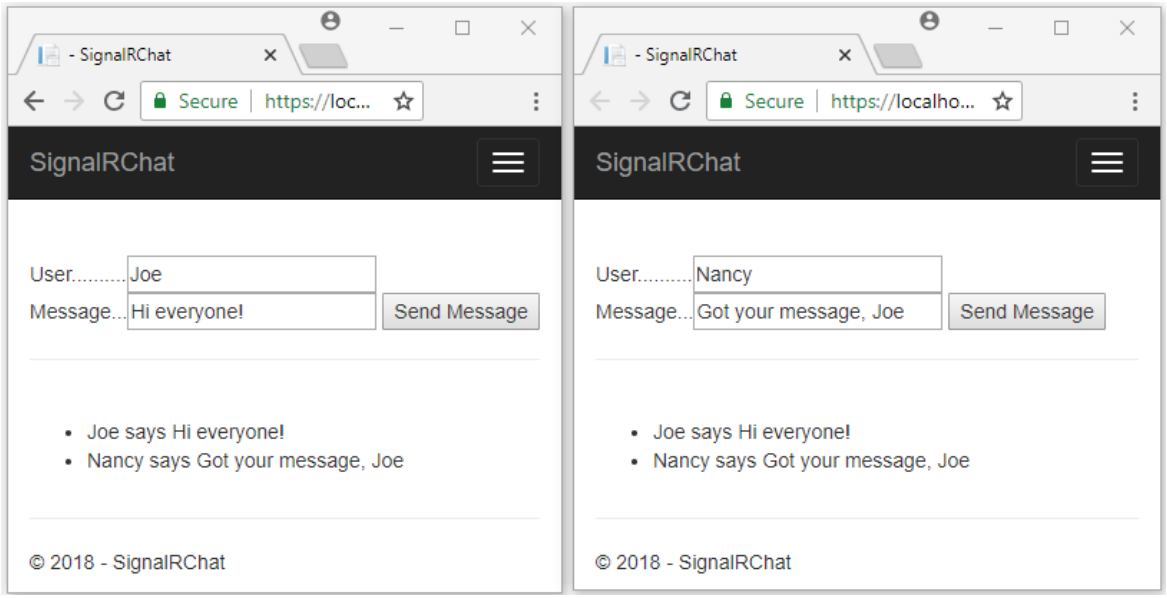
- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Press **CTRL+F5** to run the app without debugging.

- Copy the URL from the address bar, open another browser instance or tab, and paste the URL in the address bar.

- Choose either browser, enter a name and message, and select the **Send Message** button.

  The name and message are displayed on both pages instantly.



TIP

If the app doesn't work, open your browser developer tools (F12) and go to the console. You might see errors related to your HTML and JavaScript code. For example, suppose you put *signalr.js* in a different folder than directed. In that case the reference to that file won't work and you'll see a 404 error in the console.

Use ASP.NET Core SignalR with TypeScript and Webpack

9/22/2020 • 21 minutes to read • Edit Online

By Sébastien Sougnez and Scott Addie

Webpack enables developers to bundle and build the client-side resources of a web app. This tutorial demonstrates using Webpack in an ASP.NET Core SignalR web app whose client is written in TypeScript.

In this tutorial, you learn how to:

- Scaffold a starter ASP.NET Core SignalR app
- Configure the SignalR TypeScript client
- Configure a build pipeline using Webpack
- Configure the SignalR server
- Enable communication between client and server

View or download sample code (how to download)

Prerequisites

- Visual Studio
- Visual Studio Code

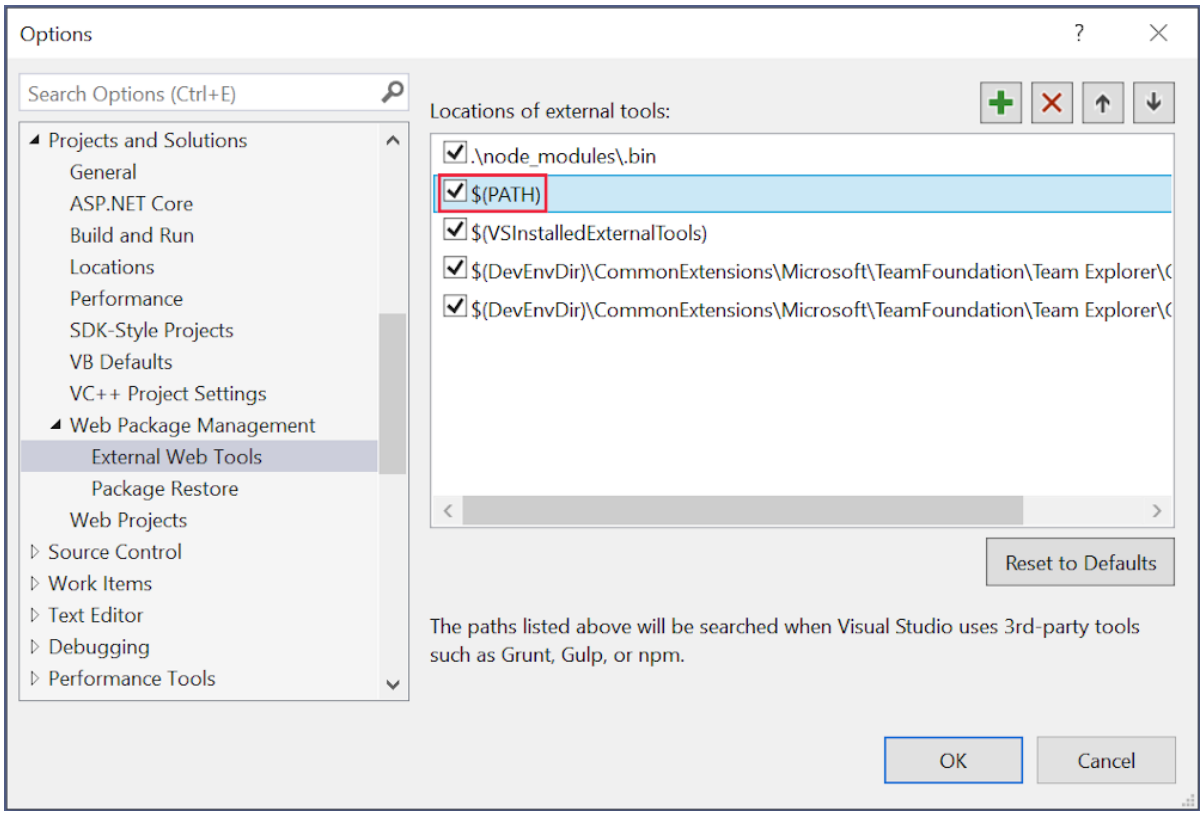
- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core SDK 3.0 or later
- Node.js with npm

Create the ASP.NET Core web app

- Visual Studio
- Visual Studio Code

Configure Visual Studio to look for npm in the *PATH* environment variable. By default, Visual Studio uses the version of npm found in its installation directory. Follow these instructions in Visual Studio:

1. Launch Visual Studio. At the start window, select **Continue without code**.
2. Navigate to **Tools** > **Options** > **Projects and Solutions** > **Web Package Management** > **External Web Tools**.
3. Select the *$(PATH)* entry from the list. Click the up arrow to move the entry to the second position in the list, and select **OK**.



Visual Studio configuration is complete.

1. Use the **File** > **New** > **Project** menu option and choose the **ASP.NET Core Web Application** template. Select **Next**.
2. Name the project *SignalRWebPack*, and select **Create**.
3. Select *.NET Core* from the target framework drop-down, and select *ASP.NET Core 3.1* from the framework selector drop-down. Select the **Empty** template, and select **Create**.

Add the `Microsoft.TypeScript.MSBuild` package to the project:

1. In **Solution Explorer** (right pane), right-click the project node and select **Manage NuGet Packages**. In the **Browse** tab, search for `Microsoft.TypeScript.MSBuild`, and then click **Install** on the right to install the package.

Visual Studio adds the NuGet package under the **Dependencies** node in **Solution Explorer**, enabling TypeScript compilation in the project.

Configure Webpack and TypeScript

The following steps configure the conversion of TypeScript to JavaScript and the bundling of client-side resources.

1. Run the following command in the project root to create a *package.json* file:

```
npm init -y
```

2. Add the highlighted property to the *package.json* file and save the file changes:

```
{
  "name": "SignalRWebPack",
  "version": "1.0.0",
  "private": true,
  "description": "",
  "main": "index.js",
  "scripts": {
    "test": "echo \"Error: no test specified\" && exit 1"
  },
  "keywords": [],
  "author": "",
  "license": "ISC"
}
```

Setting the `private` property to `true` prevents package installation warnings in the next step.

3. Install the required npm packages. Run the following command from the project root:

```
npm i -D -E clean-webpack-plugin@3.0.0 css-loader@3.4.2 html-webpack-plugin@3.2.0 mini-css-extract-plugin@0.9.0 ts-loader@6.2.1 typescript@3.7.5 webpack@4.41.5 webpack-cli@3.3.10
```

Some command details to note:

- A version number follows the `@` sign for each package name. npm installs those specific package versions.
- The `-E` option disables npm's default behavior of writing semantic versioning range operators to *package.json*. For example, `"webpack": "4.41.5"` is used instead of `"webpack": "^4.41.5"`. This option prevents unintended upgrades to newer package versions.

See the npm-install docs for more detail.

4. Replace the `scripts` property of the *package.json* file with the following code:

```
"scripts": {
  "build": "webpack --mode=development --watch",
  "release": "webpack --mode=production",
  "publish": "npm run release && dotnet publish -c Release"
},
```

Some explanation of the scripts:

- `build`: Bundles the client-side resources in development mode and watches for file changes. The file watcher causes the bundle to regenerate each time a project file changes. The `mode` option disables production optimizations, such as tree shaking and minification. Only use `build` in development.
- `release`: Bundles the client-side resources in production mode.
- `publish`: Runs the `release` script to bundle the client-side resources in production mode. It calls the .NET Core CLI's publish command to publish the app.

5. Create a file named *webpack.config.js*, in the project root, with the following code:

```
const path = require("path");
const HtmlWebpackPlugin = require("html-webpack-plugin");
const { CleanWebpackPlugin } = require("clean-webpack-plugin");
const MiniCssExtractPlugin = require("mini-css-extract-plugin");
module.exports = {
    entry: "./src/index.ts",
    output: {
        path: path.resolve(__dirname, "wwwroot"),
        filename: "[name].[chunkhash].js",
        publicPath: "/"
    },
    resolve: {
        extensions: [".js", ".ts"]
    },
    module: {
        rules: [
            {
                test: /\.ts$/,
                use: "ts-loader"
            },
            {
                test: /\.css$/,
                use: [MiniCssExtractPlugin.loader, "css-loader"]
            }
        ]
    },
    plugins: [
        new CleanWebpackPlugin(),
        new HtmlWebpackPlugin({
            template: "./src/index.html"
        }),
        new MiniCssExtractPlugin({
            filename: "css/[name].[chunkhash].css"
        })
    ]
};
```

The preceding file configures the Webpack compilation. Some configuration details to note:

- The `output` property overrides the default value of *dist*. The bundle is instead emitted in the *wwwroot* directory.
- The `resolve.extensions` array includes *.js* to import the SignalR client JavaScript.

6. Create a new *src* directory in the project root to store the project's client-side assets.

7. Create *src/index.html* with the following markup.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <title>ASP.NET Core SignalR</title>
</head>
<body>
    <div id="divMessages" class="messages">
    </div>
    <div class="input-zone">
        <label id="lblMessage" for="tbMessage">Message:</label>
        <input id="tbMessage" class="input-zone-input" type="text" />
        <button id="btnSend">Send</button>
    </div>
</body>
</html>
```

The preceding HTML defines the homepage's boilerplate markup.

8. Create a new *src/css* directory. Its purpose is to store the project's *.css* files.

9. Create *src/css/main.css* with the following CSS:

```
*, *::before, *::after {
    box-sizing: border-box;
}

html, body {
    margin: 0;
    padding: 0;
}

.input-zone {
    align-items: center;
    display: flex;
    flex-direction: row;
    margin: 10px;
}

.input-zone-input {
    flex: 1;
    margin-right: 10px;
}

.message-author {
    font-weight: bold;
}

.messages {
    border: 1px solid #000;
    margin: 10px;
    max-height: 300px;
    min-height: 300px;
    overflow-y: auto;
    padding: 5px;
}
```

The preceding *main.css* file styles the app.

10. Create *src/tsconfig.json* with the following JSON:

```
{
  "compilerOptions": {
    "target": "es5"
  }
}
```

The preceding code configures the TypeScript compiler to produce ECMAScript 5-compatible JavaScript.

11. Create *src/index.ts* with the following code:

```
import "./css/main.css";

const divMessages: HTMLDivElement = document.querySelector("#divMessages");
const tbMessage: HTMLInputElement = document.querySelector("#tbMessage");
const btnSend: HTMLButtonElement = document.querySelector("#btnSend");
const username = new Date().getTime();

tbMessage.addEventListener("keyup", (e: KeyboardEvent) => {
    if (e.key === "Enter") {
        send();
    }
});

btnSend.addEventListener("click", send);

function send() {
}
```

The preceding TypeScript retrieves references to DOM elements and attaches two event handlers:

- `keyup`: This event fires when the user types in the `tbMessage` textbox. The `send` function is called when the user presses the **Enter** key.
- `click`: This event fires when the user clicks the **Send** button. The `send` function is called.

Configure the app

1. In `Startup.Configure`, add calls to UseDefaultFiles and UseStaticFiles.

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    app.UseRouting();
    app.UseDefaultFiles();
    app.UseStaticFiles();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapHub<ChatHub>("/hub");
    });

}
```

The preceding code allows the server to locate and serve the *index.html* file. The file is served whether the user enters its full URL or the root URL of the web app.

2. At the end of `Startup.Configure`, map a */hub* route to the `ChatHub` hub. Replace the code that displays *Hello World!* with the following line:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHub<ChatHub>("/hub");
});
```

3. In `Startup.ConfigureServices`, call AddSignalR.

```
services.AddSignalR();
```

4. Create a new directory named *Hubs* in the project root *SignalRWebPack/* to store the SignalR hub.

5. Create hub *Hubs/ChatHub.cs* with the following code:

```
using Microsoft.AspNetCore.SignalR;
using System.Threading.Tasks;

namespace SignalRWebPack.Hubs
{
    public class ChatHub : Hub
    {
    }
}
```

6. Add the following `using` statement at the top of the *Startup.cs* file to resolve the `ChatHub` reference:

```
using SignalRWebPack.Hubs;
```

Enable client and server communication

The app currently displays a basic form to send messages, but is not yet functional. The server is listening to a specific route but does nothing with sent messages.

1. Run the following command at the project root:

```
npm i @microsoft/signalr @types/node
```

   The preceding command installs:

   - The SignalR TypeScript client, which allows the client to send messages to the server.
   - The TypeScript type definitions for Node.js, which enables compile-time checking of Node.js types.

2. Add the highlighted code to the *src/index.ts* file:

```
import "./css/main.css";
import * as signalR from "@microsoft/signalr";

const divMessages: HTMLDivElement = document.querySelector("#divMessages");
const tbMessage: HTMLInputElement = document.querySelector("#tbMessage");
const btnSend: HTMLButtonElement = document.querySelector("#btnSend");
const username = new Date().getTime();

const connection = new signalR.HubConnectionBuilder()
    .withUrl("/hub")
    .build();

connection.on("messageReceived", (username: string, message: string) => {
    let m = document.createElement("div");

    m.innerHTML =
        `<div class="message-author">${username}</div><div>${message}</div>`;

    divMessages.appendChild(m);
    divMessages.scrollTop = divMessages.scrollHeight;
});

connection.start().catch(err => document.write(err));

tbMessage.addEventListener("keyup", (e: KeyboardEvent) => {
    if (e.key === "Enter") {
        send();
    }
});

btnSend.addEventListener("click", send);

function send() {
}
```

The preceding code supports receiving messages from the server. The `HubConnectionBuilder` class creates a new builder for configuring the server connection. The `withUrl` function configures the hub URL.

SignalR enables the exchange of messages between a client and a server. Each message has a specific name. For example, messages with the name `messageReceived` can run the logic responsible for displaying the new message in the messages zone. Listening to a specific message can be done via the `on` function. Any number of message names can be listened to. It's also possible to pass parameters to the message, such as the author's name and the content of the message received. Once the client receives a message, a new `div` element is created with the author's name and the message content in its `innerHTML` attribute. It's added to the main `div` element displaying the messages.

3. Now that the client can receive a message, configure it to send messages. Add the highlighted code to the *src/index.ts* file:

```
import "./css/main.css";
import * as signalR from "@microsoft/signalr";

const divMessages: HTMLDivElement = document.querySelector("#divMessages");
const tbMessage: HTMLInputElement = document.querySelector("#tbMessage");
const btnSend: HTMLButtonElement = document.querySelector("#btnSend");
const username = new Date().getTime();

const connection = new signalR.HubConnectionBuilder()
    .withUrl("/hub")
    .build();

connection.on("messageReceived", (username: string, message: string) => {
    let messages = document.createElement("div");

    messages.innerHTML =
        `<div class="message-author">${username}</div><div>${message}</div>`;

    divMessages.appendChild(messages);
    divMessages.scrollTop = divMessages.scrollHeight;
});

connection.start().catch(err => document.write(err));

tbMessage.addEventListener("keyup", (e: KeyboardEvent) => {
    if (e.key === "Enter") {
        send();
    }
});

btnSend.addEventListener("click", send);

function send() {
    connection.send("newMessage", username, tbMessage.value)
        .then(() => tbMessage.value = "");
}
```

Sending a message through the WebSockets connection requires calling the `send` method. The method's first parameter is the message name. The message data inhabits the other parameters. In this example, a message identified as `newMessage` is sent to the server. The message consists of the username and the user input from a text box. If the send works, the text box value is cleared.

4. Add the `NewMessage` method to the `ChatHub` class:

```
using Microsoft.AspNetCore.SignalR;
using System.Threading.Tasks;

namespace SignalRWebPack.Hubs
{
    public class ChatHub : Hub
    {
        public async Task NewMessage(long username, string message)
        {
            await Clients.All.SendAsync("messageReceived", username, message);
        }
    }
}
```

The preceding code broadcasts received messages to all connected users once the server receives them. It's unnecessary to have a generic `on` method to receive all the messages. A method named after the message name suffices.

In this example, the TypeScript client sends a message identified as `newMessage`. The C# `NewMessage` method

expects the data sent by the client. A call is made to SendAsync on Clients.All. The received messages are sent to all clients connected to the hub.

Test the app

Confirm that the app works with the following steps.

- Visual Studio
- Visual Studio Code

1. Run Webpack in *release* mode. Using the **Package Manager Console** window, run the following command in the project root. If you are not in the project root, enter `cd SignalRWebPack` before entering the command.

   ```
   npm run release
   ```

   This command generates the client-side assets to be served when running the app. The assets are placed in the *wwwroot* folder.

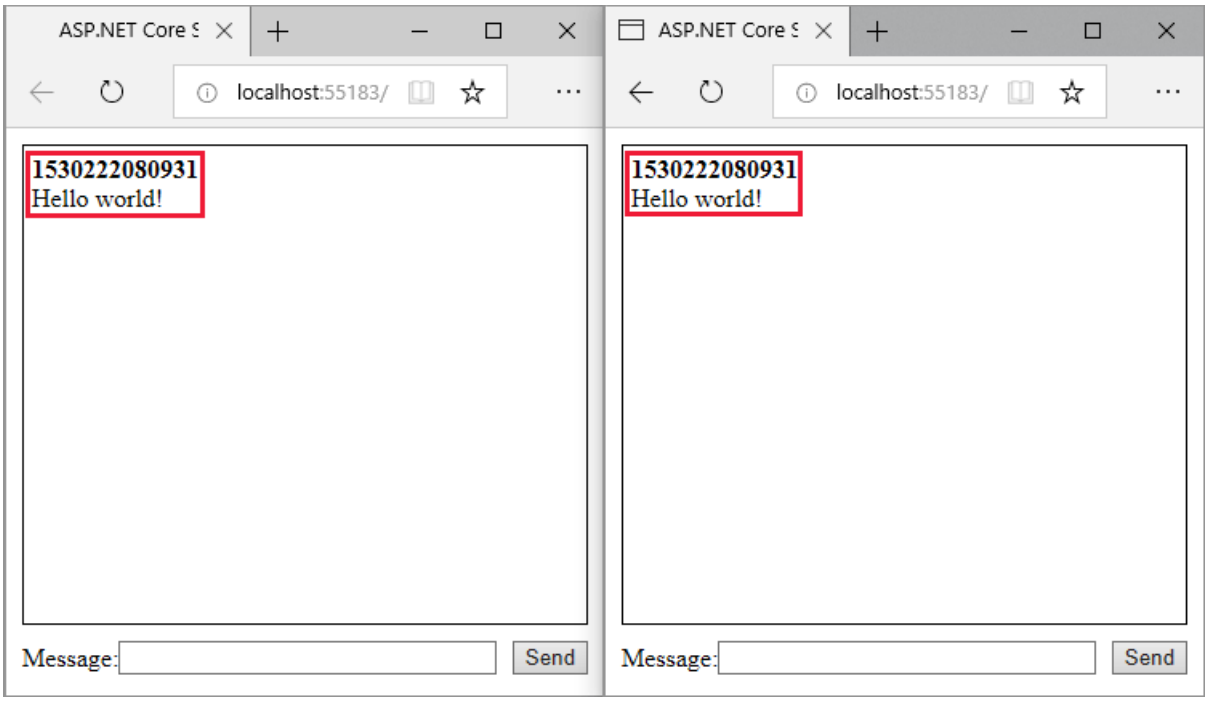
   Webpack completed the following tasks:

   - Purged the contents of the *wwwroot* directory.
   - Converted the TypeScript to JavaScript in a process known as *transpilation*.
   - Mangled the generated JavaScript to reduce file size in a process known as *minification*.
   - Copied the processed JavaScript, CSS, and HTML files from *src* to the *wwwroot* directory.
   - Injected the following elements into the *wwwroot/index.html* file:
     - A `<link>` tag, referencing the *wwwroot/main.<hash>.css* file. This tag is placed immediately before the closing `</head>` tag.
     - A `<script>` tag, referencing the minified *wwwroot/main.<hash>.js* file. This tag is placed immediately before the closing `</body>` tag.
2. Select **Debug** > **Start without debugging** to launch the app in a browser without attaching the debugger. The *wwwroot/index.html* file is served at `http://localhost:<port_number>`.

   If you get compile errors, try closing and reopening the solution.

3. Open another browser instance (any browser). Paste the URL in the address bar.

4. Choose either browser, type something in the **Message** text box, and click the **Send** button. The unique user name and message are displayed on both pages instantly.



Prerequisites

- Visual Studio
- Visual Studio Code

- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core SDK 2.2 or later
- Node.js with npm

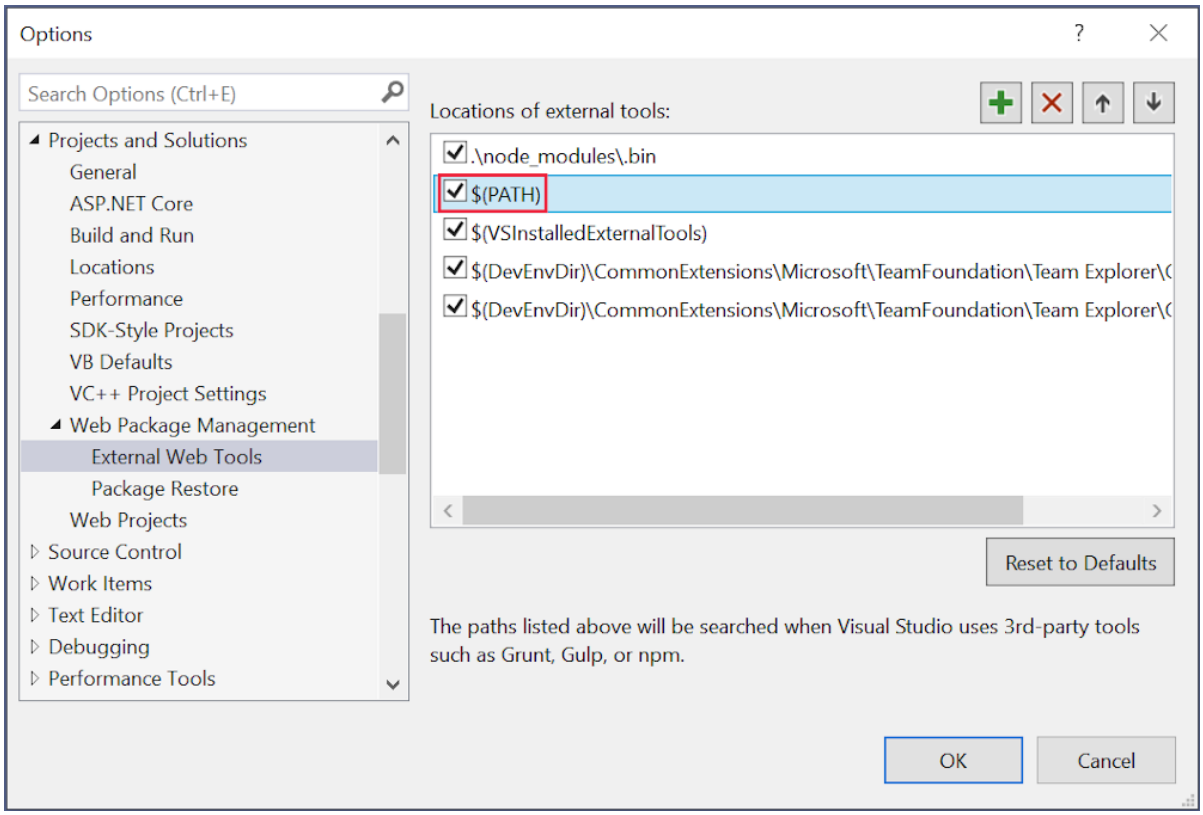
Create the ASP.NET Core web app

- Visual Studio
- Visual Studio Code

Configure Visual Studio to look for npm in the *PATH* environment variable. By default, Visual Studio uses the version of npm found in its installation directory. Follow these instructions in Visual Studio:

1. Navigate to **Tools** > **Options** > **Projects and Solutions** > **Web Package Management** > **External Web Tools**.

2. Select the *$(PATH)* entry from the list. Click the up arrow to move the entry to the second position in the list.



Visual Studio configuration is completed. It's time to create the project.

1. Use the **File** > **New** > **Project** menu option and choose the **ASP.NET Core Web Application** template.
2. Name the project *SignalRWebPack*, and select **Create**.
3. Select *.NET Core* from the target framework drop-down, and select *ASP.NET Core 2.2* from the framework selector drop-down. Select the **Empty** template, and select **Create**.

Configure Webpack and TypeScript

The following steps configure the conversion of TypeScript to JavaScript and the bundling of client-side resources.

1. Run the following command in the project root to create a *package.json* file:

```
npm init -y
```

2. Add the highlighted property to the *package.json* file:

```
{
  "name": "SignalRWebPack",
  "version": "1.0.0",
  "private": true,
  "description": "",
  "main": "index.js",
  "scripts": {
    "test": "echo \"Error: no test specified\" && exit 1"
  },
  "keywords": [],
  "author": "",
  "license": "ISC"
}
```

   Setting the `private` property to `true` prevents package installation warnings in the next step.

3. Install the required npm packages. Run the following command from the project root:

```
npm install -D -E clean-webpack-plugin@1.0.1 css-loader@2.1.0 html-webpack-plugin@4.0.0-beta.5 mini-
css-extract-plugin@0.5.0 ts-loader@5.3.3 typescript@3.3.3 webpack@4.29.3 webpack-cli@3.2.3
```

Some command details to note:

- A version number follows the `@` sign for each package name. npm installs those specific package versions.
- The `-E` option disables npm's default behavior of writing semantic versioning range operators to *package.json*. For example, `"webpack": "4.29.3"` is used instead of `"webpack": "^4.29.3"`. This option prevents unintended upgrades to newer package versions.

See the npm-install docs for more detail.

4. Replace the `scripts` property of the *package.json* file with the following code:

```
"scripts": {
  "build": "webpack --mode=development --watch",
  "release": "webpack --mode=production",
  "publish": "npm run release && dotnet publish -c Release"
},
```

Some explanation of the scripts:

- `build`: Bundles the client-side resources in development mode and watches for file changes. The file watcher causes the bundle to regenerate each time a project file changes. The `mode` option disables production optimizations, such as tree shaking and minification. Only use `build` in development.
- `release`: Bundles the client-side resources in production mode.
- `publish`: Runs the `release` script to bundle the client-side resources in production mode. It calls the .NET Core CLI's publish command to publish the app.

5. Create a file named *webpack.config.js* in the project root, with the following code:

```
const path = require("path");
const HtmlWebpackPlugin = require("html-webpack-plugin");
const CleanWebpackPlugin = require("clean-webpack-plugin");
const MiniCssExtractPlugin = require("mini-css-extract-plugin");

module.exports = {
    entry: "./src/index.ts",
    output: {
        path: path.resolve(__dirname, "wwwroot"),
        filename: "[name].[chunkhash].js",
        publicPath: "/"
    },
    resolve: {
        extensions: [".js", ".ts"]
    },
    module: {
        rules: [
            {
                test: /\.ts$/,
                use: "ts-loader"
            },
            {
                test: /\.css$/,
                use: [MiniCssExtractPlugin.loader, "css-loader"]
            }
        ]
    },
    plugins: [
        new CleanWebpackPlugin(["wwwroot/*"]),
        new HtmlWebpackPlugin({
            template: "./src/index.html"
        }),
        new MiniCssExtractPlugin({
            filename: "css/[name].[chunkhash].css"
        })
    ]
};
```

The preceding file configures the Webpack compilation. Some configuration details to note:

- The `output` property overrides the default value of *dist*. The bundle is instead emitted in the *wwwroot* directory.
- The `resolve.extensions` array includes *.js* to import the SignalR client JavaScript.

6. Create a new *src* directory in the project root to store the project's client-side assets.

7. Create *src/index.html* with the following markup.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <title>ASP.NET Core SignalR</title>
</head>
<body>
    <div id="divMessages" class="messages">
    </div>
    <div class="input-zone">
        <label id="lblMessage" for="tbMessage">Message:</label>
        <input id="tbMessage" class="input-zone-input" type="text" />
        <button id="btnSend">Send</button>
    </div>
</body>
</html>
```

The preceding HTML defines the homepage's boilerplate markup.

8. Create a new *src/css* directory. Its purpose is to store the project's *.css* files.

9. Create *src/css/main.css* with the following markup:

```
*, *::before, *::after {
    box-sizing: border-box;
}

html, body {
    margin: 0;
    padding: 0;
}

.input-zone {
    align-items: center;
    display: flex;
    flex-direction: row;
    margin: 10px;
}

.input-zone-input {
    flex: 1;
    margin-right: 10px;
}

.message-author {
    font-weight: bold;
}

.messages {
    border: 1px solid #000;
    margin: 10px;
    max-height: 300px;
    min-height: 300px;
    overflow-y: auto;
    padding: 5px;
}
```

The preceding *main.css* file styles the app.

10. Create *src/tsconfig.json* with the following JSON:

```
{
  "compilerOptions": {
    "target": "es5"
  }
}
```

The preceding code configures the TypeScript compiler to produce ECMAScript 5-compatible JavaScript.

11. Create *src/index.ts* with the following code:

```
import "./css/main.css";

const divMessages: HTMLDivElement = document.querySelector("#divMessages");
const tbMessage: HTMLInputElement = document.querySelector("#tbMessage");
const btnSend: HTMLButtonElement = document.querySelector("#btnSend");
const username = new Date().getTime();

tbMessage.addEventListener("keyup", (e: KeyboardEvent) => {
    if (e.keyCode === 13) {
        send();
    }
});

btnSend.addEventListener("click", send);

function send() {
}
```

The preceding TypeScript retrieves references to DOM elements and attaches two event handlers:

- `keyup`: This event fires when the user types in the `tbMessage` textbox. The `send` function is called when the user presses the **Enter** key.
- `click`: This event fires when the user clicks the **Send** button. The `send` function is called.

Configure the ASP.NET Core app

1. The code provided in the `Startup.Configure` method displays *Hello World!*. Replace the `app.Run` method call with calls to UseDefaultFiles and UseStaticFiles.

   ```
   app.UseDefaultFiles();
   app.UseStaticFiles();
   ```

   The preceding code allows the server to locate and serve the *index.html* file, whether the user enters its full URL or the root URL of the web app.

2. Call AddSignalR in `Startup.ConfigureServices`. It adds the SignalR services to the project.

   ```
   services.AddSignalR();
   ```

3. Map a */hub* route to the `ChatHub` hub. Add the following lines at the end of `Startup.Configure`:

   ```
   app.UseSignalR(options =>
   {
       options.MapHub<ChatHub>("/hub");
   });
   ```

4. Create a new directory, called *Hubs*, in the project root. Its purpose is to store the SignalR hub, which is created in the next step.

5. Create hub *Hubs/ChatHub.cs* with the following code:

```
using Microsoft.AspNetCore.SignalR;
using System.Threading.Tasks;

namespace SignalRWebPack.Hubs
{
    public class ChatHub : Hub
    {
    }
}
```

6. Add the following code at the top of the *Startup.cs* file to resolve the `ChatHub` reference:

```
using SignalRWebPack.Hubs;
```

Enable client and server communication

The app currently displays a simple form to send messages. Nothing happens when you try to do so. The server is listening to a specific route but does nothing with sent messages.

1. Run the following command at the project root:

```
npm install @aspnet/signalr
```

   The preceding command installs the SignalR TypeScript client, which allows the client to send messages to the server.

2. Add the highlighted code to the *src/index.ts* file:

```
import "./css/main.css";
import * as signalR from "@aspnet/signalr";

const divMessages: HTMLDivElement = document.querySelector("#divMessages");
const tbMessage: HTMLInputElement = document.querySelector("#tbMessage");
const btnSend: HTMLButtonElement = document.querySelector("#btnSend");
const username = new Date().getTime();

const connection = new signalR.HubConnectionBuilder()
    .withUrl("/hub")
    .build();

connection.on("messageReceived", (username: string, message: string) => {
    let m = document.createElement("div");

    m.innerHTML =
        `<div class="message-author">${username}</div><div>${message}</div>`;

    divMessages.appendChild(m);
    divMessages.scrollTop = divMessages.scrollHeight;
});

connection.start().catch(err => document.write(err));

tbMessage.addEventListener("keyup", (e: KeyboardEvent) => {
    if (e.keyCode === 13) {
        send();
    }
});

btnSend.addEventListener("click", send);

function send() {
}
```

The preceding code supports receiving messages from the server. The `HubConnectionBuilder` class creates a new builder for configuring the server connection. The `withUrl` function configures the hub URL.

SignalR enables the exchange of messages between a client and a server. Each message has a specific name. For example, messages with the name `messageReceived` can run the logic responsible for displaying the new message in the messages zone. Listening to a specific message can be done via the `on` function. You can listen to any number of message names. It's also possible to pass parameters to the message, such as the author's name and the content of the message received. Once the client receives a message, a new `div` element is created with the author's name and the message content in its `innerHTML` attribute. The new message is added to the main `div` element displaying the messages.

3. Now that the client can receive a message, configure it to send messages. Add the highlighted code to the *src/index.ts* file:

```
import "./css/main.css";
import * as signalR from "@aspnet/signalr";

const divMessages: HTMLDivElement = document.querySelector("#divMessages");
const tbMessage: HTMLInputElement = document.querySelector("#tbMessage");
const btnSend: HTMLButtonElement = document.querySelector("#btnSend");
const username = new Date().getTime();

const connection = new signalR.HubConnectionBuilder()
    .withUrl("/hub")
    .build();

connection.on("messageReceived", (username: string, message: string) => {
    let messageContainer = document.createElement("div");

    messageContainer.innerHTML =
        `<div class="message-author">${username}</div><div>${message}</div>`;

    divMessages.appendChild(messageContainer);
    divMessages.scrollTop = divMessages.scrollHeight;
});

connection.start().catch(err => document.write(err));

tbMessage.addEventListener("keyup", (e: KeyboardEvent) => {
    if (e.keyCode === 13) {
        send();
    }
});

btnSend.addEventListener("click", send);

function send() {
    connection.send("newMessage", username, tbMessage.value)
              .then(() => tbMessage.value = "");
}
```

Sending a message through the WebSockets connection requires calling the `send` method. The method's first parameter is the message name. The message data inhabits the other parameters. In this example, a message identified as `newMessage` is sent to the server. The message consists of the username and the user input from a text box. If the send works, the text box value is cleared.

4. Add the `NewMessage` method to the `ChatHub` class:

```
using Microsoft.AspNetCore.SignalR;
using System.Threading.Tasks;

namespace SignalRWebPack.Hubs
{
    public class ChatHub : Hub
    {
        public async Task NewMessage(long username, string message)
        {
            await Clients.All.SendAsync("messageReceived", username, message);
        }
    }
}
```

The preceding code broadcasts received messages to all connected users once the server receives them. It's unnecessary to have a generic `on` method to receive all the messages. A method named after the message name suffices.

In this example, the TypeScript client sends a message identified as `newMessage`. The C# `NewMessage` method

expects the data sent by the client. A call is made to SendAsync on Clients.All. The received messages are sent to all clients connected to the hub.

Test the app

Confirm that the app works with the following steps.

- Visual Studio
- Visual Studio Code

1. Run Webpack in *release* mode. Using the **Package Manager Console** window, run the following command in the project root. If you are not in the project root, enter `cd SignalRWebPack` before entering the command.

   ```
   npm run release
   ```

   This command generates the client-side assets to be served when running the app. The assets are placed in the *wwwroot* folder.

   Webpack completed the following tasks:

   - Purged the contents of the *wwwroot* directory.
   - Converted the TypeScript to JavaScript in a process known as *transpilation*.
   - Mangled the generated JavaScript to reduce file size in a process known as *minification*.
   - Copied the processed JavaScript, CSS, and HTML files from *src* to the *wwwroot* directory.
   - Injected the following elements into the *wwwroot/index.html* file:
     - A `<link>` tag, referencing the *wwwroot/main.<hash>.css* file. This tag is placed immediately before the closing `</head>` tag.
     - A `<script>` tag, referencing the minified *wwwroot/main.<hash>.js* file. This tag is placed immediately before the closing `</body>` tag.
2. Select **Debug** > **Start without debugging** to launch the app in a browser without attaching the debugger. The *wwwroot/index.html* file is served at `http://localhost:<port_number>`.
3. Open another browser instance (any browser). Paste the URL in the address bar.
4. Choose either browser, type something in the **Message** text box, and click the **Send** button. The unique user name and message are displayed on both pages instantly.

Use ASP.NET Core SignalR with Blazor WebAssembly

9/22/2020 • 7 minutes to read • Edit Online

By Daniel Roth and Luke Latham

This tutorial teaches the basics of building a real-time app using SignalR with Blazor WebAssembly. You learn how to:

- Create a Blazor WebAssembly Hosted app project
- Add the SignalR client library
- Add a SignalR hub
- Add SignalR services and an endpoint for the SignalR hub
- Add Razor component code for chat

At the end of this tutorial, you'll have a working chat app.

View or download sample code (how to download)

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac
- .NET Core CLI

- Visual Studio 2019 16.6 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

Create a hosted Blazor WebAssembly app project

Follow the guidance for your choice of tooling:

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac
- .NET Core CLI

> **NOTE**
> Visual Studio 16.6 or later and .NET Core SDK 3.1.300 or later are required.

1. Create a new project.
2. Select **Blazor App** and select **Next**.
3. Type `BlazorSignalRApp` in the **Project name** field. Confirm the **Location** entry is correct or provide a location for the project. Select **Create**.
4. Choose the **Blazor WebAssembly App** template.
5. Under **Advanced**, select the **ASP.NET Core hosted** check box.

6. Select **Create**.

Add the SignalR client library

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac
- .NET Core CLI

1. In **Solution Explorer**, right-click the `BlazorSignalRApp.Client` project and select **Manage NuGet Packages**.
2. In the **Manage NuGet Packages** dialog, confirm that the **Package source** is set to `nuget.org`.
3. With **Browse** selected, type `Microsoft.AspNetCore.SignalR.Client` in the search box.
4. In the search results, select the `Microsoft.AspNetCore.SignalR.Client` package and select **Install**.
5. If the **Preview Changes** dialog appears, select **OK**.
6. If the **License Acceptance** dialog appears, select **I Accept** if you agree with the license terms.

Add a SignalR hub

In the `BlazorSignalRApp.Server` project, create a `Hubs` (plural) folder and add the following `ChatHub` class (`Hubs/ChatHub.cs`):

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.SignalR;

namespace BlazorSignalRApp.Server.Hubs
{
    public class ChatHub : Hub
    {
        public async Task SendMessage(string user, string message)
        {
            await Clients.All.SendAsync("ReceiveMessage", user, message);
        }
    }
}
```

Add services and an endpoint for the SignalR hub

1. In the `BlazorSignalRApp.Server` project, open the `Startup.cs` file.
2. Add the namespace for the `ChatHub` class to the top of the file:

   ```
   using BlazorSignalRApp.Server.Hubs;
   ```

3. Add SignalR and Response Compression Middleware services to `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSignalR();
    services.AddControllersWithViews();
    services.AddResponseCompression(opts =>
    {
        opts.MimeTypes = ResponseCompressionDefaults.MimeTypes.Concat(
            new[] { "application/octet-stream" });
    });
}
```

4. In `Startup.Configure`:

   - Use Response Compression Middleware at the top of the processing pipeline's configuration.
   - Between the endpoints for controllers and the client-side fallback, add an endpoint for the hub.

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    app.UseResponseCompression();

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseWebAssemblyDebugging();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseBlazorFrameworkFiles();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
        endpoints.MapHub<ChatHub>("/chathub");
        endpoints.MapFallbackToFile("index.html");
    });
}
```

Add Razor component code for chat

1. In the `BlazorSignalRApp.Client` project, open the `Pages/Index.razor` file.
2. Replace the markup with the following code:

```
@page "/"
@using Microsoft.AspNetCore.SignalR.Client
@inject NavigationManager NavigationManager
@implements IDisposable

<div class="form-group">
    <label>
        User:
        <input @bind="userInput" />
    </label>
</div>
<div class="form-group">
    <label>
        Message:
        <input @bind="messageInput" size="50" />
    </label>
</div>
<button @onclick="Send" disabled="@(!IsConnected)">Send</button>

<hr>

<ul id="messagesList">
    @foreach (var message in messages)
    {
        <li>@message</li>
    }
</ul>

@code {
    private HubConnection hubConnection;
    private List<string> messages = new List<string>();
    private string userInput;
    private string messageInput;

    protected override async Task OnInitializedAsync()
    {
        hubConnection = new HubConnectionBuilder()
            .WithUrl(NavigationManager.ToAbsoluteUri("/chathub"))
            .Build();

        hubConnection.On<string, string>("ReceiveMessage", (user, message) =>
        {
            var encodedMsg = $"{user}: {message}";
            messages.Add(encodedMsg);
            StateHasChanged();
        });

        await hubConnection.StartAsync();
    }

    Task Send() =>
        hubConnection.SendAsync("SendMessage", userInput, messageInput);

    public bool IsConnected =>
        hubConnection.State == HubConnectionState.Connected;

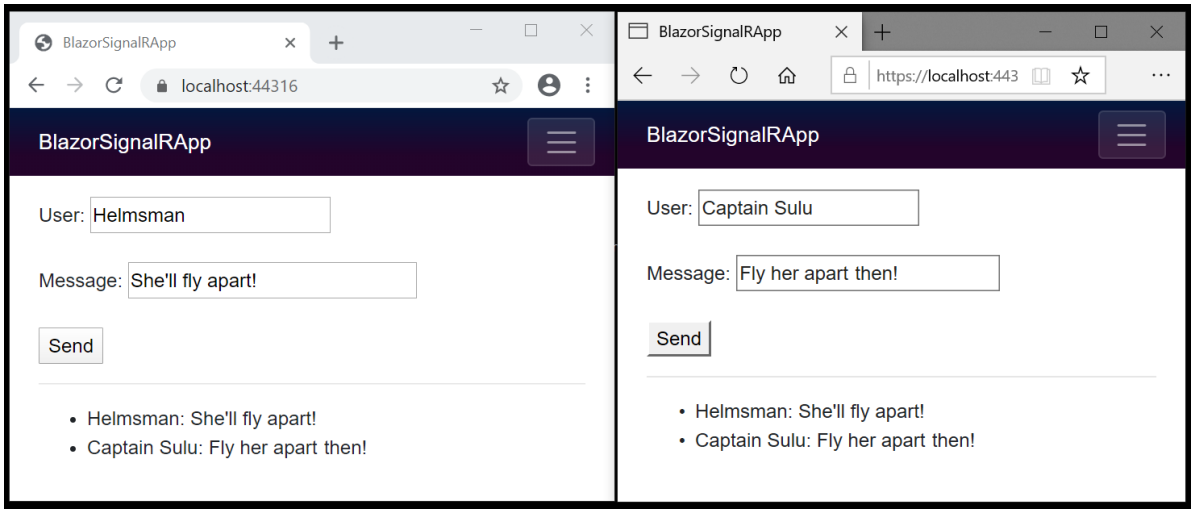
    public void Dispose()
    {
        _ = hubConnection.DisposeAsync();
    }
}
```

Run the app

1. Follow the guidance for your tooling:

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac
- .NET Core CLI

1. In **Solution Explorer**, select the `BlazorSignalRApp.Server` project. Press `F5` to run the app with debugging or `Ctrl+F5` to run the app without debugging.
2. Copy the URL from the address bar, open another browser instance or tab, and paste the URL in the address bar.
3. Choose either browser, enter a name and message, and select the button to send the message. The name and message are displayed on both pages instantly:



Quotes: *Star Trek VI: The Undiscovered Country* ©1991 Paramount

Next steps

In this tutorial, you learned how to:

- Create a Blazor WebAssembly Hosted app project
- Add the SignalR client library
- Add a SignalR hub
- Add SignalR services and an endpoint for the SignalR hub
- Add Razor component code for chat

To learn more about building Blazor apps, see the Blazor documentation:

Introduction to ASP.NET Core Blazor

Use hubs in SignalR for ASP.NET Core

9/22/2020 • 7 minutes to read • Edit Online

By Rachel Appel and Kevin Griffin

View or download sample code (how to download)

What is a SignalR hub

The SignalR Hubs API enables you to call methods on connected clients from the server. In the server code, you define methods that are called by client. In the client code, you define methods that are called from the server. SignalR takes care of everything behind the scenes that makes real-time client-to-server and server-to-client communications possible.

Configure SignalR hubs

The SignalR middleware requires some services, which are configured by calling `services.AddSignalR`.

```
services.AddSignalR();
```

When adding SignalR functionality to an ASP.NET Core app, setup SignalR routes by calling `endpoint.MapHub` in the `Startup.Configure` method's `app.UseEndpoints` callback.

```
app.UseRouting();
app.UseEndpoints(endpoints =>
{
    endpoints.MapHub<ChatHub>("/chathub");
});
```

When adding SignalR functionality to an ASP.NET Core app, setup SignalR routes by calling `app.UseSignalR` in the `Startup.Configure` method.

```
app.UseSignalR(route =>
{
    route.MapHub<ChatHub>("/chathub");
});
```

Create and use hubs

Create a hub by declaring a class that inherits from `Hub`, and add public methods to it. Clients can call methods that are defined as `public`.

```
public class ChatHub : Hub
{
    public Task SendMessage(string user, string message)
    {
        return Clients.All.SendAsync("ReceiveMessage", user, message);
    }
}
```

You can specify a return type and parameters, including complex types and arrays, as you would in any C# method. SignalR handles the serialization and deserialization of complex objects and arrays in your parameters and return values.

> **NOTE**
>
> Hubs are transient:
>
> - Don't store state in a property on the hub class. Every hub method call is executed on a new hub instance.
> - Use `await` when calling asynchronous methods that depend on the hub staying alive. For example, a method such as `Clients.All.SendAsync(...)` can fail if it's called without `await` and the hub method completes before `SendAsync` finishes.

The Context object

The `Hub` class has a `Context` property that contains the following properties with information about the connection:

PROPERTY	DESCRIPTION
`ConnectionId`	Gets the unique ID for the connection, assigned by SignalR. There is one connection ID for each connection.
`UserIdentifier`	Gets the user identifier. By default, SignalR uses the `ClaimTypes.NameIdentifier` from the `ClaimsPrincipal` associated with the connection as the user identifier.
`User`	Gets the `ClaimsPrincipal` associated with the current user.
`Items`	Gets a key/value collection that can be used to share data within the scope of this connection. Data can be stored in this collection and it will persist for the connection across different hub method invocations.
`Features`	Gets the collection of features available on the connection. For now, this collection isn't needed in most scenarios, so it isn't documented in detail yet.
`ConnectionAborted`	Gets a `CancellationToken` that notifies when the connection is aborted.

`Hub.Context` also contains the following methods:

METHOD	DESCRIPTION
`GetHttpContext`	Returns the `HttpContext` for the connection, or `null` if the connection is not associated with an HTTP request. For HTTP connections, you can use this method to get information such as HTTP headers and query strings.
`Abort`	Aborts the connection.

The Clients object

The `Hub` class has a `Clients` property that contains the following properties for communication between server and client:

PROPERTY	DESCRIPTION
`All`	Calls a method on all connected clients
`Caller`	Calls a method on the client that invoked the hub method
`Others`	Calls a method on all connected clients except the client that invoked the method

`Hub.Clients` also contains the following methods:

METHOD	DESCRIPTION
`AllExcept`	Calls a method on all connected clients except for the specified connections
`Client`	Calls a method on a specific connected client
`Clients`	Calls a method on specific connected clients
`Group`	Calls a method on all connections in the specified group
`GroupExcept`	Calls a method on all connections in the specified group, except the specified connections
`Groups`	Calls a method on multiple groups of connections
`OthersInGroup`	Calls a method on a group of connections, excluding the client that invoked the hub method
`User`	Calls a method on all connections associated with a specific user
`Users`	Calls a method on all connections associated with the specified users

Each property or method in the preceding tables returns an object with a `SendAsync` method. The `SendAsync` method allows you to supply the name and parameters of the client method to call.

Send messages to clients

To make calls to specific clients, use the properties of the `Clients` object. In the following example, there are three Hub methods:

- `SendMessage` sends a message to all connected clients, using `Clients.All`.
- `SendMessageToCaller` sends a message back to the caller, using `Clients.Caller`.
- `SendMessageToGroups` sends a message to all clients in the `SignalR Users` group.

```
public Task SendMessage(string user, string message)
{
    return Clients.All.SendAsync("ReceiveMessage", user, message);
}

public Task SendMessageToCaller(string message)
{
    return Clients.Caller.SendAsync("ReceiveMessage", message);
}

public Task SendMessageToGroup(string message)
{
    return Clients.Group("SignalR Users").SendAsync("ReceiveMessage", message);
}
```

Strongly typed hubs

A drawback of using `SendAsync` is that it relies on a magic string to specify the client method to be called. This leaves code open to runtime errors if the method name is misspelled or missing from the client.

An alternative to using `SendAsync` is to strongly type the `Hub` with Hub<T>. In the following example, the `ChatHub` client methods have been extracted out into an interface called `IChatClient`.

```
public interface IChatClient
{
    Task ReceiveMessage(string user, string message);
    Task ReceiveMessage(string message);
}
```

This interface can be used to refactor the preceding `ChatHub` example.

```
public class StronglyTypedChatHub : Hub<IChatClient>
{
    public async Task SendMessage(string user, string message)
    {
        await Clients.All.ReceiveMessage(user, message);
    }

    public Task SendMessageToCaller(string message)
    {
        return Clients.Caller.ReceiveMessage(message);
    }
}
```

Using `Hub<IChatClient>` enables compile-time checking of the client methods. This prevents issues caused by using magic strings, since `Hub<T>` can only provide access to the methods defined in the interface.

Using a strongly typed `Hub<T>` disables the ability to use `SendAsync`. Any methods defined on the interface can still be defined as asynchronous. In fact, each of these methods should return a `Task`. Since it's an interface, don't use the `async` keyword. For example:

```
public interface IClient
{
    Task ClientMethod();
}
```

> **NOTE**
>
> The `Async` suffix isn't stripped from the method name. Unless your client method is defined with `.on('MyMethodAsync')`, you shouldn't use `MyMethodAsync` as a name.

Change the name of a hub method

By default, a server hub method name is the name of the .NET method. However, you can use the HubMethodName attribute to change this default and manually specify a name for the method. The client should use this name, instead of the .NET method name, when invoking the method.

```
[HubMethodName("SendMessageToUser")]
public Task DirectMessage(string user, string message)
{
    return Clients.User(user).SendAsync("ReceiveMessage", message);
}
```

Handle events for a connection

The SignalR Hubs API provides the `OnConnectedAsync` and `OnDisconnectedAsync` virtual methods to manage and track connections. Override the `OnConnectedAsync` virtual method to perform actions when a client connects to the Hub, such as adding it to a group.

```
public override async Task OnConnectedAsync()
{
    await Groups.AddToGroupAsync(Context.ConnectionId, "SignalR Users");
    await base.OnConnectedAsync();
}
```

Override the `OnDisconnectedAsync` virtual method to perform actions when a client disconnects. If the client disconnects intentionally (by calling `connection.stop()`, for example), the `exception` parameter will be `null`. However, if the client is disconnected due to an error (such as a network failure), the `exception` parameter will contain an exception describing the failure.

```
public override async Task OnDisconnectedAsync(Exception exception)
{
    await Groups.RemoveFromGroupAsync(Context.ConnectionId, "SignalR Users");
    await base.OnDisconnectedAsync(exception);
}
```

> **WARNING**
>
> Security warning: Exposing `ConnectionId` can lead to malicious impersonation if the SignalR server or client version is ASP.NET Core 2.2 or earlier.

Handle errors

Exceptions thrown in your hub methods are sent to the client that invoked the method. On the JavaScript client, the `invoke` method returns a JavaScript Promise. When the client receives an error with a handler attached to the promise using `catch`, it's invoked and passed as a JavaScript `Error` object.

```
connection.invoke("SendMessage", user, message).catch(err => console.error(err));
```

If your Hub throws an exception, connections aren't closed. By default, SignalR returns a generic error message to the client. For example:

```
Microsoft.AspNetCore.SignalR.HubException: An unexpected error occurred invoking 'MethodName' on the
server.
```

Unexpected exceptions often contain sensitive information, such as the name of a database server in an exception triggered when the database connection fails. SignalR doesn't expose these detailed error messages by default as a security measure. See the Security considerations article for more information on why exception details are suppressed.

If you have an exceptional condition you *do* want to propagate to the client, you can use the `HubException` class. If you throw a `HubException` from your hub method, SignalR **will** send the entire message to the client, unmodified.

```
public Task ThrowException()
{
    throw new HubException("This error will be sent to the client!");
}
```

> **NOTE**
>
> SignalR only sends the `Message` property of the exception to the client. The stack trace and other properties on the exception aren't available to the client.

Send messages from outside a hub

9/22/2020 • 2 minutes to read • Edit Online

By Mikael Mengistu

The SignalR hub is the core abstraction for sending messages to clients connected to the SignalR server. It's also possible to send messages from other places in your app using the `IHubContext` service. This article explains how to access a SignalR `IHubContext` to send notifications to clients from outside a hub.

View or download sample code (how to download)

Get an instance of IHubContext

In ASP.NET Core SignalR, you can access an instance of `IHubContext` via dependency injection. You can inject an instance of `IHubContext` into a controller, middleware, or other DI service. Use the instance to send messages to clients.

> **NOTE**
> This differs from ASP.NET 4.x SignalR which used GlobalHost to provide access to the `IHubContext`. ASP.NET Core has a dependency injection framework that removes the need for this global singleton.

Inject an instance of IHubContext in a controller

You can inject an instance of `IHubContext` into a controller by adding it to your constructor:

```
public class HomeController : Controller
{
    private readonly IHubContext<NotificationHub> _hubContext;

    public HomeController(IHubContext<NotificationHub> hubContext)
    {
        _hubContext = hubContext;
    }
}
```

Now, with access to an instance of `IHubContext`, you can call hub methods as if you were in the hub itself.

```
public async Task<IActionResult> Index()
{
    await _hubContext.Clients.All.SendAsync("Notify", $"Home page loaded at: {DateTime.Now}");
    return View();
}
```

Get an instance of IHubContext in middleware

Access the `IHubContext` within the middleware pipeline like so:

```
app.Use(async (context, next) =>
{
    var hubContext = context.RequestServices
                            .GetRequiredService<IHubContext<ChatHub>>();
    //...

    if (next != null)
    {
        await next.Invoke();
    }
});
```

> **NOTE**
>
> When hub methods are called from outside of the `Hub` class, there's no caller associated with the invocation. Therefore, there's no access to the `ConnectionId`, `Caller`, and `Others` properties.

Get an instance of IHubContext from IHost

Accessing an `IHubContext` from the web host is useful for integrating with areas outside of ASP.NET Core, for example, using third-party dependency injection frameworks:

```
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateHostBuilder(args).Build();
            var hubContext = host.Services.GetService(typeof(IHubContext<ChatHub>));
            host.Run();
        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureWebHostDefaults(webBuilder => {
                    webBuilder.UseStartup<Startup>();
                });
    }
```

Inject a strongly-typed HubContext

To inject a strongly-typed HubContext, ensure your Hub inherits from `Hub<T>`. Inject it using the `IHubContext<THub, T>` interface rather than `IHubContext<THub>`.

```
public class ChatController : Controller
{
    public IHubContext<ChatHub, IChatClient> _strongChatHubContext { get; }

    public ChatController(IHubContext<ChatHub, IChatClient> chatHubContext)
    {
        _strongChatHubContext = chatHubContext;
    }

    public async Task SendMessage(string message)
    {
        await _strongChatHubContext.Clients.All.ReceiveMessage(message);
    }
}
```

Manage users and groups in SignalR

9/22/2020 • 2 minutes to read • Edit Online

By Brennan Conroy

SignalR allows messages to be sent to all connections associated with a specific user, as well as to named groups of connections.

View or download sample code (how to download)

Users in SignalR

A single user in SignalR can have multiple connections to an app. For example, a user could be connected on their desktop as well as their phone. Each device has a separate SignalR connection, but they're all associated with the same user. If a message is sent to the user, all of the connections associated with that user receive the message. The user identifier for a connection can be accessed by the `Context.UserIdentifier` property in the hub.

By default, SignalR uses the `ClaimTypes.NameIdentifier` from the `ClaimsPrincipal` associated with the connection as the user identifier. To customize this behavior, see Use claims to customize identity handling.

Send a message to a specific user by passing the user identifier to the `User` function in a hub method, as shown in the following example:

> **NOTE**
> The user identifier is case-sensitive.

```
public Task SendPrivateMessage(string user, string message)
{
    return Clients.User(user).SendAsync("ReceiveMessage", message);
}
```

Groups in SignalR

A group is a collection of connections associated with a name. Messages can be sent to all connections in a group. Groups are the recommended way to send to a connection or multiple connections because the groups are managed by the application. A connection can be a member of multiple groups. Groups are ideal for something like a chat application, where each room can be represented as a group. Connections are added to or removed from groups via the `AddToGroupAsync` and `RemoveFromGroupAsync` methods.

```
public async Task AddToGroup(string groupName)
{
    await Groups.AddToGroupAsync(Context.ConnectionId, groupName);

    await Clients.Group(groupName).SendAsync("Send", $"{Context.ConnectionId} has joined the group
{groupName}.");
}

public async Task RemoveFromGroup(string groupName)
{
    await Groups.RemoveFromGroupAsync(Context.ConnectionId, groupName);

    await Clients.Group(groupName).SendAsync("Send", $"{Context.ConnectionId} has left the group
{groupName}.");
}
```

Group membership isn't preserved when a connection reconnects. The connection needs to rejoin the group when it's re-established. It's not possible to count the members of a group, since this information is not available if the application is scaled to multiple servers.

To protect access to resources while using groups, use authentication and authorization functionality in ASP.NET Core. If a user is added to a group only when the credentials are valid for that group, messages sent to that group will only go to authorized users. However, groups are not a security feature. Authentication claims have features that groups do not, such as expiry and revocation. If a user's permission to access the group is revoked, the app must remove the user from the group explicitly.

> **NOTE**
> Group names are case-sensitive.

SignalR API design considerations

9/22/2020 • 2 minutes to read • Edit Online

By Andrew Stanton-Nurse

This article provides guidance for building SignalR-based APIs.

Use custom object parameters to ensure backwards-compatibility

Adding parameters to a SignalR hub method (on either the client or the server) is a *breaking change*. This means older clients/servers will get errors when they try to invoke the method without the appropriate number of parameters. However, adding properties to a custom object parameter is **not** a breaking change. This can be used to design compatible APIs that are resilient to changes on the client or the server.

For example, consider a server-side API like the following:

```
public async Task<string> GetTotalLength(string param1)
{
    return param1.Length;
}
```

The JavaScript client calls this method using `invoke` as follows:

```
connection.invoke("GetTotalLength", "value1");
```

If you later add a second parameter to the server method, older clients won't provide this parameter value. For example:

```
public async Task<string> GetTotalLength(string param1, string param2)
{
    return param1.Length + param2.Length;
}
```

When the old client tries to invoke this method, it will get an error like this:

```
Microsoft.AspNetCore.SignalR.HubException: Failed to invoke 'GetTotalLength' due to an error on the server.
```

On the server, you'll see a log message like this:

```
System.IO.InvalidDataException: Invocation provides 1 argument(s) but target expects 2.
```

The old client only sent one parameter, but the newer server API required two parameters. Using custom objects as parameters gives you more flexibility. Let's redesign the original API to use a custom object:

```
public class TotalLengthRequest
{
    public string Param1 { get; set; }
}

public async Task GetTotalLength(TotalLengthRequest req)
{
    return req.Param1.Length;
}
```

Now, the client uses an object to call the method:

```
connection.invoke("GetTotalLength", { param1: "value1" });
```

Instead of adding a parameter, add a property to the `TotalLengthRequest` object:

```
public class TotalLengthRequest
{
    public string Param1 { get; set; }
    public string Param2 { get; set; }
}

public async Task GetTotalLength(TotalLengthRequest req)
{
    var length = req.Param1.Length;
    if (req.Param2 != null)
    {
        length += req.Param2.Length;
    }
    return length;
}
```

When the old client sends a single parameter, the extra `Param2` property will be left `null`. You can detect a message sent by an older client by checking the `Param2` for `null` and apply a default value. A new client can send both parameters.

```
connection.invoke("GetTotalLength", { param1: "value1", param2: "value2" });
```

The same technique works for methods defined on the client. You can send a custom object from the server side:

```
public async Task Broadcast(string message)
{
    await Clients.All.SendAsync("ReceiveMessage", new
    {
        Message = message
    });
}
```

On the client side, you access the `Message` property rather than using a parameter:

```
connection.on("ReceiveMessage", (req) => {
    appendMessageToChatWindow(req.message);
});
```

If you later decide to add the sender of the message to the payload, add a property to the object:

```
public async Task Broadcast(string message)
{
    await Clients.All.SendAsync("ReceiveMessage", new
    {
        Sender = Context.User.Identity.Name,
        Message = message
    });
}
```

The older clients won't be expecting the `Sender` value, so they'll ignore it. A new client can accept it by updating to read the new property:

```
connection.on("ReceiveMessage", (req) => {
    let message = req.message;
    if (req.sender) {
        message = req.sender + ": " + message;
    }
    appendMessageToChatWindow(message);
});
```

In this case, the new client is also tolerant of an old server that doesn't provide the `Sender` value. Since the old server won't provide the `Sender` value, the client checks to see if it exists before accessing it.

Use hub filters in ASP.NET Core SignalR

9/22/2020 • 3 minutes to read • Edit Online

Hub filters:

- Are available in ASP.NET Core 5.0 or later.
- Allow logic to run before and after hub methods are invoked by clients.

This article provides guidance for writing and using hub filters.

Configure hub filters

Hub filters can be applied globally or per hub type. The order in which filters are added is the order in which the filters run. Global hub filters run before local hub filters.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSignalR(options =>
    {
        // Global filters will run first
        options.AddFilter<CustomFilter>();
    }).AddHubOptions<ChatHub>(options =>
    {
        // Local filters will run second
        options.AddFilter<CustomFilter2>();
    });
}
```

A hub filter can be added in one of the following ways:

- Add a filter by concrete type:

  ```
  hubOptions.AddFilter<TFilter>();
  ```

  This will be resolved from dependency injection (DI) or type activated.

- Add a filter by runtime type:

  ```
  hubOptions.AddFilter(typeof(TFilter));
  ```

  This will be resolved from DI or type activated.

- Add a filter by instance:

  ```
  hubOptions.AddFilter(new MyFilter());
  ```

  This instance will be used like a singleton. All hub method invocations will use the same instance.

Hub filters are created and disposed per hub invocation. If you want to store global state in the filter, or no state, add the hub filter type to DI as a singleton for better performance. Alternatively, add the filter as an instance if you can.

Create hub filters

Create a filter by declaring a class that inherits from `IHubFilter`, and add the `InvokeMethodAsync` method. There is also `OnConnectedAsync` and `OnDisconnectedAsync` that can optionally be implemented to wrap the `OnConnectedAsync` and `OnDisconnectedAsync` hub methods respectively.

```
public class CustomFilter : IHubFilter
{
    public async ValueTask<object> InvokeMethodAsync(
        HubInvocationContext invocationContext, Func<HubInvocationContext, ValueTask<object>> next)
    {
        Console.WriteLine($"Calling hub method '{invocationContext.HubMethodName}'");
        try
        {
            return await next(invocationContext);
        }
        catch (Exception ex)
        {
            Console.WriteLine($"Exception calling '{invocationContext.HubMethodName}'");
            throw ex;
        }
    }

    // Optional method
    public Task OnConnectedAsync(HubLifetimeContext context, Func<HubLifetimeContext, Task> next)
    {
        return next(context);
    }

    // Optional method
    public Task OnDisconnectedAsync(
        HubLifetimeContext context, Exception exception, Func<HubLifetimeContext, Exception, Task> next)
    {
        return next(context, exception);
    }
}
```

Filters are very similar to middleware. The `next` method invokes the next filter. The final filter will invoke the hub method. Filters can also store the result from awaiting `next` and run logic after the hub method has been called before returning the result from `next`.

To skip a hub method invocation in a filter, throw an exception of type `HubException` instead of calling `next`. The client will receive an error if it was expecting a result.

Use hub filters

When writing the filter logic, try to make it generic by using attributes on hub methods instead of checking for hub method names.

Consider a filter that will check a hub method argument for banned phrases and replace any phrases it finds with `***`. For this example, assume a `LanguageFilterAttribute` class is defined. The class has a property named `FilterArgument` that can be set when using the attribute.

1. Place the attribute on the hub method that has a string argument to be cleaned:

```
public class ChatHub
{
    [LanguageFilter(filterArgument: 0)]
    public async Task SendMessage(string message, string username)
    {
        await Clients.All.SendAsync("SendMessage", $"{username} says: {message}");
    }
}
```

2. Define a hub filter to check for the attribute and replace banned phrases in a hub method argument with `***`:

```
public class LanguageFilter : IHubFilter
{
    // populated from a file or inline
    private List<string> bannedPhrases = new List<string> { "async void", ".Result" };

    public async ValueTask<object> InvokeMethodAsync(HubInvocationContext invocationContext,
        Func<HubInvocationContext, ValueTask<object>> next)
    {
        var languageFilter = (LanguageFilterAttribute)Attribute.GetCustomAttribute(
            invocationContext.HubMethod, typeof(LanguageFilterAttribute));
        if (languageFilter != null &&
            invocationContext.HubMethodArguments.Count > languageFilter.FilterArgument &&
            invocationContext.HubMethodArguments[languageFilter.FilterArgument] is string str)
        {
            foreach (var bannedPhrase in bannedPhrases)
            {
                str = str.Replace(bannedPhrase, "***");
            }

            arguments = invocationContext.HubMethodArguments.ToArray();
            arguments[languageFilter.FilterArgument] = str;
            invocationContext = new HubInvocationContext(invocationContext.Context,
                invocationContext.ServiceProvider,
                invocationContext.Hub,
                invocationContext.HubMethod,
                arguments);
        }

        return await next(invocationContext);
    }
}
```

3. Register the hub filter in the `Startup.ConfigureServices` method. To avoid reinitializing the banned phrases list for every invocation, the hub filter is registered as a singleton:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSignalR(hubOptions =>
    {
        hubOptions.AddFilter<LanguageFilter>();
    });

    services.AddSingleton<LanguageFilter>();
}
```

The HubInvocationContext object

The `HubInvocationContext` contains information for the current hub method invocation.

PROPERTY	DESCRIPTION	TYPE
`Context`	The `HubCallerContext` contains information about the connection.	`HubCallerContext`
`Hub`	The instance of the Hub being used for this hub method invocation.	`Hub`
`HubMethodName`	The name of the hub method being invoked.	`string`
`HubMethodArguments`	The list of arguments being passed to the hub method.	`IReadOnlyList<string>`
`ServiceProvider`	The scoped service provider for this hub method invocation.	`IServiceProvider`
`HubMethod`	The hub method information.	`MethodInfo`

The HubLifetimeContext object

The `HubLifetimeContext` contains information for the `OnConnectedAsync` and `OnDisconnectedAsync` hub methods.

PROPERTY	DESCRIPTION	TYPE
`Context`	The `HubCallerContext` contains information about the connection.	`HubCallerContext`
`Hub`	The instance of the Hub being used for this hub method invocation.	`Hub`
`ServiceProvider`	The scoped service provider for this hub method invocation.	`IServiceProvider`

Authorization and filters

Authorize attributes on hub methods run before hub filters.

ASP.NET Core SignalR clients

9/22/2020 • 2 minutes to read • Edit Online

Versioning, support, and compatibility

The SignalR clients ship alongside the server components and are versioned to match. Any supported client can safely connect to any supported server, and any compatibility issues would be considered bugs to be fixed. SignalR clients are supported in the same support lifecycle as the rest of .NET Core. See the .NET Core Support Policy for details.

Many features require a compatible client **and** server. See below for a table showing the minimum versions for various features.

The 1.x versions of SignalR map to the 2.1 and 2.2 .NET Core releases and have the same lifetime. For version 3.x and above, the SignalR version exactly matches the rest of .NET and has the same support lifecycle.

SIGNALR VERSION	.NET CORE VERSION	SUPPORT LEVEL	END OF SUPPORT
1.0.x	2.1.x	Long Term Support	August 21, 2021
1.1.x	2.2.x	End Of Life	December 23, 2019
3.x or higher	*same as SignalR version*	See the the .NET Core Support Policy	

NOTE: In ASP.NET Core 3.0, the JavaScript client *moved* to the `@microsoft/signalr` npm package.

Feature distribution

The table below shows the features and support for the clients that offer real-time support. For each feature, the *minimum* version supporting this feature is listed. If no version is listed, the feature isn't supported.

FEATURE	SERVER	.NET CLIENT	JAVASCRIPT CLIENT	JAVA CLIENT
Azure SignalR Service Support	2.1.0	1.0.0	1.0.0	1.0.0
Server-to-client Streaming	2.1.0	1.0.0	1.0.0	1.0.0
Client-to-server Streaming	3.0.0	3.0.0	3.0.0	3.0.0
Automatic Reconnection (.NET, JavaScript)	3.0.0	3.0.0	3.0.0	✕
WebSockets Transport	2.1.0	1.0.0	1.0.0	1.0.0
Server-Sent Events Transport	2.1.0	1.0.0	1.0.0	✕

FEATURE	SERVER	.NET CLIENT	JAVASCRIPT CLIENT	JAVA CLIENT
Long Polling Transport	2.1.0	1.0.0	1.0.0	3.0.0
JSON Hub Protocol	2.1.0	1.0.0	1.0.0	1.0.0
MessagePack Hub Protocol	2.1.0	1.0.0	1.0.0	✕

Support for enabling additional client features is tracked in our issue tracker.

ASP.NET Core SignalR .NET Client

9/22/2020 • 7 minutes to read • Edit Online

The ASP.NET Core SignalR .NET client library lets you communicate with SignalR hubs from .NET apps.

View or download sample code (how to download)

The code sample in this article is a WPF app that uses the ASP.NET Core SignalR .NET client.

Install the SignalR .NET client package

The Microsoft.AspNetCore.SignalR.Client package is required for .NET clients to connect to SignalR hubs.

- Visual Studio
- .NET Core CLI

To install the client library, run the following command in the **Package Manager Console** window:

```
Install-Package Microsoft.AspNetCore.SignalR.Client
```

Connect to a hub

To establish a connection, create a `HubConnectionBuilder` and call `Build`. The hub URL, protocol, transport type, log level, headers, and other options can be configured while building a connection. Configure any required options by inserting any of the `HubConnectionBuilder` methods into `Build`. Start the connection with `StartAsync`.

```
using System;
using System.Threading.Tasks;
using System.Windows;
using Microsoft.AspNetCore.SignalR.Client;

namespace SignalRChatClient
{
    public partial class MainWindow : Window
    {
        HubConnection connection;
        public MainWindow()
        {
            InitializeComponent();

            connection = new HubConnectionBuilder()
                .WithUrl("http://localhost:53353/ChatHub")
                .Build();

            connection.Closed += async (error) =>
            {
                await Task.Delay(new Random().Next(0,5) * 1000);
                await connection.StartAsync();
            };
        }

        private async void connectButton_Click(object sender, RoutedEventArgs e)
        {
            connection.On<string, string>("ReceiveMessage", (user, message) =>
            {
                this.Dispatcher.Invoke(() =>
                {
                   var newMessage = $"{user}: {message}";
                   messagesList.Items.Add(newMessage);
                });
            });

            try
            {
                await connection.StartAsync();
                messagesList.Items.Add("Connection started");
                connectButton.IsEnabled = false;
                sendButton.IsEnabled = true;
            }
            catch (Exception ex)
            {
                messagesList.Items.Add(ex.Message);
            }
        }

        private async void sendButton_Click(object sender, RoutedEventArgs e)
        {
            try
            {
                await connection.InvokeAsync("SendMessage",
                    userTextBox.Text, messageTextBox.Text);
            }
            catch (Exception ex)
            {
                messagesList.Items.Add(ex.Message);
            }
        }
    }
}
```

Handle lost connection

Automatically reconnect

The HubConnection can be configured to automatically reconnect using the `WithAutomaticReconnect` method on the HubConnectionBuilder. It won't automatically reconnect by default.

```
HubConnection connection= new HubConnectionBuilder()
    .WithUrl(new Uri("http://127.0.0.1:5000/chathub"))
    .WithAutomaticReconnect()
    .Build();
```

Without any parameters, `WithAutomaticReconnect()` configures the client to wait 0, 2, 10, and 30 seconds respectively before trying each reconnect attempt, stopping after four failed attempts.

Before starting any reconnect attempts, the `HubConnection` will transition to the `HubConnectionState.Reconnecting` state and fire the `Reconnecting` event. This provides an opportunity to warn users that the connection has been lost and to disable UI elements. Non-interactive apps can start queuing or dropping messages.

```
connection.Reconnecting += error =>
{
    Debug.Assert(connection.State == HubConnectionState.Reconnecting);

    // Notify users the connection was lost and the client is reconnecting.
    // Start queuing or dropping messages.

    return Task.CompletedTask;
};
```

If the client successfully reconnects within its first four attempts, the `HubConnection` will transition back to the `Connected` state and fire the `Reconnected` event. This provides an opportunity to inform users the connection has been reestablished and dequeue any queued messages.

Since the connection looks entirely new to the server, a new `ConnectionId` will be provided to the `Reconnected` event handlers.

WARNING

The `Reconnected` event handler's `connectionId` parameter will be null if the `HubConnection` was configured to skip negotiation.

```
connection.Reconnected += connectionId =>
{
    Debug.Assert(connection.State == HubConnectionState.Connected);

    // Notify users the connection was reestablished.
    // Start dequeuing messages queued while reconnecting if any.

    return Task.CompletedTask;
};
```

`WithAutomaticReconnect()` won't configure the `HubConnection` to retry initial start failures, so start failures need to be handled manually:

```
public static async Task<bool> ConnectWithRetryAsync(HubConnection connection, CancellationToken token)
{
    // Keep trying to until we can start or the token is canceled.
    while (true)
    {
        try
        {
            await connection.StartAsync(token);
            Debug.Assert(connection.State == HubConnectionState.Connected);
            return true;
        }
        catch when (token.IsCancellationRequested)
        {
            return false;
        }
        catch
        {
            // Failed to connect, trying again in 5000 ms.
            Debug.Assert(connection.State == HubConnectionState.Disconnected);
            await Task.Delay(5000);
        }
    }
}
```

If the client doesn't successfully reconnect within its first four attempts, the `HubConnection` will transition to the `Disconnected` state and fire the Closed event. This provides an opportunity to attempt to restart the connection manually or inform users the connection has been permanently lost.

```
connection.Closed += error =>
{
    Debug.Assert(connection.State == HubConnectionState.Disconnected);

    // Notify users the connection has been closed or manually try to restart the connection.

    return Task.CompletedTask;
};
```

In order to configure a custom number of reconnect attempts before disconnecting or change the reconnect timing, `WithAutomaticReconnect` accepts an array of numbers representing the delay in milliseconds to wait before starting each reconnect attempt.

```
HubConnection connection= new HubConnectionBuilder()
    .WithUrl(new Uri("http://127.0.0.1:5000/chathub"))
    .WithAutomaticReconnect(new[] { TimeSpan.Zero, TimeSpan.Zero, TimeSpan.FromSeconds(10) })
    .Build();

    // .WithAutomaticReconnect(new[] { TimeSpan.Zero, TimeSpan.FromSeconds(2), TimeSpan.FromSeconds(10),
TimeSpan.FromSeconds(30) }) yields the default behavior.
```

The preceding example configures the `HubConnection` to start attempting reconnects immediately after the connection is lost. This is also true for the default configuration.

If the first reconnect attempt fails, the second reconnect attempt will also start immediately instead of waiting 2 seconds like it would in the default configuration.

If the second reconnect attempt fails, the third reconnect attempt will start in 10 seconds which is again like the default configuration.

The custom behavior then diverges again from the default behavior by stopping after the third reconnect attempt failure. In the default configuration there would be one more reconnect attempt in another 30 seconds.

If you want even more control over the timing and number of automatic reconnect attempts, `WithAutomaticReconnect` accepts an object implementing the `IRetryPolicy` interface, which has a single method named `NextRetryDelay`.

`NextRetryDelay` takes a single argument with the type `RetryContext`. The `RetryContext` has three properties: `PreviousRetryCount`, `ElapsedTime` and `RetryReason`, which are a `long`, a `TimeSpan` and an `Exception` respectively. Before the first reconnect attempt, both `PreviousRetryCount` and `ElapsedTime` will be zero, and the `RetryReason` will be the Exception that caused the connection to be lost. After each failed retry attempt, `PreviousRetryCount` will be incremented by one, `ElapsedTime` will be updated to reflect the amount of time spent reconnecting so far, and the `RetryReason` will be the Exception that caused the last reconnect attempt to fail.

`NextRetryDelay` must return either a TimeSpan representing the time to wait before the next reconnect attempt or `null` if the `HubConnection` should stop reconnecting.

```
public class RandomRetryPolicy : IRetryPolicy
{
    private readonly Random _random = new Random();

    public TimeSpan? NextRetryDelay(RetryContext retryContext)
    {
        // If we've been reconnecting for less than 60 seconds so far,
        // wait between 0 and 10 seconds before the next reconnect attempt.
        if (retryContext.ElapsedTime < TimeSpan.FromSeconds(60))
        {
            return TimeSpan.FromSeconds(_random.NextDouble() * 10);
        }
        else
        {
            // If we've been reconnecting for more than 60 seconds so far, stop reconnecting.
            return null;
        }
    }
}
```

```
HubConnection connection = new HubConnectionBuilder()
    .WithUrl(new Uri("http://127.0.0.1:5000/chathub"))
    .WithAutomaticReconnect(new RandomRetryPolicy())
    .Build();
```

Alternatively, you can write code that will reconnect your client manually as demonstrated in Manually reconnect.

Manually reconnect

> **WARNING**
> Prior to 3.0, the .NET client for SignalR doesn't automatically reconnect. You must write code that will reconnect your client manually.

Use the Closed event to respond to a lost connection. For example, you might want to automate reconnection.

The `Closed` event requires a delegate that returns a `Task`, which allows async code to run without using `async void`. To satisfy the delegate signature in a `Closed` event handler that runs synchronously, return `Task.CompletedTask`:

```
connection.Closed += (error) => {
    // Do your close logic.
    return Task.CompletedTask;
};
```

The main reason for the async support is so you can restart the connection. Starting a connection is an async action.

In a `Closed` handler that restarts the connection, consider waiting for some random delay to prevent overloading the server, as shown in the following example:

```
connection.Closed += async (error) =>
{
    await Task.Delay(new Random().Next(0,5) * 1000);
    await connection.StartAsync();
};
```

Call hub methods from client

`InvokeAsync` calls methods on the hub. Pass the hub method name and any arguments defined in the hub method to `InvokeAsync`. SignalR is asynchronous, so use `async` and `await` when making the calls.

```
await connection.InvokeAsync("SendMessage",
    userTextBox.Text, messageTextBox.Text);
```

The `InvokeAsync` method returns a `Task` which completes when the server method returns. The return value, if any, is provided as the result of the `Task`. Any exceptions thrown by the method on the server produce a faulted `Task`. Use `await` syntax to wait for the server method to complete and `try...catch` syntax to handle errors.

The `SendAsync` method returns a `Task` which completes when the message has been sent to the server. No return value is provided since this `Task` doesn't wait until the server method completes. Any exceptions thrown on the client while sending the message produce a faulted `Task`. Use `await` and `try...catch` syntax to handle send errors.

> **NOTE**
> Calling hub methods from a client is only supported when using the Azure SignalR Service in *Default* mode. For more information, see Frequently Asked Questions (azure-signalr GitHub repository).

Call client methods from hub

Define methods the hub calls using `connection.On` after building, but before starting the connection.

```
connection.On<string, string>("ReceiveMessage", (user, message) =>
{
    this.Dispatcher.Invoke(() =>
    {
       var newMessage = $"{user}: {message}";
       messagesList.Items.Add(newMessage);
    });
});
```

The preceding code in `connection.On` runs when server-side code calls it using the `SendAsync` method.

```
public async Task SendMessage(string user, string message)
{
    await Clients.All.SendAsync("ReceiveMessage", user,message);
}
```

Error handling and logging

Handle errors with a try-catch statement. Inspect the `Exception` object to determine the proper action to take after an error occurs.

```
try
{
    await connection.InvokeAsync("SendMessage",
        userTextBox.Text, messageTextBox.Text);
}
catch (Exception ex)
{
    messagesList.Items.Add(ex.Message);
}
```

ASP.NET Core SignalR Java client

9/22/2020 • 3 minutes to read • Edit Online

By Mikael Mengistu

The Java client enables connecting to an ASP.NET Core SignalR server from Java code, including Android apps. Like the JavaScript client and the .NET client, the Java client enables you to receive and send messages to a hub in real time. The Java client is available in ASP.NET Core 2.2 and later.

The sample Java console app referenced in this article uses the SignalR Java client.

View or download sample code (how to download)

Install the SignalR Java client package

The *signalr-1.0.0* JAR file allows clients to connect to SignalR hubs. To find the latest JAR file version number, see the Maven search results.

If using Gradle, add the following line to the `dependencies` section of your *build.gradle* file:

```
implementation 'com.microsoft.signalr:signalr:1.0.0'
```

If using Maven, add the following lines inside the `<dependencies>` element of your *pom.xml* file:

```
<dependency>
    <groupId>com.microsoft.signalr</groupId>
    <artifactId>signalr</artifactId>
    <version>1.0.0</version>
</dependency>
```

Connect to a hub

To establish a `HubConnection`, the `HubConnectionBuilder` should be used. The hub URL and log level can be configured while building a connection. Configure any required options by calling any of the `HubConnectionBuilder` methods before `build`. Start the connection with `start`.

```
HubConnection hubConnection = HubConnectionBuilder.create(input)
        .build();
```

Call hub methods from client

A call to `send` invokes a hub method. Pass the hub method name and any arguments defined in the hub method to `send`.

```
hubConnection.send("Send", input);
```

> **NOTE**
> Calling hub methods from a client is only supported when using the Azure SignalR Service in *Default* mode. For more information, see Frequently Asked Questions (azure-signalr GitHub repository).

Call client methods from hub

Use `hubConnection.on` to define methods on the client that the hub can call. Define the methods after building but before starting the connection.

```
hubConnection.on("Send", (message) -> {
    System.out.println("New Message: " + message);
}, String.class);
```

Add logging

The SignalR Java client uses the SLF4J library for logging. It's a high-level logging API that allows users of the library to chose their own specific logging implementation by bringing in a specific logging dependency. The following code snippet shows how to use `java.util.logging` with the SignalR Java client.

```
implementation 'org.slf4j:slf4j-jdk14:1.7.25'
```

If you don't configure logging in your dependencies, SLF4J loads a default no-operation logger with the following warning message:

```
SLF4J: Failed to load class "org.slf4j.impl.StaticLoggerBinder".
SLF4J: Defaulting to no-operation (NOP) logger implementation
SLF4J: See http://www.slf4j.org/codes.html#StaticLoggerBinder for further details.
```

This can safely be ignored.

Android development notes

With regards to Android SDK compatibility for the SignalR client features, consider the following items when specifying your target Android SDK version:

- The SignalR Java Client will run on Android API Level 16 and later.
- Connecting through the Azure SignalR Service will require Android API Level 20 and later because the Azure SignalR Service requires TLS 1.2 and doesn't support SHA-1-based cipher suites. Android added support for SHA-256 (and above) cipher suites in API Level 20.

Configure bearer token authentication

In the SignalR Java client, you can configure a bearer token to use for authentication by providing an "access token factory" to the HttpHubConnectionBuilder. Use withAccessTokenFactory to provide an RxJava Single<String>. With a call to Single.defer, you can write logic to produce access tokens for your client.

```
HubConnection hubConnection = HubConnectionBuilder.create("YOUR HUB URL HERE")
    .withAccessTokenProvider(Single.defer(() -> {
        // Your logic here.
        return Single.just("An Access Token");
    })).build();
```

Known limitations

- Only the JSON protocol is supported.
- Transport fallback and the Server Sent Events transport aren't supported.

- Only the JSON protocol is supported.
- Only the WebSockets transport is supported.
- Streaming isn't supported yet.

By Rachel Appel

The ASP.NET Core SignalR JavaScript client library enables developers to call server-side hub code.

View or download sample code (how to download)

Install the SignalR client package

The SignalR JavaScript client library is delivered as an npm package. The following sections outline different ways to install the client library.

Install with npm

For Visual Studio, run the following commands from **Package Manager Console** while in the root folder. For Visual Studio Code, run the following commands from the **Integrated Terminal**.

```
npm init -y
npm install @microsoft/signalr
```

npm installs the package contents in the *node_modules\@microsoft\signalr\dist\browser* folder. Create a new folder named *signalr* under the *wwwroot\lib* folder. Copy the *signalr.js* file to the *wwwroot\lib\signalr* folder.

Reference the SignalR JavaScript client in the `<script>` element. For example:

```
<script src="~/lib/signalr/signalr.js"></script>
```

Use a Content Delivery Network (CDN)

To use the client library without the npm prerequisite, reference a CDN-hosted copy of the client library. For example:

```
<script src="https://cdnjs.cloudflare.com/ajax/libs/microsoft-signalr/3.1.7/signalr.min.js"></script>
```

The client library is available on the following CDNs:

- cdnjs
- jsDelivr
- unpkg

Install with LibMan

LibMan can be used to install specific client library files from the CDN-hosted client library. For example, only add the minified JavaScript file to the project. For details on that approach, see Add the SignalR client library.

Connect to a hub

The following code creates and starts a connection. The hub's name is case insensitive:

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .configureLogging(signalR.LogLevel.Information)
    .build();

async function start() {
    try {
        await connection.start();
        console.log("SignalR Connected.");
    } catch (err) {
        console.log(err);
        setTimeout(start, 5000);
    }
};

connection.onclose(start);

// Start the connection.
start();
```

Cross-origin connections

Typically, browsers load connections from the same domain as the requested page. However, there are occasions when a connection to another domain is required.

To prevent a malicious site from reading sensitive data from another site, cross-origin connections are disabled by default. To allow a cross-origin request, enable it in the `Startup` class:

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using SignalRChat.Hubs;

namespace SignalRChat
{
    public class Startup
    {
        public void ConfigureServices(IServiceCollection services)
        {
            services.AddRazorPages();
            services.AddSignalR();

            services.AddCors(options =>
            {
                options.AddDefaultPolicy(builder =>
                {
                    builder.WithOrigins("https://example.com")
                        .AllowCredentials();
                });
            });
        }

        public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
        {
            if (env.IsDevelopment())
            {
                app.UseDeveloperExceptionPage();
            }
            else
            {
                app.UseExceptionHandler("/Error");
            }

            app.UseStaticFiles();
            app.UseRouting();

            app.UseCors();

            app.UseEndpoints(endpoints =>
            {
                endpoints.MapRazorPages();
                endpoints.MapHub<ChatHub>("/chathub");
            });
        }
    }
}
```

Call hub methods from the client

JavaScript clients call public methods on hubs via the invoke method of the HubConnection. The `invoke` method accepts:

- The name of the hub method.
- Any arguments defined in the hub method.

In the following example, the method name on the hub is `SendMessage`. The second and third arguments passed to `invoke` map to the hub method's `user` and `message` arguments:

```
try {
    await connection.invoke("SendMessage", user, message);
} catch (err) {
    console.error(err);
}
```

> **NOTE**
> Calling hub methods from a client is only supported when using the Azure SignalR Service in *Default* mode. For more information, see Frequently Asked Questions (azure-signalr GitHub repository).

The `invoke` method returns a JavaScript Promise. The `Promise` is resolved with the return value (if any) when the method on the server returns. If the method on the server throws an error, the `Promise` is rejected with the error message. Use `async` and `await` or the `Promise`'s `then` and `catch` methods to handle these cases.

JavaScript clients can also call public methods on hubs via the the send method of the `HubConnection`. Unlike the `invoke` method, the `send` method doesn't wait for a response from the server. The `send` method returns a JavaScript `Promise`. The `Promise` is resolved when the message has been sent to the server. If there is an error sending the message, the `Promise` is rejected with the error message. Use `async` and `await` or the `Promise`'s `then` and `catch` methods to handle these cases.

> **NOTE**
> Using `send` doesn't wait until the server has received the message. Consequently, it's not possible to return data or errors from the server.

Call client methods from the hub

To receive messages from the hub, define a method using the on method of the `HubConnection`.

- The name of the JavaScript client method.
- Arguments the hub passes to the method.

In the following example, the method name is `ReceiveMessage`. The argument names are `user` and `message`:

```
connection.on("ReceiveMessage", (user, message) => {
    const li = document.createElement("li");
    li.textContent = `${user}: ${message}`;
    document.getElementById("messageList").appendChild(li);
});
```

The preceding code in `connection.on` runs when server-side code calls it using the SendAsync method:

```
public async Task SendMessage(string user, string message)
{
    await Clients.All.SendAsync("ReceiveMessage", user, message);
}
```

SignalR determines which client method to call by matching the method name and arguments defined in `SendAsync` and `connection.on`.

> **NOTE**
> As a best practice, call the start method on the `HubConnection` after `on`. Doing so ensures your handlers are registered before any messages are received.

Error handling and logging

Use `try` and `catch` with `async` and `await` or the `Promise`'s `catch` method to handle client-side errors. Use `console.error` to output errors to the browser's console:

```
try {
    await connection.invoke("SendMessage", user, message);
} catch (err) {
    console.error(err);
}
```

Set up client-side log tracing by passing a logger and type of event to log when the connection is made. Messages are logged with the specified log level and higher. Available log levels are as follows:

- `signalR.LogLevel.Error`: Error messages. Logs `Error` messages only.
- `signalR.LogLevel.Warning`: Warning messages about potential errors. Logs `Warning`, and `Error` messages.
- `signalR.LogLevel.Information`: Status messages without errors. Logs `Information`, `Warning`, and `Error` messages.
- `signalR.LogLevel.Trace`: Trace messages. Logs everything, including data transported between hub and client.

Use the configureLogging method on HubConnectionBuilder to configure the log level. Messages are logged to the browser console:

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .configureLogging(signalR.LogLevel.Information)
    .build();
```

Reconnect clients

Automatically reconnect

The JavaScript client for SignalR can be configured to automatically reconnect using the `withAutomaticReconnect` method on HubConnectionBuilder. It won't automatically reconnect by default.

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .withAutomaticReconnect()
    .build();
```

Without any parameters, `withAutomaticReconnect()` configures the client to wait 0, 2, 10, and 30 seconds respectively before trying each reconnect attempt, stopping after four failed attempts.

Before starting any reconnect attempts, the `HubConnection` will transition to the `HubConnectionState.Reconnecting` state and fire its `onreconnecting` callbacks instead of transitioning to the `Disconnected` state and triggering its `onclose` callbacks like a `HubConnection` without automatic reconnect configured. This provides an opportunity to warn users that the connection has been lost and to disable UI

elements.

```
connection.onreconnecting(error => {
    console.assert(connection.state === signalR.HubConnectionState.Reconnecting);

    document.getElementById("messageInput").disabled = true;

    const li = document.createElement("li");
    li.textContent = `Connection lost due to error "${error}". Reconnecting.`;
    document.getElementById("messagesList").appendChild(li);
});
```

If the client successfully reconnects within its first four attempts, the `HubConnection` will transition back to the `Connected` state and fire its `onreconnected` callbacks. This provides an opportunity to inform users the connection has been reestablished.

Since the connection looks entirely new to the server, a new `connectionId` will be provided to the `onreconnected` callback.

WARNING

The `onreconnected` callback's `connectionId` parameter will be undefined if the `HubConnection` was configured to skip negotiation.

```
connection.onreconnected(connectionId => {
    console.assert(connection.state === signalR.HubConnectionState.Connected);

    document.getElementById("messageInput").disabled = false;

    const li = document.createElement("li");
    li.textContent = `Connection reestablished. Connected with connectionId "${connectionId}".`;
    document.getElementById("messagesList").appendChild(li);
});
```

`withAutomaticReconnect()` won't configure the `HubConnection` to retry initial start failures, so start failures need to be handled manually:

```
async function start() {
    try {
        await connection.start();
        console.assert(connection.state === signalR.HubConnectionState.Connected);
        console.log("SignalR Connected.");
    } catch (err) {
        console.assert(connection.state === signalR.HubConnectionState.Disconnected);
        console.log(err);
        setTimeout(() => start(), 5000);
    }
};
```

If the client doesn't successfully reconnect within its first four attempts, the `HubConnection` will transition to the `Disconnected` state and fire its onclose callbacks. This provides an opportunity to inform users the connection has been permanently lost and recommend refreshing the page:

```
connection.onclose(error => {
    console.assert(connection.state === signalR.HubConnectionState.Disconnected);

    document.getElementById("messageInput").disabled = true;

    const li = document.createElement("li");
    li.textContent = `Connection closed due to error "${error}". Try refreshing this page to restart the
connection.`;
    document.getElementById("messagesList").appendChild(li);
});
```

In order to configure a custom number of reconnect attempts before disconnecting or change the reconnect timing, `withAutomaticReconnect` accepts an array of numbers representing the delay in milliseconds to wait before starting each reconnect attempt.

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .withAutomaticReconnect([0, 0, 10000])
    .build();

    // .withAutomaticReconnect([0, 2000, 10000, 30000]) yields the default behavior
```

The preceding example configures the `HubConnection` to start attempting reconnects immediately after the connection is lost. This is also true for the default configuration.

If the first reconnect attempt fails, the second reconnect attempt will also start immediately instead of waiting 2 seconds like it would in the default configuration.

If the second reconnect attempt fails, the third reconnect attempt will start in 10 seconds which is again like the default configuration.

The custom behavior then diverges again from the default behavior by stopping after the third reconnect attempt failure instead of trying one more reconnect attempt in another 30 seconds like it would in the default configuration.

If you want even more control over the timing and number of automatic reconnect attempts, `withAutomaticReconnect` accepts an object implementing the `IRetryPolicy` interface, which has a single method named `nextRetryDelayInMilliseconds`.

`nextRetryDelayInMilliseconds` takes a single argument with the type `RetryContext`. The `RetryContext` has three properties: `previousRetryCount`, `elapsedMilliseconds` and `retryReason` which are a `number`, a `number` and an `Error` respectively. Before the first reconnect attempt, both `previousRetryCount` and `elapsedMilliseconds` will be zero, and the `retryReason` will be the Error that caused the connection to be lost. After each failed retry attempt, `previousRetryCount` will be incremented by one, `elapsedMilliseconds` will be updated to reflect the amount of time spent reconnecting so far in milliseconds, and the `retryReason` will be the Error that caused the last reconnect attempt to fail.

`nextRetryDelayInMilliseconds` must return either a number representing the number of milliseconds to wait before the next reconnect attempt or `null` if the `HubConnection` should stop reconnecting.

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .withAutomaticReconnect({
        nextRetryDelayInMilliseconds: retryContext => {
            if (retryContext.elapsedMilliseconds < 60000) {
                // If we've been reconnecting for less than 60 seconds so far,
                // wait between 0 and 10 seconds before the next reconnect attempt.
                return Math.random() * 10000;
            } else {
                // If we've been reconnecting for more than 60 seconds so far, stop reconnecting.
                return null;
            }
        }
    })
    .build();
```

Alternatively, you can write code that will reconnect your client manually as demonstrated in Manually reconnect.

Manually reconnect

The following code demonstrates a typical manual reconnection approach:

1. A function (in this case, the `start` function) is created to start the connection.
2. Call the `start` function in the connection's `onclose` event handler.

```
async function start() {
    try {
        await connection.start();
        console.log("SignalR Connected.");
    } catch (err) {
        console.log(err);
        setTimeout(start, 5000);
    }
};

connection.onclose(start);
```

A real-world implementation would use an exponential back-off or retry a specified number of times before giving up.

By Rachel Appel

The ASP.NET Core SignalR JavaScript client library enables developers to call server-side hub code.

View or download sample code (how to download)

Install the SignalR client package

The SignalR JavaScript client library is delivered as an npm package. The following sections outline different ways to install the client library.

Install with npm

If using Visual Studio, run the following commands from **Package Manager Console** while in the root folder. For Visual Studio Code, run the following commands from the **Integrated Terminal**.

```
npm init -y
npm install @aspnet/signalr
```

npm installs the package contents in the *node_modules\@aspnet\signalr\dist\browser* folder. Create a new folder named *signalr* under the *wwwroot\lib* folder. Copy the *signalr.js* file to the *wwwroot\lib\signalr* folder.

Reference the SignalR JavaScript client in the `<script>` element. For example:

```
<script src="~/lib/signalr/signalr.js"></script>
```

Use a Content Delivery Network (CDN)

To use the client library without the npm prerequisite, reference a CDN-hosted copy of the client library. For example:

```
<script src="https://cdnjs.cloudflare.com/ajax/libs/microsoft-signalr/3.1.3/signalr.min.js"></script>
```

The client library is available on the following CDNs:

- cdnjs
- jsDelivr
- unpkg

Install with LibMan

LibMan can be used to install specific client library files from the CDN-hosted client library. For example, only add the minified JavaScript file to the project. For details on that approach, see Add the SignalR client library.

Connect to a hub

The following code creates and starts a connection. The hub's name is case insensitive.

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chatHub")
    .configureLogging(signalR.LogLevel.Information)
    .build();

async function start() {
    try {
        await connection.start();
        console.log("connected");
    } catch (err) {
        console.log(err);
        setTimeout(() => start(), 5000);
    }
};

connection.onclose(async () => {
    await start();
});

// Start the connection.
start();

/* this is here to show an alternative to start, with a then
connection.start().then(() => console.log("connected"));
*/

/* this is here to show another alternative to start, with a catch
connection.start().catch(err => console.error(err));
*/
```

Cross-origin connections

Typically, browsers load connections from the same domain as the requested page. However, there are occasions when a connection to another domain is required.

To prevent a malicious site from reading sensitive data from another site, cross-origin connections are disabled by default. To allow a cross-origin request, enable it in the `Startup` class.

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.AspNetCore.Http;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using SignalRChat.Hubs;

namespace SignalRChat
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        public void ConfigureServices(IServiceCollection services)
        {
            services.Configure<CookiePolicyOptions>(options =>
            {
                options.CheckConsentNeeded = context => true;
                options.MinimumSameSitePolicy = SameSiteMode.None;
            });

            services.AddMvc();

            services.AddCors(options => options.AddPolicy("CorsPolicy",
            builder =>
            {
                builder.AllowAnyMethod().AllowAnyHeader()
                       .WithOrigins("http://localhost:55830")
                       .AllowCredentials();
            }));

            services.AddSignalR();
        }

        public void Configure(IApplicationBuilder app, IHostingEnvironment env)
        {
            if (env.IsDevelopment())
            {
                app.UseBrowserLink();
                app.UseDeveloperExceptionPage();
            }
            else
            {
                app.UseExceptionHandler("/Error");
                app.UseHsts();
            }

            app.UseHttpsRedirection();
            app.UseStaticFiles();
            app.UseCookiePolicy();
            app.UseCors("CorsPolicy");
            app.UseSignalR(routes =>
            {
                routes.MapHub<ChatHub>("/chathub");
            });
            app.UseMvc();
        }
    }
}
```

Call hub methods from client

JavaScript clients call public methods on hubs via the invoke method of the HubConnection. The `invoke` method accepts two arguments:

- The name of the hub method. In the following example, the method name on the hub is `SendMessage`.
- Any arguments defined in the hub method. In the following example, the argument name is `message`. The example code uses arrow function syntax that is supported in current versions of all major browsers except Internet Explorer.

```
connection.invoke("SendMessage", user, message).catch(err => console.error(err));
```

> **NOTE**
> Calling hub methods from a client is only supported when using the Azure SignalR Service in *Default* mode. For more information, see Frequently Asked Questions (azure-signalr GitHub repository).

The `invoke` method returns a JavaScript Promise. The `Promise` is resolved with the return value (if any) when the method on the server returns. If the method on the server throws an error, the `Promise` is rejected with the error message. Use the `then` and `catch` methods on the `Promise` itself to handle these cases (or `await` syntax).

The `send` method returns a JavaScript `Promise`. The `Promise` is resolved when the message has been sent to the server. If there is an error sending the message, the `Promise` is rejected with the error message. Use the `then` and `catch` methods on the `Promise` itself to handle these cases (or `await` syntax).

> **NOTE**
> Using `send` doesn't wait until the server has received the message. Consequently, it's not possible to return data or errors from the server.

Call client methods from hub

To receive messages from the hub, define a method using the on method of the `HubConnection`.

- The name of the JavaScript client method. In the following example, the method name is `ReceiveMessage`.
- Arguments the hub passes to the method. In the following example, the argument value is `message`.

```
connection.on("ReceiveMessage", (user, message) => {
    const encodedMsg = `${user} says ${message}`;
    const li = document.createElement("li");
    li.textContent = encodedMsg;
    document.getElementById("messagesList").appendChild(li);
});
```

The preceding code in `connection.on` runs when server-side code calls it using the SendAsync method.

```
public async Task SendMessage(string user, string message)
{
    await Clients.All.SendAsync("ReceiveMessage", user, message);
}
```

SignalR determines which client method to call by matching the method name and arguments defined in `SendAsync` and `connection.on`.

> **NOTE**
> As a best practice, call the start method on the `HubConnection` after `on`. Doing so ensures your handlers are registered before any messages are received.

Error handling and logging

Chain a `catch` method to the end of the `start` method to handle client-side errors. Use `console.error` to output errors to the browser's console.

```
connection.start().catch(err => console.error(err));
```

Set up client-side log tracing by passing a logger and type of event to log when the connection is made. Messages are logged with the specified log level and higher. Available log levels are as follows:

- `signalR.LogLevel.Error`: Error messages. Logs `Error` messages only.
- `signalR.LogLevel.Warning`: Warning messages about potential errors. Logs `Warning`, and `Error` messages.
- `signalR.LogLevel.Information`: Status messages without errors. Logs `Information`, `Warning`, and `Error` messages.
- `signalR.LogLevel.Trace`: Trace messages. Logs everything, including data transported between hub and client.

Use the configureLogging method on HubConnectionBuilder to configure the log level. Messages are logged to the browser console.

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chatHub")
    .configureLogging(signalR.LogLevel.Information)
    .build();
```

Reconnect clients

Manually reconnect

> **WARNING**
> Prior to 3.0, the JavaScript client for SignalR doesn't automatically reconnect. You must write code that will reconnect your client manually.

The following code demonstrates a typical manual reconnection approach:

1. A function (in this case, the `start` function) is created to start the connection.
2. Call the `start` function in the connection's `onclose` event handler.

```
async function start() {
    try {
        await connection.start();
        console.log("connected");
    } catch (err) {
        console.log(err);
        setTimeout(() => start(), 5000);
    }
};

connection.onclose(async () => {
    await start();
});
```

A real-world implementation would use an exponential back-off or retry a specified number of times before giving up.

ASP.NET Core SignalR hosting and scaling

9/22/2020 • 5 minutes to read • Edit Online

By Andrew Stanton-Nurse, Brady Gaster, and Tom Dykstra

This article explains hosting and scaling considerations for high-traffic apps that use ASP.NET Core SignalR.

Sticky Sessions

SignalR requires that all HTTP requests for a specific connection be handled by the same server process. When SignalR is running on a server farm (multiple servers), "sticky sessions" must be used. "Sticky sessions" are also called session affinity by some load balancers. Azure App Service uses Application Request Routing (ARR) to route requests. Enabling the "ARR Affinity" setting in your Azure App Service will enable "sticky sessions". The only circumstances in which sticky sessions are not required are:

1. When hosting on a single server, in a single process.
2. When using the Azure SignalR Service.
3. When all clients are configured to **only** use WebSockets, **and** the SkipNegotiation setting is enabled in the client configuration.

In all other circumstances (including when the Redis backplane is used), the server environment must be configured for sticky sessions.

For guidance on configuring Azure App Service for SignalR, see Publish an ASP.NET Core SignalR app to Azure App Service.

TCP connection resources

The number of concurrent TCP connections that a web server can support is limited. Standard HTTP clients use *ephemeral* connections. These connections can be closed when the client goes idle and reopened later. On the other hand, a SignalR connection is *persistent*. SignalR connections stay open even when the client goes idle. In a high-traffic app that serves many clients, these persistent connections can cause servers to hit their maximum number of connections.

Persistent connections also consume some additional memory, to track each connection.

The heavy use of connection-related resources by SignalR can affect other web apps that are hosted on the same server. When SignalR opens and holds the last available TCP connections, other web apps on the same server also have no more connections available to them.

If a server runs out of connections, you'll see random socket errors and connection reset errors. For example:

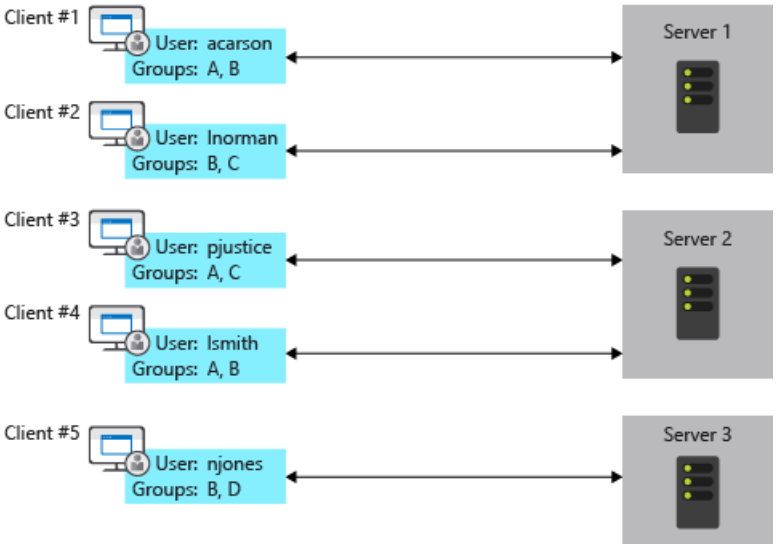
```
An attempt was made to access a socket in a way forbidden by its access permissions...
```

To keep SignalR resource usage from causing errors in other web apps, run SignalR on different servers than your other web apps.

To keep SignalR resource usage from causing errors in a SignalR app, scale out to limit the number of connections a server has to handle.

Scale out

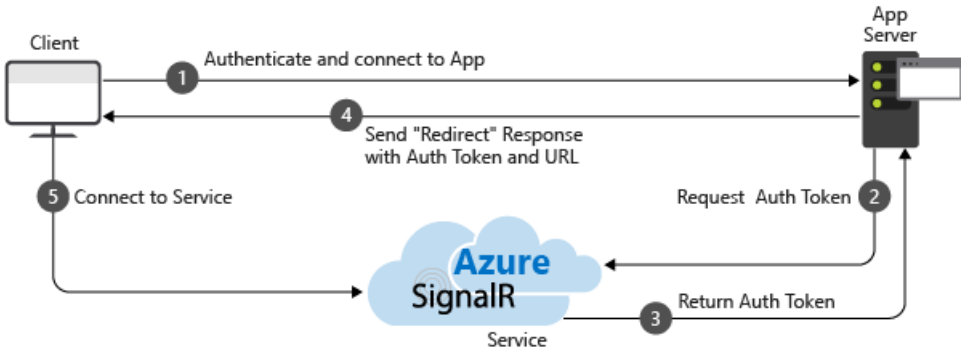
An app that uses SignalR needs to keep track of all its connections, which creates problems for a server farm. Add a server, and it gets new connections that the other servers don't know about. For example, SignalR on each server in the following diagram is unaware of the connections on the other servers. When SignalR on one of the servers wants to send a message to all clients, the message only goes to the clients connected to that server.



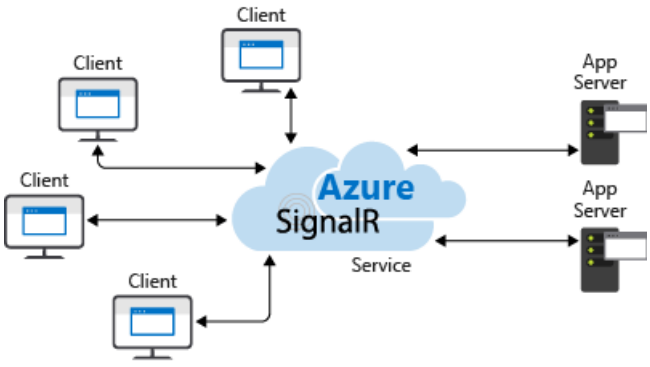
The options for solving this problem are the Azure SignalR Service and Redis backplane.

Azure SignalR Service

The Azure SignalR Service is a proxy rather than a backplane. Each time a client initiates a connection to the server, the client is redirected to connect to the service. That process is illustrated in the following diagram:



The result is that the service manages all of the client connections, while each server needs only a small constant number of connections to the service, as shown in the following diagram:



This approach to scale-out has several advantages over the Redis backplane alternative:

- Sticky sessions, also known as client affinity, is not required, because clients are immediately redirected to the Azure SignalR Service when they connect.
- A SignalR app can scale out based on the number of messages sent, while the Azure SignalR Service scales to

handle any number of connections. For example, there could be thousands of clients, but if only a few messages per second are sent, the SignalR app won't need to scale out to multiple servers just to handle the connections themselves.

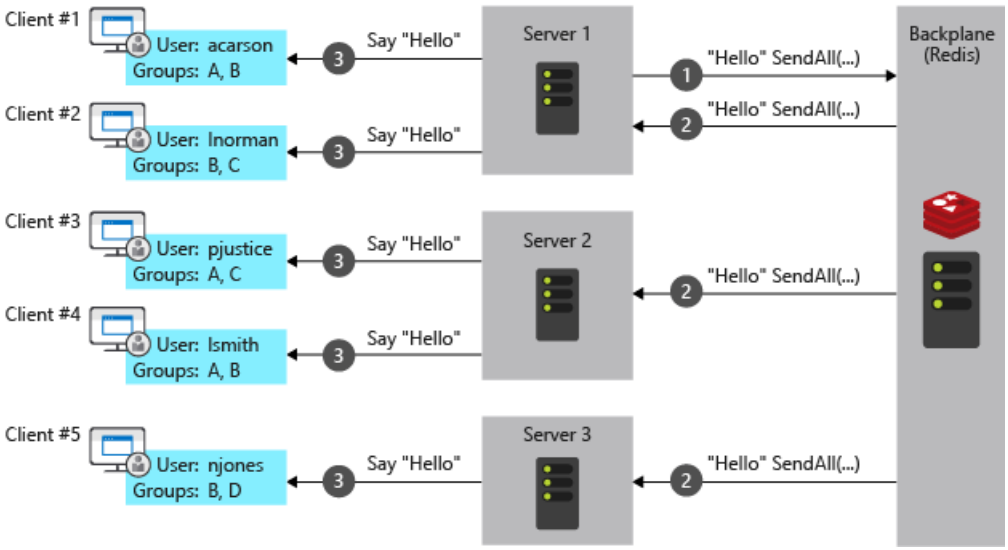
- A SignalR app won't use significantly more connection resources than a web app without SignalR.

For these reasons, we recommend the Azure SignalR Service for all ASP.NET Core SignalR apps hosted on Azure, including App Service, VMs, and containers.

For more information see the Azure SignalR Service documentation.

Redis backplane

Redis is an in-memory key-value store that supports a messaging system with a publish/subscribe model. The SignalR Redis backplane uses the pub/sub feature to forward messages to other servers. When a client makes a connection, the connection information is passed to the backplane. When a server wants to send a message to all clients, it sends to the backplane. The backplane knows all connected clients and which servers they're on. It sends the message to all clients via their respective servers. This process is illustrated in the following diagram:



The Redis backplane is the recommended scale-out approach for apps hosted on your own infrastructure. If there is significant connection latency between your data center and an Azure data center, Azure SignalR Service may not be a practical option for on-premises apps with low latency or high throughput requirements.

The Azure SignalR Service advantages noted earlier are disadvantages for the Redis backplane:

- Sticky sessions, also known as client affinity, is required, except when **both** of the following are true:
  - All clients are configured to **only** use WebSockets.
  - The SkipNegotiation setting is enabled in the client configuration. Once a connection is initiated on a server, the connection has to stay on that server.
- A SignalR app must scale out based on number of clients even if few messages are being sent.
- A SignalR app uses significantly more connection resources than a web app without SignalR.

IIS limitations on Windows client OS

Windows 10 and Windows 8.x are client operating systems. IIS on client operating systems has a limit of 10 concurrent connections. SignalR's connections are:

- Transient and frequently re-established.
- **Not** disposed immediately when no longer used.

The preceding conditions make it likely to hit the 10 connection limit on a client OS. When a client OS is used for

development, we recommend:

- Avoid IIS.
- Use Kestrel or IIS Express as deployment targets.

Linux with Nginx

Set the proxy's `Connection` and `Upgrade` headers to the following for SignalR WebSockets:

```
proxy_set_header Upgrade $http_upgrade;
proxy_set_header Connection $connection_upgrade;
```

For more information, see NGINX as a WebSocket Proxy.

Third-party SignalR backplane providers

- NCache
- Orleans

- Azure SignalR Service documentation
- Set up a Redis backplane

Publish an ASP.NET Core SignalR app to Azure App Service

9/22/2020 • 2 minutes to read • Edit Online

By Brady Gaster

Azure App Service is a Microsoft cloud computing platform service for hosting web apps, including ASP.NET Core.

> **NOTE**
> This article refers to publishing an ASP.NET Core SignalR app from Visual Studio. For more information, see SignalR service for Azure.

Publish the app

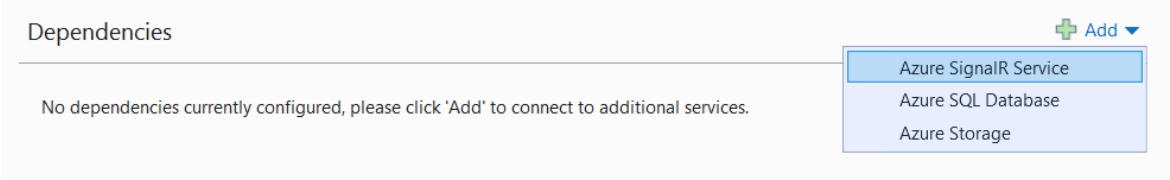
This article covers publishing using the tools in Visual Studio. Visual Studio Code users can use Azure CLI commands to publish apps to Azure. For more information, see Publish an ASP.NET Core app to Azure with command line tools.

1. Right-click on the project in **Solution Explorer** and select **Publish**.
2. Confirm that **App Service** and **Create new** are selected in the **Pick a publish target** dialog.
3. Select **Create Profile** from the **Publish** button drop down.

   Enter the information described in the following table in the **Create App Service** dialog and select **Create**.

ITEM	DESCRIPTION
Name	Unique name of the app.
Subscription	Azure subscription that the app uses.
Resource Group	Group of related resources to which the app belongs.
Hosting Plan	Pricing plan for the web app.

4. Select the **Azure SignalR Service** in the **Dependencies** > **Add** drop-down list:



5. In the **Azure SignalR Service** dialog, select **Create a new Azure SignalR Service instance**.
6. Provide a **Name**, **Resource Group**, and **Location**. Return to the **Azure SignalR Service** dialog and select **Add**.

Visual Studio completes the following tasks:

- Creates a Publish Profile containing publish settings.
- Creates an *Azure Web App* with the provided details.
- Publishes the app.
- Launches a browser, which loads the web app.

The format of the app's URL is `{APP SERVICE NAME}.azurewebsites.net`. For example, an app named `SignalRChatApp` has a URL of `https://signalrchatapp.azurewebsites.net`.

If an HTTP *502.2 - Bad Gateway* error occurs when deploying an app that targets a preview .NET Core release, see Deploy ASP.NET Core preview release to Azure App Service to resolve it.

Configure the app in Azure App Service

> **NOTE**
>
> *This section only applies to apps not using the Azure SignalR Service.*
>
> If the app uses the Azure SignalR Service, the App Service doesn't require the configuration of Application Request Routing (ARR) Affinity and Web Sockets described in this section. Clients connect their Web Sockets to the Azure SignalR Service, not directly to the app.

For apps hosted without the Azure SignalR Service, enable:

- ARR Affinity to route requests from a user back to the same App Service instance. The default setting is **On**.
- Web Sockets to allow the Web Sockets transport to function. The default setting is **Off**.

1. In the Azure portal, navigate to the web app in **App Services**.
2. Open **Configuration** > **General settings**.
3. Set **Web sockets** to **On**.
4. Verify that **ARR affinity** is set to **On**.

App Service Plan limits

Web Sockets and other transports are limited based on the App Service Plan selected. For more information, see the *Azure Cloud Services limits* and *App Service limits* sections of the Azure subscription and service limits, quotas, and constraints article.

Set up a Redis backplane for ASP.NET Core SignalR scale-out

9/22/2020 • 4 minutes to read • Edit Online

By Andrew Stanton-Nurse, Brady Gaster, and Tom Dykstra,

This article explains SignalR-specific aspects of setting up a Redis server to use for scaling out an ASP.NET Core SignalR app.

Set up a Redis backplane

- Deploy a Redis server.

  > **IMPORTANT**
  > For production use, a Redis backplane is recommended only when it runs in the same data center as the SignalR app. Otherwise, network latency degrades performance. If your SignalR app is running in the Azure cloud, we recommend Azure SignalR Service instead of a Redis backplane. You can use the Azure Redis Cache Service for development and test environments.

  For more information, see the following resources:

  - ASP.NET Core SignalR production hosting and scaling
  - Redis documentation
  - Azure Redis Cache documentation

- In the SignalR app, install the `Microsoft.AspNetCore.SignalR.Redis` NuGet package.

- In the `Startup.ConfigureServices` method, call `AddRedis` after `AddSignalR`:

  ```
  services.AddSignalR().AddRedis("<your_Redis_connection_string>");
  ```

- Configure options as needed:

  Most options can be set in the connection string or in the ConfigurationOptions object. Options specified in `ConfigurationOptions` override the ones set in the connection string.

  The following example shows how to set options in the `ConfigurationOptions` object. This example adds a channel prefix so that multiple apps can share the same Redis instance, as explained in the following step.

  ```
  services.AddSignalR()
    .AddRedis(connectionString, options => {
        options.Configuration.ChannelPrefix = "MyApp";
    });
  ```

  In the preceding code, `options.Configuration` is initialized with whatever was specified in the connection string.

- In the SignalR app, install one of the following NuGet packages:

  - `Microsoft.AspNetCore.SignalR.StackExchangeRedis` - Depends on StackExchange.Redis 2.X.X. This is the

recommended package for ASP.NET Core 2.2 and later.

  - `Microsoft.AspNetCore.SignalR.Redis` - Depends on StackExchange.Redis 1.X.X. This package isn't included in ASP.NET Core 3.0 and later.

- In the `Startup.ConfigureServices` method, call AddStackExchangeRedis:

```
services.AddSignalR().AddStackExchangeRedis("<your_Redis_connection_string>");
```

When using `Microsoft.AspNetCore.SignalR.Redis`, call AddRedis.

- Configure options as needed:

  Most options can be set in the connection string or in the ConfigurationOptions object. Options specified in `ConfigurationOptions` override the ones set in the connection string.

  The following example shows how to set options in the `ConfigurationOptions` object. This example adds a channel prefix so that multiple apps can share the same Redis instance, as explained in the following step.

```
services.AddSignalR()
  .AddStackExchangeRedis(connectionString, options => {
      options.Configuration.ChannelPrefix = "MyApp";
  });
```

When using `Microsoft.AspNetCore.SignalR.Redis`, call AddRedis.

In the preceding code, `options.Configuration` is initialized with whatever was specified in the connection string.

For information about Redis options, see the StackExchange Redis documentation.

- In the SignalR app, install the following NuGet package:

  - `Microsoft.AspNetCore.SignalR.StackExchangeRedis`

- In the `Startup.ConfigureServices` method, call AddStackExchangeRedis:

```
services.AddSignalR().AddStackExchangeRedis("<your_Redis_connection_string>");
```

- Configure options as needed:

  Most options can be set in the connection string or in the ConfigurationOptions object. Options specified in `ConfigurationOptions` override the ones set in the connection string.

  The following example shows how to set options in the `ConfigurationOptions` object. This example adds a channel prefix so that multiple apps can share the same Redis instance, as explained in the following step.

```
services.AddSignalR()
  .AddStackExchangeRedis(connectionString, options => {
      options.Configuration.ChannelPrefix = "MyApp";
  });
```

  In the preceding code, `options.Configuration` is initialized with whatever was specified in the connection string.

  For information about Redis options, see the StackExchange Redis documentation.

- If you're using one Redis server for multiple SignalR apps, use a different channel prefix for each SignalR app.

Setting a channel prefix isolates one SignalR app from others that use different channel prefixes. If you don't assign different prefixes, a message sent from one app to all of its own clients will go to all clients of all apps that use the Redis server as a backplane.

- Configure your server farm load balancing software for sticky sessions. Here are some examples of documentation on how to do that:
  - IIS
  - HAProxy
  - Nginx
  - pfSense

Redis server errors

When a Redis server goes down, SignalR throws exceptions that indicate messages won't be delivered. Some typical exception messages:

- *Failed writing message*
- *Failed to invoke hub method 'MethodName'*
- *Connection to Redis failed*

SignalR doesn't buffer messages to send them when the server comes back up. Any messages sent while the Redis server is down are lost.

SignalR automatically reconnects when the Redis server is available again.

Custom behavior for connection failures

Here's an example that shows how to handle Redis connection failure events.

```
services.AddSignalR()
        .AddRedis(o =>
        {
            o.ConnectionFactory = async writer =>
            {
                var config = new ConfigurationOptions
                {
                    AbortOnConnectFail = false
                };
                config.EndPoints.Add(IPAddress.Loopback, 0);
                config.SetDefaultPorts();
                var connection = await ConnectionMultiplexer.ConnectAsync(config, writer);
                connection.ConnectionFailed += (_, e) =>
                {
                    Console.WriteLine("Connection to Redis failed.");
                };

                if (!connection.IsConnected)
                {
                    Console.WriteLine("Did not connect to Redis.");
                }

                return connection;
            };
        });
```

```
services.AddSignalR()
        .AddMessagePackProtocol()
        .AddStackExchangeRedis(o =>
        {
            o.ConnectionFactory = async writer =>
            {
                var config = new ConfigurationOptions
                {
                    AbortOnConnectFail = false
                };
                config.EndPoints.Add(IPAddress.Loopback, 0);
                config.SetDefaultPorts();
                var connection = await ConnectionMultiplexer.ConnectAsync(config, writer);
                connection.ConnectionFailed += (_, e) =>
                {
                    Console.WriteLine("Connection to Redis failed.");
                };

                if (!connection.IsConnected)
                {
                    Console.WriteLine("Did not connect to Redis.");
                }

                return connection;
            };
        });
```

Redis Clustering

Redis Clustering is a method for achieving high availability by using multiple Redis servers. Clustering isn't officially supported, but it might work.

Host ASP.NET Core SignalR in background services

9/22/2020 • 4 minutes to read • Edit Online

By Brady Gaster

This article provides guidance for:

- Hosting SignalR Hubs using a background worker process hosted with ASP.NET Core.
- Sending messages to connected clients from within a .NET Core BackgroundService.

View or download sample code (how to download)

View or download sample code (how to download)

Enable SignalR in startup

Hosting ASP.NET Core SignalR Hubs in the context of a background worker process is identical to hosting a Hub in an ASP.NET Core web app. In the `Startup.ConfigureServices` method, calling `services.AddSignalR` adds the required services to the ASP.NET Core Dependency Injection (DI) layer to support SignalR. In `Startup.Configure`, the `MapHub` method is called in the `UseEndpoints` callback to connect the Hub endpoints in the ASP.NET Core request pipeline.

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddSignalR();
        services.AddHostedService<Worker>();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        app.UseRouting();
        app.UseEndpoints(endpoints =>
        {
            endpoints.MapHub<ClockHub>("/hubs/clock");
        });
    }
}
```

Hosting ASP.NET Core SignalR Hubs in the context of a background worker process is identical to hosting a Hub in an ASP.NET Core web app. In the `Startup.ConfigureServices` method, calling `services.AddSignalR` adds the required services to the ASP.NET Core Dependency Injection (DI) layer to support SignalR. In `Startup.Configure`, the `UseSignalR` method is called to connect the Hub endpoint(s) in the ASP.NET Core request pipeline.

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddSignalR();
        services.AddHostedService<Worker>();
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        app.UseSignalR((routes) =>
        {
            routes.MapHub<ClockHub>("/hubs/clock");
        });
    }
}
```

In the preceding example, the `ClockHub` class implements the `Hub<T>` class to create a strongly typed Hub. The `ClockHub` has been configured in the `Startup` class to respond to requests at the endpoint `/hubs/clock`.

For more information on strongly typed Hubs, see Use hubs in SignalR for ASP.NET Core.

> **NOTE**
> This functionality isn't limited to the Hub<T> class. Any class that inherits from Hub, such as DynamicHub, works.

```
public class ClockHub : Hub<IClock>
{
    public async Task SendTimeToClients(DateTime dateTime)
    {
        await Clients.All.ShowTime(dateTime);
    }
}
```

```
public class ClockHub : Hub<IClock>
{
    public async Task SendTimeToClients(DateTime dateTime)
    {
        await Clients.All.ShowTime(dateTime);
    }
}
```

The interface used by the strongly typed `ClockHub` is the `IClock` interface.

```
public interface IClock
{
    Task ShowTime(DateTime currentTime);
}
```

```
public interface IClock
{
    Task ShowTime(DateTime currentTime);
}
```

Call a SignalR Hub from a background service

During startup, the `Worker` class, a `BackgroundService`, is enabled using `AddHostedService`.

```
services.AddHostedService<Worker>();
```

Since SignalR is also enabled up during the `Startup` phase, in which each Hub is attached to an individual endpoint in ASP.NET Core's HTTP request pipeline, each Hub is represented by an `IHubContext<T>` on the server. Using ASP.NET Core's DI features, other classes instantiated by the hosting layer, like `BackgroundService` classes, MVC Controller classes, or Razor page models, can get references to server-side Hubs by accepting instances of `IHubContext<ClockHub, IClock>` during construction.

```
public class Worker : BackgroundService
{
    private readonly ILogger<Worker> _logger;
    private readonly IHubContext<ClockHub, IClock> _clockHub;

    public Worker(ILogger<Worker> logger, IHubContext<ClockHub, IClock> clockHub)
    {
        _logger = logger;
        _clockHub = clockHub;
    }

    protected override async Task ExecuteAsync(CancellationToken stoppingToken)
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            _logger.LogInformation("Worker running at: {Time}", DateTime.Now);
            await _clockHub.Clients.All.ShowTime(DateTime.Now);
            await Task.Delay(1000);
        }
    }
}
```

```
public class Worker : BackgroundService
{
    private readonly ILogger<Worker> _logger;
    private readonly IHubContext<ClockHub, IClock> _clockHub;

    public Worker(ILogger<Worker> logger, IHubContext<ClockHub, IClock> clockHub)
    {
        _logger = logger;
        _clockHub = clockHub;
    }

    protected override async Task ExecuteAsync(CancellationToken stoppingToken)
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            _logger.LogInformation("Worker running at: {Time}", DateTime.Now);
            await _clockHub.Clients.All.ShowTime(DateTime.Now);
            await Task.Delay(1000);
        }
    }
}
```

As the `ExecuteAsync` method is called iteratively in the background service, the server's current date and time are sent to the connected clients using the `ClockHub`.

React to SignalR events with background services

Like a Single Page App using the JavaScript client for SignalR or a .NET desktop app can do using the using the ASP.NET Core SignalR .NET Client, a `BackgroundService` or `IHostedService` implementation can also be used to connect to SignalR Hubs and respond to events.

The `ClockHubClient` class implements both the `IClock` interface and the `IHostedService` interface. This way it can be enabled during `Startup` to run continuously and respond to Hub events from the server.

```
public partial class ClockHubClient : IClock, IHostedService
{
}
```

During initialization, the `ClockHubClient` creates an instance of a `HubConnection` and enables the `IClock.ShowTime` method as the handler for the Hub's `ShowTime` event.

```
private readonly ILogger<ClockHubClient> _logger;
private HubConnection _connection;

public ClockHubClient(ILogger<ClockHubClient> logger)
{
    _logger = logger;

    _connection = new HubConnectionBuilder()
        .WithUrl(Strings.HubUrl)
        .Build();

    _connection.On<DateTime>(Strings.Events.TimeSent, ShowTime);
}

public Task ShowTime(DateTime currentTime)
{
    _logger.LogInformation("{CurrentTime}", currentTime.ToShortTimeString());

    return Task.CompletedTask;
}
```

In the `IHostedService.StartAsync` implementation, the `HubConnection` is started asynchronously.

```
public async Task StartAsync(CancellationToken cancellationToken)
{
    // Loop is here to wait until the server is running
    while (true)
    {
        try
        {
            await _connection.StartAsync(cancellationToken);

            break;
        }
        catch
        {
            await Task.Delay(1000);
        }
    }
}
```

During the `IHostedService.StopAsync` method, the `HubConnection` is disposed of asynchronously.

```
public Task StopAsync(CancellationToken cancellationToken)
{
    return _connection.DisposeAsync();
}
```

```
private readonly ILogger<ClockHubClient> _logger;
private HubConnection _connection;

public ClockHubClient(ILogger<ClockHubClient> logger)
{
    _logger = logger;

    _connection = new HubConnectionBuilder()
        .WithUrl(Strings.HubUrl)
        .Build();

    _connection.On<DateTime>(Strings.Events.TimeSent,
        dateTime => _ = ShowTime(dateTime));
}

public Task ShowTime(DateTime currentTime)
{
    _logger.LogInformation("{CurrentTime}", currentTime.ToShortTimeString());

    return Task.CompletedTask;
}
```

In the `IHostedService.StartAsync` implementation, the `HubConnection` is started asynchronously.

```
public async Task StartAsync(CancellationToken cancellationToken)
{
    // Loop is here to wait until the server is running
    while (true)
    {
        try
        {
            await _connection.StartAsync(cancellationToken);

            break;
        }
        catch
        {
            await Task.Delay(1000);
        }
    }
}
```

During the `IHostedService.StopAsync` method, the `HubConnection` is disposed of asynchronously.

```
public Task StopAsync(CancellationToken cancellationToken)
{
    return _connection.DisposeAsync();
}
```

ASP.NET Core SignalR configuration

9/22/2020 • 69 minutes to read • Edit Online

JSON/MessagePack serialization options

ASP.NET Core SignalR supports two protocols for encoding messages: JSON and MessagePack. Each protocol has serialization configuration options.

JSON serialization can be configured on the server using the AddJsonProtocol extension method. `AddJsonProtocol` can be added after AddSignalR in `Startup.ConfigureServices`. The `AddJsonProtocol` method takes a delegate that receives an `options` object. The PayloadSerializerOptions property on that object is a `System.Text.Json` JsonSerializerOptions object that can be used to configure serialization of arguments and return values. For more information, see the System.Text.Json documentation.

As an example, to configure the serializer to not change the casing of property names, instead of the default "camelCase" names, use the following code in `Startup.ConfigureServices`:

```
services.AddSignalR()
    .AddJsonProtocol(options => {
        options.PayloadSerializerOptions.PropertyNamingPolicy = null
    });
```

In the .NET client, the same `AddJsonProtocol` extension method exists on HubConnectionBuilder. The `Microsoft.Extensions.DependencyInjection` namespace must be imported to resolve the extension method:

```
// At the top of the file:
using Microsoft.Extensions.DependencyInjection;

// When constructing your connection:
var connection = new HubConnectionBuilder()
    .AddJsonProtocol(options => {
        options.PayloadSerializerOptions.PropertyNamingPolicy = null;
    })
    .Build();
```

> **NOTE**
> It's not possible to configure JSON serialization in the JavaScript client at this time.

Switch to Newtonsoft.Json

If you need features of `Newtonsoft.Json` that aren't supported in `System.Text.Json`, See Switch to NewtonsoftJson.

MessagePack serialization options

MessagePack serialization can be configured by providing a delegate to the AddMessagePackProtocol call. See MessagePack in SignalR for more details.

> **NOTE**
> It's not possible to configure MessagePack serialization in the JavaScript client at this time.

Configure server options

The following table describes options for configuring SignalR hubs:

OPTION	DEFAULT VALUE	DESCRIPTION
`ClientTimeoutInterval`	30 seconds	The server will consider the client disconnected if it hasn't received a message (including keep-alive) in this interval. It could take longer than this timeout interval for the client to actually be marked disconnected, due to how this is implemented. The recommended value is double the `KeepAliveInterval` value.
`HandshakeTimeout`	15 seconds	If the client doesn't send an initial handshake message within this time interval, the connection is closed. This is an advanced setting that should only be modified if handshake timeout errors are occurring due to severe network latency. For more detail on the handshake process, see the SignalR Hub Protocol Specification.
`KeepAliveInterval`	15 seconds	If the server hasn't sent a message within this interval, a ping message is sent automatically to keep the connection open. When changing `KeepAliveInterval`, change the `ServerTimeout` / `serverTimeoutInMilliseconds` setting on the client. The recommended `ServerTimeout` / `serverTimeoutInMilliseconds` value is double the `KeepAliveInterval` value.
`SupportedProtocols`	All installed protocols	Protocols supported by this hub. By default, all protocols registered on the server are allowed, but protocols can be removed from this list to disable specific protocols for individual hubs.
`EnableDetailedErrors`	`false`	If `true`, detailed exception messages are returned to clients when an exception is thrown in a Hub method. The default is `false`, as these exception messages can contain sensitive information.
`StreamBufferCapacity`	`10`	The maximum number of items that can be buffered for client upload streams. If this limit is reached, the processing of invocations is blocked until the server processes stream items.

OPTION	DEFAULT VALUE	DESCRIPTION
`MaximumReceiveMessageSize`	32 KB	Maximum size of a single incoming hub message.

Options can be configured for all hubs by providing an options delegate to the `AddSignalR` call in `Startup.ConfigureServices`.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSignalR(hubOptions =>
    {
        hubOptions.EnableDetailedErrors = true;
        hubOptions.KeepAliveInterval = TimeSpan.FromMinutes(1);
    });
}
```

Options for a single hub override the global options provided in `AddSignalR` and can be configured using AddHubOptions:

```
services.AddSignalR().AddHubOptions<ChatHub>(options =>
{
    options.EnableDetailedErrors = true;
});
```

Advanced HTTP configuration options

Use `HttpConnectionDispatcherOptions` to configure advanced settings related to transports and memory buffer management. These options are configured by passing a delegate to MapHub<T> in `Startup.Configure`.

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapHub<ChatHub>("/chathub", options =>
        {
            options.Transports =
                HttpTransportType.WebSockets |
                HttpTransportType.LongPolling;
        });
    });
}
```

The following table describes options for configuring ASP.NET Core SignalR's advanced HTTP options:

OPTION	DEFAULT VALUE	DESCRIPTION
`ApplicationMaxBufferSize`	32 KB	The maximum number of bytes received from the client that the server buffers before applying backpressure. Increasing this value allows the server to receive larger messages more quickly without applying backpressure, but can increase memory consumption.

OPTION	DEFAULT VALUE	DESCRIPTION
`AuthorizationData`	Data automatically gathered from the `Authorize` attributes applied to the Hub class.	A list of IAuthorizeData objects used to determine if a client is authorized to connect to the hub.
`TransportMaxBufferSize`	32 KB	The maximum number of bytes sent by the app that the server buffers before observing backpressure. Increasing this value allows the server to buffer larger messages more quickly without awaiting backpressure, but can increase memory consumption.
`Transports`	All Transports are enabled.	A bit flags enum of `HttpTransportType` values that can restrict the transports a client can use to connect.
`LongPolling`	See below.	Additional options specific to the Long Polling transport.
`WebSockets`	See below.	Additional options specific to the WebSockets transport.
`MinimumProtocolVersion`	0	Specify the minimum version of the negotiate protocol. This is used to limit clients to newer versions.

The Long Polling transport has additional options that can be configured using the `LongPolling` property:

OPTION	DEFAULT VALUE	DESCRIPTION
`PollTimeout`	90 seconds	The maximum amount of time the server waits for a message to send to the client before terminating a single poll request. Decreasing this value causes the client to issue new poll requests more frequently.

The WebSocket transport has additional options that can be configured using the `WebSockets` property:

OPTION	DEFAULT VALUE	DESCRIPTION
`CloseTimeout`	5 seconds	After the server closes, if the client fails to close within this time interval, the connection is terminated.
`SubProtocolSelector`	`null`	A delegate that can be used to set the `Sec-WebSocket-Protocol` header to a custom value. The delegate receives the values requested by the client as input and is expected to return the desired value.

Configure client options

Client options can be configured on the `HubConnectionBuilder` type (available in the .NET and JavaScript clients). It's also available in the Java client, but the `HttpHubConnectionBuilder` subclass is what contains the builder configuration options, as well as on the `HubConnection` itself.

Configure logging

Logging is configured in the .NET Client using the `ConfigureLogging` method. Logging providers and filters can be registered in the same way as they are on the server. See the Logging in ASP.NET Core documentation for more information.

> **NOTE**
> In order to register Logging providers, you must install the necessary packages. See the Built-in logging providers section of the docs for a full list.

For example, to enable Console logging, install the `Microsoft.Extensions.Logging.Console` NuGet package. Call the `AddConsole` extension method:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub")
    .ConfigureLogging(logging => {
        logging.SetMinimumLevel(LogLevel.Information);
        logging.AddConsole();
    })
    .Build();
```

In the JavaScript client, a similar `configureLogging` method exists. Provide a `LogLevel` value indicating the minimum level of log messages to produce. Logs are written to the browser console window.

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .configureLogging(signalR.LogLevel.Information)
    .build();
```

Instead of a `LogLevel` value, you can also provide a `string` value representing a log level name. This is useful when configuring SignalR logging in environments where you don't have access to the `LogLevel` constants.

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .configureLogging("warn")
    .build();
```

The following table lists the available log levels. The value you provide to `configureLogging` sets the **minimum** log level that will be logged. Messages logged at this level, **or the levels listed after it in the table**, will be logged.

STRING	LOGLEVEL
`trace`	`LogLevel.Trace`
`debug`	`LogLevel.Debug`
`info` **or** `information`	`LogLevel.Information`
`warn` **or** `warning`	`LogLevel.Warning`

STRING	LOGLEVEL
`error`	`LogLevel.Error`
`critical`	`LogLevel.Critical`
`none`	`LogLevel.None`

> **NOTE**
> To disable logging entirely, specify `signalR.LogLevel.None` in the `configureLogging` method.

For more information on logging, see the SignalR Diagnostics documentation.

The SignalR Java client uses the SLF4J library for logging. It's a high-level logging API that allows users of the library to chose their own specific logging implementation by bringing in a specific logging dependency. The following code snippet shows how to use `java.util.logging` with the SignalR Java client.

```
implementation 'org.slf4j:slf4j-jdk14:1.7.25'
```

If you don't configure logging in your dependencies, SLF4J loads a default no-operation logger with the following warning message:

```
SLF4J: Failed to load class "org.slf4j.impl.StaticLoggerBinder".
SLF4J: Defaulting to no-operation (NOP) logger implementation
SLF4J: See http://www.slf4j.org/codes.html#StaticLoggerBinder for further details.
```

This can safely be ignored.

Configure allowed transports

The transports used by SignalR can be configured in the `WithUrl` call (`withUrl` in JavaScript). A bitwise-OR of the values of `HttpTransportType` can be used to restrict the client to only use the specified transports. All transports are enabled by default.

For example, to disable the Server-Sent Events transport, but allow WebSockets and Long Polling connections:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", HttpTransportType.WebSockets | HttpTransportType.LongPolling)
    .Build();
```

In the JavaScript client, transports are configured by setting the `transport` field on the options object provided to `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", { transport: signalR.HttpTransportType.WebSockets |
signalR.HttpTransportType.LongPolling })
    .build();
```

In this version of the Java client websockets is the only available transport.

In the Java client, the transport is selected with the `withTransport` method on the `HttpHubConnectionBuilder`. The Java client defaults to using the WebSockets transport.

```
HubConnection hubConnection = HubConnectionBuilder.create("https://example.com/chathub")
    .withTransport(TransportEnum.WEBSOCKETS)
    .build();
```

> **NOTE**
> The SignalR Java client doesn't support transport fallback yet.

Configure bearer authentication

To provide authentication data along with SignalR requests, use the `AccessTokenProvider` option (`accessTokenFactory` in JavaScript) to specify a function that returns the desired access token. In the .NET Client, this access token is passed in as an HTTP "Bearer Authentication" token (Using the `Authorization` header with a type of `Bearer`). In the JavaScript client, the access token is used as a Bearer token, **except** in a few cases where browser APIs restrict the ability to apply headers (specifically, in Server-Sent Events and WebSockets requests). In these cases, the access token is provided as a query string value `access_token`.

In the .NET client, the `AccessTokenProvider` option can be specified using the options delegate in `WithUrl`:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options => {
        options.AccessTokenProvider = async () => {
            // Get and return the access token.
        };
    })
    .Build();
```

In the JavaScript client, the access token is configured by setting the `accessTokenFactory` field on the options object in `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", {
        accessTokenFactory: () => {
            // Get and return the access token.
            // This function can return a JavaScript Promise if asynchronous
            // logic is required to retrieve the access token.
        }
    })
    .build();
```

In the SignalR Java client, you can configure a bearer token to use for authentication by providing an access token factory to the HttpHubConnectionBuilder. Use withAccessTokenFactory to provide an RxJava Single<String>. With a call to Single.defer, you can write logic to produce access tokens for your client.

```
HubConnection hubConnection = HubConnectionBuilder.create("https://example.com/chathub")
    .withAccessTokenProvider(Single.defer(() -> {
        // Your logic here.
        return Single.just("An Access Token");
    })).build();
```

Configure timeout and keep-alive options

Additional options for configuring timeout and keep-alive behavior are available on the `HubConnection` object itself:

- .NET
- JavaScript

- Java

OPTION	DEFAULT VALUE	DESCRIPTION
`ServerTimeout`	30 seconds (30,000 milliseconds)	Timeout for server activity. If the server hasn't sent a message in this interval, the client considers the server disconnected and triggers the `Closed` event (`onclose` in JavaScript). This value must be large enough for a ping message to be sent from the server **and** received by the client within the timeout interval. The recommended value is a number at least double the server's `KeepAliveInterval` value to allow time for pings to arrive.
`HandshakeTimeout`	15 seconds	Timeout for initial server handshake. If the server doesn't send a handshake response in this interval, the client cancels the handshake and triggers the `Closed` event (`onclose` in JavaScript). This is an advanced setting that should only be modified if handshake timeout errors are occurring due to severe network latency. For more detail on the handshake process, see the SignalR Hub Protocol Specification.
`KeepAliveInterval`	15 seconds	Determines the interval at which the client sends ping messages. Sending any message from the client resets the timer to the start of the interval. If the client hasn't sent a message in the `ClientTimeoutInterval` set on the server, the server considers the client disconnected.

In the .NET Client, timeout values are specified as `TimeSpan` values.

Configure additional options

Additional options can be configured in the `WithUrl` (`withUrl` in JavaScript) method on `HubConnectionBuilder` or on the various configuration APIs on the `HttpHubConnectionBuilder` in the Java client:

- .NET
- JavaScript
- Java

.NET OPTION	DEFAULT VALUE	DESCRIPTION
`AccessTokenProvider`	`null`	A function returning a string that is provided as a Bearer authentication token in HTTP requests.

.NET OPTION	DEFAULT VALUE	DESCRIPTION
`SkipNegotiation`	`false`	Set this to `true` to skip the negotiation step. **Only supported when the WebSockets transport is the only enabled transport**. This setting can't be enabled when using the Azure SignalR Service.
`ClientCertificates`	Empty	A collection of TLS certificates to send to authenticate requests.
`Cookies`	Empty	A collection of HTTP cookies to send with every HTTP request.
`Credentials`	Empty	Credentials to send with every HTTP request.
`CloseTimeout`	5 seconds	WebSockets only. The maximum amount of time the client waits after closing for the server to acknowledge the close request. If the server doesn't acknowledge the close within this time, the client disconnects.
`Headers`	Empty	A Map of additional HTTP headers to send with every HTTP request.
`HttpMessageHandlerFactory`	`null`	A delegate that can be used to configure or replace the `HttpMessageHandler` used to send HTTP requests. Not used for WebSocket connections. This delegate must return a non-null value, and it receives the default value as a parameter. Either modify settings on that default value and return it, or return a new `HttpMessageHandler` instance. **When replacing the handler make sure to copy the settings you want to keep from the provided handler, otherwise, the configured options (such as Cookies and Headers) won't apply to the new handler.**
`Proxy`	`null`	An HTTP proxy to use when sending HTTP requests.
`UseDefaultCredentials`	`false`	Set this boolean to send the default credentials for HTTP and WebSockets requests. This enables the use of Windows authentication.
`WebSocketConfiguration`	`null`	A delegate that can be used to configure additional WebSocket options. Receives an instance of ClientWebSocketOptions that can be used to configure the options.

In the .NET Client, these options can be modified by the options delegate provided to `WithUrl`:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options => {
        options.Headers["Foo"] = "Bar";
        options.Cookies.Add(new Cookie(/* ... */);
        options.ClientCertificates.Add(/* ... */);
    })
    .Build();
```

In the JavaScript Client, these options can be provided in a JavaScript object provided to `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", {
        skipNegotiation: true,
        transport: signalR.HttpTransportType.WebSockets
    })
    .build();
```

In the Java client, these options can be configured with the methods on the `HttpHubConnectionBuilder` returned from the `HubConnectionBuilder.create("HUB URL")`

```
HubConnection hubConnection = HubConnectionBuilder.create("https://example.com/chathub")
        .withHeader("Foo", "Bar")
        .shouldSkipNegotiate(true)
        .withHandshakeResponseTimeout(30*1000)
        .build();
```

JSON/MessagePack serialization options

ASP.NET Core SignalR supports two protocols for encoding messages: JSON and MessagePack. Each protocol has serialization configuration options.

JSON serialization can be configured on the server using the AddJsonProtocol extension method. `AddJsonProtocol` can be added after AddSignalR in `Startup.ConfigureServices`. The `AddJsonProtocol` method takes a delegate that receives an `options` object. The PayloadSerializerOptions property on that object is a `System.Text.Json` JsonSerializerOptions object that can be used to configure serialization of arguments and return values. For more information, see the System.Text.Json documentation.

As an example, to configure the serializer to not change the casing of property names, instead of the default "camelCase" names, use the following code in `Startup.ConfigureServices`:

```
services.AddSignalR()
    .AddJsonProtocol(options => {
        options.PayloadSerializerOptions.PropertyNamingPolicy = null
    });
```

In the .NET client, the same `AddJsonProtocol` extension method exists on HubConnectionBuilder. The `Microsoft.Extensions.DependencyInjection` namespace must be imported to resolve the extension method:

```
// At the top of the file:
using Microsoft.Extensions.DependencyInjection;

// When constructing your connection:
var connection = new HubConnectionBuilder()
    .AddJsonProtocol(options => {
        options.PayloadSerializerOptions.PropertyNamingPolicy = null;
    })
    .Build();
```

> **NOTE**
> It's not possible to configure JSON serialization in the JavaScript client at this time.

Switch to Newtonsoft.Json

If you need features of `Newtonsoft.Json` that aren't supported in `System.Text.Json`, See Switch to NewtonsoftJson.

MessagePack serialization options

MessagePack serialization can be configured by providing a delegate to the AddMessagePackProtocol call. See MessagePack in SignalR for more details.

> **NOTE**
> It's not possible to configure MessagePack serialization in the JavaScript client at this time.

Configure server options

The following table describes options for configuring SignalR hubs:

OPTION	DEFAULT VALUE	DESCRIPTION
`ClientTimeoutInterval`	30 seconds	The server will consider the client disconnected if it hasn't received a message (including keep-alive) in this interval. It could take longer than this timeout interval for the client to actually be marked disconnected, due to how this is implemented. The recommended value is double the `KeepAliveInterval` value.

OPTION	DEFAULT VALUE	DESCRIPTION
`HandshakeTimeout`	15 seconds	If the client doesn't send an initial handshake message within this time interval, the connection is closed. This is an advanced setting that should only be modified if handshake timeout errors are occurring due to severe network latency. For more detail on the handshake process, see the SignalR Hub Protocol Specification.
`KeepAliveInterval`	15 seconds	If the server hasn't sent a message within this interval, a ping message is sent automatically to keep the connection open. When changing `KeepAliveInterval`, change the `ServerTimeout` / `serverTimeoutInMilliseconds` setting on the client. The recommended `ServerTimeout` / `serverTimeoutInMilliseconds` value is double the `KeepAliveInterval` value.
`SupportedProtocols`	All installed protocols	Protocols supported by this hub. By default, all protocols registered on the server are allowed, but protocols can be removed from this list to disable specific protocols for individual hubs.
`EnableDetailedErrors`	`false`	If `true`, detailed exception messages are returned to clients when an exception is thrown in a Hub method. The default is `false`, as these exception messages can contain sensitive information.
`StreamBufferCapacity`	`10`	The maximum number of items that can be buffered for client upload streams. If this limit is reached, the processing of invocations is blocked until the server processes stream items.
`MaximumReceiveMessageSize`	32 KB	Maximum size of a single incoming hub message.

Options can be configured for all hubs by providing an options delegate to the `AddSignalR` call in `Startup.ConfigureServices`.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSignalR(hubOptions =>
    {
        hubOptions.EnableDetailedErrors = true;
        hubOptions.KeepAliveInterval = TimeSpan.FromMinutes(1);
    });
}
```

Options for a single hub override the global options provided in `AddSignalR` and can be configured using AddHubOptions:

```
services.AddSignalR().AddHubOptions<ChatHub>(options =>
{
    options.EnableDetailedErrors = true;
});
```

Advanced HTTP configuration options

Use `HttpConnectionDispatcherOptions` to configure advanced settings related to transports and memory buffer management. These options are configured by passing a delegate to MapHub<T> in `Startup.Configure`.

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapHub<ChatHub>("/chathub", options =>
        {
            options.Transports =
                HttpTransportType.WebSockets |
                HttpTransportType.LongPolling;
        });
    });
}
```

The following table describes options for configuring ASP.NET Core SignalR's advanced HTTP options:

OPTION	DEFAULT VALUE	DESCRIPTION
`ApplicationMaxBufferSize`	32 KB	The maximum number of bytes received from the client that the server buffers before applying backpressure. Increasing this value allows the server to receive larger messages more quickly without applying backpressure, but can increase memory consumption.
`AuthorizationData`	Data automatically gathered from the `Authorize` attributes applied to the Hub class.	A list of IAuthorizeData objects used to determine if a client is authorized to connect to the hub.
`TransportMaxBufferSize`	32 KB	The maximum number of bytes sent by the app that the server buffers before observing backpressure. Increasing this value allows the server to buffer larger messages more quickly without awaiting backpressure, but can increase memory consumption.
`Transports`	All Transports are enabled.	A bit flags enum of `HttpTransportType` values that can restrict the transports a client can use to connect.
`LongPolling`	See below.	Additional options specific to the Long Polling transport.

OPTION	DEFAULT VALUE	DESCRIPTION
`WebSockets`	See below.	Additional options specific to the WebSockets transport.
`MinimumProtocolVersion`	0	Specify the minimum version of the negotiate protocol. This is used to limit clients to newer versions.

The Long Polling transport has additional options that can be configured using the `LongPolling` property:

OPTION	DEFAULT VALUE	DESCRIPTION
`PollTimeout`	90 seconds	The maximum amount of time the server waits for a message to send to the client before terminating a single poll request. Decreasing this value causes the client to issue new poll requests more frequently.

The WebSocket transport has additional options that can be configured using the `WebSockets` property:

OPTION	DEFAULT VALUE	DESCRIPTION
`CloseTimeout`	5 seconds	After the server closes, if the client fails to close within this time interval, the connection is terminated.
`SubProtocolSelector`	`null`	A delegate that can be used to set the `Sec-WebSocket-Protocol` header to a custom value. The delegate receives the values requested by the client as input and is expected to return the desired value.

Configure client options

Client options can be configured on the `HubConnectionBuilder` type (available in the .NET and JavaScript clients). It's also available in the Java client, but the `HttpHubConnectionBuilder` subclass is what contains the builder configuration options, as well as on the `HubConnection` itself.

Configure logging

Logging is configured in the .NET Client using the `ConfigureLogging` method. Logging providers and filters can be registered in the same way as they are on the server. See the Logging in ASP.NET Core documentation for more information.

> **NOTE**
> In order to register Logging providers, you must install the necessary packages. See the Built-in logging providers section of the docs for a full list.

For example, to enable Console logging, install the `Microsoft.Extensions.Logging.Console` NuGet package. Call the `AddConsole` extension method:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub")
    .ConfigureLogging(logging => {
        logging.SetMinimumLevel(LogLevel.Information);
        logging.AddConsole();
    })
    .Build();
```

In the JavaScript client, a similar `configureLogging` method exists. Provide a `LogLevel` value indicating the minimum level of log messages to produce. Logs are written to the browser console window.

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .configureLogging(signalR.LogLevel.Information)
    .build();
```

Instead of a `LogLevel` value, you can also provide a `string` value representing a log level name. This is useful when configuring SignalR logging in environments where you don't have access to the `LogLevel` constants.

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .configureLogging("warn")
    .build();
```

The following table lists the available log levels. The value you provide to `configureLogging` sets the **minimum** log level that will be logged. Messages logged at this level, **or the levels listed after it in the table**, will be logged.

STRING	LOGLEVEL
`trace`	`LogLevel.Trace`
`debug`	`LogLevel.Debug`
`info` **or** `information`	`LogLevel.Information`
`warn` **or** `warning`	`LogLevel.Warning`
`error`	`LogLevel.Error`
`critical`	`LogLevel.Critical`
`none`	`LogLevel.None`

> **NOTE**
> To disable logging entirely, specify `signalR.LogLevel.None` in the `configureLogging` method.

For more information on logging, see the SignalR Diagnostics documentation.

The SignalR Java client uses the SLF4J library for logging. It's a high-level logging API that allows users of the library to chose their own specific logging implementation by bringing in a specific logging dependency. The following code snippet shows how to use `java.util.logging` with the SignalR Java client.

```
implementation 'org.slf4j:slf4j-jdk14:1.7.25'
```

If you don't configure logging in your dependencies, SLF4J loads a default no-operation logger with the following warning message:

```
SLF4J: Failed to load class "org.slf4j.impl.StaticLoggerBinder".
SLF4J: Defaulting to no-operation (NOP) logger implementation
SLF4J: See http://www.slf4j.org/codes.html#StaticLoggerBinder for further details.
```

This can safely be ignored.

Configure allowed transports

The transports used by SignalR can be configured in the `WithUrl` call (`withUrl` in JavaScript). A bitwise-OR of the values of `HttpTransportType` can be used to restrict the client to only use the specified transports. All transports are enabled by default.

For example, to disable the Server-Sent Events transport, but allow WebSockets and Long Polling connections:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", HttpTransportType.WebSockets | HttpTransportType.LongPolling)
    .Build();
```

In the JavaScript client, transports are configured by setting the `transport` field on the options object provided to `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", { transport: signalR.HttpTransportType.WebSockets |
signalR.HttpTransportType.LongPolling })
    .build();
```

In this version of the Java client websockets is the only available transport.

In the Java client, the transport is selected with the `withTransport` method on the `HttpHubConnectionBuilder`. The Java client defaults to using the WebSockets transport.

```
HubConnection hubConnection = HubConnectionBuilder.create("https://example.com/chathub")
    .withTransport(TransportEnum.WEBSOCKETS)
    .build();
```

> **NOTE**
> The SignalR Java client doesn't support transport fallback yet.

Configure bearer authentication

To provide authentication data along with SignalR requests, use the `AccessTokenProvider` option (`accessTokenFactory` in JavaScript) to specify a function that returns the desired access token. In the .NET Client, this access token is passed in as an HTTP "Bearer Authentication" token (Using the `Authorization` header with a type of `Bearer`). In the JavaScript client, the access token is used as a Bearer token, **except** in a few cases where browser APIs restrict the ability to apply headers (specifically, in Server-Sent Events and WebSockets requests). In these cases, the access token is provided as a query string value `access_token`.

In the .NET client, the `AccessTokenProvider` option can be specified using the options delegate in `WithUrl`:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options => {
        options.AccessTokenProvider = async () => {
            // Get and return the access token.
        };
    })
    .Build();
```

In the JavaScript client, the access token is configured by setting the `accessTokenFactory` field on the options object in `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", {
        accessTokenFactory: () => {
            // Get and return the access token.
            // This function can return a JavaScript Promise if asynchronous
            // logic is required to retrieve the access token.
        }
    })
    .build();
```

In the SignalR Java client, you can configure a bearer token to use for authentication by providing an access token factory to the HttpHubConnectionBuilder. Use withAccessTokenFactory to provide an RxJava Single<String>. With a call to Single.defer, you can write logic to produce access tokens for your client.

```
HubConnection hubConnection = HubConnectionBuilder.create("https://example.com/chathub")
    .withAccessTokenProvider(Single.defer(() -> {
        // Your logic here.
        return Single.just("An Access Token");
    })).build();
```

Configure timeout and keep-alive options

Additional options for configuring timeout and keep-alive behavior are available on the `HubConnection` object itself:

- .NET
- JavaScript
- Java

OPTION	DEFAULT VALUE	DESCRIPTION
`ServerTimeout`	30 seconds (30,000 milliseconds)	Timeout for server activity. If the server hasn't sent a message in this interval, the client considers the server disconnected and triggers the `Closed` event (`onclose` in JavaScript). This value must be large enough for a ping message to be sent from the server **and** received by the client within the timeout interval. The recommended value is a number at least double the server's `KeepAliveInterval` value to allow time for pings to arrive.

OPTION	DEFAULT VALUE	DESCRIPTION
`HandshakeTimeout`	15 seconds	Timeout for initial server handshake. If the server doesn't send a handshake response in this interval, the client cancels the handshake and triggers the `Closed` event (`onclose` in JavaScript). This is an advanced setting that should only be modified if handshake timeout errors are occurring due to severe network latency. For more detail on the handshake process, see the SignalR Hub Protocol Specification.
`KeepAliveInterval`	15 seconds	Determines the interval at which the client sends ping messages. Sending any message from the client resets the timer to the start of the interval. If the client hasn't sent a message in the `ClientTimeoutInterval` set on the server, the server considers the client disconnected.

In the .NET Client, timeout values are specified as `TimeSpan` values.

Configure additional options

Additional options can be configured in the `WithUrl` (`withUrl` in JavaScript) method on `HubConnectionBuilder` or on the various configuration APIs on the `HttpHubConnectionBuilder` in the Java client:

- .NET
- JavaScript
- Java

.NET OPTION	DEFAULT VALUE	DESCRIPTION
`AccessTokenProvider`	`null`	A function returning a string that is provided as a Bearer authentication token in HTTP requests.
`SkipNegotiation`	`false`	Set this to `true` to skip the negotiation step. **Only supported when the WebSockets transport is the only enabled transport**. This setting can't be enabled when using the Azure SignalR Service.
`ClientCertificates`	Empty	A collection of TLS certificates to send to authenticate requests.
`Cookies`	Empty	A collection of HTTP cookies to send with every HTTP request.
`Credentials`	Empty	Credentials to send with every HTTP request.

.NET OPTION	DEFAULT VALUE	DESCRIPTION
`CloseTimeout`	5 seconds	WebSockets only. The maximum amount of time the client waits after closing for the server to acknowledge the close request. If the server doesn't acknowledge the close within this time, the client disconnects.
`Headers`	Empty	A Map of additional HTTP headers to send with every HTTP request.
`HttpMessageHandlerFactory`	`null`	A delegate that can be used to configure or replace the `HttpMessageHandler` used to send HTTP requests. Not used for WebSocket connections. This delegate must return a non-null value, and it receives the default value as a parameter. Either modify settings on that default value and return it, or return a new `HttpMessageHandler` instance. **When replacing the handler make sure to copy the settings you want to keep from the provided handler, otherwise, the configured options (such as Cookies and Headers) won't apply to the new handler.**
`Proxy`	`null`	An HTTP proxy to use when sending HTTP requests.
`UseDefaultCredentials`	`false`	Set this boolean to send the default credentials for HTTP and WebSockets requests. This enables the use of Windows authentication.
`WebSocketConfiguration`	`null`	A delegate that can be used to configure additional WebSocket options. Receives an instance of ClientWebSocketOptions that can be used to configure the options.

In the .NET Client, these options can be modified by the options delegate provided to `WithUrl`:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options => {
        options.Headers["Foo"] = "Bar";
        options.Cookies.Add(new Cookie(/* ... */);
        options.ClientCertificates.Add(/* ... */);
    })
    .Build();
```

In the JavaScript Client, these options can be provided in a JavaScript object provided to `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", {
        skipNegotiation: true,
        transport: signalR.HttpTransportType.WebSockets
    })
    .build();
```

In the Java client, these options can be configured with the methods on the `HttpHubConnectionBuilder` returned from the `HubConnectionBuilder.create("HUB URL")`

```
HubConnection hubConnection = HubConnectionBuilder.create("https://example.com/chathub")
        .withHeader("Foo", "Bar")
        .shouldSkipNegotiate(true)
        .withHandshakeResponseTimeout(30*1000)
        .build();
```

Additional resources

- Get started with ASP.NET Core SignalR
- Use hubs in ASP.NET Core SignalR
- ASP.NET Core SignalR JavaScript client
- ASP.NET Core SignalR .NET Client
- Use MessagePack Hub Protocol in SignalR for ASP.NET Core
- ASP.NET Core SignalR supported platforms

JSON/MessagePack serialization options

ASP.NET Core SignalR supports two protocols for encoding messages: JSON and MessagePack. Each protocol has serialization configuration options.

JSON serialization can be configured on the server using the AddJsonProtocol extension method. `AddJsonProtocol` can be added after AddSignalR in `Startup.ConfigureServices`. The `AddJsonProtocol` method takes a delegate that receives an `options` object. The PayloadSerializerOptions property on that object is a `System.Text.Json` JsonSerializerOptions object that can be used to configure serialization of arguments and return values. For more information, see the System.Text.Json documentation.

As an example, to configure the serializer to not change the casing of property names, instead of the default "camelCase" names, use the following code in `Startup.ConfigureServices`:

```
services.AddSignalR()
    .AddJsonProtocol(options => {
        options.PayloadSerializerOptions.PropertyNamingPolicy = null;
    });
```

In the .NET client, the same `AddJsonProtocol` extension method exists on HubConnectionBuilder. The `Microsoft.Extensions.DependencyInjection` namespace must be imported to resolve the extension method:

```
// At the top of the file:
using Microsoft.Extensions.DependencyInjection;

// When constructing your connection:
var connection = new HubConnectionBuilder()
    .AddJsonProtocol(options => {
        options.PayloadSerializerOptions.PropertyNamingPolicy = null;
    })
    .Build();
```

> **NOTE**
> It's not possible to configure JSON serialization in the JavaScript client at this time.

Switch to Newtonsoft.Json

If you need features of `Newtonsoft.Json` that aren't supported in `System.Text.Json`, See Switch to NewtonsoftJson.

MessagePack serialization options

MessagePack serialization can be configured by providing a delegate to the AddMessagePackProtocol call. See MessagePack in SignalR for more details.

> **NOTE**
> It's not possible to configure MessagePack serialization in the JavaScript client at this time.

Configure server options

The following table describes options for configuring SignalR hubs:

OPTION	DEFAULT VALUE	DESCRIPTION
`ClientTimeoutInterval`	30 seconds	The server will consider the client disconnected if it hasn't received a message (including keep-alive) in this interval. It could take longer than this timeout interval for the client to actually be marked disconnected, due to how this is implemented. The recommended value is double the `KeepAliveInterval` value.
`HandshakeTimeout`	15 seconds	If the client doesn't send an initial handshake message within this time interval, the connection is closed. This is an advanced setting that should only be modified if handshake timeout errors are occurring due to severe network latency. For more detail on the handshake process, see the SignalR Hub Protocol Specification.

OPTION	DEFAULT VALUE	DESCRIPTION
`KeepAliveInterval`	15 seconds	If the server hasn't sent a message within this interval, a ping message is sent automatically to keep the connection open. When changing `KeepAliveInterval`, change the `ServerTimeout` / `serverTimeoutInMilliseconds` setting on the client. The recommended `ServerTimeout` / `serverTimeoutInMilliseconds` value is double the `KeepAliveInterval` value.
`SupportedProtocols`	All installed protocols	Protocols supported by this hub. By default, all protocols registered on the server are allowed, but protocols can be removed from this list to disable specific protocols for individual hubs.
`EnableDetailedErrors`	`false`	If `true`, detailed exception messages are returned to clients when an exception is thrown in a Hub method. The default is `false`, as these exception messages can contain sensitive information.
`StreamBufferCapacity`	`10`	The maximum number of items that can be buffered for client upload streams. If this limit is reached, the processing of invocations is blocked until the server processes stream items.
`MaximumReceiveMessageSize`	32 KB	Maximum size of a single incoming hub message.

Options can be configured for all hubs by providing an options delegate to the `AddSignalR` call in `Startup.ConfigureServices`.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSignalR(hubOptions =>
    {
        hubOptions.EnableDetailedErrors = true;
        hubOptions.KeepAliveInterval = TimeSpan.FromMinutes(1);
    });
}
```

Options for a single hub override the global options provided in `AddSignalR` and can be configured using AddHubOptions:

```
services.AddSignalR().AddHubOptions<ChatHub>(options =>
{
    options.EnableDetailedErrors = true;
});
```

Advanced HTTP configuration options

Use `HttpConnectionDispatcherOptions` to configure advanced settings related to transports and memory buffer management. These options are configured by passing a delegate to MapHub<T> in `Startup.Configure`.

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapHub<ChatHub>("/chathub", options =>
        {
            options.Transports =
                HttpTransportType.WebSockets |
                HttpTransportType.LongPolling;
        });
    });
}
```

The following table describes options for configuring ASP.NET Core SignalR's advanced HTTP options:

OPTION	DEFAULT VALUE	DESCRIPTION
`ApplicationMaxBufferSize`	32 KB	The maximum number of bytes received from the client that the server buffers before applying backpressure. Increasing this value allows the server to receive larger messages more quickly without applying backpressure, but can increase memory consumption.
`AuthorizationData`	Data automatically gathered from the `Authorize` attributes applied to the Hub class.	A list of IAuthorizeData objects used to determine if a client is authorized to connect to the hub.
`TransportMaxBufferSize`	32 KB	The maximum number of bytes sent by the app that the server buffers before observing backpressure. Increasing this value allows the server to buffer larger messages more quickly without awaiting backpressure, but can increase memory consumption.
`Transports`	All Transports are enabled.	A bit flags enum of `HttpTransportType` values that can restrict the transports a client can use to connect.
`LongPolling`	See below.	Additional options specific to the Long Polling transport.
`WebSockets`	See below.	Additional options specific to the WebSockets transport.

The Long Polling transport has additional options that can be configured using the `LongPolling` property:

OPTION	DEFAULT VALUE	DESCRIPTION

OPTION	DEFAULT VALUE	DESCRIPTION
`PollTimeout`	90 seconds	The maximum amount of time the server waits for a message to send to the client before terminating a single poll request. Decreasing this value causes the client to issue new poll requests more frequently.

The WebSocket transport has additional options that can be configured using the `WebSockets` property:

OPTION	DEFAULT VALUE	DESCRIPTION
`CloseTimeout`	5 seconds	After the server closes, if the client fails to close within this time interval, the connection is terminated.
`SubProtocolSelector`	`null`	A delegate that can be used to set the `Sec-WebSocket-Protocol` header to a custom value. The delegate receives the values requested by the client as input and is expected to return the desired value.

Configure client options

Client options can be configured on the `HubConnectionBuilder` type (available in the .NET and JavaScript clients). It's also available in the Java client, but the `HttpHubConnectionBuilder` subclass is what contains the builder configuration options, as well as on the `HubConnection` itself.

Configure logging

Logging is configured in the .NET Client using the `ConfigureLogging` method. Logging providers and filters can be registered in the same way as they are on the server. See the Logging in ASP.NET Core documentation for more information.

> **NOTE**
> In order to register Logging providers, you must install the necessary packages. See the Built-in logging providers section of the docs for a full list.

For example, to enable Console logging, install the `Microsoft.Extensions.Logging.Console` NuGet package. Call the `AddConsole` extension method:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub")
    .ConfigureLogging(logging => {
        logging.SetMinimumLevel(LogLevel.Information);
        logging.AddConsole();
    })
    .Build();
```

In the JavaScript client, a similar `configureLogging` method exists. Provide a `LogLevel` value indicating the minimum level of log messages to produce. Logs are written to the browser console window.

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .configureLogging(signalR.LogLevel.Information)
    .build();
```

Instead of a `LogLevel` value, you can also provide a `string` value representing a log level name. This is useful when configuring SignalR logging in environments where you don't have access to the `LogLevel` constants.

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .configureLogging("warn")
    .build();
```

The following table lists the available log levels. The value you provide to `configureLogging` sets the **minimum** log level that will be logged. Messages logged at this level, **or the levels listed after it in the table**, will be logged.

STRING	LOGLEVEL
`trace`	`LogLevel.Trace`
`debug`	`LogLevel.Debug`
`info` **or** `information`	`LogLevel.Information`
`warn` **or** `warning`	`LogLevel.Warning`
`error`	`LogLevel.Error`
`critical`	`LogLevel.Critical`
`none`	`LogLevel.None`

> **NOTE**
> To disable logging entirely, specify `signalR.LogLevel.None` in the `configureLogging` method.

For more information on logging, see the SignalR Diagnostics documentation.

The SignalR Java client uses the SLF4J library for logging. It's a high-level logging API that allows users of the library to chose their own specific logging implementation by bringing in a specific logging dependency. The following code snippet shows how to use `java.util.logging` with the SignalR Java client.

```
implementation 'org.slf4j:slf4j-jdk14:1.7.25'
```

If you don't configure logging in your dependencies, SLF4J loads a default no-operation logger with the following warning message:

```
SLF4J: Failed to load class "org.slf4j.impl.StaticLoggerBinder".
SLF4J: Defaulting to no-operation (NOP) logger implementation
SLF4J: See http://www.slf4j.org/codes.html#StaticLoggerBinder for further details.
```

This can safely be ignored.

Configure allowed transports

The transports used by SignalR can be configured in the `WithUrl` call (`withUrl` in JavaScript). A bitwise-OR of the values of `HttpTransportType` can be used to restrict the client to only use the specified transports. All transports are enabled by default.

For example, to disable the Server-Sent Events transport, but allow WebSockets and Long Polling connections:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", HttpTransportType.WebSockets | HttpTransportType.LongPolling)
    .Build();
```

In the JavaScript client, transports are configured by setting the `transport` field on the options object provided to `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", { transport: signalR.HttpTransportType.WebSockets |
signalR.HttpTransportType.LongPolling })
    .build();
```

In this version of the Java client websockets is the only available transport.

In the Java client, the transport is selected with the `withTransport` method on the `HttpHubConnectionBuilder`. The Java client defaults to using the WebSockets transport.

```
HubConnection hubConnection = HubConnectionBuilder.create("https://example.com/chathub")
    .withTransport(TransportEnum.WEBSOCKETS)
    .build();
```

> **NOTE**
> The SignalR Java client doesn't support transport fallback yet.

Configure bearer authentication

To provide authentication data along with SignalR requests, use the `AccessTokenProvider` option (`accessTokenFactory` in JavaScript) to specify a function that returns the desired access token. In the .NET Client, this access token is passed in as an HTTP "Bearer Authentication" token (Using the `Authorization` header with a type of `Bearer`). In the JavaScript client, the access token is used as a Bearer token, **except** in a few cases where browser APIs restrict the ability to apply headers (specifically, in Server-Sent Events and WebSockets requests). In these cases, the access token is provided as a query string value `access_token`.

In the .NET client, the `AccessTokenProvider` option can be specified using the options delegate in `WithUrl`:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options => {
        options.AccessTokenProvider = async () => {
            // Get and return the access token.
        };
    })
    .Build();
```

In the JavaScript client, the access token is configured by setting the `accessTokenFactory` field on the options object in `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", {
        accessTokenFactory: () => {
            // Get and return the access token.
            // This function can return a JavaScript Promise if asynchronous
            // logic is required to retrieve the access token.
        }
    })
    .build();
```

In the SignalR Java client, you can configure a bearer token to use for authentication by providing an access token factory to the HttpHubConnectionBuilder. Use withAccessTokenFactory to provide an RxJava Single<String>. With a call to Single.defer, you can write logic to produce access tokens for your client.

```
HubConnection hubConnection = HubConnectionBuilder.create("https://example.com/chathub")
    .withAccessTokenProvider(Single.defer(() -> {
        // Your logic here.
        return Single.just("An Access Token");
    })).build();
```

Configure timeout and keep-alive options

Additional options for configuring timeout and keep-alive behavior are available on the `HubConnection` object itself:

- .NET
- JavaScript
- Java

OPTION	DEFAULT VALUE	DESCRIPTION
`ServerTimeout`	30 seconds (30,000 milliseconds)	Timeout for server activity. If the server hasn't sent a message in this interval, the client considers the server disconnected and triggers the `Closed` event (`onclose` in JavaScript). This value must be large enough for a ping message to be sent from the server **and** received by the client within the timeout interval. The recommended value is a number at least double the server's `KeepAliveInterval` value to allow time for pings to arrive.
`HandshakeTimeout`	15 seconds	Timeout for initial server handshake. If the server doesn't send a handshake response in this interval, the client cancels the handshake and triggers the `Closed` event (`onclose` in JavaScript). This is an advanced setting that should only be modified if handshake timeout errors are occurring due to severe network latency. For more detail on the handshake process, see the SignalR Hub Protocol Specification.

OPTION	DEFAULT VALUE	DESCRIPTION
`KeepAliveInterval`	15 seconds	Determines the interval at which the client sends ping messages. Sending any message from the client resets the timer to the start of the interval. If the client hasn't sent a message in the `ClientTimeoutInterval` set on the server, the server considers the client disconnected.

In the .NET Client, timeout values are specified as `TimeSpan` values.

Configure additional options

Additional options can be configured in the `WithUrl` (`withUrl` in JavaScript) method on `HubConnectionBuilder` or on the various configuration APIs on the `HttpHubConnectionBuilder` in the Java client:

- .NET
- JavaScript
- Java

.NET OPTION	DEFAULT VALUE	DESCRIPTION
`AccessTokenProvider`	`null`	A function returning a string that is provided as a Bearer authentication token in HTTP requests.
`SkipNegotiation`	`false`	Set this to `true` to skip the negotiation step. **Only supported when the WebSockets transport is the only enabled transport**. This setting can't be enabled when using the Azure SignalR Service.
`ClientCertificates`	Empty	A collection of TLS certificates to send to authenticate requests.
`Cookies`	Empty	A collection of HTTP cookies to send with every HTTP request.
`Credentials`	Empty	Credentials to send with every HTTP request.
`CloseTimeout`	5 seconds	WebSockets only. The maximum amount of time the client waits after closing for the server to acknowledge the close request. If the server doesn't acknowledge the close within this time, the client disconnects.
`Headers`	Empty	A Map of additional HTTP headers to send with every HTTP request.

.NET OPTION	DEFAULT VALUE	DESCRIPTION
`HttpMessageHandlerFactory`	`null`	A delegate that can be used to configure or replace the `HttpMessageHandler` used to send HTTP requests. Not used for WebSocket connections. This delegate must return a non-null value, and it receives the default value as a parameter. Either modify settings on that default value and return it, or return a new `HttpMessageHandler` instance. **When replacing the handler make sure to copy the settings you want to keep from the provided handler, otherwise, the configured options (such as Cookies and Headers) won't apply to the new handler.**
`Proxy`	`null`	An HTTP proxy to use when sending HTTP requests.
`UseDefaultCredentials`	`false`	Set this boolean to send the default credentials for HTTP and WebSockets requests. This enables the use of Windows authentication.
`WebSocketConfiguration`	`null`	A delegate that can be used to configure additional WebSocket options. Receives an instance of ClientWebSocketOptions that can be used to configure the options.

In the .NET Client, these options can be modified by the options delegate provided to `WithUrl`:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options => {
        options.Headers["Foo"] = "Bar";
        options.Cookies.Add(new Cookie(/* ... */);
        options.ClientCertificates.Add(/* ... */);
    })
    .Build();
```

In the JavaScript Client, these options can be provided in a JavaScript object provided to `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", {
        skipNegotiation: true,
        transport: signalR.HttpTransportType.WebSockets
    })
    .build();
```

In the Java client, these options can be configured with the methods on the `HttpHubConnectionBuilder` returned from the `HubConnectionBuilder.create("HUB URL")`

```
HubConnection hubConnection = HubConnectionBuilder.create("https://example.com/chathub")
        .withHeader("Foo", "Bar")
        .shouldSkipNegotiate(true)
        .withHandshakeResponseTimeout(30*1000)
        .build();
```

Additional resources

- Get started with ASP.NET Core SignalR
- Use hubs in ASP.NET Core SignalR
- ASP.NET Core SignalR JavaScript client
- ASP.NET Core SignalR .NET Client
- Use MessagePack Hub Protocol in SignalR for ASP.NET Core
- ASP.NET Core SignalR supported platforms

JSON/MessagePack serialization options

ASP.NET Core SignalR supports two protocols for encoding messages: JSON and MessagePack. Each protocol has serialization configuration options.

JSON serialization can be configured on the server using the AddJsonProtocol extension method, which can be added after AddSignalR in your `Startup.ConfigureServices` method. The `AddJsonProtocol` method takes a delegate that receives an `options` object. The PayloadSerializerSettings property on that object is a JSON.NET `JsonSerializerSettings` object that can be used to configure serialization of arguments and return values. For more information, see the JSON.NET documentation.

As an example, to configure the serializer to use "PascalCase" property names, instead of the default "camelCase" names, use the following code in `Startup.ConfigureServices`:

```
services.AddSignalR()
    .AddJsonProtocol(options => {
        options.PayloadSerializerSettings.ContractResolver =
            new DefaultContractResolver();
    });
```

In the .NET client, the same `AddJsonProtocol` extension method exists on HubConnectionBuilder. The `Microsoft.Extensions.DependencyInjection` namespace must be imported to resolve the extension method:

```
// At the top of the file:
using Microsoft.Extensions.DependencyInjection;

// When constructing your connection:
var connection = new HubConnectionBuilder()
    .AddJsonProtocol(options => {
        options.PayloadSerializerSettings.ContractResolver =
            new DefaultContractResolver();
    })
    .Build();
```

> **NOTE**
> It's not possible to configure JSON serialization in the JavaScript client at this time.

MessagePack serialization options

MessagePack serialization can be configured by providing a delegate to the AddMessagePackProtocol call. See MessagePack in SignalR for more details.

> **NOTE**
> It's not possible to configure MessagePack serialization in the JavaScript client at this time.

Configure server options

The following table describes options for configuring SignalR hubs:

OPTION	DEFAULT VALUE	DESCRIPTION
`ClientTimeoutInterval`	30 seconds	The server will consider the client disconnected if it hasn't received a message (including keep-alive) in this interval. It could take longer than this timeout interval for the client to actually be marked disconnected, due to how this is implemented. The recommended value is double the `KeepAliveInterval` value.
`HandshakeTimeout`	15 seconds	If the client doesn't send an initial handshake message within this time interval, the connection is closed. This is an advanced setting that should only be modified if handshake timeout errors are occurring due to severe network latency. For more detail on the handshake process, see the SignalR Hub Protocol Specification.
`KeepAliveInterval`	15 seconds	If the server hasn't sent a message within this interval, a ping message is sent automatically to keep the connection open. When changing `KeepAliveInterval`, change the `ServerTimeout` / `serverTimeoutInMilliseconds` setting on the client. The recommended `ServerTimeout` / `serverTimeoutInMilliseconds` value is double the `KeepAliveInterval` value.
`SupportedProtocols`	All installed protocols	Protocols supported by this hub. By default, all protocols registered on the server are allowed, but protocols can be removed from this list to disable specific protocols for individual hubs.
`EnableDetailedErrors`	`false`	If `true`, detailed exception messages are returned to clients when an exception is thrown in a Hub method. The default is `false`, as these exception messages can contain sensitive information.

Options can be configured for all hubs by providing an options delegate to the `AddSignalR` call in `Startup.ConfigureServices`.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSignalR(hubOptions =>
    {
        hubOptions.EnableDetailedErrors = true;
        hubOptions.KeepAliveInterval = TimeSpan.FromMinutes(1);
    });
}
```

Options for a single hub override the global options provided in `AddSignalR` and can be configured using AddHubOptions:

```
services.AddSignalR().AddHubOptions<ChatHub>(options =>
{
    options.EnableDetailedErrors = true;
});
```

Advanced HTTP configuration options

Use `HttpConnectionDispatcherOptions` to configure advanced settings related to transports and memory buffer management. These options are configured by passing a delegate to MapHub<T> in `Startup.Configure`.

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    app.UseSignalR((configure) =>
    {
        var desiredTransports =
            HttpTransportType.WebSockets |
            HttpTransportType.LongPolling;

        configure.MapHub<ChatHub>("/chathub", (options) =>
        {
            options.Transports = desiredTransports;
        });
    });
}
```

The following table describes options for configuring ASP.NET Core SignalR's advanced HTTP options:

OPTION	DEFAULT VALUE	DESCRIPTION
`ApplicationMaxBufferSize`	32 KB	The maximum number of bytes received from the client that the server buffers. Increasing this value allows the server to receive larger messages, but can negatively impact memory consumption.
`AuthorizationData`	Data automatically gathered from the `Authorize` attributes applied to the Hub class.	A list of IAuthorizeData objects used to determine if a client is authorized to connect to the hub.

OPTION	DEFAULT VALUE	DESCRIPTION
`TransportMaxBufferSize`	32 KB	The maximum number of bytes sent by the app that the server buffers. Increasing this value allows the server to send larger messages, but can negatively impact memory consumption.
`Transports`	All Transports are enabled.	A bit flags enum of `HttpTransportType` values that can restrict the transports a client can use to connect.
`LongPolling`	See below.	Additional options specific to the Long Polling transport.
`WebSockets`	See below.	Additional options specific to the WebSockets transport.

The Long Polling transport has additional options that can be configured using the `LongPolling` property:

OPTION	DEFAULT VALUE	DESCRIPTION
`PollTimeout`	90 seconds	The maximum amount of time the server waits for a message to send to the client before terminating a single poll request. Decreasing this value causes the client to issue new poll requests more frequently.

The WebSocket transport has additional options that can be configured using the `WebSockets` property:

OPTION	DEFAULT VALUE	DESCRIPTION
`CloseTimeout`	5 seconds	After the server closes, if the client fails to close within this time interval, the connection is terminated.
`SubProtocolSelector`	`null`	A delegate that can be used to set the `Sec-WebSocket-Protocol` header to a custom value. The delegate receives the values requested by the client as input and is expected to return the desired value.

Configure client options

Client options can be configured on the `HubConnectionBuilder` type (available in the .NET and JavaScript clients). It's also available in the Java client, but the `HttpHubConnectionBuilder` subclass is what contains the builder configuration options, as well as on the `HubConnection` itself.

Configure logging

Logging is configured in the .NET Client using the `ConfigureLogging` method. Logging providers and filters can be registered in the same way as they are on the server. See the Logging in ASP.NET Core documentation for more information.

> **NOTE**
> In order to register Logging providers, you must install the necessary packages. See the Built-in logging providers section of the docs for a full list.

For example, to enable Console logging, install the `Microsoft.Extensions.Logging.Console` NuGet package. Call the `AddConsole` extension method:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub")
    .ConfigureLogging(logging => {
        logging.SetMinimumLevel(LogLevel.Information);
        logging.AddConsole();
    })
    .Build();
```

In the JavaScript client, a similar `configureLogging` method exists. Provide a `LogLevel` value indicating the minimum level of log messages to produce. Logs are written to the browser console window.

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .configureLogging(signalR.LogLevel.Information)
    .build();
```

> **NOTE**
> To disable logging entirely, specify `signalR.LogLevel.None` in the `configureLogging` method.

For more information on logging, see the SignalR Diagnostics documentation.

The SignalR Java client uses the SLF4J library for logging. It's a high-level logging API that allows users of the library to chose their own specific logging implementation by bringing in a specific logging dependency. The following code snippet shows how to use `java.util.logging` with the SignalR Java client.

```
implementation 'org.slf4j:slf4j-jdk14:1.7.25'
```

If you don't configure logging in your dependencies, SLF4J loads a default no-operation logger with the following warning message:

```
SLF4J: Failed to load class "org.slf4j.impl.StaticLoggerBinder".
SLF4J: Defaulting to no-operation (NOP) logger implementation
SLF4J: See http://www.slf4j.org/codes.html#StaticLoggerBinder for further details.
```

This can safely be ignored.

Configure allowed transports

The transports used by SignalR can be configured in the `WithUrl` call (`withUrl` in JavaScript). A bitwise-OR of the values of `HttpTransportType` can be used to restrict the client to only use the specified transports. All transports are enabled by default.

For example, to disable the Server-Sent Events transport, but allow WebSockets and Long Polling connections:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", HttpTransportType.WebSockets | HttpTransportType.LongPolling)
    .Build();
```

In the JavaScript client, transports are configured by setting the `transport` field on the options object provided to `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", { transport: signalR.HttpTransportType.WebSockets |
signalR.HttpTransportType.LongPolling })
    .build();
```

In this version of the Java client websockets is the only available transport.

Configure bearer authentication

To provide authentication data along with SignalR requests, use the `AccessTokenProvider` option (`accessTokenFactory` in JavaScript) to specify a function that returns the desired access token. In the .NET Client, this access token is passed in as an HTTP "Bearer Authentication" token (Using the `Authorization` header with a type of `Bearer`). In the JavaScript client, the access token is used as a Bearer token, **except** in a few cases where browser APIs restrict the ability to apply headers (specifically, in Server-Sent Events and WebSockets requests). In these cases, the access token is provided as a query string value `access_token`.

In the .NET client, the `AccessTokenProvider` option can be specified using the options delegate in `WithUrl`:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options => {
        options.AccessTokenProvider = async () => {
            // Get and return the access token.
        };
    })
    .Build();
```

In the JavaScript client, the access token is configured by setting the `accessTokenFactory` field on the options object in `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", {
        accessTokenFactory: () => {
            // Get and return the access token.
            // This function can return a JavaScript Promise if asynchronous
            // logic is required to retrieve the access token.
        }
    })
    .build();
```

In the SignalR Java client, you can configure a bearer token to use for authentication by providing an access token factory to the HttpHubConnectionBuilder. Use withAccessTokenFactory to provide an RxJava Single<String>. With a call to Single.defer, you can write logic to produce access tokens for your client.

```
HubConnection hubConnection = HubConnectionBuilder.create("https://example.com/chathub")
    .withAccessTokenProvider(Single.defer(() -> {
        // Your logic here.
        return Single.just("An Access Token");
    })).build();
```

Configure timeout and keep-alive options

Additional options for configuring timeout and keep-alive behavior are available on the `HubConnection` object itself:

- .NET
- JavaScript
- Java

OPTION	DEFAULT VALUE	DESCRIPTION
`ServerTimeout`	30 seconds (30,000 milliseconds)	Timeout for server activity. If the server hasn't sent a message in this interval, the client considers the server disconnected and triggers the `Closed` event (`onclose` in JavaScript). This value must be large enough for a ping message to be sent from the server **and** received by the client within the timeout interval. The recommended value is a number at least double the server's `KeepAliveInterval` value to allow time for pings to arrive.
`HandshakeTimeout`	15 seconds	Timeout for initial server handshake. If the server doesn't send a handshake response in this interval, the client cancels the handshake and triggers the `Closed` event (`onclose` in JavaScript). This is an advanced setting that should only be modified if handshake timeout errors are occurring due to severe network latency. For more detail on the handshake process, see the SignalR Hub Protocol Specification.
`KeepAliveInterval`	15 seconds	Determines the interval at which the client sends ping messages. Sending any message from the client resets the timer to the start of the interval. If the client hasn't sent a message in the `ClientTimeoutInterval` set on the server, the server considers the client disconnected.

In the .NET Client, timeout values are specified as `TimeSpan` values.

Configure additional options

Additional options can be configured in the `WithUrl` (`withUrl` in JavaScript) method on `HubConnectionBuilder` or on the various configuration APIs on the `HttpHubConnectionBuilder` in the Java client:

- .NET
- JavaScript
- Java

.NET OPTION	DEFAULT VALUE	DESCRIPTION
`AccessTokenProvider`	`null`	A function returning a string that is provided as a Bearer authentication token in HTTP requests.

.NET OPTION	DEFAULT VALUE	DESCRIPTION
`SkipNegotiation`	`false`	Set this to `true` to skip the negotiation step. **Only supported when the WebSockets transport is the only enabled transport**. This setting can't be enabled when using the Azure SignalR Service.
`ClientCertificates`	Empty	A collection of TLS certificates to send to authenticate requests.
`Cookies`	Empty	A collection of HTTP cookies to send with every HTTP request.
`Credentials`	Empty	Credentials to send with every HTTP request.
`CloseTimeout`	5 seconds	WebSockets only. The maximum amount of time the client waits after closing for the server to acknowledge the close request. If the server doesn't acknowledge the close within this time, the client disconnects.
`Headers`	Empty	A Map of additional HTTP headers to send with every HTTP request.
`HttpMessageHandlerFactory`	`null`	A delegate that can be used to configure or replace the `HttpMessageHandler` used to send HTTP requests. Not used for WebSocket connections. This delegate must return a non-null value, and it receives the default value as a parameter. Either modify settings on that default value and return it, or return a new `HttpMessageHandler` instance. **When replacing the handler make sure to copy the settings you want to keep from the provided handler, otherwise, the configured options (such as Cookies and Headers) won't apply to the new handler.**
`Proxy`	`null`	An HTTP proxy to use when sending HTTP requests.
`UseDefaultCredentials`	`false`	Set this boolean to send the default credentials for HTTP and WebSockets requests. This enables the use of Windows authentication.
`WebSocketConfiguration`	`null`	A delegate that can be used to configure additional WebSocket options. Receives an instance of ClientWebSocketOptions that can be used to configure the options.

In the .NET Client, these options can be modified by the options delegate provided to `WithUrl`:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options => {
        options.Headers["Foo"] = "Bar";
        options.Cookies.Add(new Cookie(/* ... */);
        options.ClientCertificates.Add(/* ... */);
    })
    .Build();
```

In the JavaScript Client, these options can be provided in a JavaScript object provided to `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", {
        skipNegotiation: true,
        transport: signalR.HttpTransportType.WebSockets
    })
    .build();
```

In the Java client, these options can be configured with the methods on the `HttpHubConnectionBuilder` returned from the `HubConnectionBuilder.create("HUB URL")`

```
HubConnection hubConnection = HubConnectionBuilder.create("https://example.com/chathub")
        .withHeader("Foo", "Bar")
        .shouldSkipNegotiate(true)
        .withHandshakeResponseTimeout(30*1000)
        .build();
```

- ASP.NET Core SignalR supported platforms

JSON/MessagePack serialization options

ASP.NET Core SignalR supports two protocols for encoding messages: JSON and MessagePack. Each protocol has serialization configuration options.

JSON serialization can be configured on the server using the AddJsonProtocol extension method, which can be added after AddSignalR in your `Startup.ConfigureServices` method. The `AddJsonProtocol` method takes a delegate that receives an `options` object. The PayloadSerializerSettings property on that object is a JSON.NET `JsonSerializerSettings` object that can be used to configure serialization of arguments and return values. For more information, see the JSON.NET documentation.

As an example, to configure the serializer to use "PascalCase" property names, instead of the default "camelCase" names, use the following code in `Startup.ConfigureServices`:

```
services.AddSignalR()
    .AddJsonProtocol(options => {
        options.PayloadSerializerSettings.ContractResolver =
            new DefaultContractResolver();
    });
```

In the .NET client, the same `AddJsonProtocol` extension method exists on HubConnectionBuilder. The `Microsoft.Extensions.DependencyInjection` namespace must be imported to resolve the extension method:

```
// At the top of the file:
using Microsoft.Extensions.DependencyInjection;

// When constructing your connection:
var connection = new HubConnectionBuilder()
    .AddJsonProtocol(options => {
        options.PayloadSerializerSettings.ContractResolver =
            new DefaultContractResolver();
    })
    .Build();
```

> **NOTE**
> It's not possible to configure JSON serialization in the JavaScript client at this time.

MessagePack serialization options

MessagePack serialization can be configured by providing a delegate to the AddMessagePackProtocol call. See MessagePack in SignalR for more details.

> **NOTE**
> It's not possible to configure MessagePack serialization in the JavaScript client at this time.

Configure server options

The following table describes options for configuring SignalR hubs:

OPTION	DEFAULT VALUE	DESCRIPTION
`HandshakeTimeout`	15 seconds	If the client doesn't send an initial handshake message within this time interval, the connection is closed. This is an advanced setting that should only be modified if handshake timeout errors are occurring due to severe network latency. For more detail on the handshake process, see the SignalR Hub Protocol Specification.

OPTION	DEFAULT VALUE	DESCRIPTION
`KeepAliveInterval`	15 seconds	If the server hasn't sent a message within this interval, a ping message is sent automatically to keep the connection open. When changing `KeepAliveInterval`, change the `ServerTimeout` / `serverTimeoutInMilliseconds` setting on the client. The recommended `ServerTimeout` / `serverTimeoutInMilliseconds` value is double the `KeepAliveInterval` value.
`SupportedProtocols`	All installed protocols	Protocols supported by this hub. By default, all protocols registered on the server are allowed, but protocols can be removed from this list to disable specific protocols for individual hubs.
`EnableDetailedErrors`	`false`	If `true`, detailed exception messages are returned to clients when an exception is thrown in a Hub method. The default is `false`, as these exception messages can contain sensitive information.

Options can be configured for all hubs by providing an options delegate to the `AddSignalR` call in `Startup.ConfigureServices`.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSignalR(hubOptions =>
    {
        hubOptions.EnableDetailedErrors = true;
        hubOptions.KeepAliveInterval = TimeSpan.FromMinutes(1);
    });
}
```

Options for a single hub override the global options provided in `AddSignalR` and can be configured using AddHubOptions:

```
services.AddSignalR().AddHubOptions<ChatHub>(options =>
{
    options.EnableDetailedErrors = true;
});
```

Advanced HTTP configuration options

Use `HttpConnectionDispatcherOptions` to configure advanced settings related to transports and memory buffer management. These options are configured by passing a delegate to MapHub<T> in `Startup.Configure`.

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    app.UseSignalR((configure) =>
    {
        var desiredTransports =
            HttpTransportType.WebSockets |
            HttpTransportType.LongPolling;

        configure.MapHub<ChatHub>("/chathub", (options) =>
        {
            options.Transports = desiredTransports;
        });
    });
}
```

The following table describes options for configuring ASP.NET Core SignalR's advanced HTTP options:

OPTION	DEFAULT VALUE	DESCRIPTION
`ApplicationMaxBufferSize`	32 KB	The maximum number of bytes received from the client that the server buffers. Increasing this value allows the server to receive larger messages, but can negatively impact memory consumption.
`AuthorizationData`	Data automatically gathered from the `Authorize` attributes applied to the Hub class.	A list of IAuthorizeData objects used to determine if a client is authorized to connect to the hub.
`TransportMaxBufferSize`	32 KB	The maximum number of bytes sent by the app that the server buffers. Increasing this value allows the server to send larger messages, but can negatively impact memory consumption.
`Transports`	All Transports are enabled.	A bit flags enum of `HttpTransportType` values that can restrict the transports a client can use to connect.
`LongPolling`	See below.	Additional options specific to the Long Polling transport.
`WebSockets`	See below.	Additional options specific to the WebSockets transport.

The Long Polling transport has additional options that can be configured using the `LongPolling` property:

OPTION	DEFAULT VALUE	DESCRIPTION
`PollTimeout`	90 seconds	The maximum amount of time the server waits for a message to send to the client before terminating a single poll request. Decreasing this value causes the client to issue new poll requests more frequently.

The WebSocket transport has additional options that can be configured using the `WebSockets` property:

OPTION	DEFAULT VALUE	DESCRIPTION
`CloseTimeout`	5 seconds	After the server closes, if the client fails to close within this time interval, the connection is terminated.
`SubProtocolSelector`	`null`	A delegate that can be used to set the `Sec-WebSocket-Protocol` header to a custom value. The delegate receives the values requested by the client as input and is expected to return the desired value.

Configure client options

Client options can be configured on the `HubConnectionBuilder` type (available in the .NET and JavaScript clients). It's also available in the Java client, but the `HttpHubConnectionBuilder` subclass is what contains the builder configuration options, as well as on the `HubConnection` itself.

Configure logging

Logging is configured in the .NET Client using the `ConfigureLogging` method. Logging providers and filters can be registered in the same way as they are on the server. See the Logging in ASP.NET Core documentation for more information.

> **NOTE**
> In order to register Logging providers, you must install the necessary packages. See the Built-in logging providers section of the docs for a full list.

For example, to enable Console logging, install the `Microsoft.Extensions.Logging.Console` NuGet package. Call the `AddConsole` extension method:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub")
    .ConfigureLogging(logging => {
        logging.SetMinimumLevel(LogLevel.Information);
        logging.AddConsole();
    })
    .Build();
```

In the JavaScript client, a similar `configureLogging` method exists. Provide a `LogLevel` value indicating the minimum level of log messages to produce. Logs are written to the browser console window.

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .configureLogging(signalR.LogLevel.Information)
    .build();
```

> **NOTE**
> To disable logging entirely, specify `signalR.LogLevel.None` in the `configureLogging` method.

For more information on logging, see the SignalR Diagnostics documentation.

The SignalR Java client uses the SLF4J library for logging. It's a high-level logging API that allows users of the library to chose their own specific logging implementation by bringing in a specific logging dependency. The following code snippet shows how to use `java.util.logging` with the SignalR Java client.

```
implementation 'org.slf4j:slf4j-jdk14:1.7.25'
```

If you don't configure logging in your dependencies, SLF4J loads a default no-operation logger with the following warning message:

```
SLF4J: Failed to load class "org.slf4j.impl.StaticLoggerBinder".
SLF4J: Defaulting to no-operation (NOP) logger implementation
SLF4J: See http://www.slf4j.org/codes.html#StaticLoggerBinder for further details.
```

This can safely be ignored.

Configure allowed transports

The transports used by SignalR can be configured in the `WithUrl` call (`withUrl` in JavaScript). A bitwise-OR of the values of `HttpTransportType` can be used to restrict the client to only use the specified transports. All transports are enabled by default.

For example, to disable the Server-Sent Events transport, but allow WebSockets and Long Polling connections:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", HttpTransportType.WebSockets | HttpTransportType.LongPolling)
    .Build();
```

In the JavaScript client, transports are configured by setting the `transport` field on the options object provided to `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", { transport: signalR.HttpTransportType.WebSockets |
signalR.HttpTransportType.LongPolling })
    .build();
```

Configure bearer authentication

To provide authentication data along with SignalR requests, use the `AccessTokenProvider` option (`accessTokenFactory` in JavaScript) to specify a function that returns the desired access token. In the .NET Client, this access token is passed in as an HTTP "Bearer Authentication" token (Using the `Authorization` header with a type of `Bearer`). In the JavaScript client, the access token is used as a Bearer token, **except** in a few cases where browser APIs restrict the ability to apply headers (specifically, in Server-Sent Events and WebSockets requests). In these cases, the access token is provided as a query string value `access_token`.

In the .NET client, the `AccessTokenProvider` option can be specified using the options delegate in `WithUrl`:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options => {
        options.AccessTokenProvider = async () => {
            // Get and return the access token.
        };
    })
    .Build();
```

In the JavaScript client, the access token is configured by setting the `accessTokenFactory` field on the options object in `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", {
        accessTokenFactory: () => {
            // Get and return the access token.
            // This function can return a JavaScript Promise if asynchronous
            // logic is required to retrieve the access token.
        }
    })
    .build();
```

In the SignalR Java client, you can configure a bearer token to use for authentication by providing an access token factory to the HttpHubConnectionBuilder. Use withAccessTokenFactory to provide an RxJava Single<String>. With a call to Single.defer, you can write logic to produce access tokens for your client.

```
HubConnection hubConnection = HubConnectionBuilder.create("https://example.com/chathub")
    .withAccessTokenProvider(Single.defer(() -> {
        // Your logic here.
        return Single.just("An Access Token");
    })).build();
```

Configure timeout and keep-alive options

Additional options for configuring timeout and keep-alive behavior are available on the `HubConnection` object itself:

- .NET
- JavaScript
- Java

OPTION	DEFAULT VALUE	DESCRIPTION
`ServerTimeout`	30 seconds (30,000 milliseconds)	Timeout for server activity. If the server hasn't sent a message in this interval, the client considers the server disconnected and triggers the `Closed` event (`onclose` in JavaScript). This value must be large enough for a ping message to be sent from the server **and** received by the client within the timeout interval. The recommended value is a number at least double the server's `KeepAliveInterval` value to allow time for pings to arrive.
`HandshakeTimeout`	15 seconds	Timeout for initial server handshake. If the server doesn't send a handshake response in this interval, the client cancels the handshake and triggers the `Closed` event (`onclose` in JavaScript). This is an advanced setting that should only be modified if handshake timeout errors are occurring due to severe network latency. For more detail on the handshake process, see the SignalR Hub Protocol Specification.

In the .NET Client, timeout values are specified as `TimeSpan` values.

Configure additional options

Additional options can be configured in the `WithUrl` (`withUrl` in JavaScript) method on `HubConnectionBuilder` or on the various configuration APIs on the `HttpHubConnectionBuilder` in the Java client:

- .NET
- JavaScript
- Java

.NET OPTION	DEFAULT VALUE	DESCRIPTION
`AccessTokenProvider`	`null`	A function returning a string that is provided as a Bearer authentication token in HTTP requests.
`SkipNegotiation`	`false`	Set this to `true` to skip the negotiation step. **Only supported when the WebSockets transport is the only enabled transport**. This setting can't be enabled when using the Azure SignalR Service.
`ClientCertificates`	Empty	A collection of TLS certificates to send to authenticate requests.
`Cookies`	Empty	A collection of HTTP cookies to send with every HTTP request.
`Credentials`	Empty	Credentials to send with every HTTP request.
`CloseTimeout`	5 seconds	WebSockets only. The maximum amount of time the client waits after closing for the server to acknowledge the close request. If the server doesn't acknowledge the close within this time, the client disconnects.
`Headers`	Empty	A Map of additional HTTP headers to send with every HTTP request.
`HttpMessageHandlerFactory`	`null`	A delegate that can be used to configure or replace the `HttpMessageHandler` used to send HTTP requests. Not used for WebSocket connections. This delegate must return a non-null value, and it receives the default value as a parameter. Either modify settings on that default value and return it, or return a new `HttpMessageHandler` instance. **When replacing the handler make sure to copy the settings you want to keep from the provided handler, otherwise, the configured options (such as Cookies and Headers) won't apply to the new handler.**

.NET OPTION	DEFAULT VALUE	DESCRIPTION
`Proxy`	`null`	An HTTP proxy to use when sending HTTP requests.
`UseDefaultCredentials`	`false`	Set this boolean to send the default credentials for HTTP and WebSockets requests. This enables the use of Windows authentication.
`WebSocketConfiguration`	`null`	A delegate that can be used to configure additional WebSocket options. Receives an instance of ClientWebSocketOptions that can be used to configure the options.

In the .NET Client, these options can be modified by the options delegate provided to `WithUrl`:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options => {
        options.Headers["Foo"] = "Bar";
        options.Cookies.Add(new Cookie(/* ... */);
        options.ClientCertificates.Add(/* ... */);
    })
    .Build();
```

In the JavaScript Client, these options can be provided in a JavaScript object provided to `withUrl`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", {
        skipNegotiation: true,
        transport: signalR.HttpTransportType.WebSockets
    })
    .build();
```

In the Java client, these options can be configured with the methods on the `HttpHubConnectionBuilder` returned from the `HubConnectionBuilder.create("HUB URL")`

```
HubConnection hubConnection = HubConnectionBuilder.create("https://example.com/chathub")
        .withHeader("Foo", "Bar")
        .shouldSkipNegotiate(true)
        .withHandshakeResponseTimeout(30*1000)
        .build();
```

Authentication and authorization in ASP.NET Core SignalR

9/22/2020 • 9 minutes to read • Edit Online

By Andrew Stanton-Nurse

View or download sample code (how to download)

Authenticate users connecting to a SignalR hub

SignalR can be used with ASP.NET Core authentication to associate a user with each connection. In a hub, authentication data can be accessed from the HubConnectionContext.User property. Authentication allows the hub to call methods on all connections associated with a user. For more information, see Manage users and groups in SignalR. Multiple connections may be associated with a single user.

The following is an example of `Startup.Configure` which uses SignalR and ASP.NET Core authentication:

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapHub<ChatHub>("/chat");
        endpoints.MapControllerRoute("default", "{controller=Home}/{action=Index}/{id?}");
    });
}
```

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseStaticFiles();

    app.UseAuthentication();

    app.UseSignalR(hubs =>
    {
        hubs.MapHub<ChatHub>("/chat");
    });

    app.UseMvc(routes =>
    {
        routes.MapRoute("default", "{controller=Home}/{action=Index}/{id?}");
    });
}
```

> **NOTE**
>
> The order in which you register the SignalR and ASP.NET Core authentication middleware matters. Always call `UseAuthentication` before `UseSignalR` so that SignalR has a user on the `HttpContext`.

Cookie authentication

In a browser-based app, cookie authentication allows your existing user credentials to automatically flow to SignalR connections. When using the browser client, no additional configuration is needed. If the user is logged in to your app, the SignalR connection automatically inherits this authentication.

Cookies are a browser-specific way to send access tokens, but non-browser clients can send them. When using the .NET Client, the `Cookies` property can be configured in the `.WithUrl` call to provide a cookie. However, using cookie authentication from the .NET client requires the app to provide an API to exchange authentication data for a cookie.

Bearer token authentication

The client can provide an access token instead of using a cookie. The server validates the token and uses it to identify the user. This validation is done only when the connection is established. During the life of the connection, the server doesn't automatically revalidate to check for token revocation.

On the server, bearer token authentication is configured using the JWT Bearer middleware.

In the JavaScript client, the token can be provided using the accessTokenFactory option.

```
// Connect, using the token we got.
this.connection = new signalR.HubConnectionBuilder()
    .withUrl("/hubs/chat", { accessTokenFactory: () => this.loginToken })
    .build();
```

In the .NET client, there's a similar AccessTokenProvider property that can be used to configure the token:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options =>
    {
        options.AccessTokenProvider = () => Task.FromResult(_myAccessToken);
    })
    .Build();
```

> **NOTE**
>
> The access token function you provide is called before **every** HTTP request made by SignalR. If you need to renew the token in order to keep the connection active (because it may expire during the connection), do so from within this function and return the updated token.

In standard web APIs, bearer tokens are sent in an HTTP header. However, SignalR is unable to set these headers in browsers when using some transports. When using WebSockets and Server-Sent Events, the token is transmitted as a query string parameter. To support this on the server, additional configuration is required:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(Configuration.GetConnectionString("DefaultConnection")));

    services.AddIdentity<ApplicationUser, IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
```

```
            .AddDefaultTokenProviders();

        services.AddAuthentication(options =>
            {
                // Identity made Cookie authentication the default.
                // However, we want JWT Bearer Auth to be the default.
                options.DefaultAuthenticateScheme = JwtBearerDefaults.AuthenticationScheme;
                options.DefaultChallengeScheme = JwtBearerDefaults.AuthenticationScheme;
            })
            .AddJwtBearer(options =>
            {
                // Configure the Authority to the expected value for your authentication provider
                // This ensures the token is appropriately validated
                options.Authority = /* TODO: Insert Authority URL here */;

                // We have to hook the OnMessageReceived event in order to
                // allow the JWT authentication handler to read the access
                // token from the query string when a WebSocket or
                // Server-Sent Events request comes in.

                // Sending the access token in the query string is required due to
                // a limitation in Browser APIs. We restrict it to only calls to the
                // SignalR hub in this code.
                // See https://docs.microsoft.com/aspnet/core/signalr/security#access-token-logging
                // for more information about security considerations when using
                // the query string to transmit the access token.
                options.Events = new JwtBearerEvents
                {
                    OnMessageReceived = context =>
                    {
                        var accessToken = context.Request.Query["access_token"];

                        // If the request is for our hub...
                        var path = context.HttpContext.Request.Path;
                        if (!string.IsNullOrEmpty(accessToken) &&
                            (path.StartsWithSegments("/hubs/chat")))
                        {
                            // Read the token out of the query string
                            context.Token = accessToken;
                        }
                        return Task.CompletedTask;
                    }
                };
            });

        services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);

        services.AddSignalR();

        // Change to use Name as the user identifier for SignalR
        // WARNING: This requires that the source of your JWT token
        // ensures that the Name claim is unique!
        // If the Name claim isn't unique, users could receive messages
        // intended for a different user!
        services.AddSingleton<IUserIdProvider, NameUserIdProvider>();

        // Change to use email as the user identifier for SignalR
        // services.AddSingleton<IUserIdProvider, EmailBasedUserIdProvider>();

        // WARNING: use *either* the NameUserIdProvider *or* the
        // EmailBasedUserIdProvider, but do not use both.
    }
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

> **NOTE**
>
> The query string is used on browsers when connecting with WebSockets and Server-Sent Events due to browser API limitations. When using HTTPS, query string values are secured by the TLS connection. However, many servers log query string values. For more information, see Security considerations in ASP.NET Core SignalR. SignalR uses headers to transmit tokens in environments which support them (such as the .NET and Java clients).

Cookies vs. bearer tokens

Cookies are specific to browsers. Sending them from other kinds of clients adds complexity compared to sending bearer tokens. Consequently, cookie authentication isn't recommended unless the app only needs to authenticate users from the browser client. Bearer token authentication is the recommended approach when using clients other than the browser client.

Windows authentication

If Windows authentication is configured in your app, SignalR can use that identity to secure hubs. However, to send messages to individual users, you need to add a custom User ID provider. The Windows authentication system doesn't provide the "Name Identifier" claim. SignalR uses the claim to determine the user name.

Add a new class that implements `IUserIdProvider` and retrieve one of the claims from the user to use as the identifier. For example, to use the "Name" claim (which is the Windows username in the form `[Domain]\[Username]`), create the following class:

```
public class NameUserIdProvider : IUserIdProvider
{
    public string GetUserId(HubConnectionContext connection)
    {
        return connection.User?.Identity?.Name;
    }
}
```

Rather than `ClaimTypes.Name`, you can use any value from the `User` (such as the Windows SID identifier, and so on).

> **NOTE**
>
> The value you choose must be unique among all the users in your system. Otherwise, a message intended for one user could end up going to a different user.

Register this component in your `Startup.ConfigureServices` method.

```
public void ConfigureServices(IServiceCollection services)
{
    // ... other services ...

    services.AddSignalR();
    services.AddSingleton<IUserIdProvider, NameUserIdProvider>();
}
```

In the .NET Client, Windows Authentication must be enabled by setting the UseDefaultCredentials property:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options =>
    {
        options.UseDefaultCredentials = true;
    })
    .Build();
```

Windows authentication is supported in Internet Explorer and Microsoft Edge, but not in all browsers. For example, in Chrome and Safari, attempting to use Windows authentication and WebSockets fails. When Windows authentication fails, the client attempts to fall back to other transports which might work.

Use claims to customize identity handling

An app that authenticates users can derive SignalR user IDs from user claims. To specify how SignalR creates user IDs, implement `IUserIdProvider` and register the implementation.

The sample code demonstrates how you would use claims to select the user's email address as the identifying property.

> **NOTE**
> The value you choose must be unique among all the users in your system. Otherwise, a message intended for one user could end up going to a different user.

```
public class EmailBasedUserIdProvider : IUserIdProvider
{
    public virtual string GetUserId(HubConnectionContext connection)
    {
        return connection.User?.FindFirst(ClaimTypes.Email)?.Value;
    }
}
```

The account registration adds a claim with type `ClaimsTypes.Email` to the ASP.NET identity database.

```
// create a new user
var user = new ApplicationUser { UserName = Input.Email, Email = Input.Email };
var result = await _userManager.CreateAsync(user, Input.Password);

// add the email claim and value for this user
await _userManager.AddClaimAsync(user, new Claim(ClaimTypes.Email, Input.Email));
```

Register this component in your `Startup.ConfigureServices`.

```
services.AddSingleton<IUserIdProvider, EmailBasedUserIdProvider>();
```

Authorize users to access hubs and hub methods

By default, all methods in a hub can be called by an unauthenticated user. To require authentication, apply the Authorize attribute to the hub:

```
[Authorize]
public class ChatHub: Hub
{
}
```

You can use the constructor arguments and properties of the `[Authorize]` attribute to restrict access to only users matching specific authorization policies. For example, if you have a custom authorization policy called `MyAuthorizationPolicy` you can ensure that only users matching that policy can access the hub using the following code:

```
[Authorize("MyAuthorizationPolicy")]
public class ChatHub : Hub
{
}
```

Individual hub methods can have the `[Authorize]` attribute applied as well. If the current user doesn't match the policy applied to the method, an error is returned to the caller:

```
[Authorize]
public class ChatHub : Hub
{
    public async Task Send(string message)
    {
        // ... send a message to all users ...
    }

    [Authorize("Administrators")]
    public void BanUser(string userName)
    {
        // ... ban a user from the chat room (something only Administrators can do) ...
    }
}
```

Use authorization handlers to customize hub method authorization

SignalR provides a custom resource to authorization handlers when a hub method requires authorization. The resource is an instance of `HubInvocationContext`. The `HubInvocationContext` includes the `HubCallerContext`, the name of the hub method being invoked, and the arguments to the hub method.

Consider the example of a chat room allowing multiple organization sign-in via Azure Active Directory. Anyone with a Microsoft account can sign in to chat, but only members of the owning organization should be able to ban users or view users' chat histories. Furthermore, we might want to restrict certain functionality from certain users. Using the updated features in ASP.NET Core 3.0, this is entirely possible. Note how the `DomainRestrictedRequirement` serves as a custom `IAuthorizationRequirement`. Now that the `HubInvocationContext` resource parameter is being passed in, the internal logic can inspect the context in which the Hub is being called and make decisions on allowing the user to execute individual Hub methods.

```
[Authorize]
public class ChatHub : Hub
{
    public void SendMessage(string message)
    {
    }

    [Authorize("DomainRestricted")]
    public void BanUser(string username)
    {
    }

    [Authorize("DomainRestricted")]
    public void ViewUserHistory(string username)
    {
    }
}

public class DomainRestrictedRequirement :
    AuthorizationHandler<DomainRestrictedRequirement, HubInvocationContext>,
    IAuthorizationRequirement
{
    protected override Task HandleRequirementAsync(AuthorizationHandlerContext context,
        DomainRestrictedRequirement requirement,
        HubInvocationContext resource)
    {
        if (IsUserAllowedToDoThis(resource.HubMethodName, context.User.Identity.Name) &&
            context.User.Identity.Name.EndsWith("@microsoft.com"))
        {
            context.Succeed(requirement);
        }
        return Task.CompletedTask;
    }

    private bool IsUserAllowedToDoThis(string hubMethodName,
        string currentUsername)
    {
        return !(currentUsername.Equals("asdf42@microsoft.com") &&
            hubMethodName.Equals("banUser", StringComparison.OrdinalIgnoreCase));
    }
}
```

In `Startup.ConfigureServices`, add the new policy, providing the custom `DomainRestrictedRequirement` requirement as a parameter to create the `DomainRestricted` policy.

```
public void ConfigureServices(IServiceCollection services)
{
    // ... other services ...

    services
        .AddAuthorization(options =>
        {
            options.AddPolicy("DomainRestricted", policy =>
            {
                policy.Requirements.Add(new DomainRestrictedRequirement());
            });
        });
}
```

In the preceding example, the `DomainRestrictedRequirement` class is both an `IAuthorizationRequirement` and its own `AuthorizationHandler` for that requirement. It's acceptable to split these two components into separate classes to separate concerns. A benefit of the example's approach is there's no need to inject the `AuthorizationHandler` during startup, as the requirement and the handler are the same thing.

Security considerations in ASP.NET Core SignalR

9/22/2020 • 5 minutes to read • Edit Online

By Andrew Stanton-Nurse

This article provides information on securing SignalR.

Cross-origin resource sharing

Cross-origin resource sharing (CORS) can be used to allow cross-origin SignalR connections in the browser. If JavaScript code is hosted on a different domain from the SignalR app, CORS middleware must be enabled to allow the JavaScript to connect to the SignalR app. Allow cross-origin requests only from domains you trust or control. For example:

- Your site is hosted on `http://www.example.com`
- Your SignalR app is hosted on `http://signalr.example.com`

CORS should be configured in the SignalR app to only allow the origin `www.example.com`.

For more information on configuring CORS, see Enable Cross-Origin Requests (CORS). SignalR **requires** the following CORS policies:

- Allow the specific expected origins. Allowing any origin is possible but is **not** secure or recommended.
- HTTP methods `GET` and `POST` must be allowed.
- Credentials must be allowed in order for cookie-based sticky sessions to work correctly. They must be enabled even when authentication isn't used.

However, in 5.0 we have provided an option in the TypeScript client to not use credentials. The option to not use credentials should only be used when you know 100% that credentials like Cookies are not needed in your app (cookies are used by azure app service when using multiple servers for sticky sessions).

For example, the following CORS policy allows a SignalR browser client hosted on `https://example.com` to access the SignalR app hosted on `https://signalr.example.com`:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    // ... other middleware ...

    // Make sure the CORS middleware is ahead of SignalR.
    app.UseCors(builder =>
    {
        builder.WithOrigins("https://example.com")
            .AllowAnyHeader()
            .WithMethods("GET", "POST")
            .AllowCredentials();
    });

    // ... other middleware ...
    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapHub<ChatHub>("/chathub");
    });

    // ... other middleware ...
}
```

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    // ... other middleware ...

    // Make sure the CORS middleware is ahead of SignalR.
    app.UseCors(builder =>
    {
        builder.WithOrigins("https://example.com")
            .AllowAnyHeader()
            .WithMethods("GET", "POST")
            .AllowCredentials();
    });

    // ... other middleware ...

    app.UseSignalR(routes =>
    {
        routes.MapHub<ChatHub>("/chathub");
    });

    // ... other middleware ...
}
```

WebSocket Origin Restriction

The protections provided by CORS don't apply to WebSockets. For origin restriction on WebSockets, read WebSockets origin restriction.

The protections provided by CORS don't apply to WebSockets. Browsers do **not**:

- Perform CORS pre-flight requests.
- Respect the restrictions specified in `Access-Control` headers when making WebSocket requests.

However, browsers do send the `Origin` header when issuing WebSocket requests. Applications should be configured to validate these headers to ensure that only WebSockets coming from the expected origins are allowed.

In ASP.NET Core 2.1 and later, header validation can be achieved using a custom middleware placed **before** `UseSignalR`, **and authentication middleware** in `Configure`:

```
// In Startup, add a static field listing the allowed Origin values:
private static readonly HashSet<string> _allowedOrigins = new HashSet<string>()
{
    // Add allowed origins here. For example:
    "https://www.mysite.com",
    "https://mysite.com",
};

public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    // ... other middleware ...

    // Validate Origin header on WebSocket requests to prevent unexpected cross-site
    // WebSocket requests.
    app.Use((context, next) =>
    {
        // Check for a WebSocket request.
        if (string.Equals(context.Request.Headers["Upgrade"], "websocket"))
        {
            var origin = context.Request.Headers["Origin"];

            // If there is an origin header, and the origin header doesn't match
            // an allowed value:
            if (!string.IsNullOrEmpty(origin) && !_allowedOrigins.Contains(origin))
            {
                // The origin is not allowed, reject the request
                context.Response.StatusCode = StatusCodes.Status403Forbidden;
                return Task.CompletedTask;
            }
        }

        // The request is a valid Origin or not a WebSocket request, so continue.
        return next();
    });

    // ... other middleware ...

    app.UseSignalR(routes =>
    {
        routes.MapHub<ChatHub>("/chathub");
    });

    // ... other middleware ...
}
```

> **NOTE**
>
> The `Origin` header is controlled by the client and, like the `Referer` header, can be faked. These headers should **not** be used as an authentication mechanism.

ConnectionId

Exposing `ConnectionId` can lead to malicious impersonation if the SignalR server or client version is ASP.NET Core 2.2 or earlier. If the SignalR server and client version are ASP.NET Core 3.0 or later, the `ConnectionToken` rather than the `ConnectionId` must be kept secret. The `ConnectionToken` is purposely not exposed in any API. It can be difficult to ensure that older SignalR clients aren't connecting to the server, so even if your SignalR server version is

ASP.NET Core 3.0 or later, the `ConnectionId` shouldn't be exposed.

Access token logging

When using WebSockets or Server-Sent Events, the browser client sends the access token in the query string. Receiving the access token via query string is generally secure as using the standard `Authorization` header. Always use HTTPS to ensure a secure end-to-end connection between the client and the server. Many web servers log the URL for each request, including the query string. Logging the URLs may log the access token. ASP.NET Core logs the URL for each request by default, which will include the query string. For example:

```
info: Microsoft.AspNetCore.Hosting.Internal.WebHost[1]
      Request starting HTTP/1.1 GET http://localhost:5000/chathub?access_token=1234
```

If you have concerns about logging this data with your server logs, you can disable this logging entirely by configuring the `Microsoft.AspNetCore.Hosting` logger to the `Warning` level or above (these messages are written at `Info` level). For more information, see Log Filtering for more information. If you still want to log certain request information, you can write a middleware to log the data you require and filter out the `access_token` query string value (if present).

Exceptions

Exception messages are generally considered sensitive data that shouldn't be revealed to a client. By default, SignalR doesn't send the details of an exception thrown by a hub method to the client. Instead, the client receives a generic message indicating an error occurred. Exception message delivery to the client can be overridden (for example in development or test) with EnableDetailedErrors. Exception messages should not be exposed to the client in production apps.

Buffer management

SignalR uses per-connection buffers to manage incoming and outgoing messages. By default, SignalR limits these buffers to 32 KB. The largest message a client or server can send is 32 KB. The maximum memory consumed by a connection for messages is 32 KB. If your messages are always smaller than 32 KB, you can reduce the limit, which:

- Prevents a client from being able to send a larger message.
- The server will never need to allocate large buffers to accept messages.

If your messages are larger than 32 KB, you can increase the limit. Increasing this limit means:

- The client can cause the server to allocate large memory buffers.
- Server allocation of large buffers may reduce the number of concurrent connections.

There are limits for incoming and outgoing messages, both can be configured on the HttpConnectionDispatcherOptions object configured in `MapHub`:

- `ApplicationMaxBufferSize` represents the maximum number of bytes from the client that the server buffers. If the client attempts to send a message larger than this limit, the connection may be closed.
- `TransportMaxBufferSize` represents the maximum number of bytes the server can send. If the server attempts to send a message (including return values from hub methods) larger than this limit, an exception will be thrown.

Setting the limit to `0` disables the limit. Removing the limit allows a client to send a message of any size. Malicious clients sending large messages can cause excess memory to be allocated. Excess memory usage can significantly reduce the number of concurrent connections.

Use MessagePack Hub Protocol in SignalR for ASP.NET Core

9/22/2020 • 15 minutes to read • Edit Online

This article assumes the reader is familiar with the topics covered in Get Started.

What is MessagePack?

MessagePack is a fast and compact binary serialization format. It's useful when performance and bandwidth are a concern because it creates smaller messages compared to JSON. The binary messages are unreadable when looking at network traces and logs unless the bytes are passed through a MessagePack parser. SignalR has built-in support for the MessagePack format and provides APIs for the client and server to use.

Configure MessagePack on the server

To enable the MessagePack Hub Protocol on the server, install the `Microsoft.AspNetCore.SignalR.Protocols.MessagePack` package in your app. In the `Startup.ConfigureServices` method, add `AddMessagePackProtocol` to the `AddSignalR` call to enable MessagePack support on the server.

> **NOTE**
> JSON is enabled by default. Adding MessagePack enables support for both JSON and MessagePack clients.

```
services.AddSignalR()
    .AddMessagePackProtocol();
```

To customize how MessagePack will format your data, `AddMessagePackProtocol` takes a delegate for configuring options. In that delegate, the `SerializerOptions` property can be used to configure MessagePack serialization options. For more information on how the resolvers work, visit the MessagePack library at MessagePack-CSharp. Attributes can be used on the objects you want to serialize to define how they should be handled.

```
services.AddSignalR()
    .AddMessagePackProtocol(options =>
    {
        options.SerializerOptions = MessagePackSerializerOptions.Standard
            .WithResolver(new CustomResolver())
            .WithSecurity(MessagePackSecurity.UntrustedData);
    });
```

> **WARNING**
> We strongly recommend reviewing CVE-2020-5234 and applying the recommended patches. For example, calling `.WithSecurity(MessagePackSecurity.UntrustedData)` when replacing the `SerializerOptions`.

Configure MessagePack on the client

> **NOTE**
> JSON is enabled by default for the supported clients. Clients can only support a single protocol. Adding MessagePack support will replace any previously configured protocols.

.NET client

To enable MessagePack in the .NET Client, install the `Microsoft.AspNetCore.SignalR.Protocols.MessagePack` package and call `AddMessagePackProtocol` on `HubConnectionBuilder`.

```
var hubConnection = new HubConnectionBuilder()
                        .WithUrl("/chathub")
                        .AddMessagePackProtocol()
                        .Build();
```

> **NOTE**
> This `AddMessagePackProtocol` call takes a delegate for configuring options just like the server.

JavaScript client

MessagePack support for the JavaScript client is provided by the @microsoft/signalr-protocol-msgpack npm package. Install the package by executing the following command in a command shell:

```
npm install @microsoft/signalr-protocol-msgpack
```

After installing the npm package, the module can be used directly via a JavaScript module loader or imported into the browser by referencing the following file:

node_modules\@microsoft\signalr-protocol-msgpack\dist\browser\signalr-protocol-msgpack.js

In a browser, the `msgpack5` library must also be referenced. Use a `<script>` tag to create a reference. The library can be found at *node_modules\msgpack5\dist\msgpack5.js*.

> **NOTE**
> When using the `<script>` element, the order is important. If *signalr-protocol-msgpack.js* is referenced before *msgpack5.js*, an error occurs when trying to connect with MessagePack. *signalr.js* is also required before *signalr-protocol-msgpack.js*.

```
<script src="~/lib/signalr/signalr.js"></script>
<script src="~/lib/msgpack5/msgpack5.js"></script>
<script src="~/lib/signalr/signalr-protocol-msgpack.js"></script>
```

Adding `.withHubProtocol(new signalR.protocols.msgpack.MessagePackHubProtocol())` to the `HubConnectionBuilder` will configure the client to use the MessagePack protocol when connecting to a server.

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .withHubProtocol(new signalR.protocols.msgpack.MessagePackHubProtocol())
    .build();
```

> **NOTE**
> At this time, there are no configuration options for the MessagePack protocol on the JavaScript client.

MessagePack quirks

There are a few issues to be aware of when using the MessagePack Hub Protocol.

MessagePack is case-sensitive

The MessagePack protocol is case-sensitive. For example, consider the following C# class:

```
public class ChatMessage
{
    public string Sender { get; }
    public string Message { get; }
}
```

When sending from the JavaScript client, you must use `PascalCased` property names, since the casing must match the C# class exactly. For example:

```
connection.invoke("SomeMethod", { Sender: "Sally", Message: "Hello!" });
```

Using `camelCased` names won't properly bind to the C# class. You can work around this by using the `Key` attribute to specify a different name for the MessagePack property. For more information, see the MessagePack-CSharp documentation.

DateTime.Kind is not preserved when serializing/deserializing

The MessagePack protocol doesn't provide a way to encode the `Kind` value of a `DateTime`. As a result, when deserializing a date, the MessagePack Hub Protocol will convert to the UTC format if the `DateTime.Kind` is `DateTimeKind.Local` otherwise it will not touch the time and pass it as is. If you're working with `DateTime` values, we recommend converting to UTC before sending them. Convert them from UTC to local time when you receive them.

DateTime.MinValue is not supported by MessagePack in JavaScript

The msgpack5 library used by the SignalR JavaScript client doesn't support the `timestamp96` type in MessagePack. This type is used to encode very large date values (either very early in the past or very far in the future). The value of `DateTime.MinValue` is `January 1, 0001`, which must be encoded in a `timestamp96` value. Because of this, sending `DateTime.MinValue` to a JavaScript client isn't supported. When `DateTime.MinValue` is received by the JavaScript client, the following error is thrown:

```
Uncaught Error: unable to find ext type 255 at decoder.js:427
```

Usually, `DateTime.MinValue` is used to encode a "missing" or `null` value. If you need to encode that value in MessagePack, use a nullable `DateTime` value (`DateTime?`) or encode a separate `bool` value indicating if the date is present.

For more information on this limitation, see GitHub issue aspnet/SignalR#2228.

MessagePack support in "ahead-of-time" compilation environment

The MessagePack-CSharp library used by the .NET client and server uses code generation to optimize serialization. As a result, it isn't supported by default on environments that use "ahead-of-time" compilation (such as Xamarin iOS or Unity). It's possible to use MessagePack in these environments by "pre-generating" the

serializer/deserializer code. For more information, see the MessagePack-CSharp documentation. Once you have pre-generated the serializers, you can register them using the configuration delegate passed to `AddMessagePackProtocol`:

```
services.AddSignalR()
    .AddMessagePackProtocol(options =>
    {
        StaticCompositeResolver.Instance.Register(
            MessagePack.Resolvers.GeneratedResolver.Instance,
            MessagePack.Resolvers.StandardResolver.Instance
        );
        options.SerializerOptions = MessagePackSerializerOptions.Standard
            .WithResolver(StaticCompositeResolver.Instance)
            .WithSecurity(MessagePackSecurity.UntrustedData);
    });
```

Type checks are more strict in MessagePack

The JSON Hub Protocol will perform type conversions during deserialization. For example, if the incoming object has a property value that is a number (`{ foo: 42 }`) but the property on the .NET class is of type `string`, the value will be converted. However, MessagePack doesn't perform this conversion and will throw an exception that can be seen in server-side logs (and in the console):

```
InvalidDataException: Error binding arguments. Make sure that the types of the provided values match the
types of the hub method being invoked.
```

For more information on this limitation, see GitHub issue aspnet/SignalR#2937.

What is MessagePack?

MessagePack is a fast and compact binary serialization format. It's useful when performance and bandwidth are a concern because it creates smaller messages compared to JSON. The binary messages are unreadable when looking at network traces and logs unless the bytes are passed through a MessagePack parser. SignalR has built-in support for the MessagePack format, and provides APIs for the client and server to use.

Configure MessagePack on the server

To enable the MessagePack Hub Protocol on the server, install the `Microsoft.AspNetCore.SignalR.Protocols.MessagePack` package in your app. In the `Startup.ConfigureServices` method, add `AddMessagePackProtocol` to the `AddSignalR` call to enable MessagePack support on the server.

> **NOTE**
> JSON is enabled by default. Adding MessagePack enables support for both JSON and MessagePack clients.

```
services.AddSignalR()
    .AddMessagePackProtocol();
```

To customize how MessagePack will format your data, `AddMessagePackProtocol` takes a delegate for configuring options. In that delegate, the `FormatterResolvers` property can be used to configure MessagePack serialization options. For more information on how the resolvers work, visit the MessagePack library at MessagePack-CSharp. Attributes can be used on the objects you want to serialize to define how they should be handled.

```
services.AddSignalR()
    .AddMessagePackProtocol(options =>
    {
        options.FormatterResolvers = new List<MessagePack.IFormatterResolver>()
        {
            MessagePack.Resolvers.StandardResolver.Instance
        };
    });
```

WARNING

We strongly recommend reviewing CVE-2020-5234 and applying the recommended patches. For example, setting the `MessagePackSecurity.Active` static property to `MessagePackSecurity.UntrustedData`. Setting the `MessagePackSecurity.Active` requires manually installing a 1.9.x version of MessagePack. Installing `MessagePack` 1.9.x upgrades the version SignalR uses. When `MessagePackSecurity.Active` is not set to `MessagePackSecurity.UntrustedData`, a malicious client could cause a denial of service. Set `MessagePackSecurity.Active` in `Program.Main`, as shown in the following code:

```
public static void Main(string[] args)
{
  MessagePackSecurity.Active = MessagePackSecurity.UntrustedData;

  CreateHostBuilder(args).Build().Run();
}
```

Configure MessagePack on the client

NOTE

JSON is enabled by default for the supported clients. Clients can only support a single protocol. Adding MessagePack support will replace any previously configured protocols.

.NET client

To enable MessagePack in the .NET Client, install the `Microsoft.AspNetCore.SignalR.Protocols.MessagePack` package and call `AddMessagePackProtocol` on `HubConnectionBuilder`.

```
var hubConnection = new HubConnectionBuilder()
                        .WithUrl("/chathub")
                        .AddMessagePackProtocol()
                        .Build();
```

> **NOTE**
>
> This `AddMessagePackProtocol` call takes a delegate for configuring options just like the server.

JavaScript client

MessagePack support for the JavaScript client is provided by the @microsoft/signalr-protocol-msgpack npm package. Install the package by executing the following command in a command shell:

```
npm install @microsoft/signalr-protocol-msgpack
```

After installing the npm package, the module can be used directly via a JavaScript module loader or imported into the browser by referencing the following file:

node_modules\@microsoft\signalr-protocol-msgpack\dist\browser\signalr-protocol-msgpack.js

In a browser, the `msgpack5` library must also be referenced. Use a `<script>` tag to create a reference. The library can be found at *node_modules\msgpack5\dist\msgpack5.js*.

> **NOTE**
>
> When using the `<script>` element, the order is important. If *signalr-protocol-msgpack.js* is referenced before *msgpack5.js*, an error occurs when trying to connect with MessagePack. *signalr.js* is also required before *signalr-protocol-msgpack.js*.

```
<script src="~/lib/signalr/signalr.js"></script>
<script src="~/lib/msgpack5/msgpack5.js"></script>
<script src="~/lib/signalr/signalr-protocol-msgpack.js"></script>
```

Adding `.withHubProtocol(new signalR.protocols.msgpack.MessagePackHubProtocol())` to the `HubConnectionBuilder` will configure the client to use the MessagePack protocol when connecting to a server.

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .withHubProtocol(new signalR.protocols.msgpack.MessagePackHubProtocol())
    .build();
```

> **NOTE**
>
> At this time, there are no configuration options for the MessagePack protocol on the JavaScript client.

MessagePack quirks

There are a few issues to be aware of when using the MessagePack Hub Protocol.

MessagePack is case-sensitive

The MessagePack protocol is case-sensitive. For example, consider the following C# class:

```
public class ChatMessage
{
    public string Sender { get; }
    public string Message { get; }
}
```

When sending from the JavaScript client, you must use `PascalCased` property names, since the casing must match the C# class exactly. For example:

```
connection.invoke("SomeMethod", { Sender: "Sally", Message: "Hello!" });
```

Using `camelCased` names won't properly bind to the C# class. You can work around this by using the `Key` attribute to specify a different name for the MessagePack property. For more information, see the MessagePack-CSharp documentation.

DateTime.Kind is not preserved when serializing/deserializing

The MessagePack protocol doesn't provide a way to encode the `Kind` value of a `DateTime`. As a result, when deserializing a date, the MessagePack Hub Protocol assumes the incoming date is in UTC format. If you're working with `DateTime` values in local time, we recommend converting to UTC before sending them. Convert them from UTC to local time when you receive them.

For more information on this limitation, see GitHub issue aspnet/SignalR#2632.

DateTime.MinValue is not supported by MessagePack in JavaScript

The msgpack5 library used by the SignalR JavaScript client doesn't support the `timestamp96` type in MessagePack. This type is used to encode very large date values (either very early in the past or very far in the future). The value of `DateTime.MinValue` is `January 1, 0001`, which must be encoded in a `timestamp96` value. Because of this, sending `DateTime.MinValue` to a JavaScript client isn't supported. When `DateTime.MinValue` is received by the JavaScript client, the following error is thrown:

```
Uncaught Error: unable to find ext type 255 at decoder.js:427
```

Usually, `DateTime.MinValue` is used to encode a "missing" or `null` value. If you need to encode that value in MessagePack, use a nullable `DateTime` value (`DateTime?`) or encode a separate `bool` value indicating if the date is present.

For more information on this limitation, see GitHub issue aspnet/SignalR#2228.

MessagePack support in "ahead-of-time" compilation environment

The MessagePack-CSharp library used by the .NET client and server uses code generation to optimize serialization. As a result, it isn't supported by default on environments that use "ahead-of-time" compilation (such as Xamarin iOS or Unity). It's possible to use MessagePack in these environments by "pre-generating" the serializer/deserializer code. For more information, see the MessagePack-CSharp documentation. Once you have pre-generated the serializers, you can register them using the configuration delegate passed to `AddMessagePackProtocol`:

```
services.AddSignalR()
    .AddMessagePackProtocol(options =>
    {
        options.FormatterResolvers = new List<MessagePack.IFormatterResolver>()
        {
            MessagePack.Resolvers.GeneratedResolver.Instance,
            MessagePack.Resolvers.StandardResolver.Instance
        };
    });
```

Type checks are more strict in MessagePack

The JSON Hub Protocol will perform type conversions during deserialization. For example, if the incoming object has a property value that is a number (`{ foo: 42 }`) but the property on the .NET class is of type `string`, the value will be converted. However, MessagePack doesn't perform this conversion and will throw an exception that can be seen in server-side logs (and in the console):

```
InvalidDataException: Error binding arguments. Make sure that the types of the provided values match the
types of the hub method being invoked.
```

For more information on this limitation, see GitHub issue aspnet/SignalR#2937.

- .NET client
- JavaScript client

This article assumes the reader is familiar with the topics covered in Get Started.

What is MessagePack?

MessagePack is a fast and compact binary serialization format. It's useful when performance and bandwidth are a concern because it creates smaller messages compared to JSON. The binary messages are unreadable when looking at network traces and logs unless the bytes are passed through a MessagePack parser. SignalR has built-in support for the MessagePack format, and provides APIs for the client and server to use.

Configure MessagePack on the server

To enable the MessagePack Hub Protocol on the server, install the `Microsoft.AspNetCore.SignalR.Protocols.MessagePack` package in your app. In the `Startup.ConfigureServices` method, add `AddMessagePackProtocol` to the `AddSignalR` call to enable MessagePack support on the server.

> **NOTE**
> JSON is enabled by default. Adding MessagePack enables support for both JSON and MessagePack clients.

```
services.AddSignalR()
    .AddMessagePackProtocol();
```

To customize how MessagePack will format your data, `AddMessagePackProtocol` takes a delegate for configuring options. In that delegate, the `FormatterResolvers` property can be used to configure MessagePack serialization options. For more information on how the resolvers work, visit the MessagePack library at MessagePack-CSharp.

Attributes can be used on the objects you want to serialize to define how they should be handled.

```
services.AddSignalR()
    .AddMessagePackProtocol(options =>
    {
        options.FormatterResolvers = new List<MessagePack.IFormatterResolver>()
        {
            MessagePack.Resolvers.StandardResolver.Instance
        };
    });
```

WARNING

We strongly recommend reviewing CVE-2020-5234 and applying the recommended patches. For example, setting the `MessagePackSecurity.Active` static property to `MessagePackSecurity.UntrustedData`. Setting the `MessagePackSecurity.Active` requires manually installing a 1.9.x version of MessagePack. Installing `MessagePack` 1.9.x upgrades the version SignalR uses. When `MessagePackSecurity.Active` is not set to `MessagePackSecurity.UntrustedData`, a malicious client could cause a denial of service. Set `MessagePackSecurity.Active` in `Program.Main`, as shown in the following code:

```
public static void Main(string[] args)
{
  MessagePackSecurity.Active = MessagePackSecurity.UntrustedData;

  CreateHostBuilder(args).Build().Run();
}
```

Configure MessagePack on the client

NOTE

JSON is enabled by default for the supported clients. Clients can only support a single protocol. Adding MessagePack support will replace any previously configured protocols.

.NET client

To enable MessagePack in the .NET Client, install the `Microsoft.AspNetCore.SignalR.Protocols.MessagePack` package and call `AddMessagePackProtocol` on `HubConnectionBuilder`.

```
var hubConnection = new HubConnectionBuilder()
                        .WithUrl("/chathub")
                        .AddMessagePackProtocol()
                        .Build();
```

NOTE

This `AddMessagePackProtocol` call takes a delegate for configuring options just like the server.

JavaScript client

MessagePack support for the JavaScript client is provided by the @aspnet/signalr-protocol-msgpack npm package. Install the package by executing the following command in a command shell:

```
npm install @aspnet/signalr-protocol-msgpack
```

After installing the npm package, the module can be used directly via a JavaScript module loader or imported into the browser by referencing the following file:

node_modules\@aspnet\signalr-protocol-msgpack\dist\browser\signalr-protocol-msgpack.js

In a browser, the `msgpack5` library must also be referenced. Use a `<script>` tag to create a reference. The library can be found at *node_modules\msgpack5\dist\msgpack5.js*.

> **NOTE**
>
> When using the `<script>` element, the order is important. If *signalr-protocol-msgpack.js* is referenced before *msgpack5.js*, an error occurs when trying to connect with MessagePack. *signalr.js* is also required before *signalr-protocol-msgpack.js*.

```
<script src="~/lib/signalr/signalr.js"></script>
<script src="~/lib/msgpack5/msgpack5.js"></script>
<script src="~/lib/signalr/signalr-protocol-msgpack.js"></script>
```

Adding `.withHubProtocol(new signalR.protocols.msgpack.MessagePackHubProtocol())` to the `HubConnectionBuilder` will configure the client to use the MessagePack protocol when connecting to a server.

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .withHubProtocol(new signalR.protocols.msgpack.MessagePackHubProtocol())
    .build();
```

> **NOTE**
>
> At this time, there are no configuration options for the MessagePack protocol on the JavaScript client.

MessagePack quirks

There are a few issues to be aware of when using the MessagePack Hub Protocol.

MessagePack is case-sensitive

The MessagePack protocol is case-sensitive. For example, consider the following C# class:

```
public class ChatMessage
{
    public string Sender { get; }
    public string Message { get; }
}
```

When sending from the JavaScript client, you must use `PascalCased` property names, since the casing must match the C# class exactly. For example:

```
connection.invoke("SomeMethod", { Sender: "Sally", Message: "Hello!" });
```

Using `camelCased` names won't properly bind to the C# class. You can work around this by using the `Key`

attribute to specify a different name for the MessagePack property. For more information, see the MessagePack-CSharp documentation.

DateTime.Kind is not preserved when serializing/deserializing

The MessagePack protocol doesn't provide a way to encode the `Kind` value of a `DateTime`. As a result, when deserializing a date, the MessagePack Hub Protocol assumes the incoming date is in UTC format. If you're working with `DateTime` values in local time, we recommend converting to UTC before sending them. Convert them from UTC to local time when you receive them.

For more information on this limitation, see GitHub issue aspnet/SignalR#2632.

DateTime.MinValue is not supported by MessagePack in JavaScript

The msgpack5 library used by the SignalR JavaScript client doesn't support the `timestamp96` type in MessagePack. This type is used to encode very large date values (either very early in the past or very far in the future). The value of `DateTime.MinValue` is `January 1, 0001` which must be encoded in a `timestamp96` value. Because of this, sending `DateTime.MinValue` to a JavaScript client isn't supported. When `DateTime.MinValue` is received by the JavaScript client, the following error is thrown:

```
Uncaught Error: unable to find ext type 255 at decoder.js:427
```

Usually, `DateTime.MinValue` is used to encode a "missing" or `null` value. If you need to encode that value in MessagePack, use a nullable `DateTime` value (`DateTime?`) or encode a separate `bool` value indicating if the date is present.

For more information on this limitation, see GitHub issue aspnet/SignalR#2228.

MessagePack support in "ahead-of-time" compilation environment

The MessagePack-CSharp library used by the .NET client and server uses code generation to optimize serialization. As a result, it isn't supported by default on environments that use "ahead-of-time" compilation (such as Xamarin iOS or Unity). It's possible to use MessagePack in these environments by "pre-generating" the serializer/deserializer code. For more information, see the MessagePack-CSharp documentation. Once you have pre-generated the serializers, you can register them using the configuration delegate passed to `AddMessagePackProtocol`:

```
services.AddSignalR()
    .AddMessagePackProtocol(options =>
    {
        options.FormatterResolvers = new List<MessagePack.IFormatterResolver>()
        {
            MessagePack.Resolvers.GeneratedResolver.Instance,
            MessagePack.Resolvers.StandardResolver.Instance
        };
    });
```

Type checks are more strict in MessagePack

The JSON Hub Protocol will perform type conversions during deserialization. For example, if the incoming object has a property value that is a number (`{ foo: 42 }`) but the property on the .NET class is of type `string`, the value will be converted. However, MessagePack doesn't perform this conversion and will throw an exception that can be seen in server-side logs (and in the console):

```
InvalidDataException: Error binding arguments. Make sure that the types of the provided values match the
types of the hub method being invoked.
```

For more information on this limitation, see GitHub issue aspnet/SignalR#2937.

Use streaming in ASP.NET Core SignalR

9/22/2020 • 9 minutes to read • Edit Online

By Brennan Conroy

ASP.NET Core SignalR supports streaming from client to server and from server to client. This is useful for scenarios where fragments of data arrive over time. When streaming, each fragment is sent to the client or server as soon as it becomes available, rather than waiting for all of the data to become available.

ASP.NET Core SignalR supports streaming return values of server methods. This is useful for scenarios where fragments of data arrive over time. When a return value is streamed to the client, each fragment is sent to the client as soon as it becomes available, rather than waiting for all the data to become available.

View or download sample code (how to download)

Set up a hub for streaming

A hub method automatically becomes a streaming hub method when it returns IAsyncEnumerable<T>, ChannelReader<T>, `Task<IAsyncEnumerable<T>>`, or `Task<ChannelReader<T>>`.

A hub method automatically becomes a streaming hub method when it returns a ChannelReader<T> or a `Task<ChannelReader<T>>`.

Server-to-client streaming

Streaming hub methods can return `IAsyncEnumerable<T>` in addition to `ChannelReader<T>`. The simplest way to return `IAsyncEnumerable<T>` is by making the hub method an async iterator method as the following sample demonstrates. Hub async iterator methods can accept a `CancellationToken` parameter that's triggered when the client unsubscribes from the stream. Async iterator methods avoid problems common with Channels, such as not returning the `ChannelReader` early enough or exiting the method without completing the ChannelWriter<T>.

> **NOTE**
> The following sample requires C# 8.0 or later.

```
public class AsyncEnumerableHub : Hub
{
    public async IAsyncEnumerable<int> Counter(
        int count,
        int delay,
        [EnumeratorCancellation]
        CancellationToken cancellationToken)
    {
        for (var i = 0; i < count; i++)
        {
            // Check the cancellation token regularly so that the server will stop
            // producing items if the client disconnects.
            cancellationToken.ThrowIfCancellationRequested();

            yield return i;

            // Use the cancellationToken in other APIs that accept cancellation
            // tokens so the cancellation can flow down to them.
            await Task.Delay(delay, cancellationToken);
        }
    }
}
```

The following sample shows the basics of streaming data to the client using Channels. Whenever an object is written to the ChannelWriter<T>, the object is immediately sent to the client. At the end, the `ChannelWriter` is completed to tell the client the stream is closed.

NOTE

Write to the `ChannelWriter<T>` on a background thread and return the `ChannelReader` as soon as possible. Other hub invocations are blocked until a `ChannelReader` is returned.

Wrap logic in a `try ... catch`. Complete the `Channel` in the `catch` and outside the `catch` to make sure the hub method invocation is completed properly.

```
public ChannelReader<int> Counter(
    int count,
    int delay,
    CancellationToken cancellationToken)
{
    var channel = Channel.CreateUnbounded<int>();

    // We don't want to await WriteItemsAsync, otherwise we'd end up waiting
    // for all the items to be written before returning the channel back to
    // the client.
    _ = WriteItemsAsync(channel.Writer, count, delay, cancellationToken);

    return channel.Reader;
}

private async Task WriteItemsAsync(
    ChannelWriter<int> writer,
    int count,
    int delay,
    CancellationToken cancellationToken)
{
    Exception localException = null;
    try
    {
        for (var i = 0; i < count; i++)
        {
            await writer.WriteAsync(i, cancellationToken);

            // Use the cancellationToken in other APIs that accept cancellation
            // tokens so the cancellation can flow down to them.
            await Task.Delay(delay, cancellationToken);
        }
    }
    catch (Exception ex)
    {
        localException = ex;
    }

    writer.Complete(localException);
}
```

```
public class StreamHub : Hub
{
    public ChannelReader<int> Counter(
        int count,
        int delay,
        CancellationToken cancellationToken)
    {
        var channel = Channel.CreateUnbounded<int>();

        // We don't want to await WriteItemsAsync, otherwise we'd end up waiting
        // for all the items to be written before returning the channel back to
        // the client.
        _ = WriteItemsAsync(channel.Writer, count, delay, cancellationToken);

        return channel.Reader;
    }

    private async Task WriteItemsAsync(
        ChannelWriter<int> writer,
        int count,
        int delay,
        CancellationToken cancellationToken)
    {
        try
        {
            for (var i = 0; i < count; i++)
            {
                // Check the cancellation token regularly so that the server will stop
                // producing items if the client disconnects.
                cancellationToken.ThrowIfCancellationRequested();
                await writer.WriteAsync(i);

                // Use the cancellationToken in other APIs that accept cancellation
                // tokens so the cancellation can flow down to them.
                await Task.Delay(delay, cancellationToken);
            }
        }
        catch (Exception ex)
        {
            writer.TryComplete(ex);
        }

        writer.TryComplete();
    }
}
```

```
public class StreamHub : Hub
{
    public ChannelReader<int> Counter(int count, int delay)
    {
        var channel = Channel.CreateUnbounded<int>();

        // We don't want to await WriteItemsAsync, otherwise we'd end up waiting
        // for all the items to be written before returning the channel back to
        // the client.
        _ = WriteItemsAsync(channel.Writer, count, delay);

        return channel.Reader;
    }

    private async Task WriteItemsAsync(
        ChannelWriter<int> writer,
        int count,
        int delay)
    {
        try
        {
            for (var i = 0; i < count; i++)
            {
                await writer.WriteAsync(i);
                await Task.Delay(delay);
            }
        }
        catch (Exception ex)
        {
            writer.TryComplete(ex);
        }

        writer.TryComplete();
    }
}
```

Server-to-client streaming hub methods can accept a `CancellationToken` parameter that's triggered when the client unsubscribes from the stream. Use this token to stop the server operation and release any resources if the client disconnects before the end of the stream.

Client-to-server streaming

A hub method automatically becomes a client-to-server streaming hub method when it accepts one or more objects of type ChannelReader<T> or IAsyncEnumerable<T>. The following sample shows the basics of reading streaming data sent from the client. Whenever the client writes to the ChannelWriter<T>, the data is written into the `ChannelReader` on the server from which the hub method is reading.

```
public async Task UploadStream(ChannelReader<string> stream)
{
    while (await stream.WaitToReadAsync())
    {
        while (stream.TryRead(out var item))
        {
            // do something with the stream item
            Console.WriteLine(item);
        }
    }
}
```

An IAsyncEnumerable<T> version of the method follows.

> **NOTE**
> The following sample requires C# 8.0 or later.

```
public async Task UploadStream(IAsyncEnumerable<string> stream)
{
    await foreach (var item in stream)
    {
        Console.WriteLine(item);
    }
}
```

.NET client

Server-to-client streaming

The `StreamAsync` and `StreamAsChannelAsync` methods on `HubConnection` are used to invoke server-to-client streaming methods. Pass the hub method name and arguments defined in the hub method to `StreamAsync` or `StreamAsChannelAsync`. The generic parameter on `StreamAsync<T>` and `StreamAsChannelAsync<T>` specifies the type of objects returned by the streaming method. An object of type `IAsyncEnumerable<T>` or `ChannelReader<T>` is returned from the stream invocation and represents the stream on the client.

A `StreamAsync` example that returns `IAsyncEnumerable<int>`:

```
// Call "Cancel" on this CancellationTokenSource to send a cancellation message to
// the server, which will trigger the corresponding token in the hub method.
var cancellationTokenSource = new CancellationTokenSource();
var stream = await hubConnection.StreamAsync<int>(
    "Counter", 10, 500, cancellationTokenSource.Token);

await foreach (var count in stream)
{
    Console.WriteLine($"{count}");
}

Console.WriteLine("Streaming completed");
```

A corresponding `StreamAsChannelAsync` example that returns `ChannelReader<int>`:

```
// Call "Cancel" on this CancellationTokenSource to send a cancellation message to
// the server, which will trigger the corresponding token in the hub method.
var cancellationTokenSource = new CancellationTokenSource();
var channel = await hubConnection.StreamAsChannelAsync<int>(
    "Counter", 10, 500, cancellationTokenSource.Token);

// Wait asynchronously for data to become available
while (await channel.WaitToReadAsync())
{
    // Read all currently available data synchronously, before waiting for more data
    while (channel.TryRead(out var count))
    {
        Console.WriteLine($"{count}");
    }
}

Console.WriteLine("Streaming completed");
```

The `StreamAsChannelAsync` method on `HubConnection` is used to invoke a server-to-client streaming method. Pass

the hub method name and arguments defined in the hub method to `StreamAsChannelAsync`. The generic parameter on `StreamAsChannelAsync<T>` specifies the type of objects returned by the streaming method. A `ChannelReader<T>` is returned from the stream invocation and represents the stream on the client.

```
// Call "Cancel" on this CancellationTokenSource to send a cancellation message to
// the server, which will trigger the corresponding token in the hub method.
var cancellationTokenSource = new CancellationTokenSource();
var channel = await hubConnection.StreamAsChannelAsync<int>(
    "Counter", 10, 500, cancellationTokenSource.Token);

// Wait asynchronously for data to become available
while (await channel.WaitToReadAsync())
{
    // Read all currently available data synchronously, before waiting for more data
    while (channel.TryRead(out var count))
    {
        Console.WriteLine($"{count}");
    }
}

Console.WriteLine("Streaming completed");
```

The `StreamAsChannelAsync` method on `HubConnection` is used to invoke a server-to-client streaming method. Pass the hub method name and arguments defined in the hub method to `StreamAsChannelAsync`. The generic parameter on `StreamAsChannelAsync<T>` specifies the type of objects returned by the streaming method. A `ChannelReader<T>` is returned from the stream invocation and represents the stream on the client.

```
var channel = await hubConnection
    .StreamAsChannelAsync<int>("Counter", 10, 500, CancellationToken.None);

// Wait asynchronously for data to become available
while (await channel.WaitToReadAsync())
{
    // Read all currently available data synchronously, before waiting for more data
    while (channel.TryRead(out var count))
    {
        Console.WriteLine($"{count}");
    }
}

Console.WriteLine("Streaming completed");
```

Client-to-server streaming

There are two ways to invoke a client-to-server streaming hub method from the .NET client. You can either pass in an `IAsyncEnumerable<T>` or a `ChannelReader` as an argument to `SendAsync`, `InvokeAsync`, or `StreamAsChannelAsync`, depending on the hub method invoked.

Whenever data is written to the `IAsyncEnumerable` or `ChannelWriter` object, the hub method on the server receives a new item with the data from the client.

If using an `IAsyncEnumerable` object, the stream ends after the method returning stream items exits.

> **NOTE**
>
> The following sample requires C# 8.0 or later.

```
async IAsyncEnumerable<string> clientStreamData()
{
    for (var i = 0; i < 5; i++)
    {
        var data = await FetchSomeData();
        yield return data;
    }
    //After the for loop has completed and the local function exits the stream completion will be sent.
}

await connection.SendAsync("UploadStream", clientStreamData());
```

Or if you're using a `ChannelWriter`, you complete the channel with `channel.Writer.Complete()`:

```
var channel = Channel.CreateBounded<string>(10);
await connection.SendAsync("UploadStream", channel.Reader);
await channel.Writer.WriteAsync("some data");
await channel.Writer.WriteAsync("some more data");
channel.Writer.Complete();
```

JavaScript client

Server-to-client streaming

JavaScript clients call server-to-client streaming methods on hubs with `connection.stream`. The `stream` method accepts two arguments:

- The name of the hub method. In the following example, the hub method name is `Counter`.
- Arguments defined in the hub method. In the following example, the arguments are a count for the number of stream items to receive and the delay between stream items.

`connection.stream` returns an `IStreamResult`, which contains a `subscribe` method. Pass an `IStreamSubscriber` to `subscribe` and set the `next`, `error`, and `complete` callbacks to receive notifications from the `stream` invocation.

```
connection.stream("Counter", 10, 500)
    .subscribe({
        next: (item) => {
            var li = document.createElement("li");
            li.textContent = item;
            document.getElementById("messagesList").appendChild(li);
        },
        complete: () => {
            var li = document.createElement("li");
            li.textContent = "Stream completed";
            document.getElementById("messagesList").appendChild(li);
        },
        error: (err) => {
            var li = document.createElement("li");
            li.textContent = err;
            document.getElementById("messagesList").appendChild(li);
        },
});
```

To end the stream from the client, call the `dispose` method on the `ISubscription` that's returned from the `subscribe` method. Calling this method causes cancellation of the `CancellationToken` parameter of the Hub method, if you provided one.

```
connection.stream("Counter", 10, 500)
    .subscribe({
        next: (item) => {
            var li = document.createElement("li");
            li.textContent = item;
            document.getElementById("messagesList").appendChild(li);
        },
        complete: () => {
            var li = document.createElement("li");
            li.textContent = "Stream completed";
            document.getElementById("messagesList").appendChild(li);
        },
        error: (err) => {
            var li = document.createElement("li");
            li.textContent = err;
            document.getElementById("messagesList").appendChild(li);
        },
});
```

To end the stream from the client, call the `dispose` method on the `ISubscription` that's returned from the `subscribe` method.

Client-to-server streaming

JavaScript clients call client-to-server streaming methods on hubs by passing in a `Subject` as an argument to `send`, `invoke`, or `stream`, depending on the hub method invoked. The `Subject` is a class that looks like a `Subject`. For example in RxJS, you can use the Subject class from that library.

```
const subject = new signalR.Subject();
yield connection.send("UploadStream", subject);
var iteration = 0;
const intervalHandle = setInterval(() => {
    iteration++;
    subject.next(iteration.toString());
    if (iteration === 10) {
        clearInterval(intervalHandle);
        subject.complete();
    }
}, 500);
```

Calling `subject.next(item)` with an item writes the item to the stream, and the hub method receives the item on the server.

To end the stream, call `subject.complete()`.

Java client

Server-to-client streaming

The SignalR Java client uses the `stream` method to invoke streaming methods. `stream` accepts three or more arguments:

- The expected type of the stream items.
- The name of the hub method.
- Arguments defined in the hub method.

```
hubConnection.stream(String.class, "ExampleStreamingHubMethod", "Arg1")
    .subscribe(
        (item) -> {/* Define your onNext handler here. */ },
        (error) -> {/* Define your onError handler here. */},
        () -> {/* Define your onCompleted handler here. */});
```

The `stream` method on `HubConnection` returns an Observable of the stream item type. The Observable type's `subscribe` method is where `onNext`, `onError` and `onCompleted` handlers are defined.

Differences between ASP.NET SignalR and ASP.NET Core SignalR

9/22/2020 • 5 minutes to read • Edit Online

ASP.NET Core SignalR isn't compatible with clients or servers for ASP.NET SignalR. This article details features which have been removed or changed in ASP.NET Core SignalR.

How to identify the SignalR version

	ASP.NET SIGNALR	ASP.NET CORE SIGNALR
Server NuGet package	Microsoft.AspNet.SignalR	None. Included in the Microsoft.AspNetCore.App shared framework.
Client NuGet packages	Microsoft.AspNet.SignalR.Client Microsoft.AspNet.SignalR.JS	Microsoft.AspNetCore.SignalR.Client
JavaScript client npm package	signalr	`@microsoft/signalr`
Java client	GitHub Repository (deprecated)	Maven package com.microsoft.signalr
Server app type	ASP.NET (System.Web) or OWIN Self-Host	ASP.NET Core
Supported server platforms	.NET Framework 4.5 or later	.NET Core 3.0 or later

	ASP.NET SIGNALR	ASP.NET CORE SIGNALR
Server NuGet package	Microsoft.AspNet.SignalR	Microsoft.AspNetCore.App (.NET Core) Microsoft.AspNetCore.SignalR (.NET Framework)
Client NuGet packages	Microsoft.AspNet.SignalR.Client Microsoft.AspNet.SignalR.JS	Microsoft.AspNetCore.SignalR.Client
JavaScript client npm package	signalr	`@aspnet/signalr`
Java client	GitHub Repository (deprecated)	Maven package com.microsoft.signalr
Server app type	ASP.NET (System.Web) or OWIN Self-Host	ASP.NET Core
Supported server platforms	.NET Framework 4.5 or later	.NET Framework 4.6.1 or later .NET Core 2.1 or later

Feature differences

Automatic reconnects

In ASP.NET SignalR:

- By default, SignalR attempts to reconnect to the server if the connection is dropped.

In ASP.NET Core SignalR:

- Automatic reconnects are opt-in with both the .NET client and the JavaScript client:

```
HubConnection connection = new HubConnectionBuilder()
    .WithUrl(new Uri("http://127.0.0.1:5000/chathub"))
    .WithAutomaticReconnect()
    .Build();
```

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .withAutomaticReconnect()
    .build();
```

Prior to ASP.NET Core 3.0, SignalR doesn't support automatic reconnects. If the client is disconnected, the user must explicitly start a new connection to reconnect. In ASP.NET SignalR, SignalR attempts to reconnect to the server if the connection is dropped.

Protocol support

ASP.NET Core SignalR supports JSON, as well as a new binary protocol based on MessagePack. Additionally, custom protocols can be created.

Transports

The Forever Frame transport isn't supported in ASP.NET Core SignalR.

Differences on the server

The ASP.NET Core SignalR server-side libraries are included in Microsoft.AspNetCore.App, which is used in the **ASP.NET Core Web Application** template for both Razor and MVC projects.

ASP.NET Core SignalR is an ASP.NET Core middleware. It must be configured by calling AddSignalR in `Startup.ConfigureServices`.

```
services.AddSignalR()
```

To configure routing, map routes to hubs inside the UseEndpoints method call in the `Startup.Configure` method.

```
app.UseRouting();

app.UseEndpoints(endpoints =>
{
    endpoints.MapHub<ChatHub>("/hub");
});
```

To configure routing, map routes to hubs inside the UseSignalR method call in the `Startup.Configure` method.

```
app.UseSignalR(routes =>
{
    routes.MapHub<ChatHub>("/hub");
});
```

Sticky sessions

The scaleout model for ASP.NET SignalR allows clients to reconnect and send messages to any server in the farm. In ASP.NET Core SignalR, the client must interact with the same server for the duration of the connection. For scaleout using Redis, that means sticky sessions are required. For scaleout using Azure SignalR Service, sticky sessions aren't required because the service handles connections to clients.

Single hub per connection

In ASP.NET Core SignalR, the connection model has been simplified. Connections are made directly to a single hub, rather than a single connection being used to share access to multiple hubs.

Streaming

ASP.NET Core SignalR now supports streaming data from the hub to the client.

State

The ability to pass arbitrary state between clients and the hub (often called `HubState`) has been removed, as well as support for progress messages. There is no counterpart of hub proxies at the moment.

PersistentConnection removal

In ASP.NET Core SignalR, the PersistentConnection class has been removed.

GlobalHost

ASP.NET Core has dependency injection (DI) built into the framework. Services can use DI to access the HubContext. The `GlobalHost` object that is used in ASP.NET SignalR to get a `HubContext` doesn't exist in ASP.NET Core SignalR.

HubPipeline

ASP.NET Core SignalR doesn't have support for `HubPipeline` modules.

Differences on the client

TypeScript

The ASP.NET Core SignalR client is written in TypeScript. You can write in JavaScript or TypeScript when using the JavaScript client.

The JavaScript client is hosted at npm

In ASP.NET versions, the JavaScript client was obtained through a NuGet package in Visual Studio. In the ASP.NET Core versions, the `@microsoft/signalr` npm package contains the JavaScript libraries. This package isn't included in the **ASP.NET Core Web Application** template. Use npm to obtain and install the `@microsoft/signalr` npm package.

```
npm init -y
npm install @microsoft/signalr
```

In ASP.NET versions, the JavaScript client was obtained through a NuGet package in Visual Studio. In the ASP.NET Core versions, the `@aspnet/signalr` npm package contains the JavaScript libraries. This package isn't included in the **ASP.NET Core Web Application** template. Use npm to obtain and install the `@aspnet/signalr` npm package.

```
npm init -y
npm install @aspnet/signalr
```

jQuery

The dependency on jQuery has been removed, however projects can still use jQuery.

Internet Explorer support

ASP.NET Core SignalR requires Microsoft Internet Explorer 11 or later (ASP.NET SignalR supported Microsoft Internet Explorer 8 and later).

JavaScript client method syntax

The JavaScript syntax has changed from the ASP.NET version of SignalR. Rather than using the `$connection` object, create a connection using the HubConnectionBuilder API.

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/hub")
    .build();
```

Use the on method to specify client methods that the hub can call.

The JavaScript syntax has changed from the ASP.NET version of SignalR. Rather than using the `$connection` object, create a connection using the HubConnectionBuilder API.

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/hub")
    .build();
```

Use the on method to specify client methods that the hub can call.

```
connection.on("ReceiveMessage", (user, message) => {
    const msg = message.replace(/&/g, "&amp;").replace(/</g, "&lt;").replace(/>/g, "&gt;");
    const encodedMsg = `${user} says ${msg}`;
    console.log(encodedMsg);
});
```

After creating the client method, start the hub connection. Chain a catch method to log or handle errors.

```
connection.start().catch(err => console.error(err));
```

Hub proxies

Hub proxies are no longer automatically generated. Instead, the method name is passed into the invoke API as a string.

Hub proxies are no longer automatically generated. Instead, the method name is passed into the invoke API as a string.

.NET and other clients

The Microsoft.AspNetCore.SignalR.Client NuGet package contains the .NET client libraries for ASP.NET Core SignalR.

Use the HubConnectionBuilder to create and build an instance of a connection to a hub.

```
connection = new HubConnectionBuilder()
    .WithUrl("url")
    .Build();
```

Scaleout differences

ASP.NET SignalR supports SQL Server and Redis. ASP.NET Core SignalR supports Azure SignalR Service and Redis.

ASP.NET

- SignalR scaleout with Azure Service Bus

- SignalR scaleout with Redis
- SignalR scaleout with SQL Server

ASP.NET Core

- Azure SignalR Service
- Redis Backplane

Additional resources

- Hubs
- JavaScript client
- .NET client
- Supported platforms

WebSockets support in ASP.NET Core

9/22/2020 • 7 minutes to read • Edit Online

By Tom Dykstra and Andrew Stanton-Nurse

This article explains how to get started with WebSockets in ASP.NET Core. WebSocket (RFC 6455) is a protocol that enables two-way persistent communication channels over TCP connections. It's used in apps that benefit from fast, real-time communication, such as chat, dashboard, and game apps.

View or download sample code (how to download). How to run.

SignalR

ASP.NET Core SignalR is a library that simplifies adding real-time web functionality to apps. It uses WebSockets whenever possible.

For most applications, we recommend SignalR over raw WebSockets. SignalR provides transport fallback for environments where WebSockets is not available. It also provides a simple remote procedure call app model. And in most scenarios, SignalR has no significant performance disadvantage compared to using raw WebSockets.

Prerequisites

- ASP.NET Core 1.1 or later
- Any OS that supports ASP.NET Core:
  - Windows 7 / Windows Server 2008 or later
  - Linux
  - macOS
- If the app runs on Windows with IIS:
  - Windows 8 / Windows Server 2012 or later
  - IIS 8 / IIS 8 Express
  - WebSockets must be enabled (See the IIS/IIS Express support section.).
- If the app runs on HTTP.sys:
  - Windows 8 / Windows Server 2012 or later
- For supported browsers, see https://caniuse.com/#feat=websockets.

NuGet package

Install the Microsoft.AspNetCore.WebSockets package.

Configure the middleware

Add the WebSockets middleware in the `Configure` method of the `Startup` class:

```
app.UseWebSockets();
```

The following settings can be configured:

- `KeepAliveInterval` - How frequently to send "ping" frames to the client to ensure proxies keep the connection open. The default is two minutes.
- `ReceiveBufferSize` - The size of the buffer used to receive data. Advanced users may need to change this for performance tuning based on the size of the data. The default is 4 KB.

The following settings can be configured:

- `KeepAliveInterval` - How frequently to send "ping" frames to the client to ensure proxies keep the connection open. The default is two minutes.
- ReceiveBufferSize - The size of the buffer used to receive data. Advanced users may need to change this for performance tuning based on the size of the data. The default is 4 KB.
- `AllowedOrigins` - A list of allowed Origin header values for WebSocket requests. By default, all origins are allowed. See "WebSocket origin restriction" below for details.

```
var webSocketOptions = new WebSocketOptions()
{
    KeepAliveInterval = TimeSpan.FromSeconds(120),
    ReceiveBufferSize = 4 * 1024
};

app.UseWebSockets(webSocketOptions);
```

Accept WebSocket requests

Somewhere later in the request life cycle (later in the `Configure` method or in an action method, for example) check if it's a WebSocket request and accept the WebSocket request.

The following example is from later in the `Configure` method:

```
app.Use(async (context, next) =>
{
    if (context.Request.Path == "/ws")
    {
        if (context.WebSockets.IsWebSocketRequest)
        {
            WebSocket webSocket = await context.WebSockets.AcceptWebSocketAsync();
            await Echo(context, webSocket);
        }
        else
        {
            context.Response.StatusCode = 400;
        }
    }
    else
    {
        await next();
    }

});
```

A WebSocket request could come in on any URL, but this sample code only accepts requests for `/ws`.

When using a WebSocket, you **must** keep the middleware pipeline running for the duration of the connection. If you attempt to send or receive a WebSocket message after the middleware pipeline ends, you may get an exception like the following:

```
System.Net.WebSockets.WebSocketException (0x80004005): The remote party closed the WebSocket connection
without completing the close handshake. ---> System.ObjectDisposedException: Cannot write to the response
body, the response has completed.
Object name: 'HttpResponseStream'.
```

If you're using a background service to write data to a WebSocket, make sure you keep the middleware pipeline running. Do this by using a TaskCompletionSource<TResult>. Pass the `TaskCompletionSource` to your background service and have it call TrySetResult when you finish with the WebSocket. Then `await` the Task property during the request, as shown in the following example:

```
app.Use(async (context, next) => {
    var socket = await context.WebSockets.AcceptWebSocketAsync();
    var socketFinishedTcs = new TaskCompletionSource<object>();

    BackgroundSocketProcessor.AddSocket(socket, socketFinishedTcs);

    await socketFinishedTcs.Task;
});
```

The WebSocket closed exception can also happen if you return too soon from an action method. If you accept a socket in an action method, wait for the code that uses the socket to complete before returning from the action method.

Never use `Task.Wait()`, `Task.Result`, or similar blocking calls to wait for the socket to complete, as that can cause serious threading issues. Always use `await`.

Send and receive messages

The `AcceptWebSocketAsync` method upgrades the TCP connection to a WebSocket connection and provides a WebSocket object. Use the `WebSocket` object to send and receive messages.

The code shown earlier that accepts the WebSocket request passes the `WebSocket` object to an `Echo` method. The code receives a message and immediately sends back the same message. Messages are sent and received in a loop until the client closes the connection:

```
private async Task Echo(HttpContext context, WebSocket webSocket)
{
    var buffer = new byte[1024 * 4];
    WebSocketReceiveResult result = await webSocket.ReceiveAsync(new ArraySegment<byte>(buffer),
CancellationToken.None);
    while (!result.CloseStatus.HasValue)
    {
        await webSocket.SendAsync(new ArraySegment<byte>(buffer, 0, result.Count), result.MessageType,
result.EndOfMessage, CancellationToken.None);

        result = await webSocket.ReceiveAsync(new ArraySegment<byte>(buffer), CancellationToken.None);
    }
    await webSocket.CloseAsync(result.CloseStatus.Value, result.CloseStatusDescription,
CancellationToken.None);
}
```

When accepting the WebSocket connection before beginning the loop, the middleware pipeline ends. Upon closing the socket, the pipeline unwinds. That is, the request stops moving forward in the pipeline when the WebSocket is accepted. When the loop is finished and the socket is closed, the request proceeds back up the pipeline.

Handle client disconnects

The server is not automatically informed when the client disconnects due to loss of connectivity. The server receives a disconnect message only if the client sends it, which can't be done if the internet connection is lost. If you want to take some action when that happens, set a timeout after nothing is received from the client within a certain time window.

If the client isn't always sending messages and you don't want to timeout just because the connection goes idle, have the client use a timer to send a ping message every X seconds. On the server, if a message hasn't arrived within 2*X seconds after the previous one, terminate the connection and report that the client disconnected. Wait for twice the expected time interval to leave extra time for network delays that might hold up the ping message.

WebSocket origin restriction

The protections provided by CORS don't apply to WebSockets. Browsers do **not**:

- Perform CORS pre-flight requests.
- Respect the restrictions specified in `Access-Control` headers when making WebSocket requests.

However, browsers do send the `Origin` header when issuing WebSocket requests. Applications should be configured to validate these headers to ensure that only WebSockets coming from the expected origins are allowed.

If you're hosting your server on "https://server.com" and hosting your client on "https://client.com", add "https://client.com" to the `AllowedOrigins` list for WebSockets to verify.

```
var webSocketOptions = new WebSocketOptions()
{
    KeepAliveInterval = TimeSpan.FromSeconds(120),
    ReceiveBufferSize = 4 * 1024
};
webSocketOptions.AllowedOrigins.Add("https://client.com");
webSocketOptions.AllowedOrigins.Add("https://www.client.com");

app.UseWebSockets(webSocketOptions);
```

> **NOTE**
>
> The `Origin` header is controlled by the client and, like the `Referer` header, can be faked. Do **not** use these headers as an authentication mechanism.

IIS/IIS Express support

Windows Server 2012 or later and Windows 8 or later with IIS/IIS Express 8 or later has support for the WebSocket protocol.

> **NOTE**
>
> WebSockets are always enabled when using IIS Express.

Enabling WebSockets on IIS

To enable support for the WebSocket protocol on Windows Server 2012 or later:

> **NOTE**
> These steps are not required when using IIS Express

1. Use the **Add Roles and Features** wizard from the **Manage** menu or the link in **Server Manager**.
2. Select **Role-based or Feature-based Installation**. Select **Next**.
3. Select the appropriate server (the local server is selected by default). Select **Next**.
4. Expand **Web Server (IIS)** in the **Roles** tree, expand **Web Server**, and then expand **Application Development**.
5. Select **WebSocket Protocol**. Select **Next**.
6. If additional features aren't needed, select **Next**.
7. Select **Install**.
8. When the installation completes, select **Close** to exit the wizard.

To enable support for the WebSocket protocol on Windows 8 or later:

> **NOTE**
> These steps are not required when using IIS Express

1. Navigate to **Control Panel** > **Programs** > **Programs and Features** > **Turn Windows features on or off** (left side of the screen).
2. Open the following nodes: **Internet Information Services** > **World Wide Web Services** > **Application Development Features**.
3. Select the **WebSocket Protocol** feature. Select **OK**.

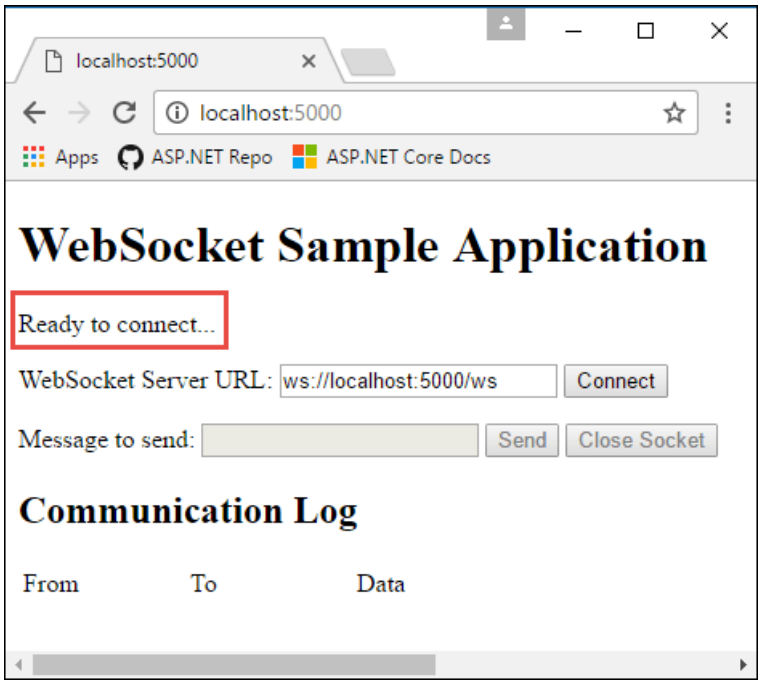
Disable WebSocket when using socket.io on Node.js

If using the WebSocket support in socket.io on Node.js, disable the default IIS WebSocket module using the `webSocket` element in *web.config* or *applicationHost.config*. If this step isn't performed, the IIS WebSocket module attempts to handle the WebSocket communication rather than Node.js and the app.

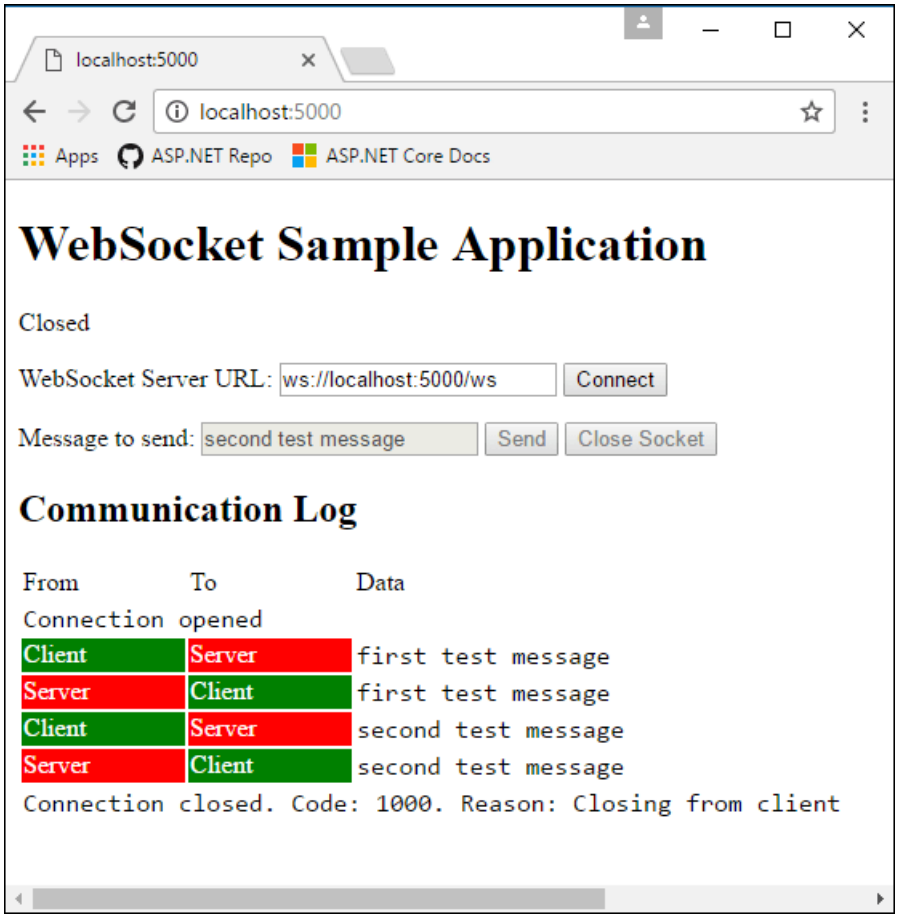
```
<system.webServer>
  <webSocket enabled="false" />
</system.webServer>
```

Sample app

The sample app that accompanies this article is an echo app. It has a web page that makes WebSocket connections, and the server resends any messages it receives back to the client. Run the app from a command prompt (it's not set up to run from Visual Studio with IIS Express) and navigate to http://localhost:5000. The web page shows the connection status in the upper left:



Select **Connect** to send a WebSocket request to the URL shown. Enter a test message and select **Send**. When done, select **Close Socket**. The **Communication Log** section reports each open, send, and close action as it happens.



Logging and diagnostics in ASP.NET Core SignalR

9/22/2020 • 8 minutes to read • Edit Online

By Andrew Stanton-Nurse

This article provides guidance for gathering diagnostics from your ASP.NET Core SignalR app to help troubleshoot issues.

Server-side logging

> **WARNING**
> Server-side logs may contain sensitive information from your app. **Never** post raw logs from production apps to public forums like GitHub.

Since SignalR is part of ASP.NET Core, it uses the ASP.NET Core logging system. In the default configuration, SignalR logs very little information, but this can configured. See the documentation on ASP.NET Core logging for details on configuring ASP.NET Core logging.

SignalR uses two logger categories:

- `Microsoft.AspNetCore.SignalR`: For logs related to Hub Protocols, activating Hubs, invoking methods, and other Hub-related activities.
- `Microsoft.AspNetCore.Http.Connections`: For logs related to transports, such as WebSockets, Long Polling, Server-Sent Events, and low-level SignalR infrastructure.

To enable detailed logs from SignalR, configure both of the preceding prefixes to the `Debug` level in your *appsettings.json* file by adding the following items to the `LogLevel` sub-section in `Logging`:

```
{
    "Logging": {
        "LogLevel": {
            "Default": "Debug",
            "System": "Information",
            "Microsoft": "Information",
            "Microsoft.AspNetCore.SignalR": "Debug",
            "Microsoft.AspNetCore.Http.Connections": "Debug"
        }
    }
}
```

You can also configure this in code in your `CreateWebHostBuilder` method:

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .ConfigureLogging(logging =>
        {
            logging.AddFilter("Microsoft.AspNetCore.SignalR", LogLevel.Debug);
            logging.AddFilter("Microsoft.AspNetCore.Http.Connections", LogLevel.Debug);
        })
        .UseStartup<Startup>();
```

If you aren't using JSON-based configuration, set the following configuration values in your configuration system:

- `Logging:LogLevel:Microsoft.AspNetCore.SignalR` = `Debug`
- `Logging:LogLevel:Microsoft.AspNetCore.Http.Connections` = `Debug`

Check the documentation for your configuration system to determine how to specify nested configuration values. For example, when using environment variables, two `_` characters are used instead of the `:` (for example, `Logging__LogLevel__Microsoft.AspNetCore.SignalR`).

We recommend using the `Debug` level when gathering more detailed diagnostics for your app. The `Trace` level produces very low-level diagnostics and is rarely needed to diagnose issues in your app.

Access server-side logs

How you access server-side logs depends on the environment in which you're running.

As a console app outside IIS

If you're running in a console app, the Console logger should be enabled by default. SignalR logs will appear in the console.

Within IIS Express from Visual Studio

Visual Studio displays the log output in the **Output** window. Select the **ASP.NET Core Web Server** drop down option.

Azure App Service

Enable the **Application Logging (Filesystem)** option in the **Diagnostics logs** section of the Azure App Service portal and configure the **Level** to `Verbose`. Logs should be available from the **Log streaming** service and in logs on the file system of the App Service. For more information, see Azure log streaming.

Other environments

If the app is deployed to another environment (for example, Docker, Kubernetes, or Windows Service), see Logging in .NET Core and ASP.NET Core for more information on how to configure logging providers suitable for the environment.

JavaScript client logging

> **WARNING**
> Client-side logs may contain sensitive information from your app. **Never** post raw logs from production apps to public forums like GitHub.

When using the JavaScript client, you can configure logging options using the `configureLogging` method on `HubConnectionBuilder`:

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/my/hub/url")
    .configureLogging(signalR.LogLevel.Debug)
    .build();
```

To disable logging entirely, specify `signalR.LogLevel.None` in the `configureLogging` method.

The following table shows log levels available to the JavaScript client. Setting the log level to one of these values enables logging at that level and all levels above it in the table.

LEVEL	DESCRIPTION
`None`	No messages are logged.
`Critical`	Messages that indicate a failure in the entire app.
`Error`	Messages that indicate a failure in the current operation.
`Warning`	Messages that indicate a non-fatal problem.
`Information`	Informational messages.
`Debug`	Diagnostic messages useful for debugging.
`Trace`	Very detailed diagnostic messages designed for diagnosing specific issues.

Once you've configured the verbosity, the logs will be written to the Browser Console (or Standard Output in a NodeJS app).

If you want to send logs to a custom logging system, you can provide a JavaScript object implementing the `ILogger` interface. The only method that needs to be implemented is `log`, which takes the level of the event and the message associated with the event. For example:

```
import { ILogger, LogLevel, HubConnectionBuilder } from "@aspnet/signalr";

export class MyLogger implements ILogger {
    log(logLevel: LogLevel, message: string) {
        // Use `message` and `logLevel` to record the log message to your own system
    }
}

// later on, when configuring your connection...

let connection = new HubConnectionBuilder()
    .withUrl("/my/hub/url")
    .configureLogging(new MyLogger())
    .build();
```

.NET client logging

> **WARNING**
> Client-side logs may contain sensitive information from your app. **Never** post raw logs from production apps to public forums like GitHub.

To get logs from the .NET client, you can use the `ConfigureLogging` method on `HubConnectionBuilder`. This works the same way as the `ConfigureLogging` method on `WebHostBuilder` and `HostBuilder`. You can configure the same logging providers you use in ASP.NET Core. However, you have to manually install and enable the NuGet packages for the individual logging providers.

To add .NET client logging to a Blazor WebAssembly app, see ASP.NET Core Blazor logging.

Console logging

In order to enable Console logging, add the Microsoft.Extensions.Logging.Console package. Then, use the

`AddConsole` method to configure the console logger:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/my/hub/url")
    .ConfigureLogging(logging =>
    {
        // Log to the Console
        logging.AddConsole();

        // This will set ALL logging to Debug level
        logging.SetMinimumLevel(LogLevel.Debug);
    })
    .Build();
```

Debug output window logging

You can also configure logs to go to the **Output** window in Visual Studio. Install the Microsoft.Extensions.Logging.Debug package and use the `AddDebug` method:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/my/hub/url")
    .ConfigureLogging(logging =>
    {
        // Log to the Output Window
        logging.AddDebug();

        // This will set ALL logging to Debug level
        logging.SetMinimumLevel(LogLevel.Debug)
    })
    .Build();
```

Other logging providers

SignalR supports other logging providers such as Serilog, Seq, NLog, or any other logging system that integrates with `Microsoft.Extensions.Logging`. If your logging system provides an `ILoggerProvider`, you can register it with `AddProvider`:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/my/hub/url")
    .ConfigureLogging(logging =>
    {
        // Log to your custom provider
        logging.AddProvider(new MyCustomLoggingProvider());

        // This will set ALL logging to Debug level
        logging.SetMinimumLevel(LogLevel.Debug)
    })
    .Build();
```

Control verbosity

If you are logging from other places in your app, changing the default level to `Debug` may be too verbose. You can use a Filter to configure the logging level for SignalR logs. This can be done in code, in much the same way as on the server:

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/my/hub/url")
    .ConfigureLogging(logging =>
    {
        // Register your providers

        // Set the default log level to Information, but to Debug for SignalR-related loggers.
        logging.SetMinimumLevel(LogLevel.Information);
        logging.AddFilter("Microsoft.AspNetCore.SignalR", LogLevel.Debug);
        logging.AddFilter("Microsoft.AspNetCore.Http.Connections", LogLevel.Debug);
    })
    .Build();
```

Network traces

> **WARNING**
> A network trace contains the full contents of every message sent by your app. **Never** post raw network traces from production apps to public forums like GitHub.

If you encounter an issue, a network trace can sometimes provide a lot of helpful information. This is particularly useful if you're going to file an issue on our issue tracker.

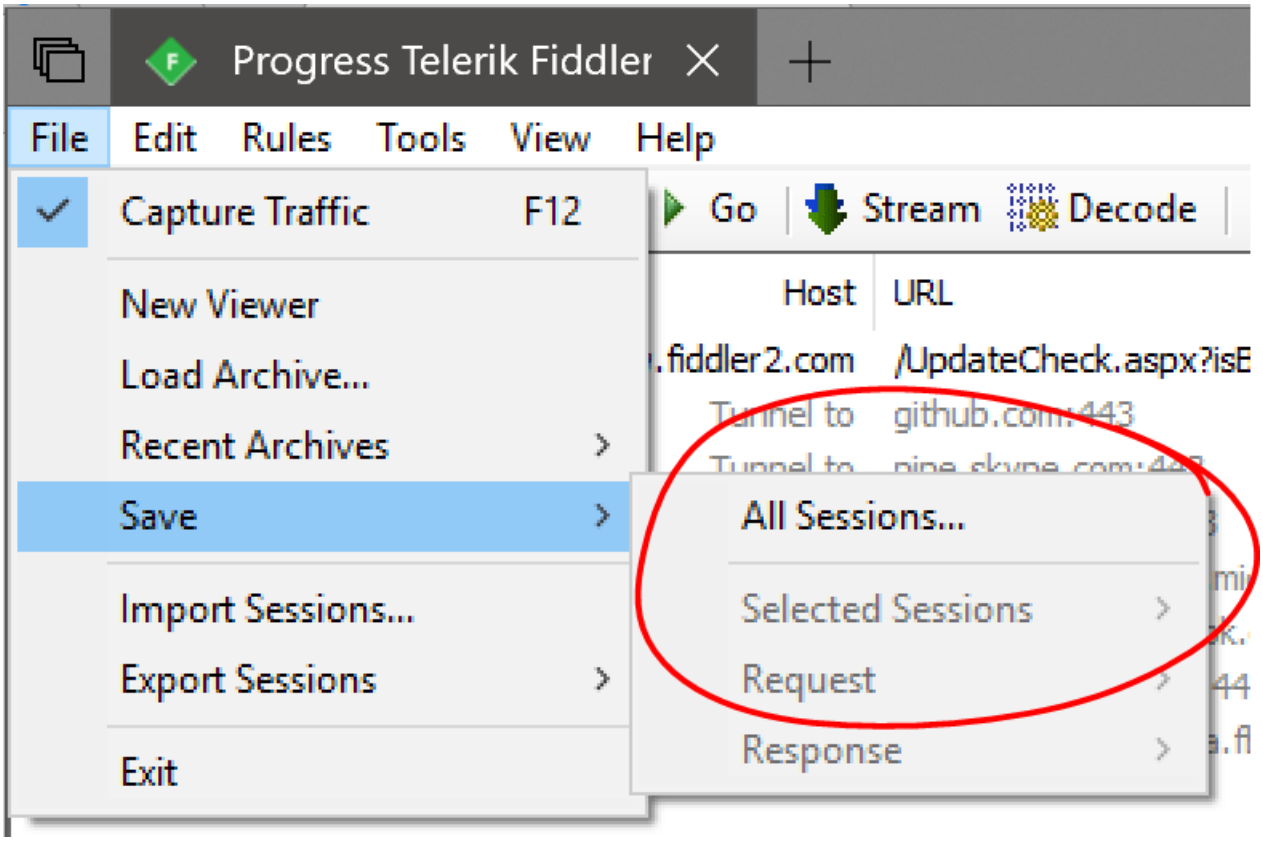
Collect a network trace with Fiddler (preferred option)

This method works for all apps.

Fiddler is a very powerful tool for collecting HTTP traces. Install it from telerik.com/fiddler, launch it, and then run your app and reproduce the issue. Fiddler is available for Windows, and there are beta versions for macOS and Linux.

If you connect using HTTPS, there are some extra steps to ensure Fiddler can decrypt the HTTPS traffic. For more details, see the Fiddler documentation.

Once you've collected the trace, you can export the trace by choosing **File** > **Save** > **All Sessions** from the menu bar.



Collect a network trace with tcpdump (macOS and Linux only)

This method works for all apps.

You can collect raw TCP traces using tcpdump by running the following command from a command shell. You may need to be `root` or prefix the command with `sudo` if you get a permissions error:

```
tcpdump -i [interface] -w trace.pcap
```

Replace `[interface]` with the network interface you wish to capture on. Usually, this is something like `/dev/eth0` (for your standard Ethernet interface) or `/dev/lo0` (for localhost traffic). For more information, see the `tcpdump` man page on your host system.

Collect a network trace in the browser

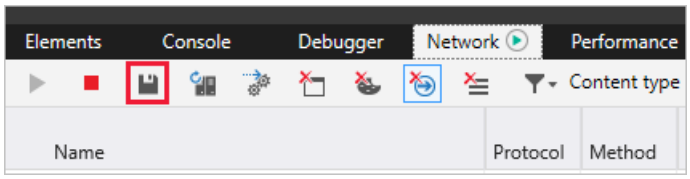
This method only works for browser-based apps.

Most browser Developer Tools have a "Network" tab that allows you to capture network activity between the browser and the server. However, these traces don't include WebSocket and Server-Sent Event messages. If you are using those transports, using a tool like Fiddler or TcpDump (described below) is a better approach.

Microsoft Edge and Internet Explorer

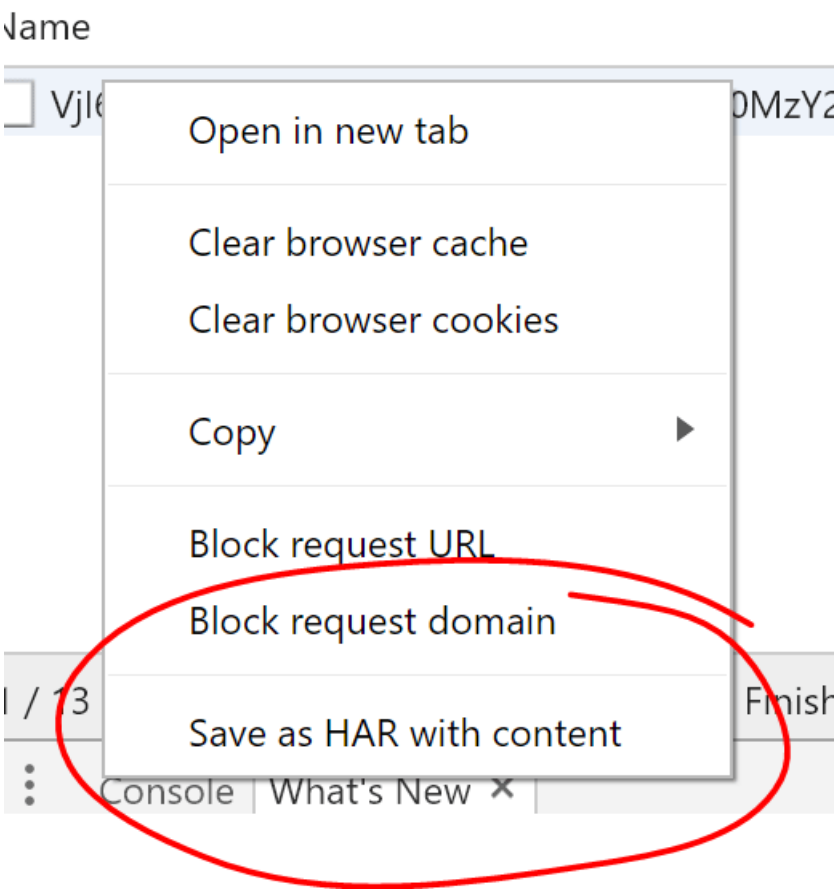
(The instructions are the same for both Edge and Internet Explorer)

1. Press F12 to open the Dev Tools
2. Click the Network Tab
3. Refresh the page (if needed) and reproduce the problem
4. Click the Save icon in the toolbar to export the trace as a "HAR" file:



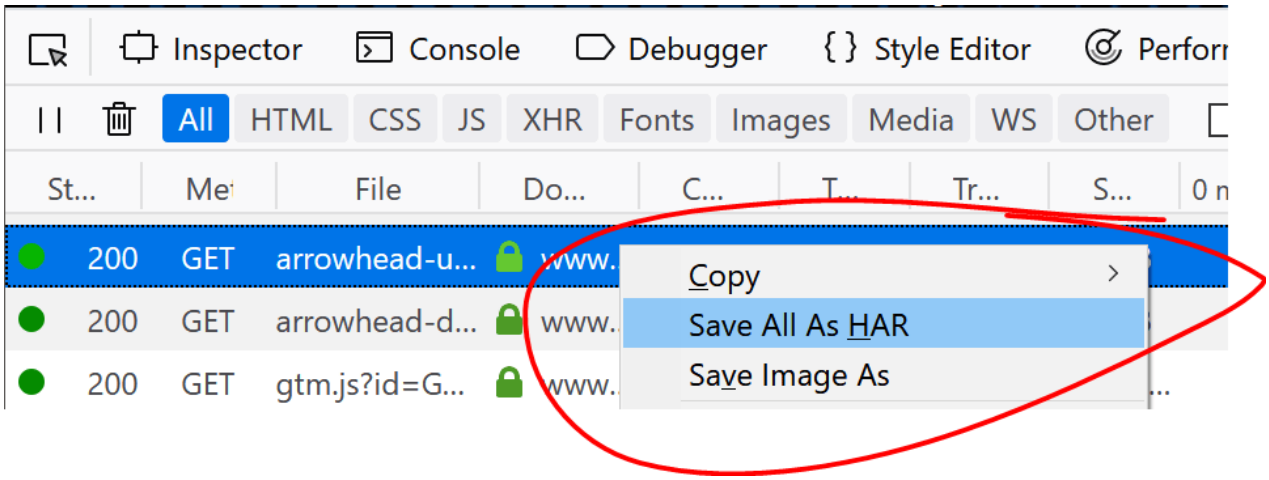
Google Chrome

1. Press F12 to open the Dev Tools
2. Click the Network Tab
3. Refresh the page (if needed) and reproduce the problem
4. Right click anywhere in the list of requests and choose "Save as HAR with content":



Mozilla Firefox

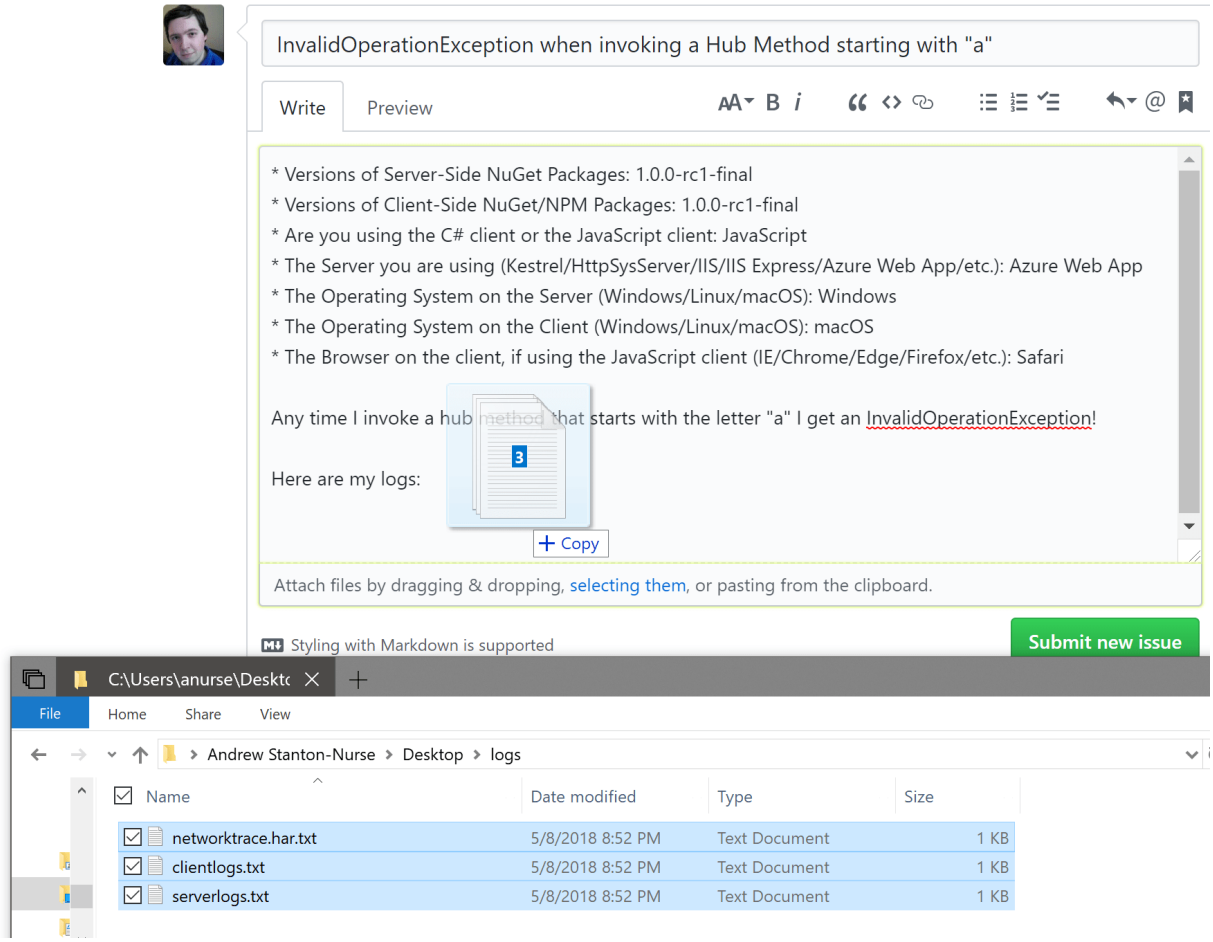
1. Press F12 to open the Dev Tools
2. Click the Network Tab
3. Refresh the page (if needed) and reproduce the problem
4. Right click anywhere in the list of requests and choose "Save All As HAR"



Attach diagnostics files to GitHub issues

You can attach Diagnostics files to GitHub issues by renaming them so they have a `.txt` extension and then dragging and dropping them on to the issue.

> **NOTE**
> Please don't paste the content of log files or network traces into a GitHub issue. These logs and traces can be quite large, and GitHub usually truncates them.



Metrics

Metrics is a representation of data measures over intervals of time. For example, requests per second. Metrics data allows observation of the state of an app at a high level. .NET gRPC metrics are emitted using EventCounter.

SignalR server metrics

SignalR server metrics are reported on the Microsoft.AspNetCore.Http.Connections event source.

NAME	DESCRIPTION
`connections-started`	Total connections started
`connections-stopped`	Total connections stopped
`connections-timed-out`	Total connections timed out
`current-connections`	Current connections
`connections-duration`	Average connection duration

Observe metrics

dotnet-counters is a performance monitoring tool for ad-hoc health monitoring and first-level performance investigation. Monitor a .NET app with `Microsoft.AspNetCore.Http.Connections` as the provider name. For example:

```
> dotnet-counters monitor --process-id 37016 Microsoft.AspNetCore.Http.Connections

Press p to pause, r to resume, q to quit.
    Status: Running
[Microsoft.AspNetCore.Http.Connections]
    Average Connection Duration (ms)       16,040.56
    Current Connections                            1
    Total Connections Started                      8
    Total Connections Stopped                      7
    Total Connections Timed Out                    0
```

Introduction to gRPC on .NET Core

9/22/2020 • 2 minutes to read • Edit Online

By John Luo and James Newton-King

gRPC is a language agnostic, high-performance Remote Procedure Call (RPC) framework.

The main benefits of gRPC are:

- Modern, high-performance, lightweight RPC framework.
- Contract-first API development, using Protocol Buffers by default, allowing for language agnostic implementations.
- Tooling available for many languages to generate strongly-typed servers and clients.
- Supports client, server, and bi-directional streaming calls.
- Reduced network usage with Protobuf binary serialization.

These benefits make gRPC ideal for:

- Lightweight microservices where efficiency is critical.
- Polyglot systems where multiple languages are required for development.
- Point-to-point real-time services that need to handle streaming requests or responses.

> **WARNING**
>
> ASP.NET Core gRPC is not currently supported on Azure App Service or IIS. The HTTP/2 implementation of Http.Sys does not support HTTP response trailing headers which gRPC relies on. For more information, see this GitHub issue.

C# Tooling support for .proto files

gRPC uses a contract-first approach to API development. Services and messages are defined in **.proto* files:

```
syntax = "proto3";

service Greeter {
  rpc SayHello (HelloRequest) returns (HelloReply);
}

message HelloRequest {
  string name = 1;
}

message HelloReply {
  string message = 1;
}
```

.NET types for services, clients and messages are automatically generated by including **.proto* files in a project:

- Add a package reference to Grpc.Tools package.
- Add **.proto* files to the `<Protobuf>` item group.

```
<ItemGroup>
  <Protobuf Include="Protos\greet.proto" />
</ItemGroup>
```

For more information on gRPC tooling support, see gRPC services with C#.

gRPC services on ASP.NET Core

gRPC services can be hosted on ASP.NET Core. Services have full integration with popular ASP.NET Core features such as logging, dependency injection (DI), authentication and authorization.

The gRPC service project template provides a starter service:

```
public class GreeterService : Greeter.GreeterBase
{
    private readonly ILogger<GreeterService> _logger;

    public GreeterService(ILogger<GreeterService> logger)
    {
        _logger = logger;
    }

    public override Task<HelloReply> SayHello(HelloRequest request,
        ServerCallContext context)
    {
        _logger.LogInformation("Saying hello to {Name}", request.Name);
        return Task.FromResult(new HelloReply
        {
            Message = "Hello " + request.Name
        });
    }
}
```

`GreeterService` inherits from the `GreeterBase` type, which is generated from the `Greeter` service in the **.proto* file. The service is made accessible to clients in *Startup.cs*:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapGrpcService<GreeterService>();
});
```

To learn more about gRPC services on ASP.NET Core, see gRPC services with ASP.NET Core.

Call gRPC services with a .NET client

gRPC clients are concrete client types that are generated from **.proto* files. The concrete gRPC client has methods that translate to the gRPC service in the **.proto* file.

```
var channel = GrpcChannel.ForAddress("https://localhost:5001");
var client = new Greeter.GreeterClient(channel);

var response = await client.SayHelloAsync(
    new HelloRequest { Name = "World" });

Console.WriteLine(response.Message);
```

A gRPC client is created using a channel, which represents a long-lived connection to a gRPC service. A channel can be created using `GrpcChannel.ForAddress`.

For more information on creating clients, and calling different service methods, see Call gRPC services with the .NET client.

Tutorial: Create a gRPC client and server in ASP.NET Core

9/22/2020 • 9 minutes to read • Edit Online

By John Luo

This tutorial shows how to create a .NET Core gRPC client and an ASP.NET Core gRPC Server.

At the end, you'll have a gRPC client that communicates with the gRPC Greeter service.

View or download sample code (how to download).

In this tutorial, you:

- Create a gRPC Server.
- Create a gRPC client.
- Test the gRPC client service with the gRPC Greeter service.

Prerequisites

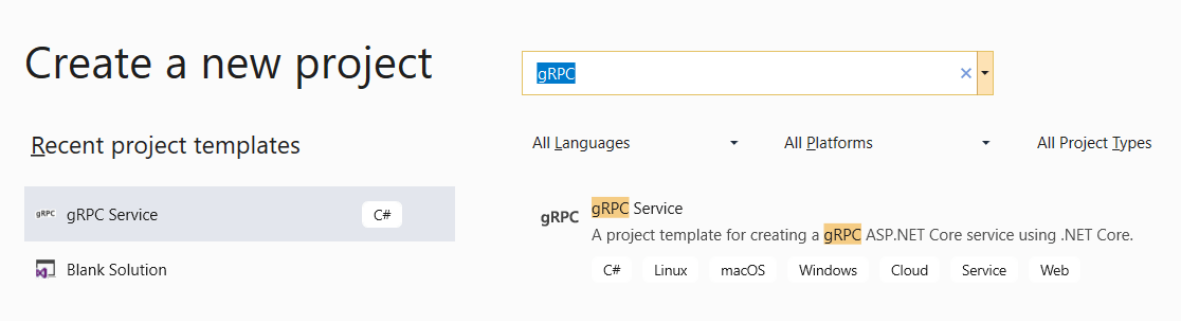
- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 16.4 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

Create a gRPC service

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Start Visual Studio and select **Create a new project**. Alternatively, from the Visual Studio **File** menu, select **New** > **Project**.
- In the **Create a new project** dialog, select **gRPC Service** and select **Next**:



- Name the project **GrpcGreeter**. It's important to name the project *GrpcGreeter* so the namespaces will match when you copy and paste code.
- Select **Create**.

- In the **Create a new gRPC service** dialog:
  - The **gRPC Service** template is selected.
  - Select **Create**.

Run the service

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Press Ctrl+F5 to run without the debugger.

  Visual Studio displays the following dialog:

  Select **Yes** if you trust the IIS Express SSL certificate.

  The following dialog is displayed:

  Select **Yes** if you agree to trust the development certificate.

  Visual Studio starts IIS Express and runs the app. The address bar shows `localhost:port#` and not something like `example.com`. That's because `localhost` is the standard hostname for the local computer. Localhost only serves web requests from the local computer. When Visual Studio creates a web project, a random port is used for the web server.

The logs show the service listening on `https://localhost:5001`.

```
info: Microsoft.Hosting.Lifetime[0]
      Now listening on: https://localhost:5001
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
```

> **NOTE**
>
> The gRPC template is configured to use Transport Layer Security (TLS). gRPC clients need to use HTTPS to call the server.
>
> macOS doesn't support ASP.NET Core gRPC with TLS. Additional configuration is required to successfully run gRPC services on macOS. For more information, see Unable to start ASP.NET Core gRPC app on macOS.

Examine the project files

GrpcGreeter project files:

- *greet.proto*: The *Protos/greet.proto* file defines the `Greeter` gRPC and is used to generate the gRPC server assets. For more information, see Introduction to gRPC.
- *Services* folder: Contains the implementation of the `Greeter` service.
- *appSettings.json*: Contains configuration data, such as protocol used by Kestrel. For more information, see Configuration in ASP.NET Core.
- *Program.cs*: Contains the entry point for the gRPC service. For more information, see .NET Generic Host.
- *Startup.cs*: Contains code that configures app behavior. For more information, see App startup.

Create the gRPC client in a .NET console app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Open a second instance of Visual Studio and select **Create a new project**.
- In the **Create a new project** dialog, select **Console App (.NET Core)** and select **Next**.
- In the **Project name** text box, enter **GrpcGreeterClient** and select **Create**.

Add required packages

The gRPC client project requires the following packages:

- Grpc.Net.Client, which contains the .NET Core client.
- Google.Protobuf, which contains protobuf message APIs for C#.
- Grpc.Tools, which contains C# tooling support for protobuf files. The tooling package isn't required at runtime, so the dependency is marked with `PrivateAssets="All"`.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Install the packages using either the Package Manager Console (PMC) or Manage NuGet Packages.

PMC option to install packages

- From Visual Studio, select **Tools** > **NuGet Package Manager** > **Package Manager Console**
- From the **Package Manager Console** window, run `cd GrpcGreeterClient` to change directories to the folder containing the *GrpcGreeterClient.csproj* files.

- Run the following commands:

```
Install-Package Grpc.Net.Client
Install-Package Google.Protobuf
Install-Package Grpc.Tools
```

Manage NuGet Packages option to install packages

- Right-click the project in **Solution Explorer** > **Manage NuGet Packages**
- Select the **Browse** tab.
- Enter **Grpc.Net.Client** in the search box.
- Select the **Grpc.Net.Client** package from the **Browse** tab and select **Install**.
- Repeat for `Google.Protobuf` and `Grpc.Tools`.

Add greet.proto

- Create a *Protos* folder in the gRPC client project.
- Copy the *Protos\greet.proto* file from the gRPC Greeter service to the gRPC client project.
- Edit the *GrpcGreeterClient.csproj* project file:
  - Visual Studio
  - Visual Studio Code
  - Visual Studio for Mac

  Right-click the project and select **Edit Project File**.

- Add an item group with a `<Protobuf>` element that refers to the *greet.proto* file:

```
<ItemGroup>
  <Protobuf Include="Protos\greet.proto" GrpcServices="Client" />
</ItemGroup>
```

Create the Greeter client

Build the project to create the types in the `GrpcGreeter` namespace. The `GrpcGreeter` types are generated automatically by the build process.

Update the gRPC client *Program.cs* file with the following code:

```
using System;
using System.Net.Http;
using System.Threading.Tasks;
using GrpcGreeter;
using Grpc.Net.Client;

namespace GrpcGreeterClient
{
    class Program
    {
        static async Task Main(string[] args)
        {
            // The port number(5001) must match the port of the gRPC server.
            using var channel = GrpcChannel.ForAddress("https://localhost:5001");
            var client =  new Greeter.GreeterClient(channel);
            var reply = await client.SayHelloAsync(
                              new HelloRequest { Name = "GreeterClient" });
            Console.WriteLine("Greeting: " + reply.Message);
            Console.WriteLine("Press any key to exit...");
            Console.ReadKey();
        }
    }
}
```

Program.cs contains the entry point and logic for the gRPC client.

The Greeter client is created by:

- Instantiating a `GrpcChannel` containing the information for creating the connection to the gRPC service.
- Using the `GrpcChannel` to construct the Greeter client:

```
static async Task Main(string[] args)
{
    // The port number(5001) must match the port of the gRPC server.
    using var channel = GrpcChannel.ForAddress("https://localhost:5001");
    var client =  new Greeter.GreeterClient(channel);
    var reply = await client.SayHelloAsync(
                      new HelloRequest { Name = "GreeterClient" });
    Console.WriteLine("Greeting: " + reply.Message);
    Console.WriteLine("Press any key to exit...");
    Console.ReadKey();
}
```

The Greeter client calls the asynchronous `SayHello` method. The result of the `SayHello` call is displayed:

```
static async Task Main(string[] args)
{
    // The port number(5001) must match the port of the gRPC server.
    using var channel = GrpcChannel.ForAddress("https://localhost:5001");
    var client =  new Greeter.GreeterClient(channel);
    var reply = await client.SayHelloAsync(
                      new HelloRequest { Name = "GreeterClient" });
    Console.WriteLine("Greeting: " + reply.Message);
    Console.WriteLine("Press any key to exit...");
    Console.ReadKey();
}
```

Test the gRPC client with the gRPC Greeter service

- Visual Studio

- Visual Studio Code
- Visual Studio for Mac

- In the Greeter service, press `Ctrl+F5` to start the server without the debugger.
- In the `GrpcGreeterClient` project, press `Ctrl+F5` to start the client without the debugger.

The client sends a greeting to the service with a message containing its name, *GreeterClient*. The service sends the message "Hello GreeterClient" as a response. The "Hello GreeterClient" response is displayed in the command prompt:

```
Greeting: Hello GreeterClient
Press any key to exit...
```

The gRPC service records the details of the successful call in the logs written to the command prompt:

```
info: Microsoft.Hosting.Lifetime[0]
      Now listening on: https://localhost:5001
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
info: Microsoft.Hosting.Lifetime[0]
      Content root path: C:\GH\aspnet\docs\4\Docs\aspnetcore\tutorials\grpc\grpc-start\sample\GrpcGreeter
info: Microsoft.AspNetCore.Hosting.Diagnostics[1]
      Request starting HTTP/2 POST https://localhost:5001/Greet.Greeter/SayHello application/grpc
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[0]
      Executing endpoint 'gRPC - /Greet.Greeter/SayHello'
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[1]
      Executed endpoint 'gRPC - /Greet.Greeter/SayHello'
info: Microsoft.AspNetCore.Hosting.Diagnostics[2]
      Request finished in 78.32260000000001ms 200 application/grpc
```

> **NOTE**
>
> The code in this article requires the ASP.NET Core HTTPS development certificate to secure the gRPC service. If the .NET gRPC client fails with the message `The remote certificate is invalid according to the validation procedure.` or `The SSL connection could not be established.`, the development certificate isn't trusted. To fix this issue, see Call a gRPC service with an untrusted/invalid certificate.

> **WARNING**
>
> ASP.NET Core gRPC is not currently supported on Azure App Service or IIS. The HTTP/2 implementation of Http.Sys does not support HTTP response trailing headers which gRPC relies on. For more information, see this GitHub issue.

- Migrating gRPC services from C-core to ASP.NET Core

gRPC services with C#

9/22/2020 • 3 minutes to read • Edit Online

This document outlines the concepts needed to write gRPC apps in C#. The topics covered here apply to both C-core-based and ASP.NET Core-based gRPC apps.

> **WARNING**
>
> ASP.NET Core gRPC is not currently supported on Azure App Service or IIS. The HTTP/2 implementation of Http.Sys does not support HTTP response trailing headers which gRPC relies on. For more information, see this GitHub issue.

proto file

gRPC uses a contract-first approach to API development. Protocol buffers (protobuf) are used as the Interface Definition Language (IDL) by default. The **.proto* file contains:

- The definition of the gRPC service.
- The messages sent between clients and servers.

For more information on the syntax of protobuf files, see Create Protobuf messages for .NET apps.

For example, consider the *greet.proto* file used in Get started with gRPC service:

- Defines a `Greeter` service.
- The `Greeter` service defines a `SayHello` call.
- `SayHello` sends a `HelloRequest` message and receives a `HelloReply` message:

```
syntax = "proto3";

option csharp_namespace = "GrpcGreeter";

package greet;

// The greeting service definition.
service Greeter {
  // Sends a greeting
  rpc SayHello (HelloRequest) returns (HelloReply);
}

// The request message containing the user's name.
message HelloRequest {
  string name = 1;
}

// The response message containing the greetings.
message HelloReply {
  string message = 1;
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

Add a .proto file to a C# app

The **.proto* file is included in a project by adding it to the `<Protobuf>` item group:

```
<ItemGroup>
  <Protobuf Include="Protos\greet.proto" GrpcServices="Server" />
</ItemGroup>
```

By default, a `<Protobuf>` reference generates a concrete client and a service base class. The reference element's `GrpcServices` attribute can be used to limit C# asset generation. Valid `GrpcServices` options are:

- `Both` (default when not present)
- `Server`
- `Client`
- `None`

C# Tooling support for .proto files

The tooling package Grpc.Tools is required to generate the C# assets from **.proto* files. The generated assets (files):

- Are generated on an as-needed basis each time the project is built.
- Aren't added to the project or checked into source control.
- Are a build artifact contained in the *obj* directory.

This package is required by both the server and client projects. The `Grpc.AspNetCore` metapackage includes a reference to `Grpc.Tools`. Server projects can add `Grpc.AspNetCore` using the Package Manager in Visual Studio or by adding a `<PackageReference>` to the project file:

```
<PackageReference Include="Grpc.AspNetCore" Version="2.28.0" />
```

Client projects should directly reference `Grpc.Tools` alongside the other packages required to use the gRPC client. The tooling package isn't required at runtime, so the dependency is marked with `PrivateAssets="All"`:

```
<PackageReference Include="Google.Protobuf" Version="3.11.4" />
<PackageReference Include="Grpc.Net.Client" Version="2.28.0" />
<PackageReference Include="Grpc.Tools" Version="2.28.1">
```

Generated C# assets

The tooling package generates the C# types representing the messages defined in the included **.proto* files.

For server-side assets, an abstract service base type is generated. The base type contains the definitions of all the gRPC calls contained in the *.proto* file. Create a concrete service implementation that derives from this base type and implements the logic for the gRPC calls. For the `greet.proto`, the example described previously, an abstract `GreeterBase` type that contains a virtual `SayHello` method is generated. A concrete implementation `GreeterService` overrides the method and implements the logic handling the gRPC call.

```
public class GreeterService : Greeter.GreeterBase
{
    private readonly ILogger<GreeterService> _logger;
    public GreeterService(ILogger<GreeterService> logger)
    {
        _logger = logger;
    }

    public override Task<HelloReply> SayHello(HelloRequest request, ServerCallContext context)
    {
        return Task.FromResult(new HelloReply
        {
            Message = "Hello " + request.Name
        });
    }
}
```

For client-side assets, a concrete client type is generated. The gRPC calls in the *.proto* file are translated into methods on the concrete type, which can be called. For the `greet.proto`, the example described previously, a concrete `GreeterClient` type is generated. Call `GreeterClient.SayHelloAsync` to initiate a gRPC call to the server.

```
static async Task Main(string[] args)
{
    // The port number(5001) must match the port of the gRPC server.
    using var channel = GrpcChannel.ForAddress("https://localhost:5001");
    var client =  new Greeter.GreeterClient(channel);
    var reply = await client.SayHelloAsync(
                      new HelloRequest { Name = "GreeterClient" });
    Console.WriteLine("Greeting: " + reply.Message);
    Console.WriteLine("Press any key to exit...");
    Console.ReadKey();
}
```

By default, server and client assets are generated for each **.proto* file included in the `<Protobuf>` item group. To ensure only the server assets are generated in a server project, the `GrpcServices` attribute is set to `Server`.

```
<ItemGroup>
  <Protobuf Include="Protos\greet.proto" GrpcServices="Server" />
</ItemGroup>
```

Similarly, the attribute is set to `Client` in client projects.

Create gRPC services and methods

9/22/2020 • 5 minutes to read • Edit Online

By James Newton-King

This document explains how to create gRPC services and methods in C#. Topics include:

- How to define services and methods in *.proto* files.
- Generated code using gRPC C# tooling.
- Implementing gRPC services and methods.

Create new gRPC services

gRPC services with C# introduced gRPC's contract-first approach to API development. Services and messages are defined in *.proto* files. C# tooling then generates code from *.proto* files. For server-side assets, an abstract base type is generated for each service, along with classes for any messages.

The following *.proto* file:

- Defines a `Greeter` service.
- The `Greeter` service defines a `SayHello` call.
- `SayHello` sends a `HelloRequest` message and receives a `HelloReply` message

```
syntax = "proto3";

service Greeter {
  rpc SayHello (HelloRequest) returns (HelloReply);
}

message HelloRequest {
  string name = 1;
}

message HelloReply {
  string message = 1;
}
```

C# tooling generates the C# `GreeterBase` base type:

```
public abstract partial class GreeterBase
{
    public virtual Task<HelloReply> SayHello(HelloRequest request, ServerCallContext context)
    {
        throw new RpcException(new Status(StatusCode.Unimplemented, ""));
    }
}

public class HelloRequest
{
    public string Name { get; set; }
}

public class HelloReply
{
    public string Message { get; set; }
}
```

By default the generated `GreeterBase` doesn't do anything. Its virtual `SayHello` method will return an `UNIMPLEMENTED` error to any clients that call it. For the service to be useful an app must create a concrete implementation of `GreeterBase`:

```
public class GreeterService : GreeterBase
{
    public override Task<HelloReply> UnaryCall(HelloRequest request, ServerCallContext context)
    {
        return Task.FromResult(new HelloRequest { Message = $"Hello {request.Name}" });
    }
}
```

The service implementation is registered with the app. If the service is hosted by ASP.NET Core gRPC, it should be added to the routing pipeline with the `MapGrpcService` method.

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapGrpcService<GreeterService>();
});
```

See gRPC services with ASP.NET Core for more information.

Implement gRPC methods

A gRPC service can have different types of methods. How messages are sent and received by a service depends on the type of method defined. The gRPC method types are:

- Unary
- Server streaming
- Client streaming
- Bi-directional streaming

Streaming calls are specified with the `stream` keyword in the *.proto* file. `stream` can be placed on a call's request message, response message, or both.

```
syntax = "proto3";

service ExampleService {
  // Unary
  rpc UnaryCall (ExampleRequest) returns (ExampleResponse);

  // Server streaming
  rpc StreamingFromServer (ExampleRequest) returns (stream ExampleResponse);

  // Client streaming
  rpc StreamingFromClient (stream ExampleRequest) returns (ExampleResponse);

  // Bi-directional streaming
  rpc StreamingBothWays (stream ExampleRequest) returns (stream ExampleResponse);
}
```

Each call type has a different method signature. Overriding generated methods from the abstract base service type in a concrete implementation ensures the correct arguments and return type are used.

Unary method

A unary method gets the request message as a parameter, and returns the response. A unary call is complete when the response is returned.

```
public override Task<ExampleResponse> UnaryCall(ExampleRequest request,
    ServerCallContext context)
{
    var response = new ExampleResponse();
    return Task.FromResult(response);
}
```

Unary calls are the most similar to actions on web API controllers. One important difference gRPC methods have from actions is gRPC methods are not able to bind parts of a request to different method arguments. gRPC methods always have one message argument for the incoming request data. Multiple values can still be sent to a gRPC service by making them fields on the request message:

```
message ExampleRequest {
    int pageIndex = 1;
    int pageSize = 2;
    bool isDescending = 3;
}
```

Server streaming method

A server streaming method gets the request message as a parameter. Because multiple messages can be streamed back to the caller, `responseStream.WriteAsync` is used to send response messages. A server streaming call is complete when the method returns.

```
public override async Task StreamingFromServer(ExampleRequest request,
    IServerStreamWriter<ExampleResponse> responseStream, ServerCallContext context)
{
    for (var i = 0; i < 5; i++)
    {
        await responseStream.WriteAsync(new ExampleResponse());
        await Task.Delay(TimeSpan.FromSeconds(1));
    }
}
```

The client has no way to send additional messages or data once the server streaming method has started. Some

streaming methods are designed to run forever. For continuous streaming methods, a client can cancel the call when it's no longer needed. When cancellation happens the client sends a signal to the server and the ServerCallContext.CancellationToken is raised. The `CancellationToken` token should be used on the server with async methods so that:

- Any asynchronous work is canceled together with the streaming call.
- The method exits quickly.

```
public override async Task StreamingFromServer(ExampleRequest request,
    IServerStreamWriter<ExampleResponse> responseStream, ServerCallContext context)
{
    while (!context.CancellationToken.IsCancellationRequested)
    {
        await responseStream.WriteAsync(new ExampleResponse());
        await Task.Delay(TimeSpan.FromSeconds(1), context.CancellationToken);
    }
}
```

Client streaming method

A client streaming method starts *without* the method receiving a message. The `requestStream` parameter is used to read messages from the client. A client streaming call is complete when a response message is returned:

```
public override async Task<ExampleResponse> StreamingFromClient(
    IAsyncStreamReader<ExampleRequest> requestStream, ServerCallContext context)
{
    while (await requestStream.MoveNext())
    {
        var message = requestStream.Current;
        // ...
    }
    return new ExampleResponse();
}
```

When using C# 8 or later, the `await foreach` syntax can be used to read messages. The `IAsyncStreamReader<T>.ReadAllAsync()` extension method reads all messages from the request stream:

```
public override async Task<ExampleResponse> StreamingFromClient(
    IAsyncStreamReader<ExampleRequest> requestStream, ServerCallContext context)
{
    await foreach (var message in requestStream.ReadAllAsync())
    {
        // ...
    }
    return new ExampleResponse();
}
```

Bi-directional streaming method

A bi-directional streaming method starts *without* the method receiving a message. The `requestStream` parameter is used to read messages from the client. The method can choose to send messages with `responseStream.WriteAsync`.
A bi-directional streaming call is complete when the the method returns:

```
public override async Task StreamingBothWays(IAsyncStreamReader<ExampleRequest> requestStream,
    IServerStreamWriter<ExampleResponse> responseStream, ServerCallContext context)
{
    await foreach (var message in requestStream.ReadAllAsync())
    {
        await responseStream.WriteAsync(new ExampleResponse());
    }
}
```

The preceding code:

- Sends a response for each request.
- Is a basic usage of bi-directional streaming.

It is possible to support more complex scenarios, such as reading requests and sending responses simultaneously:

```
public override async Task StreamingBothWays(IAsyncStreamReader<ExampleRequest> requestStream,
    IServerStreamWriter<ExampleResponse> responseStream, ServerCallContext context)
{
    // Read requests in a background task.
    var readTask = Task.Run(async () =>
    {
        await foreach (var message in requestStream.ReadAllAsync())
        {
            // Process request.
        }
    });

    // Send responses until the client signals that it is complete.
    while (!readTask.IsCompleted)
    {
        await responseStream.WriteAsync(new ExampleResponse());
        await Task.Delay(TimeSpan.FromSeconds(1), context.CancellationToken);
    }
}
```

In a bi-directional streaming method, the client and service can send messages to each other at any time. The best implementation of a bi-directional method varies depending upon requirements.

Access gRPC request headers

A request message is not the only way for a client to send data to a gRPC service. Header values are available in a service using `ServerCallContext.RequestHeaders`.

```
public override Task<ExampleResponse> UnaryCall(ExampleRequest request, ServerCallContext context)
{
    var userAgent = context.RequestHeaders.GetValue("user-agent");
    // ...

    return Task.FromResult(new ExampleResponse());
}
```

Create Protobuf messages for .NET apps

9/22/2020 • 9 minutes to read • Edit Online

By James Newton-King and Mark Rendle

gRPC uses Protobuf as its Interface Definition Language (IDL). Protobuf IDL is a language neutral format for specifying the messages sent and received by gRPC services. Protobuf messages are defined in `.proto` files. This document explains how Protobuf concepts map to .NET.

Protobuf messages

Messages are the main data transfer object in Protobuf. They are conceptually similar to .NET classes.

```
syntax = "proto3";

option csharp_namespace = "Contoso.Messages";

message Person {
    int32 id = 1;
    string first_name = 2;
    string last_name = 3;
}
```

The preceding message definition specifies three fields as name-value pairs. Like properties on .NET types, each field has a name and a type. The field type can be a Protobuf scalar value type, e.g. `int32`, or another message.

In addition to a name, each field in the message definition has a unique number. Field numbers are used to identify fields when the message is serialized to Protobuf. Serializing a small number is faster than serializing the entire field name. Because field numbers identify a field it is important to take care when changing them. For more information about changing Protobuf messages see Versioning gRPC services.

When an app is built the Protobuf tooling generates .NET types from `.proto` files. The `Person` message generates a .NET class:

```
public class Person
{
    public int Id { get; set; }
    public string FirstName { get; set; }
    public string LastName { get; set; }
}
```

For more information about Protobuf messages see the Protobuf language guide.

Scalar Value Types

Protobuf supports a range of native scalar value types. The following table lists them all with their equivalent C# type:

PROTOBUF TYPE	C# TYPE
`double`	`double`

PROTOBUF TYPE	C# TYPE
`float`	`float`
`int32`	`int`
`int64`	`long`
`uint32`	`uint`
`uint64`	`ulong`
`sint32`	`int`
`sint64`	`long`
`fixed32`	`uint`
`fixed64`	`ulong`
`sfixed32`	`int`
`sfixed64`	`long`
`bool`	`bool`
`string`	`string`
`bytes`	`ByteString`

Scalar values always have a default value and can't be set to `null`. This constraint includes `string` and `ByteString` which are C# classes. `string` defaults to an empty string value and `ByteString` defaults to an empty bytes value. Attempting to set them to `null` throws an error.

Nullable wrapper types can be used to support null values.

Dates and times

The native scalar types don't provide for date and time values, equivalent to .NET's DateTimeOffset, DateTime, and TimeSpan. These types can be specified by using some of Protobuf's *Well-Known Types* extensions. These extensions provide code generation and runtime support for complex field types across the supported platforms.

The following table shows the date and time types:

.NET TYPE	PROTOBUF WELL-KNOWN TYPE
`DateTimeOffset`	`google.protobuf.Timestamp`
`DateTime`	`google.protobuf.Timestamp`
`TimeSpan`	`google.protobuf.Duration`

```
syntax = "proto3"

import "google/protobuf/duration.proto";
import "google/protobuf/timestamp.proto";

message Meeting {
    string subject = 1;
    google.protobuf.Timestamp start = 2;
    google.protobuf.Duration duration = 3;
}
```

The generated properties in the C# class aren't the .NET date and time types. The properties use the `Timestamp` and `Duration` classes in the `Google.Protobuf.WellKnownTypes` namespace. These classes provide methods for converting to and from `DateTimeOffset`, `DateTime`, and `TimeSpan`.

```
// Create Timestamp and Duration from .NET DateTimeOffset and TimeSpan.
var meeting = new Meeting
{
    Time = Timestamp.FromDateTimeOffset(meetingTime), // also FromDateTime()
    Duration = Duration.FromTimeSpan(meetingLength)
};

// Convert Timestamp and Duration to .NET DateTimeOffset and TimeSpan.
var time = meeting.Time.ToDateTimeOffset();
var duration = meeting.Duration?.ToTimeSpan();
```

> **NOTE**
>
> The `Timestamp` type works with UTC times. `DateTimeOffset` values always have an offset of zero, and the `DateTime.Kind` property is always `DateTimeKind.Utc`.

Nullable types

The Protobuf code generation for C# uses the native types, such as `int` for `int32`. So the values are always included and can't be `null`.

For values that require explicit `null`, such as using `int?` in C# code, Protobuf's Well-Known Types include wrappers that are compiled to nullable C# types. To use them, import `wrappers.proto` into your `.proto` file, like the following code:

```
syntax = "proto3"

import "google/protobuf/wrappers.proto"

message Person {
    // ...
    google.protobuf.Int32Value age = 5;
}
```

`wrappers.proto` types aren't exposed in generated properties. Protobuf automatically maps them to appropriate .NET nullable types in C# messages. For example, a `google.protobuf.Int32Value` field generates an `int?` property. Reference type properties like `string` and `ByteString` are unchanged except `null` can be assigned to them without error.

The following table shows the complete list of wrapper types with their equivalent C# type:

C# TYPE	WELL-KNOWN TYPE WRAPPER
`bool?`	`google.protobuf.BoolValue`
`double?`	`google.protobuf.DoubleValue`
`float?`	`google.protobuf.FloatValue`
`int?`	`google.protobuf.Int32Value`
`long?`	`google.protobuf.Int64Value`
`uint?`	`google.protobuf.UInt32Value`
`ulong?`	`google.protobuf.UInt64Value`
`string`	`google.protobuf.StringValue`
`ByteString`	`google.protobuf.BytesValue`

Bytes

Binary payloads are supported in Protobuf with the `bytes` scalar value type. A generated property in C# uses `ByteString` as the property type.

Use `ByteString.CopyFrom(byte[] data)` to create a new instance from a byte array:

```
var data = await File.ReadAllBytesAsync(path);

var payload = new PayloadResponse();
payload.Data = ByteString.CopyFrom(data);
```

`ByteString` data is accessed directly using `ByteString.Span` or `ByteString.Memory`. Or call `ByteString.ToByteArray()` to convert an instance back into a byte array:

```
var payload = await client.GetPayload(new PayloadRequest());

await File.WriteAllBytesAsync(path, payload.Data.ToByteArray());
```

Decimals

Protobuf doesn't natively support the .NET `decimal` type, just `double` and `float`. There's an ongoing discussion in the Protobuf project about the possibility of adding a standard decimal type to the Well-Known Types, with platform support for languages and frameworks that support it. Nothing has been implemented yet.

It's possible to create a message definition to represent the `decimal` type that works for safe serialization between .NET clients and servers. But developers on other platforms would have to understand the format being used and implement their own handling for it.

Creating a custom decimal type for Protobuf

```
package CustomTypes;

// Example: 12345.6789 -> { units = 12345, nanos = 678900000 }
message DecimalValue {

    // Whole units part of the amount
    int64 units = 1;

    // Nano units of the amount (10^-9)
    // Must be same sign as units
    sfixed32 nanos = 2;
}
```

The `nanos` field represents values from `0.999_999_999` to `-0.999_999_999`. For example, the `decimal` value `1.5m` would be represented as `{ units = 1, nanos = 500_000_000 }`. This is why the `nanos` field in this example uses the `sfixed32` type, which encodes more efficiently than `int32` for larger values. If the `units` field is negative, the `nanos` field should also be negative.

> **NOTE**
> There are multiple other algorithms for encoding `decimal` values as byte strings, but this message is easier to understand than any of them. The values are not affected by big-endian or little-endian on different platforms.

Conversion between this type and the BCL `decimal` type might be implemented in C# like this:

```
namespace CustomTypes
{
    public partial class DecimalValue
    {
        private const decimal NanoFactor = 1_000_000_000;
        public DecimalValue(long units, int nanos)
        {
            Units = units;
            Nanos = nanos;
        }

        public long Units { get; }
        public int Nanos { get; }

        public static implicit operator decimal(CustomTypes.DecimalValue grpcDecimal)
        {
            return grpcDecimal.Units + grpcDecimal.Nanos / NanoFactor;
        }

        public static implicit operator CustomTypes.DecimalValue(decimal value)
        {
            var units = decimal.ToInt64(value);
            var nanos = decimal.ToInt32((value - units) * NanoFactor);
            return new CustomTypes.DecimalValue(units, nanos);
        }
    }
}
```

Collections

Lists

Lists in Protobuf are specified by using the `repeated` prefix keyword on a field. The following example shows how to create a list:

```
message Person {
    // ...
    repeated string roles = 8;
}
```

In the generated code, `repeated` fields are represented by the `Google.Protobuf.Collections.RepeatedField<T>` generic type.

```
public class Person
{
    // ...
    public RepeatedField<string> Roles { get; }
}
```

`RepeatedField<T>` implements IList<T>. So you can use LINQ queries or convert it to an array or a list. `RepeatedField<T>` properties don't have a public setter. Items should be added to the existing collection.

```
var person = new Person();

// Add one item.
person.Roles.Add("user");

// Add all items from another collection.
var roles = new [] { "admin", "manager" };
person.Roles.Add(roles);
```

Dictionaries

The .NET IDictionary<TKey,TValue> type is represented in Protobuf using `map<key_type, value_type>`.

```
message Person {
    // ...
    map<string, string> attributes = 9;
}
```

In generated .NET code, `map` fields are represented by the `Google.Protobuf.Collections.MapField<TKey, TValue>` generic type. `MapField<TKey, TValue>` implements IDictionary<TKey,TValue>. Like `repeated` properties, `map` properties don't have a public setter. Items should be added to the existing collection.

```
var person = new Person();

// Add one item.
person.Attributes["created_by"] = "James";

// Add all items from another collection.
var attributes = new Dictionary<string, string>
{
    ["last_modified"] = DateTime.UtcNow.ToString()
};
person.Attributes.Add(attributes);
```

Unstructured and conditional messages

Protobuf is a contract-first messaging format. An app's messages, including its fields and types, must be specified in `.proto` files when the app is built. Protobuf's contract-first design is great at enforcing message content but can limit scenarios where a strict contract isn't required:

- Messages with unknown payloads. For example, a message with a field that could contain any message.
- Conditional messages. For example, a message returned from a gRPC service might be a success result or an error result.
- Dynamic values. For example, a message with a field that contains an unstructured collection of values, similar to JSON.

Protobuf offers language features and types to support these scenarios.

Any

The `Any` type lets you use messages as embedded types without having their `.proto` definition. To use the `Any` type, import `any.proto`.

```
import "google/protobuf/any.proto";

message Status {
    string message = 1;
    google.protobuf.Any detail = 2;
}
```

```
// Create a status with a Person message set to detail.
var status = new ErrorStatus();
status.Detail = Any.Pack(new Person { FirstName = "James" });

// Read Person message from detail.
if (status.Detail.Is(Person.Descriptor))
{
    var person = status.Detail.Unpack<Person>();
    // ...
}
```

Oneof

`oneof` fields are a language feature. The compiler handles the `oneof` keyword when it generates the message class. Using `oneof` to specify a response message that could either return a `Person` or `Error` might look like this:

```
message Person {
    // ...
}

message Error {
    // ...
}

message ResponseMessage {
  oneof result {
    Error error = 1;
    Person person = 2;
  }
}
```

Fields within the `oneof` set must have unique field numbers in the overall message declaration.

When using `oneof`, the generated C# code includes an enum that specifies which of the fields has been set. You can test the enum to find which field is set. Fields that aren't set return `null` or the default value, rather than throwing an exception.

```
var response = await client.GetPersonAsync(new RequestMessage());

switch (response.ResultCase)
{
    case ResponseMessage.ResultOneofCase.Person:
        HandlePerson(response.Person);
        break;
    case ResponseMessage.ResultOneofCase.Error:
        HandleError(response.Error);
        break;
    default:
        throw new ArgumentException("Unexpected result.");
}
```

Value

The `Value` type represents a dynamically typed value. It can be either `null`, a number, a string, a boolean, a dictionary of values (`Struct`), or a list of values (`ValueList`). `Value` is a Protobuf Well-Known Type that uses the previously discussed `oneof` feature. To use the `Value` type, import `struct.proto`.

```
import "google/protobuf/struct.proto";

message Status {
    // ...
    google.protobuf.Value data = 3;
}
```

```
// Create dynamic values.
var status = new Status();
status.Data = Value.FromStruct(new Struct
{
    Fields =
    {
        ["enabled"] = Value.ForBoolean(true),
        ["metadata"] = Value.ForList(
            Value.FromString("value1"),
            Value.FromString("value2"))
    }
});

// Read dynamic values.
switch (status.Data.KindCase)
{
    case Value.KindOneofCase.StructValue:
        foreach (var field in status.Data.StructValue.Fields)
        {
            // Read struct fields...
        }
        break;
    // ...
}
```

Using `Value` directly can be verbose. An alternative way to use `Value` is with Protobuf's built-in support for mapping messages to JSON. Protobuf's `JsonFormatter` and `JsonWriter` types can be used with any Protobuf message. `Value` is particularly well suited to being converted to and from JSON.

This is the JSON equivalent of the previous code:

```
// Create dynamic values from JSON.
var status = new Status();
status.Data = Value.Parser.ParseJson(@"{
    ""enabled"": true,
    ""metadata"": [ ""value1"", ""value2"" ]
}");

// Convert dynamic values to JSON.
// JSON can be read with a library like System.Text.Json or Newtonsoft.Json
var json = JsonFormatter.Default.Format(status.Metadata);
var document = JsonDocument.Parse(json);
```

Versioning gRPC services

9/22/2020 • 5 minutes to read • Edit Online

By James Newton-King

New features added to an app can require gRPC services provided to clients to change, sometimes in unexpected and breaking ways. When gRPC services change:

- Consideration should be given on how changes impact clients.
- A versioning strategy to support changes should be implemented.

Backwards compatibility

The gRPC protocol is designed to support services that change over time. Generally, additions to gRPC services and methods are non-breaking. Non-breaking changes allow existing clients to continue working without changes. Changing or deleting gRPC services are breaking changes. When gRPC services have breaking changes, clients using that service have to be updated and redeployed.

Making non-breaking changes to a service has a number of benefits:

- Existing clients continue to run.
- Avoids work involved with notifying clients of breaking changes, and updating them.
- Only one version of the service needs to be documented and maintained.

Non-breaking changes

These changes are non-breaking at a gRPC protocol level and .NET binary level.

- **Adding a new service**
- **Adding a new method to a service**
- **Adding a field to a request message** - Fields added to a request message are deserialized with the default value on the server when not set. To be a non-breaking change, the service must succeed when the new field isn't set by older clients.
- **Adding a field to a response message** - Fields added to a response message are deserialized into the message's unknown fields collection on the client.
- **Adding a value to an enum** - Enums are serialized as a numeric value. New enum values are deserialized on the client to the enum value without an enum name. To be a non-breaking change, older clients must run correctly when receiving the new enum value.

Binary breaking changes

The following changes are non-breaking at a gRPC protocol level, but the client needs to be updated if it upgrades to the latest *.proto* contract or client .NET assembly. Binary compatibility is important if you plan to publish a gRPC library to NuGet.

- **Removing a field** - Values from a removed field are deserialized to a message's unknown fields. This isn't a gRPC protocol breaking change, but the client needs to be updated if it upgrades to the latest contract. It's important that a removed field number isn't accidentally reused in the future. To ensure this doesn't happen, specify deleted field numbers and names on the message using Protobuf's reserved keyword.
- **Renaming a message** - Message names aren't typically sent on the network, so this isn't a gRPC protocol breaking change. The client will need to be updated if it upgrades to the latest contract. One situation where message names **are** sent on the network is with Any fields, when the message name is used to identify the message type.

- **Changing csharp_namespace** - Changing `csharp_namespace` will change the namespace of generated .NET types. This isn't a gRPC protocol breaking change, but the client needs to be updated if it upgrades to the latest contract.

Protocol breaking changes

The following items are protocol and binary breaking changes:

- **Renaming a field** - With Protobuf content, the field names are only used in generated code. The field number is used to identify fields on the network. Renaming a field isn't a protocol breaking change for Protobuf. However, if a server is using JSON content then renaming a field is a breaking change.
- **Changing a field data type** - Changing a field's data type to an incompatible type will cause errors when deserializing the message. Even if the new data type is compatible, it's likely the client needs to be updated to support the new type if it upgrades to the latest contract.
- **Changing a field number** - With Protobuf payloads, the field number is used to identify fields on the network.
- **Renaming a package, service or method** - gRPC uses the package name, service name, and method name to build the URL. The client gets an *UNIMPLEMENTED* status from the server.
- **Removing a service or method** - The client gets an *UNIMPLEMENTED* status from the server when calling the removed method.

Behavior breaking changes

When making non-breaking changes, you must also consider whether older clients can continue working with the new service behavior. For example, adding a new field to a request message:

- Isn't a protocol breaking change.
- Returning an error status on the server if the new field isn't set makes it a breaking change for old clients.

Behavior compatibility is determined by your app-specific code.

Version number services

Services should strive to remain backwards compatible with old clients. Eventually changes to your app may require breaking changes. Breaking old clients and forcing them to be updated along with your service isn't a good user experience. A way to maintain backwards compatibility while making breaking changes is to publish multiple versions of a service.

gRPC supports an optional package specifier, which functions much like a .NET namespace. In fact, the `package` will be used as the .NET namespace for generated .NET types if `option csharp_namespace` is not set in the *.proto* file. The package can be used to specify a version number for your service and its messages:

```
syntax = "proto3";

package greet.v1;

service Greeter {
  rpc SayHello (HelloRequest) returns (HelloReply);
}

message HelloRequest {
  string name = 1;
}

message HelloReply {
  string message = 1;
}
```

The package name is combined with the service name to identify a service address. A service address allows

multiple versions of a service to be hosted side-by-side:

- `greet.v1.Greeter`
- `greet.v2.Greeter`

Implementations of the versioned service are registered in *Startup.cs*:

```
app.UseEndpoints(endpoints =>
{
    // Implements greet.v1.Greeter
    endpoints.MapGrpcService<GreeterServiceV1>();

    // Implements greet.v2.Greeter
    endpoints.MapGrpcService<GreeterServiceV2>();
});
```

Including a version number in the package name gives you the opportunity to publish a *v2* version of your service with breaking changes, while continuing to support older clients who call the *v1* version. Once clients have updated to use the *v2* service, you can choose to remove the old version. When planning to publish multiple versions of a service:

- Avoid breaking changes if reasonable.
- Don't update the version number unless making breaking changes.
- Do update the version number when you make breaking changes.

Publishing multiple versions of a service duplicates it. To reduce duplication, consider moving business logic from the service implementations to a centralized location that can be reused by the old and new implementations:

```
using Greet.V1;
using Grpc.Core;
using System.Threading.Tasks;

namespace Services
{
    public class GreeterServiceV1 : Greeter.GreeterBase
    {
        private readonly IGreeter _greeter;
        public GreeterServiceV1(IGreeter greeter)
        {
            _greeter = greeter;
        }

        public override Task<HelloReply> SayHello(HelloRequest request, ServerCallContext context)
        {
            return Task.FromResult(new HelloReply
            {
                Message = _greeter.GetHelloMessage(request.Name)
            });
        }
    }
}
```

Services and messages generated with different package names are **different .NET types**. Moving business logic to a centralized location requires mapping messages to common types.

Call gRPC services with the .NET client

9/22/2020 • 7 minutes to read • Edit Online

A .NET gRPC client library is available in the Grpc.Net.Client NuGet package. This document explains how to:

- Configure a gRPC client to call gRPC services.
- Make gRPC calls to unary, server streaming, client streaming, and bi-directional streaming methods.

Configure gRPC client

gRPC clients are concrete client types that are generated from **.proto* files. The concrete gRPC client has methods that translate to the gRPC service in the **.proto* file. For example, a service called `Greeter` generates a `GreeterClient` type with methods to call the service.

A gRPC client is created from a channel. Start by using `GrpcChannel.ForAddress` to create a channel, and then use the channel to create a gRPC client:

```
var channel = GrpcChannel.ForAddress("https://localhost:5001");
var client = new Greet.GreeterClient(channel);
```

A channel represents a long-lived connection to a gRPC service. When a channel is created, it is configured with options related to calling a service. For example, the `HttpClient` used to make calls, the maximum send and receive message size, and logging can be specified on `GrpcChannelOptions` and used with `GrpcChannel.ForAddress`. For a complete list of options, see client configuration options.

```
var channel = GrpcChannel.ForAddress("https://localhost:5001");

var greeterClient = new Greet.GreeterClient(channel);
var counterClient = new Count.CounterClient(channel);

// Use clients to call gRPC services
```

Configure TLS

A gRPC client must use the same connection-level security as the called service. gRPC client Transport Layer Security (TLS) is configured when the gRPC channel is created. A gRPC client throws an error when it calls a service and the connection-level security of the channel and service don't match.

To configure a gRPC channel to use TLS, ensure the server address starts with `https`. For example, `GrpcChannel.ForAddress("https://localhost:5001")` uses HTTPS protocol. The gRPC channel automatically negotiates a connection secured by TLS and uses a secure connection to make gRPC calls.

> **TIP**
>
> gRPC supports client certificate authentication over TLS. For information on configuring client certificates with a gRPC channel, see Authentication and authorization in gRPC for ASP.NET Core.

To call unsecured gRPC services, ensure the server address starts with `http`. For example, `GrpcChannel.ForAddress("http://localhost:5000")` uses HTTP protocol. In .NET Core 3.1 or later, additional configuration is required to call insecure gRPC services with the .NET client.

Client performance

Channel and client performance and usage:

- Creating a channel can be an expensive operation. Reusing a channel for gRPC calls provides performance benefits.
- gRPC clients are created with channels. gRPC clients are lightweight objects and don't need to be cached or reused.
- Multiple gRPC clients can be created from a channel, including different types of clients.
- A channel and clients created from the channel can safely be used by multiple threads.
- Clients created from the channel can make multiple simultaneous calls.

`GrpcChannel.ForAddress` isn't the only option for creating a gRPC client. If calling gRPC services from an ASP.NET Core app, consider gRPC client factory integration. gRPC integration with `HttpClientFactory` offers a centralized alternative to creating gRPC clients.

> **NOTE**
> Calling gRPC over HTTP/2 with `Grpc.Net.Client` is currently not supported on Xamarin. We are working to improve HTTP/2 support in a future Xamarin release. Grpc.Core and gRPC-Web are viable alternatives that work today.

Make gRPC calls

A gRPC call is initiated by calling a method on the client. The gRPC client will handle message serialization and addressing the gRPC call to the correct service.

gRPC has different types of methods. How the client is used to make a gRPC call depends on the type of method called. The gRPC method types are:

- Unary
- Server streaming
- Client streaming
- Bi-directional streaming

Unary call

A unary call starts with the client sending a request message. A response message is returned when the service finishes.

```
var client = new Greet.GreeterClient(channel);
var response = await client.SayHelloAsync(new HelloRequest { Name = "World" });

Console.WriteLine("Greeting: " + response.Message);
// Greeting: Hello World
```

Each unary service method in the **.proto* file will result in two .NET methods on the concrete gRPC client type for calling the method: an asynchronous method and a blocking method. For example, on `GreeterClient` there are two ways of calling `SayHello`:

- `GreeterClient.SayHelloAsync` - calls `Greeter.SayHello` service asynchronously. Can be awaited.
- `GreeterClient.SayHello` - calls `Greeter.SayHello` service and blocks until complete. Don't use in asynchronous code.

Server streaming call

A server streaming call starts with the client sending a request message. `ResponseStream.MoveNext()` reads

messages streamed from the service. The server streaming call is complete when `ResponseStream.MoveNext()` returns `false`.

```
var client = new Greet.GreeterClient(channel);
using var call = client.SayHellos(new HelloRequest { Name = "World" });

while (await call.ResponseStream.MoveNext())
{
    Console.WriteLine("Greeting: " + call.ResponseStream.Current.Message);
    // "Greeting: Hello World" is written multiple times
}
```

When using C# 8 or later, the `await foreach` syntax can be used to read messages. The `IAsyncStreamReader<T>.ReadAllAsync()` extension method reads all messages from the response stream:

```
var client = new Greet.GreeterClient(channel);
using var call = client.SayHellos(new HelloRequest { Name = "World" });

await foreach (var response in call.ResponseStream.ReadAllAsync())
{
    Console.WriteLine("Greeting: " + response.Message);
    // "Greeting: Hello World" is written multiple times
}
```

Client streaming call

A client streaming call starts *without* the client sending a message. The client can choose to send messages with `RequestStream.WriteAsync`. When the client has finished sending messages, `RequestStream.CompleteAsync()` should be called to notify the service. The call is finished when the service returns a response message.

```
var client = new Counter.CounterClient(channel);
using var call = client.AccumulateCount();

for (var i = 0; i < 3; i++)
{
    await call.RequestStream.WriteAsync(new CounterRequest { Count = 1 });
}
await call.RequestStream.CompleteAsync();

var response = await call;
Console.WriteLine($"Count: {response.Count}");
// Count: 3
```

Bi-directional streaming call

A bi-directional streaming call starts *without* the client sending a message. The client can choose to send messages with `RequestStream.WriteAsync`. Messages streamed from the service are accessible with `ResponseStream.MoveNext()` or `ResponseStream.ReadAllAsync()`. The bi-directional streaming call is complete when the `ResponseStream` has no more messages.

```
var client = new Echo.EchoClient(channel);
using var call = client.Echo();

Console.WriteLine("Starting background task to receive messages");
var readTask = Task.Run(async () =>
{
    await foreach (var response in call.ResponseStream.ReadAllAsync())
    {
        Console.WriteLine(response.Message);
        // Echo messages sent to the service
    }
});

Console.WriteLine("Starting to send messages");
Console.WriteLine("Type a message to echo then press enter.");
while (true)
{
    var result = Console.ReadLine();
    if (string.IsNullOrEmpty(result))
    {
        break;
    }

    await call.RequestStream.WriteAsync(new EchoMessage { Message = result });
}

Console.WriteLine("Disconnecting");
await call.RequestStream.CompleteAsync();
await readTask;
```

For best performance, and to avoid unnecessary errors in the client and service, try to complete bi-directional streaming calls gracefully. A bi-directional call completes gracefully when the server has finished reading the request stream and the client has finished reading the response stream. The preceding sample call is one example of a bi-directional call that ends gracefully. In the call, the client:

1. Starts a new bi-directional streaming call by calling `EchoClient.Echo`.
2. Creates a background task to read messages from the service using `ResponseStream.ReadAllAsync()`.
3. Sends messages to the server with `RequestStream.WriteAsync`.
4. Notifies the server it has finished sending messages with `RequestStream.CompleteAsync()`.
5. Waits until the background task has read all incoming messages.

During a bi-directional streaming call, the client and service can send messages to each other at any time. The best client logic for interacting with a bi-directional call varies depending upon the service logic.

Access gRPC trailers

gRPC calls may return gRPC trailers. gRPC trailers are used to provide name/value metadata about a call. Trailers provide similar functionality to HTTP headers, but are received at the end of the call.

gRPC trailers are accessible using `GetTrailers()`, which returns a collection of metadata. Trailers are returned after the response is complete, therefore, you must await all response messages before accessing the trailers.

Unary and client streaming calls must await `ResponseAsync` before calling `GetTrailers()`:

```
var client = new Greet.GreeterClient(channel);
using var call = client.SayHelloAsync(new HelloRequest { Name = "World" });
var response = await call.ResponseAsync;

Console.WriteLine("Greeting: " + response.Message);
// Greeting: Hello World

var trailers = call.GetTrailers();
var myValue = trailers.GetValue("my-trailer-name");
```

Server and bidirectional streaming calls must finish awaiting the response stream before calling `GetTrailers()`:

```
var client = new Greet.GreeterClient(channel);
using var call = client.SayHellos(new HelloRequest { Name = "World" });

await foreach (var response in call.ResponseStream.ReadAllAsync())
{
    Console.WriteLine("Greeting: " + response.Message);
    // "Greeting: Hello World" is written multiple times
}

var trailers = call.GetTrailers();
var myValue = trailers.GetValue("my-trailer-name");
```

gRPC trailers are also accessible from `RpcException`. A service may return trailers together with a non-OK gRPC status. In this situation the trailers are retrieved from the exception thrown by the gRPC client:

```
var client = new Greet.GreeterClient(channel);
string myValue = null;

try
{
    using var call = client.SayHelloAsync(new HelloRequest { Name = "World" });
    var response = await call.ResponseAsync;

    Console.WriteLine("Greeting: " + response.Message);
    // Greeting: Hello World

    var trailers = call.GetTrailers();
    myValue = trailers.GetValue("my-trailer-name");
}
catch (RpcException ex)
{
    var trailers = ex.Trailers;
    myValue = trailers.GetValue("my-trailer-name");
}
```

Configure deadline

Configuring a gRPC call deadline is recommended because it provides an upper limit on how long a call can run for. It stops misbehaving services from running forever and exhausting server resources. Deadlines are a useful tool for building reliable apps.

Configure `CallOptions.Deadline` to set a deadline for a gRPC call:

```
var client = new Greet.GreeterClient(channel);

try
{
    var response = await client.SayHelloAsync(
        new HelloRequest { Name = "World" },
        deadline: DateTime.UtcNow.AddSeconds(5));

    // Greeting: Hello World
    Console.WriteLine("Greeting: " + response.Message);
}
catch (RpcException ex) when (ex.StatusCode == StatusCode.DeadlineExceeded)
{
    Console.WriteLine("Greeting timeout.");
}
```

For more information, see Reliable gRPC services with deadlines and cancellation.

gRPC client factory integration in .NET Core

9/22/2020 • 2 minutes to read • Edit Online

gRPC integration with `HttpClientFactory` offers a centralized way to create gRPC clients. It can be used as an alternative to configuring stand-alone gRPC client instances. Factory integration is available in the Grpc.Net.ClientFactory NuGet package.

The factory offers the following benefits:

- Provides a central location for configuring logical gRPC client instances
- Manages the lifetime of the underlying `HttpClientMessageHandler`
- Automatic propagation of deadline and cancellation in an ASP.NET Core gRPC service

Register gRPC clients

To register a gRPC client, the generic `AddGrpcClient` extension method can be used within `Startup.ConfigureServices`, specifying the gRPC typed client class and service address:

```
services.AddGrpcClient<Greeter.GreeterClient>(o =>
{
    o.Address = new Uri("https://localhost:5001");
});
```

The gRPC client type is registered as transient with dependency injection (DI). The client can now be injected and consumed directly in types created by DI. ASP.NET Core MVC controllers, SignalR hubs and gRPC services are places where gRPC clients can automatically be injected:

```
public class AggregatorService : Aggregator.AggregatorBase
{
    private readonly Greeter.GreeterClient _client;

    public AggregatorService(Greeter.GreeterClient client)
    {
        _client = client;
    }

    public override async Task SayHellos(HelloRequest request,
        IServerStreamWriter<HelloReply> responseStream, ServerCallContext context)
    {
        // Forward the call on to the greeter service
        using (var call = _client.SayHellos(request))
        {
            await foreach (var response in call.ResponseStream.ReadAllAsync())
            {
                await responseStream.WriteAsync(response);
            }
        }
    }
}
```

Configure HttpClient

`HttpClientFactory` creates the `HttpClient` used by the gRPC client. Standard `HttpClientFactory` methods can be used to add outgoing request middleware or to configure the underlying `HttpClientHandler` of the `HttpClient`:

```
services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .ConfigurePrimaryHttpMessageHandler(() =>
    {
        var handler = new HttpClientHandler();
        handler.ClientCertificates.Add(LoadCertificate());
        return handler;
    });
```

For more information, see Make HTTP requests using IHttpClientFactory.

Configure Channel and Interceptors

gRPC-specific methods are available to:

- Configure a gRPC client's underlying channel.
- Add `Interceptor` instances that the client will use when making gRPC calls.

```
services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .AddInterceptor(() => new LoggingInterceptor())
    .ConfigureChannel(o =>
    {
        o.Credentials = new CustomCredentials();
    });
```

Deadline and cancellation propagation

gRPC clients created by the factory in a gRPC service can be configured with `EnableCallContextPropagation()` to automatically propagate the deadline and cancellation token to child calls. The `EnableCallContextPropagation()` extension method is available in the Grpc.AspNetCore.Server.ClientFactory NuGet package.

Call context propagation works by reading the deadline and cancellation token from the current gRPC request context and automatically propagating them to outgoing calls made by the gRPC client. Call context propagation is an excellent way of ensuring that complex, nested gRPC scenarios always propagate the deadline and cancellation.

```
services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .EnableCallContextPropagation();
```

By default, `EnableCallContextPropagation` raises an error if the client is used outside the context of a gRPC call. The error is designed to alert you that there isn't a call context to propagate. If you want to use the client outside of a call context, suppress the error when the client is configured with `SuppressContextNotFoundErrors`:

```
services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .EnableCallContextPropagation(o => o.SuppressContextNotFoundErrors = true);
```

For more information about deadlines and RPC cancellation, see RPC life cycle.

Reliable gRPC services with deadlines and cancellation

9/22/2020 • 3 minutes to read • Edit Online

By James Newton-King

Deadlines and cancellation are features used by gRPC clients to abort in-progress calls. This article discusses why deadlines and cancellation are important, and how to use them in .NET gRPC apps.

Deadlines

A deadline allows a gRPC client to specify how long it will wait for a call to complete. When a deadline is exceeded, the call is canceled. Setting a deadline is important because it provides an upper limit on how long a call can run for. It stops misbehaving services from running forever and exhausting server resources. Deadlines are a useful tool for building reliable apps and should be configured.

Deadline configuration:

- A deadline is configured using `CallOptions.Deadline` when a call is made.
- There is no default deadline value. gRPC calls aren't time limited unless a deadline is specified.
- A deadline is the UTC time of when the deadline is exceeded. For example, `DateTime.UtcNow.AddSeconds(5)` is a deadline of 5 seconds from now.
- If a past or current time is used then the call immediately exceeds the deadline.
- The deadline is sent with the gRPC call to the service and is independently tracked by both the client and the service. It is possible that a gRPC call completes on one machine, but by the time the response has returned to the client the deadline has been exceeded.

If a deadline is exceeded, the client and service have different behavior:

- The client immediately aborts the underlying HTTP request and throws a `DeadlineExceeded` error. The client app can choose to catch the error and display a timeout message to the user.
- On the server, the executing HTTP request is aborted and ServerCallContext.CancellationToken is raised. Although the HTTP request is aborted, the gRPC call continues to run on the server until the method completes. It's important that the cancellation token is passed to async methods so they are cancelled along with the call. For example, passing a cancellation token to async database queries and HTTP requests. Passing a cancellation token allows the canceled call to complete quickly on the server and free up resources for other calls.

Configure `CallOptions.Deadline` to set a deadline for a gRPC call:

```
var client = new Greet.GreeterClient(channel);

try
{
    var response = await client.SayHelloAsync(
        new HelloRequest { Name = "World" },
        deadline: DateTime.UtcNow.AddSeconds(5));

    // Greeting: Hello World
    Console.WriteLine("Greeting: " + response.Message);
}
catch (RpcException ex) when (ex.StatusCode == StatusCode.DeadlineExceeded)
{
    Console.WriteLine("Greeting timeout.");
}
```

Using `ServerCallContext.CancellationToken` in a gRPC service:

```
public override async Task<HelloReply> SayHello(HelloRequest request,
    ServerCallContext context)
{
    var user = await _databaseContext.GetUserAsync(request.Name,
        context.CancellationToken);

    return new HelloReply { Message = "Hello " + user.DisplayName };
}
```

Propagating deadlines

When a gRPC call is made from an executing gRPC service, the deadline should be propagated. For example:

1. Client app calls `FrontendService.GetUser` with a deadline.
2. `FrontendService` calls `UserService.GetUser`. The deadline specified by the client should be specified with the new gRPC call.
3. `UserService.GetUser` receives the deadline. It correctly times-out if the client app's deadline is exceeded.

The call context provides the deadline with `ServerCallContext.Deadline`:

```
public override async Task<UserResponse> GetUser(UserRequest request,
    ServerCallContext context)
{
    var client = new User.UserServiceClient(_channel);
    var response = await client.GetUserAsync(
        new UserRequest { Id = request.Id },
        deadline: context.Deadline);

    return response;
}
```

Manually propagating deadlines can be cumbersome. The deadline needs to be passed to every call, and it's easy to accidentally miss. An automatic solution is available with gRPC client factory. Specifying `EnableCallContextPropagation`:

- Automatically propagates the deadline and cancellation token to child calls.
- Is an excellent way of ensuring that complex, nested gRPC scenarios always propagate the deadline and cancellation.

```
services
    .AddGrpcClient<User.UserServiceClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .EnableCallContextPropagation();
```

For more information, see gRPC client factory integration in .NET Core.

Cancellation

Cancellation allows a gRPC client to cancel long running calls that are no longer needed. For example, a gRPC call that streams realtime updates is started when the user visits a page on a website. The stream should be canceled when the user navigates away from the page.

A gRPC call can be canceled in the client by passing a cancellation token with CallOptions.CancellationToken or calling `Dispose` on the call.

```
private AsyncServerStreamingCall<HelloReply> _call;

public void StartStream()
{
    _call = client.SayHellos(new HelloRequest { Name = "World" });

    // Read response in background task.
    _ = Task.Run(async () =>
    {
        await foreach (var response in _call.ResponseStream.ReadAllAsync())
        {
            Console.WriteLine("Greeting: " + response.Message);
        }
    });
}

public void StopStream()
{
    _call.Dispose();
}
```

gRPC services that can be cancelled should:

- Pass `ServerCallContext.CancellationToken` to async methods. Canceling async methods allows the call on the server to complete quickly.
- Propagate the cancellation token to child calls. Propagating the cancellation token ensures that child calls are canceled with their parent. gRPC client factory and `EnableCallContextPropagation()` automatically propagates the cancellation token.

gRPC services with ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

This document shows how to get started with gRPC services using ASP.NET Core.

> **WARNING**
> ASP.NET Core gRPC is not currently supported on Azure App Service or IIS. The HTTP/2 implementation of Http.Sys does not support HTTP response trailing headers which gRPC relies on. For more information, see this GitHub issue.

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core 3.0 SDK or later

Get started with gRPC service in ASP.NET Core

View or download sample code (how to download).

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

See Get started with gRPC services for detailed instructions on how to create a gRPC project.

Add gRPC services to an ASP.NET Core app

gRPC requires the Grpc.AspNetCore package.

Configure gRPC

In *Startup.cs*:

- gRPC is enabled with the `AddGrpc` method.
- Each gRPC service is added to the routing pipeline through the `MapGrpcService` method.

```
public class Startup
{
    // This method gets called by the runtime. Use this method to add services to the container.
    // For more information on how to configure your application, visit https://go.microsoft.com/fwlink/?
LinkID=398940
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddGrpc();
    }

    // This method gets called by the runtime. Use this method to configure the HTTP request pipeline.
    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        app.UseRouting();

        app.UseEndpoints(endpoints =>
        {
            // Communication with gRPC endpoints must be made through a gRPC client.
            // To learn how to create a client, visit: https://go.microsoft.com/fwlink/?linkid=2086909
            endpoints.MapGrpcService<GreeterService>();
        });
    }
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

ASP.NET Core middlewares and features share the routing pipeline, therefore an app can be configured to serve additional request handlers. The additional request handlers, such as MVC controllers, work in parallel with the configured gRPC services.

Configure Kestrel

Kestrel gRPC endpoints:

- Require HTTP/2.
- Should be secured with Transport Layer Security (TLS).

HTTP/2

gRPC requires HTTP/2. gRPC for ASP.NET Core validates HttpRequest.Protocol is `HTTP/2`.

Kestrel supports HTTP/2 on most modern operating systems. Kestrel endpoints are configured to support HTTP/1.1 and HTTP/2 connections by default.

TLS

Kestrel endpoints used for gRPC should be secured with TLS. In development, an endpoint secured with TLS is automatically created at `https://localhost:5001` when the ASP.NET Core development certificate is present. No configuration is required. An `https` prefix verifies the Kestrel endpoint is using TLS.

In production, TLS must be explicitly configured. In the following *appsettings.json* example, an HTTP/2 endpoint secured with TLS is provided:

```
{
  "Kestrel": {
    "Endpoints": {
      "HttpsInlineCertFile": {
        "Url": "https://localhost:5001",
        "Protocols": "Http2",
        "Certificate": {
          "Path": "<path to .pfx file>",
          "Password": "<certificate password>"
        }
      }
    }
  }
}
```

Alternatively, Kestrel endpoints can be configured in *Program.cs*:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.ConfigureKestrel(options =>
            {
                options.Listen(IPAddress.Any, 5001, listenOptions =>
                {
                    listenOptions.Protocols = HttpProtocols.Http2;
                    listenOptions.UseHttps("<path to .pfx file>",
                        "<certificate password>");
                });
            });
            webBuilder.UseStartup<Startup>();
        });
```

Protocol negotiation

TLS is used for more than securing communication. The TLS Application-Layer Protocol Negotiation (ALPN) handshake is used to negotiate the connection protocol between the client and the server when an endpoint supports multiple protocols. This negotiation determines whether the connection uses HTTP/1.1 or HTTP/2.

If an HTTP/2 endpoint is configured without TLS, the endpoint's ListenOptions.Protocols must be set to `HttpProtocols.Http2`. An endpoint with multiple protocols (for example, `HttpProtocols.Http1AndHttp2`) can't be used without TLS because there is no negotiation. All connections to the unsecured endpoint default to HTTP/1.1, and gRPC calls fail.

For more information on enabling HTTP/2 and TLS with Kestrel, see Kestrel endpoint configuration.

> **NOTE**
> macOS doesn't support ASP.NET Core gRPC with TLS. Additional configuration is required to successfully run gRPC services on macOS. For more information, see Unable to start ASP.NET Core gRPC app on macOS.

Integration with ASP.NET Core APIs

gRPC services have full access to the ASP.NET Core features such as Dependency Injection (DI) and Logging. For example, the service implementation can resolve a logger service from the DI container via the constructor:

```
public class GreeterService : Greeter.GreeterBase
{
    public GreeterService(ILogger<GreeterService> logger)
    {
    }
}
```

By default, the gRPC service implementation can resolve other DI services with any lifetime (Singleton, Scoped, or Transient).

Resolve HttpContext in gRPC methods

The gRPC API provides access to some HTTP/2 message data, such as the method, host, header, and trailers. Access is through the `ServerCallContext` argument passed to each gRPC method:

```
public class GreeterService : Greeter.GreeterBase
{
    public override Task<HelloReply> SayHello(
        HelloRequest request, ServerCallContext context)
    {
        return Task.FromResult(new HelloReply
        {
            Message = "Hello " + request.Name
        });
    }
}
```

`ServerCallContext` does not provide full access to `HttpContext` in all ASP.NET APIs. The `GetHttpContext` extension method provides full access to the `HttpContext` representing the underlying HTTP/2 message in ASP.NET APIs:

```
public class GreeterService : Greeter.GreeterBase
{
    public override Task<HelloReply> SayHello(
        HelloRequest request, ServerCallContext context)
    {
        var httpContext = context.GetHttpContext();
        var clientCertificate = httpContext.Connection.ClientCertificate;

        return Task.FromResult(new HelloReply
        {
            Message = "Hello " + request.Name + " from " + clientCertificate.Issuer
        });
    }
}
```

Use gRPC in browser apps

9/22/2020 • 5 minutes to read • Edit Online

By James Newton-King

Learn how to configure an existing ASP.NET Core gRPC service to be callable from browser apps, using the gRPC-Web protocol. gRPC-Web allows browser JavaScript and Blazor apps to call gRPC services. It's not possible to call an HTTP/2 gRPC service from a browser-based app. gRPC services hosted in ASP.NET Core can be configured to support gRPC-Web alongside HTTP/2 gRPC.

For instructions on adding a gRPC service to an existing ASP.NET Core app, see Add gRPC services to an ASP.NET Core app.

For instructions on creating a gRPC project, see Create a .NET Core gRPC client and server in ASP.NET Core.

gRPC-Web in ASP.NET Core vs. Envoy

There are two choices for how to add gRPC-Web to an ASP.NET Core app:

- Support gRPC-Web alongside gRPC HTTP/2 in ASP.NET Core. This option uses middleware provided by the `Grpc.AspNetCore.Web` package.
- Use the Envoy proxy's gRPC-Web support to translate gRPC-Web to gRPC HTTP/2. The translated call is then forwarded onto the ASP.NET Core app.

There are pros and cons to each approach. If an app's environment is already using Envoy as a proxy, it might make sense to also use Envoy to provide gRPC-Web support. For a basic solution for gRPC-Web that only requires ASP.NET Core, `Grpc.AspNetCore.Web` is a good choice.

Configure gRPC-Web in ASP.NET Core

gRPC services hosted in ASP.NET Core can be configured to support gRPC-Web alongside HTTP/2 gRPC. gRPC-Web does not require any changes to services. The only modification is startup configuration.

To enable gRPC-Web with an ASP.NET Core gRPC service:

- Add a reference to the Grpc.AspNetCore.Web package.
- Configure the app to use gRPC-Web by adding `UseGrpcWeb` and `EnableGrpcWeb` to *Startup.cs*:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc();
}

public void Configure(IApplicationBuilder app)
{
    app.UseRouting();

    app.UseGrpcWeb(); // Must be added between UseRouting and UseEndpoints

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapGrpcService<GreeterService>().EnableGrpcWeb();
    });
}
```

The preceding code:

- Adds the gRPC-Web middleware, `UseGrpcWeb`, after routing and before endpoints.
- Specifies the `endpoints.MapGrpcService<GreeterService>()` method supports gRPC-Web with `EnableGrpcWeb`.

Alternatively, the gRPC-Web middleware can be configured so all services support gRPC-Web by default and `EnableGrpcWeb` isn't required. Specify `new GrpcWebOptions { DefaultEnabled = true }` when the middleware is added.

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddGrpc();
    }

    public void Configure(IApplicationBuilder app)
    {
        app.UseRouting();

        app.UseGrpcWeb(new GrpcWebOptions { DefaultEnabled = true });

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapGrpcService<GreeterService>();
        });
    }
}
```

> **NOTE**
>
> There is a known issue that causes gRPC-Web to fail when hosted by Http.sys in .NET Core 3.x.
>
> A workaround to get gRPC-Web working on Http.sys is available here.

gRPC-Web and CORS

Browser security prevents a web page from making requests to a different domain than the one that served the web page. This restriction applies to making gRPC-Web calls with browser apps. For example, a browser app served by `https://www.contoso.com` is blocked from calling gRPC-Web services hosted on `https://services.contoso.com`. Cross Origin Resource Sharing (CORS) can be used to relax this restriction.

To allow a browser app to make cross-origin gRPC-Web calls, set up CORS in ASP.NET Core. Use the built-in CORS support, and expose gRPC-specific headers with WithExposedHeaders.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc();

    services.AddCors(o => o.AddPolicy("AllowAll", builder =>
    {
        builder.AllowAnyOrigin()
               .AllowAnyMethod()
               .AllowAnyHeader()
               .WithExposedHeaders("Grpc-Status", "Grpc-Message", "Grpc-Encoding", "Grpc-Accept-Encoding");
    }));
}

public void Configure(IApplicationBuilder app)
{
    app.UseRouting();

    app.UseGrpcWeb();
    app.UseCors();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapGrpcService<GreeterService>().EnableGrpcWeb()
                                                   .RequireCors("AllowAll");
    });
}
```

The preceding code:

- Calls `AddCors` to add CORS services and configures a CORS policy that exposes gRPC-specific headers.
- Calls `UseCors` to add the CORS middleware after routing and before endpoints.
- Specifies the `endpoints.MapGrpcService<GreeterService>()` method supports CORS with `RequiresCors`.

gRPC-Web and streaming

Traditional gRPC over HTTP/2 supports streaming in all directions. gRPC-Web offers limited support for streaming:

- gRPC-Web browser clients don't support calling client streaming and bidirectional streaming methods.
- ASP.NET Core gRPC services hosted on Azure App Service and IIS don't support bidirectional streaming.

When using gRPC-Web, we only recommend the use of unary methods and server streaming methods.

Call gRPC-Web from the browser

Browser apps can use gRPC-Web to call gRPC services. There are some requirements and limitations when calling gRPC services with gRPC-Web from the browser:

- The server must have been configured to support gRPC-Web.
- Client streaming and bidirectional streaming calls aren't supported. Server streaming is supported.
- Calling gRPC services on a different domain requires CORS to be configured on the server.

JavaScript gRPC-Web client

There is a JavaScript gRPC-Web client. For instructions on how to use gRPC-Web from JavaScript, see write JavaScript client code with gRPC-Web.

Configure gRPC-Web with the .NET gRPC client

The .NET gRPC client can be configured to make gRPC-Web calls. This is useful for Blazor WebAssembly apps, which are hosted in the browser and have the same HTTP limitations of JavaScript code. Calling gRPC-Web with a .NET client is the same as HTTP/2 gRPC. The only modification is how the channel is created.

To use gRPC-Web:

- Add a reference to the Grpc.Net.Client.Web package.
- Ensure the reference to Grpc.Net.Client package is 2.29.0 or greater.
- Configure the channel to use the `GrpcWebHandler`:

```
var channel = GrpcChannel.ForAddress("https://localhost:5001", new GrpcChannelOptions
    {
        HttpHandler = new GrpcWebHandler(new HttpClientHandler())
    });

var client = new Greeter.GreeterClient(channel);
var response = await client.SayHelloAsync(new HelloRequest { Name = ".NET" });
```

The preceding code:

- Configures a channel to use gRPC-Web.
- Creates a client and makes a call using the channel.

`GrpcWebHandler` has the following configuration options:

- **InnerHandler**: The underlying HttpMessageHandler that makes the gRPC HTTP request, for example, `HttpClientHandler`.
- **GrpcWebMode**: An enumeration type that specifies whether the gRPC HTTP request `Content-Type` is `application/grpc-web` or `application/grpc-web-text`.
  - `GrpcWebMode.GrpcWeb` configures content to be sent without encoding. Default value.
  - `GrpcWebMode.GrpcWebText` configures content to be base64 encoded. Required for server streaming calls in browsers.
- **HttpVersion**: HTTP protocol `Version` used to set HttpRequestMessage.Version on the underlying gRPC HTTP request. gRPC-Web doesn't require a specific version and doesn't override the default unless specified.

> **IMPORTANT**
> Generated gRPC clients have sync and async methods for calling unary methods. For example, `SayHello` is sync and `SayHelloAsync` is async. Calling a sync method in a Blazor WebAssembly app will cause the app to become unresponsive. Async methods must always be used in Blazor WebAssembly.

Use gRPC client factory with gRPC-Web

A gRPC-Web compatible .NET client can be created using gRPC's integration with HttpClientFactory.

To use gRPC-Web with client factory:

- Add package references to the project file for the following packages:
  - Grpc.Net.Client.Web
  - Grpc.Net.ClientFactory
- Register a gRPC client with dependency injection (DI) using the generic `AddGrpcClient` extension method. In a Blazor WebAssembly app, services are registered with DI in `Program.cs`.
- Configure `GrpcWebHandler` using the ConfigurePrimaryHttpMessageHandler extension method.

```
builder.Services
    .AddGrpcClient<Greet.GreeterClient>((services, options) =>
    {
        options.Address = new Uri("https://localhost:5001");
    })
    .ConfigurePrimaryHttpMessageHandler(
        () => new GrpcWebHandler(GrpcWebMode.GrpcWebText, new HttpClientHandler()));
```

For more information, see gRPC client factory integration in .NET Core.

gRPC for .NET configuration

9/22/2020 • 4 minutes to read • Edit Online

Configure services options

gRPC services are configured with `AddGrpc` in *Startup.cs*. The following table describes options for configuring gRPC services:

OPTION	DEFAULT VALUE	DESCRIPTION
MaxSendMessageSize	`null`	The maximum message size in bytes that can be sent from the server. Attempting to send a message that exceeds the configured maximum message size results in an exception. When set to `null`, the message size is unlimited.
MaxReceiveMessageSize	4 MB	The maximum message size in bytes that can be received by the server. If the server receives a message that exceeds this limit, it throws an exception. Increasing this value allows the server to receive larger messages, but can negatively impact memory consumption. When set to `null`, the message size is unlimited.
EnableDetailedErrors	`false`	If `true`, detailed exception messages are returned to clients when an exception is thrown in a service method. The default is `false`. Setting `EnableDetailedErrors` to `true` can leak sensitive information.
CompressionProviders	gzip	A collection of compression providers used to compress and decompress messages. Custom compression providers can be created and added to the collection. The default configured providers support **gzip** compression.
ResponseCompressionAlgorithm	`null`	The compression algorithm used to compress messages sent from the server. The algorithm must match a compression provider in `CompressionProviders`. For the algorithm to compress a response, the client must indicate it supports the algorithm by sending it in the **grpc-accept-encoding** header.
ResponseCompressionLevel	`null`	The compress level used to compress messages sent from the server.

OPTION	DEFAULT VALUE	DESCRIPTION
Interceptors	None	A collection of interceptors that are run with each gRPC call. Interceptors are run in the order they are registered. Globally configured interceptors are run before interceptors configured for a single service. For more information about gRPC interceptors, see gRPC Interceptors vs. Middleware.
IgnoreUnknownServices	`false`	If `true`, calls to unknown services and methods don't return an **UNIMPLEMENTED** status, and the request passes to the next registered middleware in ASP.NET Core.

Options can be configured for all services by providing an options delegate to the `AddGrpc` call in `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc(options =>
    {
        options.EnableDetailedErrors = true;
        options.MaxReceiveMessageSize = 2 * 1024 * 1024; // 2 MB
        options.MaxSendMessageSize = 5 * 1024 * 1024; // 5 MB
    });
}
```

Options for a single service override the global options provided in `AddGrpc` and can be configured using `AddServiceOptions<TService>`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc().AddServiceOptions<MyService>(options =>
    {
        options.MaxReceiveMessageSize = 2 * 1024 * 1024; // 2 MB
        options.MaxSendMessageSize = 5 * 1024 * 1024; // 5 MB
    });
}
```

Configure client options

gRPC client configuration is set on `GrpcChannelOptions`. The following table describes options for configuring gRPC channels:

OPTION	DEFAULT VALUE	DESCRIPTION

OPTION	DEFAULT VALUE	DESCRIPTION
HttpHandler	New instance	The `HttpMessageHandler` used to make gRPC calls. A client can be set to configure a custom `HttpClientHandler` or add additional handlers to the HTTP pipeline for gRPC calls. If no `HttpMessageHandler` is specified, a new `HttpClientHandler` instance is created for the channel with automatic disposal.
HttpClient	`null`	The `HttpClient` used to make gRPC calls. This setting is an alternative to `HttpHandler`.
DisposeHttpClient	`false`	If set to `true` and an `HttpMessageHandler` or `HttpClient` is specified, then either the `HttpHandler` or `HttpClient`, respectively, is disposed when the `GrpcChannel` is disposed.
LoggerFactory	`null`	The `LoggerFactory` used by the client to log information about gRPC calls. A `LoggerFactory` instance can be resolved from dependency injection or created using `LoggerFactory.Create`. For examples of configuring logging, see Logging and diagnostics in gRPC on .NET.
MaxSendMessageSize	`null`	The maximum message size in bytes that can be sent from the client. Attempting to send a message that exceeds the configured maximum message size results in an exception. When set to `null`, the message size is unlimited.
MaxReceiveMessageSize	4 MB	The maximum message size in bytes that can be received by the client. If the client receives a message that exceeds this limit, it throws an exception. Increasing this value allows the client to receive larger messages, but can negatively impact memory consumption. When set to `null`, the message size is unlimited.
Credentials	`null`	A `ChannelCredentials` instance. Credentials are used to add authentication metadata to gRPC calls.

OPTION	DEFAULT VALUE	DESCRIPTION
CompressionProviders	gzip	A collection of compression providers used to compress and decompress messages. Custom compression providers can be created and added to the collection. The default configured providers support **gzip** compression.

The following code:

- Sets the maximum send and receive message size on the channel.
- Creates a client.

```
static async Task Main(string[] args)
{
    var channel = GrpcChannel.ForAddress("https://localhost:5001", new GrpcChannelOptions
    {
        MaxReceiveMessageSize = 5 * 1024 * 1024, // 5 MB
        MaxSendMessageSize = 2 * 1024 * 1024 // 2 MB
    });
    var client = new Greeter.GreeterClient(channel);

    var reply = await client.SayHelloAsync(
                      new HelloRequest { Name = "GreeterClient" });
    Console.WriteLine("Greeting: " + reply.Message);
}
```

WARNING

ASP.NET Core gRPC is not currently supported on Azure App Service or IIS. The HTTP/2 implementation of Http.Sys does not support HTTP response trailing headers which gRPC relies on. For more information, see this GitHub issue.

Authentication and authorization in gRPC for ASP.NET Core

9/22/2020 • 4 minutes to read • Edit Online

By James Newton-King

View or download sample code (how to download)

Authenticate users calling a gRPC service

gRPC can be used with ASP.NET Core authentication to associate a user with each call.

The following is an example of `Startup.Configure` which uses gRPC and ASP.NET Core authentication:

```
public void Configure(IApplicationBuilder app)
{
    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapGrpcService<GreeterService>();
    });
}
```

> **NOTE**
> The order in which you register the ASP.NET Core authentication middleware matters. Always call `UseAuthentication` and `UseAuthorization` after `UseRouting` and before `UseEndpoints`.

The authentication mechanism your app uses during a call needs to be configured. Authentication configuration is added in `Startup.ConfigureServices` and will be different depending upon the authentication mechanism your app uses. For examples of how to secure ASP.NET Core apps, see Authentication samples.

Once authentication has been setup, the user can be accessed in a gRPC service methods via the `ServerCallContext`.

```
public override Task<BuyTicketsResponse> BuyTickets(
    BuyTicketsRequest request, ServerCallContext context)
{
    var user = context.GetHttpContext().User;

    // ... access data from ClaimsPrincipal ...
}
```

Bearer token authentication

The client can provide an access token for authentication. The server validates the token and uses it to identify the user.

On the server, bearer token authentication is configured using the JWT Bearer middleware.

In the .NET gRPC client, the token can be sent with calls as a header:

```
public bool DoAuthenticatedCall(
    Ticketer.TicketerClient client, string token)
{
    var headers = new Metadata();
    headers.Add("Authorization", $"Bearer {token}");

    var request = new BuyTicketsRequest { Count = 1 };
    var response = await client.BuyTicketsAsync(request, headers);

    return response.Success;
}
```

Configuring `ChannelCredentials` on a channel is an alternative way to send the token to the service with gRPC calls. The credential is run each time a gRPC call is made, which avoids the need to write code in multiple places to pass the token yourself.

The credential in the following example configures the channel to send the token with every gRPC call:

```
private static GrpcChannel CreateAuthenticatedChannel(string address)
{
    var credentials = CallCredentials.FromInterceptor((context, metadata) =>
    {
        if (!string.IsNullOrEmpty(_token))
        {
            metadata.Add("Authorization", $"Bearer {_token}");
        }
        return Task.CompletedTask;
    });

    // SslCredentials is used here because this channel is using TLS.
    // CallCredentials can't be used with ChannelCredentials.Insecure on non-TLS channels.
    var channel = GrpcChannel.ForAddress(address, new GrpcChannelOptions
    {
        Credentials = ChannelCredentials.Create(new SslCredentials(), credentials)
    });
    return channel;
}
```

Client certificate authentication

A client could alternatively provide a client certificate for authentication. Certificate authentication happens at the TLS level, long before it ever gets to ASP.NET Core. When the request enters ASP.NET Core, the client certificate authentication package allows you to resolve the certificate to a `ClaimsPrincipal`.

> **NOTE**
>
> Configure the server to accept client certificates. For information on accepting client certificates in Kestrel, IIS, and Azure, see Configure certificate authentication in ASP.NET Core.

In the .NET gRPC client, the client certificate is added to `HttpClientHandler` that is then used to create the gRPC client:

```
public Ticketer.TicketerClient CreateClientWithCert(
    string baseAddress,
    X509Certificate2 certificate)
{
    // Add client cert to the handler
    var handler = new HttpClientHandler();
    handler.ClientCertificates.Add(certificate);

    // Create the gRPC channel
    var channel = GrpcChannel.ForAddress(baseAddress, new GrpcChannelOptions
    {
        HttpHandler = handler
    });

    return new Ticketer.TicketerClient(channel);
}
```

Other authentication mechanisms

Many ASP.NET Core supported authentication mechanisms work with gRPC:

- Azure Active Directory
- Client Certificate
- IdentityServer
- JWT Token
- OAuth 2.0
- OpenID Connect
- WS-Federation

For more information on configuring authentication on the server, see ASP.NET Core authentication.

Configuring the gRPC client to use authentication will depend on the authentication mechanism you are using. The previous bearer token and client certificate examples show a couple of ways the gRPC client can be configured to send authentication metadata with gRPC calls:

- Strongly typed gRPC clients use `HttpClient` internally. Authentication can be configured on HttpClientHandler, or by adding custom HttpMessageHandler instances to the `HttpClient`.
- Each gRPC call has an optional `CallOptions` argument. Custom headers can be sent using the option's headers collection.

> **NOTE**
> Windows Authentication (NTLM/Kerberos/Negotiate) can't be used with gRPC. gRPC requires HTTP/2, and HTTP/2 doesn't support Windows Authentication.

Authorize users to access services and service methods

By default, all methods in a service can be called by unauthenticated users. To require authentication, apply the `[Authorize]` attribute to the service:

```
[Authorize]
public class TicketerService : Ticketer.TicketerBase
{
}
```

You can use the constructor arguments and properties of the `[Authorize]` attribute to restrict access to only users

matching specific authorization policies. For example, if you have a custom authorization policy called `MyAuthorizationPolicy`, ensure that only users matching that policy can access the service using the following code:

```
[Authorize("MyAuthorizationPolicy")]
public class TicketerService : Ticketer.TicketerBase
{
}
```

Individual service methods can have the `[Authorize]` attribute applied as well. If the current user doesn't match the policies applied to **both** the method and the class, an error is returned to the caller:

```
[Authorize]
public class TicketerService : Ticketer.TicketerBase
{
    public override Task<AvailableTicketsResponse> GetAvailableTickets(
        Empty request, ServerCallContext context)
    {
        // ... buy tickets for the current user ...
    }

    [Authorize("Administrators")]
    public override Task<BuyTicketsResponse> RefundTickets(
        BuyTicketsRequest request, ServerCallContext context)
    {
        // ... refund tickets (something only Administrators can do) ..
    }
}
```

Logging and diagnostics in gRPC on .NET

9/22/2020 • 7 minutes to read • Edit Online

By James Newton-King

This article provides guidance for gathering diagnostics from a gRPC app to help troubleshoot issues. Topics covered include:

- **Logging** - Structured logs written to .NET Core logging. ILogger is used by app frameworks to write logs, and by users for their own logging in an app.
- **Tracing** - Events related to an operation written using `DiaganosticSource` and `Activity`. Traces from diagnostic source are commonly used to collect app telemetry by libraries such as Application Insights and OpenTelemetry.
- **Metrics** - Representation of data measures over intervals of time, for example, requests per second. Metrics are emitted using `EventCounter` and can be observed using dotnet-counters command line tool or with Application Insights.

Logging

gRPC services and the gRPC client write logs using .NET Core logging. Logs are a good place to start when you need to debug unexpected behavior in your apps.

gRPC services logging

> **WARNING**
> Server-side logs may contain sensitive information from your app. **Never** post raw logs from production apps to public forums like GitHub.

Since gRPC services are hosted on ASP.NET Core, it uses the ASP.NET Core logging system. In the default configuration, gRPC logs very little information, but this can configured. See the documentation on ASP.NET Core logging for details on configuring ASP.NET Core logging.

gRPC adds logs under the `Grpc` category. To enable detailed logs from gRPC, configure the `Grpc` prefixes to the `Debug` level in your *appsettings.json* file by adding the following items to the `LogLevel` sub-section in `Logging`:

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Debug",
      "System": "Information",
      "Microsoft": "Information",
      "Grpc": "Debug"
    }
  }
}
```

You can also configure this in *Startup.cs* with `ConfigureLogging`:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureLogging(logging =>
        {
            logging.AddFilter("Grpc", LogLevel.Debug);
        })
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

If you aren't using JSON-based configuration, set the following configuration value in your configuration system:

- `Logging:LogLevel:Grpc` = `Debug`

Check the documentation for your configuration system to determine how to specify nested configuration values. For example, when using environment variables, two `_` characters are used instead of the `:` (for example, `Logging__LogLevel__Grpc`).

We recommend using the `Debug` level when gathering more detailed diagnostics for your app. The `Trace` level produces very low-level diagnostics and is rarely needed to diagnose issues in your app.

Sample logging output

Here is an example of console output at the `Debug` level of a gRPC service:

```
info: Microsoft.AspNetCore.Hosting.Diagnostics[1]
      Request starting HTTP/2 POST https://localhost:5001/Greet.Greeter/SayHello application/grpc
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[0]
      Executing endpoint 'gRPC - /Greet.Greeter/SayHello'
dbug: Grpc.AspNetCore.Server.ServerCallHandler[1]
      Reading message.
info: GrpcService.GreeterService[0]
      Hello World
dbug: Grpc.AspNetCore.Server.ServerCallHandler[6]
      Sending message.
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[1]
      Executed endpoint 'gRPC - /Greet.Greeter/SayHello'
info: Microsoft.AspNetCore.Hosting.Diagnostics[2]
      Request finished in 1.4113ms 200 application/grpc
```

Access server-side logs

How you access server-side logs depends on the environment in which you're running.

As a console app

If you're running in a console app, the Console logger should be enabled by default. gRPC logs will appear in the console.

Other environments

If the app is deployed to another environment (for example, Docker, Kubernetes, or Windows Service), see Logging in .NET Core and ASP.NET Core for more information on how to configure logging providers suitable for the environment.

gRPC client logging

> **WARNING**
>
> Client-side logs may contain sensitive information from your app. **Never** post raw logs from production apps to public forums like GitHub.

To get logs from the .NET client, you can set the `GrpcChannelOptions.LoggerFactory` property when the client's channel is created. If you are calling a gRPC service from an ASP.NET Core app then the logger factory can be resolved from dependency injection (DI):

```
[ApiController]
[Route("[controller]")]
public class GreetingController : ControllerBase
{
    private ILoggerFactory _loggerFactory;

    public GreetingController(ILoggerFactory loggerFactory)
    {
        _loggerFactory = loggerFactory;
    }

    [HttpGet]
    public async Task<ActionResult<string>> Get(string name)
    {
        var channel = GrpcChannel.ForAddress("https://localhost:5001",
            new GrpcChannelOptions { LoggerFactory = _loggerFactory });
        var client = new Greeter.GreeterClient(channel);

        var reply = await client.SayHelloAsync(new HelloRequest { Name = name });
        return Ok(reply.Message);
    }
}
```

An alternative way to enable client logging is to use the gRPC client factory to create the client. A gRPC client registered with the client factory and resolved from DI will automatically use the app's configured logging.

If your app isn't using DI then you can create a new `ILoggerFactory` instance with LoggerFactory.Create. To access this method add the Microsoft.Extensions.Logging package to your app.

```
var loggerFactory = LoggerFactory.Create(logging =>
{
    logging.AddConsole();
    logging.SetMinimumLevel(LogLevel.Debug);
});

var channel = GrpcChannel.ForAddress("https://localhost:5001",
    new GrpcChannelOptions { LoggerFactory = loggerFactory });

var client = Greeter.GreeterClient(channel);
```

gRPC client log scopes

The gRPC client adds a logging scope to logs made during a gRPC call. The scope has metadata related to the gRPC call:

- **GrpcMethodType** - The gRPC method type. Possible values are names from `Grpc.Core.MethodType` enum, e.g. Unary
- **GrpcUri** - The relative URI of the gRPC method, e.g. /greet.Greeter/SayHellos

Sample logging output

Here is an example of console output at the `Debug` level of a gRPC client:

```
dbug: Grpc.Net.Client.Internal.GrpcCall[1]
      Starting gRPC call. Method type: 'Unary', URI: 'https://localhost:5001/Greet.Greeter/SayHello'.
dbug: Grpc.Net.Client.Internal.GrpcCall[6]
      Sending message.
dbug: Grpc.Net.Client.Internal.GrpcCall[1]
      Reading message.
dbug: Grpc.Net.Client.Internal.GrpcCall[4]
      Finished gRPC call.
```

Tracing

gRPC services and the gRPC client provide information about gRPC calls using DiagnosticSource and Activity.

- .NET gRPC uses an activity to represent a gRPC call.
- Tracing events are written to the diagnostic source at the start and stop of the gRPC call activity.
- Tracing doesn't capture information about when messages are sent over the lifetime of gRPC streaming calls.

gRPC service tracing

gRPC services are hosted on ASP.NET Core which reports events about incoming HTTP requests. gRPC specific metadata is added to the existing HTTP request diagnostics that ASP.NET Core provides.

- Diagnostic source name is `Microsoft.AspNetCore`.
- Activity name is `Microsoft.AspNetCore.Hosting.HttpRequestIn`.
  - Name of the gRPC method invoked by the gRPC call is added as a tag with the name `grpc.method`.
  - Status code of the gRPC call when it is complete is added as a tag with the name `grpc.status_code`.

gRPC client tracing

The .NET gRPC client uses `HttpClient` to make gRPC calls. Although `HttpClient` writes diagnostic events, the .NET gRPC client provides a custom diagnostic source, activity and events so that complete information about a gRPC call can be collected.

- Diagnostic source name is `Grpc.Net.Client`.
- Activity name is `Grpc.Net.Client.GrpcOut`.
  - Name of the gRPC method invoked by the gRPC call is added as a tag with the name `grpc.method`.
  - Status code of the gRPC call when it is complete is added as a tag with the name `grpc.status_code`.

Collecting tracing

The easiest way to use `DiagnosticSource` is to configure a telemetry library such as Application Insights or OpenTelemetry in your app. The library will process information about gRPC calls along-side other app telemetry.

Tracing can be viewed in a managed service like Application Insights, or you can choose to run your own distributed tracing system. OpenTelemetry supports exporting tracing data to Jaeger and Zipkin.

`DiagnosticSource` can consume tracing events in code using `DiagnosticListener`. For information about listening to a diagnostic source with code, see the DiagnosticSource user's guide.

> **NOTE**
>
> Telemetry libraries do not capture gRPC specific `Grpc.Net.Client.GrpcOut` telemetry currently. Work to improve telemetry libraries capturing this tracing is ongoing.

Metrics

Metrics is a representation of data measures over intervals of time, for example, requests per second. Metrics data

allows observation of the state of an app at a high-level. .NET gRPC metrics are emitted using `EventCounter`.

gRPC service metrics

gRPC server metrics are reported on `Grpc.AspNetCore.Server` event source.

NAME	DESCRIPTION
`total-calls`	Total Calls
`current-calls`	Current Calls
`calls-failed`	Total Calls Failed
`calls-deadline-exceeded`	Total Calls Deadline Exceeded
`messages-sent`	Total Messages Sent
`messages-received`	Total Messages Received
`calls-unimplemented`	Total Calls Unimplemented

ASP.NET Core also provides its own metrics on `Microsoft.AspNetCore.Hosting` event source.

gRPC client metrics

gRPC client metrics are reported on `Grpc.Net.Client` event source.

NAME	DESCRIPTION
`total-calls`	Total Calls
`current-calls`	Current Calls
`calls-failed`	Total Calls Failed
`calls-deadline-exceeded`	Total Calls Deadline Exceeded
`messages-sent`	Total Messages Sent
`messages-received`	Total Messages Received

Observe metrics

dotnet-counters is a performance monitoring tool for ad-hoc health monitoring and first-level performance investigation. Monitor a .NET app with either `Grpc.AspNetCore.Server` or `Grpc.Net.Client` as the provider name.

```
> dotnet-counters monitor --process-id 1902 Grpc.AspNetCore.Server

Press p to pause, r to resume, q to quit.
    Status: Running
[Grpc.AspNetCore.Server]
    Total Calls                                 300
    Current Calls                               5
    Total Calls Failed                          0
    Total Calls Deadline Exceeded               0
    Total Messages Sent                         295
    Total Messages Received                     300
    Total Calls Unimplemented                   0
```

Another way to observe gRPC metrics is to capture counter data using Application Insights's Microsoft.ApplicationInsights.EventCounterCollector package. Once setup, Application Insights collects common .NET counters at runtime. gRPC's counters are not collected by default, but App Insights can be customized to include additional counters.

Specify the gRPC counters for Application Insight to collect in *Startup.cs*:

```
    using Microsoft.ApplicationInsights.Extensibility.EventCounterCollector;

    public void ConfigureServices(IServiceCollection services)
    {
        //... other code...

        services.ConfigureTelemetryModule<EventCounterCollectionModule>(
            (module, o) =>
            {
                // Configure App Insights to collect gRPC counters gRPC services hosted in an ASP.NET Core app
                module.Counters.Add(new EventCounterCollectionRequest("Grpc.AspNetCore.Server", "current-
calls"));
                module.Counters.Add(new EventCounterCollectionRequest("Grpc.AspNetCore.Server", "total-
calls"));
                module.Counters.Add(new EventCounterCollectionRequest("Grpc.AspNetCore.Server", "calls-
failed"));
            }
        );
    }
```

Security considerations in gRPC for ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

By James Newton-King

This article provides information on securing gRPC with .NET Core.

Transport security

gRPC messages are sent and received using HTTP/2. We recommend:

- Transport Layer Security (TLS) be used to secure messages in production gRPC apps.
- gRPC services should only listen and respond over secured ports.

TLS is configured in Kestrel. For more information on configuring Kestrel endpoints, see Kestrel endpoint configuration.

Exceptions

Exception messages are generally considered sensitive data that shouldn't be revealed to a client. By default, gRPC doesn't send the details of an exception thrown by a gRPC service to the client. Instead, the client receives a generic message indicating an error occurred. Exception message delivery to the client can be overridden (for example, in development or test) with EnableDetailedErrors. Exception messages shouldn't be exposed to the client in production apps.

Message size limits

Incoming messages to gRPC clients and services are loaded into memory. Message size limits are a mechanism to help prevent gRPC from consuming excessive resources.

gRPC uses per-message size limits to manage incoming and outgoing messages. By default, gRPC limits incoming messages to 4 MB. There is no limit on outgoing messages.

On the server, gRPC message limits can be configured for all services in an app with `AddGrpc`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc(options =>
    {
        options.MaxReceiveMessageSize = 1 * 1024 * 1024; // 1 MB
        options.MaxSendMessageSize = 1 * 1024 * 1024; // 1 MB
    });
}
```

Limits can also be configured for an individual service using `AddServiceOptions<TService>`. For more information on configuring message size limits, see gRPC configuration.

Client certificate validation

Client certificates are initially validated when the connection is established. By default, Kestrel doesn't perform additional validation of a connection's client certificate.

We recommend that gRPC services secured by client certificates use the

Microsoft.AspNetCore.Authentication.Certificate package. ASP.NET Core certification authentication will perform additional validation on a client certificate, including:

- Certificate has a valid extended key use (EKU)
- Is within its validity period
- Check certificate revocation

Performance best practices with gRPC

9/22/2020 • 6 minutes to read • Edit Online

By James Newton-King

gRPC is designed for high-performance services. This document explains how to get the best performance possible from gRPC.

Reuse gRPC channels

A gRPC channel should be reused when making gRPC calls. Reusing a channel allows calls to be multiplexed through an existing HTTP/2 connection.

If a new channel is created for each gRPC call then the amount of time it takes to complete can increase significantly. Each call will require multiple network round-trips between the client and the server to create a new HTTP/2 connection:

1. Opening a socket
2. Establishing TCP connection
3. Negotiating TLS
4. Starting HTTP/2 connection
5. Making the gRPC call

Channels are safe to share and reuse between gRPC calls:

- gRPC clients are created with channels. gRPC clients are lightweight objects and don't need to be cached or reused.
- Multiple gRPC clients can be created from a channel, including different types of clients.
- A channel and clients created from the channel can safely be used by multiple threads.
- Clients created from the channel can make multiple simultaneous calls.

gRPC client factory offers a centralized way to configure channels. It automatically reuses underlying channels. For more information, see gRPC client factory integration in .NET Core.

Connection concurrency

HTTP/2 connections typically have a limit on the number of maximum concurrent streams (active HTTP requests) on a connection at one time. By default, most servers set this limit to 100 concurrent streams.

A gRPC channel uses a single HTTP/2 connection, and concurrent calls are multiplexed on that connection. When the number of active calls reaches the connection stream limit, additional calls are queued in the client. Queued calls wait for active calls to complete before they are sent. Applications with high load, or long running streaming gRPC calls, could see performance issues caused by calls queuing because of this limit.

.NET 5 introduces the `SocketsHttpHandler.EnableMultipleHttp2Connections` property. When set to `true`, additional HTTP/2 connections are created by a channel when the concurrent stream limit is reached. When a `GrpcChannel` is created its internal `SocketsHttpHandler` is automatically configured to create additional HTTP/2 connections. If an app configures its own handler, consider setting `EnableMultipleHttp2Connections` to `true`:

```
var channel = GrpcChannel.ForAddress("https://localhost", new GrpcChannelOptions
{
    HttpHandler = new SocketsHttpHandler
    {
        EnableMultipleHttp2Connections = true,

        // ...configure other handler settings
    }
});
```

There are a couple of workarounds for .NET Core 3.1 apps:

- Create separate gRPC channels for areas of the app with high load. For example, the `Logger` gRPC service might have a high load. Use a separate channel to create the `LoggerClient` in the app.
- Use a pool of gRPC channels, for example, create a list of gRPC channels. `Random` is used to pick a channel from the list each time a gRPC channel is needed. Using `Random` randomly distributes calls over multiple connections.

> **IMPORTANT**
>
> Increasing the maximum concurrent stream limit on the server is another way to solve this problem. In Kestrel this is configured with MaxStreamsPerConnection.
>
> Increasing the maximum concurrent stream limit is not recommended. Too many streams on a single HTTP/2 connection introduces new performance issues:
>
> - Thread contention between streams trying to write to the connection.
> - Connection packet loss causes all calls to be blocked at the TCP layer.

Load balancing

Some load balancers don't work effectively with gRPC. L4 (transport) load balancers operate at a connection level, by distributing TCP connections across endpoints. This approach works well for loading balancing API calls made with HTTP/1.1. Concurrent calls made with HTTP/1.1 are sent on different connections, allowing calls to be load balanced across endpoints.

Because L4 load balancers operate at a connection level, they don't work well with gRPC. gRPC uses HTTP/2, which multiplexes multiple calls on a single TCP connection. All gRPC calls over that connection go to one endpoint.

There are two options to effectively load balance gRPC:

- Client-side load balancing
- L7 (application) proxy load balancing

> **NOTE**
>
> Only gRPC calls can be load balanced between endpoints. Once a streaming gRPC call is established, all messages sent over the stream go to one endpoint.

Client-side load balancing

With client-side load balancing, the client knows about endpoints. For each gRPC call it selects a different endpoint to send the call to. Client-side load balancing is a good choice when latency is important. There is no proxy between the client and the service so the call is sent to the service directly. The downside to client-side load balancing is that each client must keep track of available endpoints it should use.

Lookaside client load balancing is a technique where load balancing state is stored in a central location. Clients

periodically query the central location for information to use when making load balancing decisions.

`Grpc.Net.Client` currently doesn't support client-side load balancing. Grpc.Core is a good choice if client-side load balancing is required in .NET.

Proxy load balancing

An L7 (application) proxy works at a higher level than an L4 (transport) proxy. L7 proxies understand HTTP/2, and are able to distribute gRPC calls multiplexed to the proxy on one HTTP/2 connection across multiple endpoints. Using a proxy is simpler than client-side load balancing, but can add extra latency to gRPC calls.

There are many L7 proxies available. Some options are:

- Envoy - A popular open source proxy.
- Linkerd - Service mesh for Kubernetes.
- YARP: A Reverse Proxy - A preview open source proxy written in .NET.

Inter-process communication

gRPC calls between a client and service are usually sent over TCP sockets. TCP is great for communicating across a network, but inter-process communication (IPC) is more efficient when the client and service are on the same machine.

Consider using a transport like Unix domain sockets or named pipes for gRPC calls between processes on the same machine. For more information, see Inter-process communication with gRPC.

Keep alive pings

Keep alive pings can be used to keep HTTP/2 connections alive during periods of inactivity. Having an existing HTTP/2 connection ready when an app resumes activity allows for the initial gRPC calls to be made quickly, without a delay caused by the connection being reestablished.

Keep alive pings are configured on SocketsHttpHandler:

```
var handler = new SocketsHttpHandler
{
    PooledConnectionIdleTimeout = Timeout.InfiniteTimeSpan,
    KeepAlivePingDelay = TimeSpan.FromSeconds(60),
    KeepAlivePingTimeout = TimeSpan.FromSeconds(30),
    EnableMultipleHttp2Connections = true
};

var channel = GrpcChannel.ForAddress("https://localhost:5001", new GrpcChannelOptions
{
    HttpHandler = handler
});
```

The preceding code configures a channel that sends a keep alive ping to the server every 60 seconds during periods of inactivity. The ping ensures the server and any proxies in use won't close the connection because of inactivity.

Streaming

gRPC bidirectional streaming can be used to replace unary gRPC calls in high-performance scenarios. Once a bidirectional stream has started, streaming messages back and forth is faster than sending messages with multiple unary gRPC calls. Streamed messages are sent as data on an existing HTTP/2 request and eliminates the overhead of creating a new HTTP/2 request for each unary call.

Example service:

```
public override async Task SayHello(IAsyncStreamReader<HelloRequest> requestStream,
    IServerStreamWriter<HelloReply> responseStream, ServerCallContext context)
{
    await foreach (var request in requestStream.ReadAllAsync())
    {
        var helloReply = new HelloReply { Message = "Hello " + request.Name };

        await responseStream.WriteAsync(helloReply);
    }
}
```

Example client:

```
var client = new Greet.GreeterClient(channel);
using var call = client.SayHello();

Console.WriteLine("Type a name then press enter.");
while (true)
{
    var text = Console.ReadLine();

    // Send and receive messages over the stream
    await call.RequestStream.WriteAsync(new HelloRequest { Name = text });
    await call.ResponseStream.MoveNext();

    Console.WriteLine($"Greeting: {call.ResponseStream.Current.Message}");
}
```

Replacing unary calls with bidirectional streaming for performance reasons is an advanced technique and is not appropriate in many situations.

Using streaming calls is a good choice when:

1. High throughput or low latency is required.
2. gRPC and HTTP/2 are identified as a performance bottleneck.
3. A worker in the client is sending or receiving regular messages with a gRPC service.

Be aware of the additional complexity and limitations of using streaming calls instead of unary:

1. A stream can be interrupted by a service or connection error. Logic is required to restart stream if there is an error.
2. `RequestStream.WriteAsync` is not safe for multi-threading. Only one message can be written to a stream at a time. Sending messages from multiple threads over a single stream requires a producer/consumer queue like Channel<T> to marshall messages.
3. A gRPC streaming method is limited to receiving one type of message and sending one type of message. For example, `rpc StreamingCall(stream RequestMessage) returns (stream ResponseMessage)` receives `RequestMessage` and sends `ResponseMessage`. Protobuf's support for unknown or conditional messages using `Any` and `oneof` can work around this limitation.

Inter-process communication with gRPC

9/22/2020 • 2 minutes to read • Edit Online

By James Newton-King

gRPC calls between a client and service are usually sent over TCP sockets. TCP was designed for communicating across a network. Inter-process communication (IPC) is more efficient than TCP when the client and service are on the same machine. This document explains how to use gRPC with custom transports in IPC scenarios.

Server configuration

Custom transports are supported by Kestrel. Kestrel is configured in *Program.cs*:

```
public static readonly string SocketPath = Path.Combine(Path.GetTempPath(), "socket.tmp");

public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
            webBuilder.ConfigureKestrel(options =>
            {
                if (File.Exists(SocketPath))
                {
                    File.Delete(SocketPath);
                }
                options.ListenUnixSocket(SocketPath);
            });
        });
```

The preceding example:

- Configures Kestrel's endpoints in `ConfigureKestrel`.
- Calls ListenUnixSocket to listen to a Unix domain socket (UDS) with the specified path.

Kestrel has built-in support for UDS endpoints. UDS are supported on Linux, macOS and modern versions of Windows.

Client configuration

`GrpcChannel` supports making gRPC calls over custom transports. When a channel is created, it can be configured with a `SocketsHttpHandler` that has a custom `ConnectCallback`. The callback allows the client to make connections over custom transports and then send HTTP requests over that transport.

> **IMPORTANT**
>
> `SocketsHttpHandler.ConnectCallback` is a new API in .NET 5 release candidate 2.

Unix domain sockets connection factory example:

```
public class UnixDomainSocketConnectionFactory
{
    private readonly EndPoint _endPoint;

    public UnixDomainSocketConnectionFactory(EndPoint endPoint)
    {
        _endPoint = endPoint;
    }

    public async ValueTask<Stream> ConnectAsync(SocketsHttpConnectionContext _,
        CancellationToken cancellationToken = default)
    {
        var socket = new Socket(AddressFamily.Unix, SocketType.Stream, ProtocolType.Unspecified);

        try
        {
            await socket.ConnectAsync(_endPoint, cancellationToken).ConfigureAwait(false);
            return new NetworkStream(socket, true);
        }
        catch
        {
            socket.Dispose();
            throw;
        }
    }
}
```

Using the custom connection factory to create a channel:

```
public static readonly string SocketPath = Path.Combine(Path.GetTempPath(), "socket.tmp");

public static GrpcChannel CreateChannel()
{
    var udsEndPoint = new UnixDomainSocketEndPoint(SocketPath);
    var connectionFactory = new UnixDomainSocketConnectionFactory(udsEndPoint);
    var socketsHttpHandler = new SocketsHttpHandler
    {
        ConnectCallback = connectionFactory.ConnectAsync
    };

    return GrpcChannel.ForAddress("http://localhost", new GrpcChannelOptions
    {
        HttpHandler = socketsHttpHandler
    });
}
```

Channels created using the preceding code send gRPC calls over Unix domain sockets. Support for other IPC technologies can be implemented using the extensibility in Kestrel and `SocketsHttpHandler`.

Create JSON Web APIs from gRPC

9/22/2020 • 3 minutes to read • Edit Online

By James Newton-King

> **IMPORTANT**
>
> gRPC HTTP API is an experimental project, not a committed product. We want to:
>
> - Test that our approach to creating JSON Web APIs for gRPC services works.
> - Get feedback on if this approach is useful to .NET developers.
>
> Please leave feedback to ensure we build something that developers like and are productive with.

gRPC is a modern way to communicate between apps. gRPC uses HTTP/2, streaming, Protobuf and message contracts to create high-performance, real-time services.

One limitation with gRPC is not every platform can use it. Browsers don't fully support HTTP/2, making REST and JSON the primary way to get data into browser apps. Even with the benefits that gRPC brings, REST and JSON have an important place in modern apps. Building gRPC ***and*** JSON Web APIs adds unwanted overhead to app development.

This document discusses how to create JSON Web APIs using gRPC services.

gRPC HTTP API

gRPC HTTP API is an experimental extension for ASP.NET Core that creates RESTful JSON APIs for gRPC services. Once configured, gRPC HTTP API allows apps to call gRPC services with familiar HTTP concepts:

- HTTP verbs
- URL parameter binding
- JSON requests/responses

gRPC can still be used to call services.

Usage

1. Add a package reference to Microsoft.AspNetCore.Grpc.HttpApi.
2. Register services in *Startup.cs* with `AddGrpcHttpApi`.
3. Add google/api/http.proto and google/api/annotations.proto files to your project.
4. Annotate gRPC methods in your *.proto* files with HTTP bindings and routes:

```
syntax = "proto3";

import "google/api/annotations.proto";

package greet;

service Greeter {
  rpc SayHello (HelloRequest) returns (HelloReply) {
    option (google.api.http) = {
      get: "v1/greeter/{name}"
    };
  }
}

message HelloRequest {
  string name = 1;
}

message HelloReply {
  string message = 1;
}
```

The `SayHello` gRPC method can now be invoked as gRPC+Protobuf and as an HTTP API:

- Request: `HTTP/1.1 GET /v1/greeter/world`
- Response: `{ "message": "Hello world" }`

Server logs show that the HTTP call is executed by a gRPC service. gRPC HTTP API maps the incoming HTTP request to a gRPC message, and then converts the response message to JSON.

```
info: Microsoft.AspNetCore.Hosting.Diagnostics[1]
      Request starting HTTP/1.1 GET https://localhost:5001/v1/greeter/world
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[0]
      Executing endpoint 'gRPC - v1/greeter/{name}'
info: Server.GreeterService[0]
      Sending hello to world
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[1]
      Executed endpoint 'gRPC - v1/greeter/{name}'
info: Microsoft.AspNetCore.Hosting.Diagnostics[2]
      Request finished in 1.996ms 200 application/json
```

This is a basic example. See HttpRule for more customization options.

gRPC HTTP API vs gRPC-Web

Both gRPC HTTP API and gRPC-Web allow gRPC services to be called from a browser. However, the way each does this is different:

- gRPC-Web lets browser apps call gRPC services from the browser with the gRPC-Web client and Protobuf. gRPC-Web requires the browser app generate a gRPC client, and has the advantage of sending small, fast Protobuf messages.
- gRPC HTTP API allows browser apps to call gRPC services as if they were RESTful APIs with JSON. The browser app doesn't need to generate a gRPC client or know anything about gRPC.

No generated client is created for gRPC HTTP API. The previous `Greeter` service can be called using browser JavaScript APIs:

```
var name = nameInput.value;

fetch("/v1/greeter/" + name).then(function (response) {
  response.json().then(function (data) {
    console.log("Result: " + data.message);
  });
});
```

Experimental status

gRPC HTTP API is an experiment. It is not complete and it is not supported. We're interested in this technology, and the ability it gives app developers to quickly create gRPC and JSON services at the same time. There is no commitment to completing the gRPC HTTP API.

We want to gauge developer interest in gRPC HTTP API. If gRPC HTTP API is interesting to you then please give feedback.

grpc-gateway

grpc-gateway is another technology for creating RESTful JSON APIs from gRPC services. It uses the same *.proto* annotations to map HTTP concepts to gRPC services.

The biggest difference between grpc-gateway and gRPC HTTP API is grpc-gateway uses code generation to create a reverse-proxy server. The reverse-proxy translates RESTful calls into gRPC and then sends them on to the gRPC service.

For installation and usage of grpc-gateway, see the grpc-gateway documentation.

Manage Protobuf references with dotnet-grpc

9/22/2020 • 4 minutes to read • Edit Online

By John Luo

`dotnet-grpc` is a .NET Core Global Tool for managing Protobuf (*.proto*) references within a .NET gRPC project. The tool can be used to add, refresh, remove, and list Protobuf references.

Installation

To install the `dotnet-grpc` .NET Core Global Tool, run the following command:

```
dotnet tool install -g dotnet-grpc
```

Add references

`dotnet-grpc` can be used to add Protobuf references as `<Protobuf />` items to the *.csproj* file:

```
<Protobuf Include="Protos\greet.proto" GrpcServices="Server" />
```

The Protobuf references are used to generate the C# client and/or server assets. The `dotnet-grpc` tool can:

- Create a Protobuf reference from local files on disk.
- Create a Protobuf reference from a remote file specified by a URL.
- Ensure the correct gRPC package dependencies are added to the project.

For example, the `Grpc.AspNetCore` package is added to a web app. `Grpc.AspNetCore` contains gRPC server and client libraries and tooling support. Alternatively, the `Grpc.Net.Client`, `Grpc.Tools` and `Google.Protobuf` packages, which contain only the gRPC client libraries and tooling support, are added to a Console app.

Add file

The `add-file` command is used to add local files on disk as Protobuf references. The file paths provided:

- Can be relative to the current directory or absolute paths.
- May contain wild cards for pattern-based file globbing.

If any files are outside the project directory, a `Link` element is added to display the file under the folder `Protos` in Visual Studio.

Usage

```
dotnet grpc add-file [options] <files>...
```

Arguments

ARGUMENT	DESCRIPTION
files	The protobuf file references. These can be a path to glob for local protobuf files.

Options

SHORT OPTION	LONG OPTION	DESCRIPTION
-p	--project	The path to the project file to operate on. If a file is not specified, the command searches the current directory for one.
-s	--services	The type of gRPC services that should be generated. If `Default` is specified, `Both` is used for Web projects and `Client` is used for non-Web projects. Accepted values are `Both`, `Client`, `Default`, `None`, `Server`.
-i	--additional-import-dirs	Additional directories to be used when resolving imports for the protobuf files. This is a semicolon separated list of paths.
	--access	The access modifier to use for the generated C# classes. The default value is `Public`. Accepted values are `Internal` and `Public`.

Add URL

The `add-url` command is used to add a remote file specified by an source URL as Protobuf reference. A file path must be provided to specify where to download the remote file. The file path can be relative to the current directory or an absolute path. If the file path is outside the project directory, a `Link` element is added to display the file under the virtual folder `Protos` in Visual Studio.

Usage

```
dotnet-grpc add-url [options] <url>
```

Arguments

ARGUMENT	DESCRIPTION
url	The URL to a remote protobuf file.

Options

SHORT OPTION	LONG OPTION	DESCRIPTION
-o	--output	Specifies the download path for the remote protobuf file. This is a required option.
-p	--project	The path to the project file to operate on. If a file is not specified, the command searches the current directory for one.

SHORT OPTION	LONG OPTION	DESCRIPTION
-s	--services	The type of gRPC services that should be generated. If `Default` is specified, `Both` is used for Web projects and `Client` is used for non-Web projects. Accepted values are `Both`, `Client`, `Default`, `None`, `Server`.
-i	--additional-import-dirs	Additional directories to be used when resolving imports for the protobuf files. This is a semicolon separated list of paths.
	--access	The access modifier to use for the generated C# classes. Default value is `Public`. Accepted values are `Internal` and `Public`.

Remove

The `remove` command is used to remove Protobuf references from the *.csproj* file. The command accepts path arguments and source URLs as arguments. The tool:

- Only removes the Protobuf reference.
- Does not delete the *.proto* file, even if it was originally downloaded from a remote URL.

Usage

```
dotnet-grpc remove [options] <references>...
```

Arguments

ARGUMENT	DESCRIPTION
references	The URLs or file paths of the protobuf references to remove.

Options

SHORT OPTION	LONG OPTION	DESCRIPTION
-p	--project	The path to the project file to operate on. If a file is not specified, the command searches the current directory for one.

Refresh

The `refresh` command is used to update a remote reference with the latest content from the source URL. Both the download file path and the source URL can be used to specify the reference to be updated. Note:

- The hashes of the file contents are compared to determine whether the local file should be updated.
- No timestamp information is compared.

The tool always replaces the local file with the remote file if an update is needed.

Usage

```
dotnet-grpc refresh [options] [<references>...]
```

Arguments

ARGUMENT	DESCRIPTION
references	The URLs or file paths to remote protobuf references that should be updated. Leave this argument empty to refresh all remote references.

Options

SHORT OPTION	LONG OPTION	DESCRIPTION
-p	--project	The path to the project file to operate on. If a file is not specified, the command searches the current directory for one.
	--dry-run	Outputs a list of files that would be updated without downloading any new content.

List

The `list` command is used to display all the Protobuf references in the project file. If all values of a column are default values, the column may be omitted.

Usage

```
dotnet-grpc list [options]
```

Options

SHORT OPTION	LONG OPTION	DESCRIPTION
-p	--project	The path to the project file to operate on. If a file is not specified, the command searches the current directory for one.

Test gRPC services with gRPCurl in ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

By James Newton-King

Tooling is available for gRPC that allows developers to test services without building client apps:

- gRPCurl is a command-line tool that provides interaction with gRPC services.
- gRPCui builds on top of gRPCurl and adds an interactive web UI for gRPC, similar to tools such as Postman and Swagger UI.

This article discusses how to:

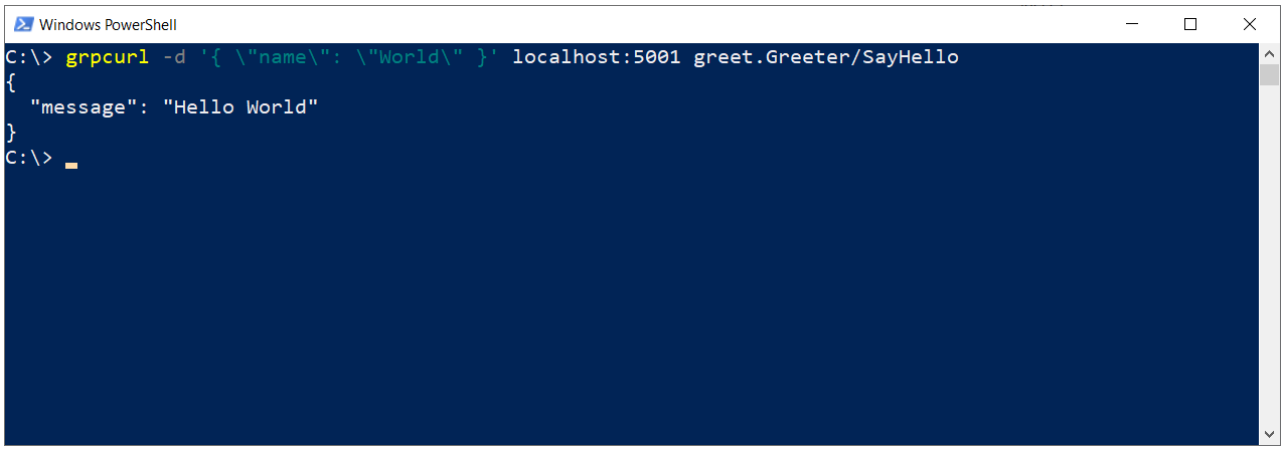
- Download and install gRPCurl and gRPCui.
- Set up gRPC reflection with a gRPC ASP.NET Core app.
- Discover and test gRPC services with `grpcurl`.
- Interact with gRPC services via a browser using `grpcui`.

About gRPCurl

gRPCurl is a command-line tool created by the gRPC community. Its features include:

- Calling gRPC services, including streaming services.
- Service discovery using gRPC reflection.
- Listing and describing gRPC services.
- Works with secure (TLS) and insecure (plain-text) servers.

For information about downloading and installing `grpcurl`, see the gRPCurl GitHub homepage.



Set up gRPC reflection

`grpcurl` must know the Protobuf contract of services before it can call them. There are two ways to do this:

- Set up gRPC reflection on the server. gRPCurl automatically discovers service contracts.
- Specify `.proto` files in command-line arguments to gRPCurl.

It's easier to use gRPCurl with gRPC reflection. gRPC reflection adds a new gRPC service to the app that clients can call to discover services.

gRPC ASP.NET Core has built-in support for gRPC reflection with the `Grpc.AspNetCore.Server.Reflection` package. To configure reflection in an app:

- Add a `Grpc.AspNetCore.Server.Reflection` package reference.
- Register reflection in `Startup.cs`:
  - `AddGrpcReflection` to register services that enable reflection.
  - `MapGrpcReflectionService` to add a reflection service endpoint.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc();
    services.AddGrpcReflection();
}

public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapGrpcService<GreeterService>();

        if (env.IsDevelopment())
        {
            endpoints.MapGrpcReflectionService();
        }
    });
}
```

When gRPC reflection is set up:

- A gRPC reflection service is added to the server app.
- Client apps that support gRPC reflection can call the reflection service to discover services hosted by the server.
- gRPC services are still called from the client. Reflection only enables service discovery and doesn't bypass server-side security. Endpoints protected by authentication and authorization require the caller to pass credentials for the endpoint to be called successfully.

Use `grpcurl`

The `-help` argument explains `grpcurl` command-line options:

```
$ grpcurl -help
```

Discover services

Use the `describe` verb to view the services defined by the server:

```
$ grpcurl localhost:5001 describe
greet.Greeter is a service:
service Greeter {
  rpc SayHello ( .greet.HelloRequest ) returns ( .greet.HelloReply );
  rpc SayHellos ( .greet.HelloRequest ) returns ( stream .greet.HelloReply );
}
grpc.reflection.v1alpha.ServerReflection is a service:
service ServerReflection {
  rpc ServerReflectionInfo ( stream .grpc.reflection.v1alpha.ServerReflectionRequest ) returns ( stream
.grpc.reflection.v1alpha.ServerReflectionResponse );
}
```

The preceding example:

- Runs the `describe` verb on server `localhost:5001`.
- Prints services and methods returned by gRPC reflection.
  - `Greeter` is a service implemented by the app.
  - `ServerReflection` is the service added by the `Grpc.AspNetCore.Server.Reflection` package.

Combine `describe` with a service, method, or message name to view its detail:

```
$ grpcurl localhost:5001 describe greet.HelloRequest
greet.HelloRequest is a message:
message HelloRequest {
  string name = 1;
}
```

Call gRPC services

Call a gRPC service by specifying a service and method name along with a JSON argument that represents the request message. The JSON is converted into Protobuf and sent to the service.

```
$ grpcurl -d '{ \"name\": \"World\" }' localhost:5001 greet.Greeter/SayHello
{
  "message": "Hello World"
}
```

In the preceding example:

- The `-d` argument specifies a request message with JSON. This argument must come before the server address and method name.
- Calls the `SayHello` method on the `greeter.Greeter` service.
- Prints the response message as JSON.

About gRPCui

gRPCui is an interactive web UI for gRPC. It builds on top of gRPCurl and offers a GUI for discovering and testing gRPC services, similar to HTTP tools such as Postman or Swagger UI.

For information about downloading and installing `grpcui`, see the gRPCui GitHub homepage.

Using `grpcui`

Run `grpcui` with the server address to interact with as an argument:

```
$ grpcui localhost:5001
gRPC Web UI available at http://127.0.0.1:55038/
```

The tool launches a browser window with the interactive web UI. gRPC services are automatically discovered using gRPC reflection.

Migrating gRPC services from C-core to ASP.NET Core

9/22/2020 • 3 minutes to read • Edit Online

By John Luo

Due to the implementation of the underlying stack, not all features work in the same way between C-core-based gRPC apps and ASP.NET Core-based apps. This document highlights the key differences for migrating between the two stacks.

gRPC service implementation lifetime

In the ASP.NET Core stack, gRPC services, by default, are created with a scoped lifetime. In contrast, gRPC C-core by default binds to a service with a singleton lifetime.

A scoped lifetime allows the service implementation to resolve other services with scoped lifetimes. For example, a scoped lifetime can also resolve `DbContext` from the DI container through constructor injection. Using scoped lifetime:

- A new instance of the service implementation is constructed for each request.
- It isn't possible to share state between requests via instance members on the implementation type.
- The expectation is to store shared states in a singleton service in the DI container. The stored shared states are resolved in the constructor of the gRPC service implementation.

For more information on service lifetimes, see Dependency injection in ASP.NET Core.

Add a singleton service

To facilitate the transition from a gRPC C-core implementation to ASP.NET Core, it's possible to change the service lifetime of the service implementation from scoped to singleton. This involves adding an instance of the service implementation to the DI container:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc();
    services.AddSingleton(new GreeterService());
}
```

However, a service implementation with a singleton lifetime is no longer able to resolve scoped services through constructor injection.

Configure gRPC services options

In C-core-based apps, settings such as `grpc.max_receive_message_length` and `grpc.max_send_message_length` are configured with `ChannelOption` when constructing the Server instance.

In ASP.NET Core, gRPC provides configuration through the `GrpcServiceOptions` type. For example, a gRPC service's the maximum incoming message size can be configured via `AddGrpc`. The following example changes the default `MaxReceiveMessageSize` of 4 MB to 16 MB:

```
